"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, MAY 2, 1907.

THE ENIGMA OF LIFE.

(1) *The Evolution of Life.* By Dr. H. Charlton Bastian, F.R.S. Pp. xviii+319; with diagrams and many photomicrographs. (London: Methuen and Co., n.d.) Price 7*s.* 6*d.* net.

(2) *The Nature and Origin of Life in the Light of New Knowledge.* By Prof. Felix Le Dantec. An introductory preface by Robert K. Duncan, author of "The New Knowledge." Pp. xvi+250; 21 figures. (London: Hodder and Stoughton, 1907.) Price 6*s.* net.

(1) DR. H. CHARLTON BASTIAN re-affirms his conviction that living organisms continue to arise from not-living material. It is a long time since, in his "Beginnings of Life" (1872), Bastian sought to establish the reality of this "archebiosis" and also of heterogenesis—that strange process by which organisms or parts of organisms of definite kind give rise to organisms of a quite different kind, as when the ovum of the rotifer Hydatina produces the infusorian Otostoma. In 1876–7 there was a notable and useful controversy between Bastian, on the one side, Tyndall and Pasteur on the other, the issue of which seemed to most experts to be that Bastian failed to make good his case for the present-day occurrence of spontaneous generation. The claims of professional work forced the heretic to renounce his investigations for about twenty years, but he has recently been able to return with unabated vigour to the study of both heterogenesis and abiogenesis. His "Studies in Heterogenesis" and his work on "The Nature and Origin of Living Matter" have been already reviewed in NATURE, and we have now before us an account of his recent researches on "archebiosis" and a clear exposition of his views as to "The Evolution of Life." It is impossible not to admire the author's strong desire to get at the truth, the courage of his convictions, and his incomparable good humour.

Dr. Bastian begins by indicating some of the objections to the term "spontaneous generation," which is almost as bad as "generatio equivoca"; he advocates the use of the word "archebiosis"—the past or present origination of living things from not-living material—and he contrasts it with "heterogenetic reproduction," which presupposes pre-existing organisms. In the first part of his book he points out that inorganic evolution (recently studied in ways not a little upsetting) has not stopped, and argues against the dogmatism of those who, while admitting that archebiosis probably occurred very long ago, refuse to discuss the possibility of its occurrence now. Because it has been shown that maggots are not really produced by the flesh in which they crawl, it does not follow that minute specks of living matter may not arise *de novo* in suitable not-living fluids, and to base the formula *omne vivum ex vivo* on the "past experience of mankind" is ridiculously naïve. It has become the fashion to call "spontaneous generation" a "chimera," and the study of it a search for a mare's nest. But "neither Darwin, Huxley, nor Spencer ever undertook any experimental work on this subject themselves," and as for Tyndall and Pasteur, both were convinced beforehand. The whole story is gone over again (pp. 95–228), and it is (psychologically, at least) very instructive. Since 1878, Dr. Bastian had not, before the present work, published anything on the subject of archebiosis, save one chapter in his 1905 volume, and it is interesting to read his retrospect of a famous controversy and his undismayed conclusions in spite of all.

"Mere observation," the author points out, "can never settle the question whether Archebiosis does or does not take place at the present day." In a fluid believed to be quite not-living, minute living creatures appear, but observation cannot decide whether they arise from invisible germs of pre-existing organisms, or "whether they have come into being in the mother liquid as a result of life-giving synthetic processes." Therefore we must resort to experiment, and the fallacies to be guarded against are two. The heat employed in the sterilising process must be adequate to kill all pre-existing living things within the experimental vessels, and there must be no subsequent contamination with atmospheric germs. Therefore Bastian heated his fluids to 115° C. or 130° C., and hermetically sealed the tubes. But these precautions involve disadvantages; the degrading effect of the initial purifying heat process may render the medium unfit for the occurrence of future processes that may lead to life-origination, and the glass of the hermetically sealed vessel in which the fluid is contained partially excludes actinic rays which might be potential, or at least helpful, in bringing about the combinations in question. In spite of these disadvantages, Dr. Bastian found living creatures—" Bacilli, Vibriones, Cocci, Streptococci, Torulæ, and other germs of Fungi "—in saline solutions within tubes that had been heated at 115° C. to 130° C. for from ten to twenty minutes, and the present subdirector of the Pasteur Institute has declared, in regard to spores of bacilli in all such fluids, that "a temperature of 115° C. sterilises them completely and most rapidly." Some of the photomicrographic figures of "organisms" are not very like organisms at all, but others are. The alternative interpretations are (1) that Dr. Bastian's methods were not rigorous enough; (2) that the fatal temperature has been estimated at too low a figure; (3) that contamination occurred during the preparation of the photographed slides, or (*d*) that archebiosis actually takes place. Personally, we are not disposed to accept the last interpretation until every possibility of error has been excluded, and we are not convinced by Dr. Bastian's " final decisive experiments." We suspect that the sterilisation was imperfect; we suspect that there were " germs "—where we have often seen them—on the slides and cover-slips; we suspect everything to a degree that Dr. Bastian—with a tolerant smile—would say outrages common sense. For we belong to the prejudiced, illogical, conservative sect of St. Thomas who doubt and doubt. The whole business is so analogous to belief in " spooks " that no amount of argument is of any use until we have seen for ourselves. Why, then, Dr. Bastian says, will you not experiment? And why will you not, in the name of St. Thomas, point out precisely where my experiments are fallacious? As to the first question, we think the answer is that we regard archebiosis as so great a miracle that we do not expect to see it repeated. As to the second question, we do not know what to answer, unless it be that the sterilisation was inadequate, or that the preparations were contaminated before the photographs were taken. At the same time, recent physicochemical discoveries centred around the fact of radio-activity warn us that dogmatism as to possibilities is far from being consistent with the truly scientific mood.

Harking back to heterogenesis, perhaps it may be useful to say that Dr. Bastian was good enough to show us the mummy of an Otostoma reposing within the egg-case of Hydatina. There can be no doubt about it. But what remains unproved is that the organisation of a Hydatina ovum gives rise by heterogenesis to the organisation of the infusorian Otostoma. We suspected parasitism, and we watched many ova of Hydatina. But neither the expected nor the unexpected happened. On one occasion, however, Dr. John Rennie, lecturer on parasitology in the University of Aberdeen, an expert investigator who was good enough to assist in watching for the advent of Otostoma, observed two (not identified) infusorians moving inside the rotifer's egg, but he did not regard the phenomenon as a proof of heterogenesis. As a matter of fact, the egg-envelope showed a small split, through which the infusorians soon passed out, doubtless following the path by which they formerly entered.

(2) Prof. Felix Le Dantec has entitled his book "The Nature and Origin of Life," but with a humour which we appreciate he has entirely shirked the question of *origin*, only referring to it in a casual, half-hearted sort of way on the last page, where he tells us that " the time will come when methodic analysis will allow of a reasoned synthesis " of protoplasm. It is probable that the solution will be found in the study of diastases.

" When the effective synthesis is obtained, it will have no surprises in it—and it will be utterly useless. With the new knowledge acquired by science, the enlightened mind no longer needs to see the fabrication of protoplasm in order to be convinced of the absence of all essential difference and all absolute discontinuity between living and not-living matter."

Prof. Le Dantec's book—which discusses the nature of life—ranges over the whole field of biology from bacteria to the nervous system, from karyokinesis to mutations, from tropisms to natural selection, and he leaves one with the general impression that even " in the light of new knowledge " the riddle of " life " remains very obscure. In a popular elusive manner, with abundant concrete illustrations, the author seeks to show that the living creature is a mechanism and nothing more, and that " the study of life belongs to chemical physics." " A higher animal such as man is *a mechanism of mechanisms of mechanisms*." This rather cryptic conclusion is expanded into the statement that man is an anatomical mechanism of colloid mechanisms of chemical mechanisms. The wonder is that they all hold together. " More and more the living being appears to us a superposition of dead things." But it is a fell superposition. " A rat trap would be alive if, while exercising its normal function of loosing its spring, it should impress on its constituent substances a chemical activity whose result would be a tension of the spring tighter than before." This seems to us rather a clap-trap theory of life. We mean that the author gives the problem a false simplicity; he conveys the impression that we can really give a mechanical re-description of the development, the growth, the reproduction, the behaviour, the evolution—the life of living creatures. But he does not go thoroughly enough into any single instance to win conviction, and he is continually retreating into the mystery of colloids. Some of his utterances strike us as rather intemperate, as when he tells us that " life is an aquatic phenomenon," or that " Life is only a surface accident in the history of the thermic evolution of the globe," or that "*The fact of being conscious* does not intervene in the slightest degree in directing vital movements." Yet when we were conscious of this sentence we turned back several pages and re-read the preface, where the editor takes an optimistic view of mechanistic theories.

The author has full faith in the theory of *epiphenomenal* consciousness; it is a negligible shadow. He prefers to keep to the purely objective, *e.g.* the mechanism of colloids and the polarities of the cell. He is very strong on bipolarity. "The living cell is a bipolar apparatus, since it needs a cytoplasm and a nucleus." "In each bipolar element of protoplasm there is a male pole and a female pole." "Maturation is explained by the disappearance in cytoplasm and nucleus of all elements of the *sex opposed* to that of the mature element finally obtained." "Fecundation is the operation in which the spermatozooid, introduced by sexual attraction into the ovule, completes by means of its male poles the female poles of the ovule's elements, which are incomplete." "Assimilation is a bipolar phenomenon," and "alternating generation is also related with the bipolarity of the living elements." All this is "in the light of new knowledge," as is also the conclusion that "strictly speaking there is never any hereditary transmission except of acquired characters." The author corrects some of the errors of Claude Bernard, Darwin, and Weismann.

The book has been translated by Stoddard Dewey, and it is just possible that the original may have suffered a little. "If the hen fabricates the egg, the egg in its turn will fabricate the hen. We shall not therefore be astonished when we come to verify the marvellous phenomenon which governs the entire evolution of living beings: the heredity of acquired characters." "Lichens result from the association of seaweed and mushrooms." This lacks precision. "The embryology of an animal reproduces its genealogy." This lacks elegance. Speaking of crabs and lobsters, he says, "All variation, all modification is limited in such animals to this phenomenon of moulting." This lacks clearness.

J. A. T.

ZOOLOGY OF THE INDIAN OCEAN.

(1) *The Fauna and Geography of the Maldive and Laccadive Archipelagoes.* By J. Stanley Gardiner. Vol. ii. Part iv. and Supplements i. and ii., with index. Pp. 807–1079; 34 plates and figures in the text. (Cambridge: University Press, 1905 and 1906.)

(2) *An Account of the Alcyonarians collected by the Royal Indian Marine Survey Ship "Investigator" in the Indian Ocean.* I. *The Alcyonarians of the Deep Sea.* By J. Arthur Thomson and W. D. Henderson. Pp. xvi+132; 10 plates, with colours. (Calcutta: The Indian Museum, 1906.)

THE memoirs contained in the above-named publications belong, if taken alone, to that large class of scientific papers which are commonly said to be "of interest only to specialists," but in reality they betoken much more than this, since they denote a great activity in the investigation of the biological problems presented by the Indian Ocean. Far from overlapping, they are complementary to each other and to a third piece of contemporary work which does not fall within the scope of this notice—the Ceylon pearl-oyster report.

The research conducted by Mr. Stanley Gardiner upon the bionomical conditions or "biocœnosis" of the Maldive and Laccadive Archipelagoes, the earlier parts of which have been already reviewed in NATURE, is now brought to a close with the completion of the second volume, and, as Mr. Gardiner points out in his concluding remarks, the whole report contains fifty-four separate papers by thirty-two different authors. It is not easy to estimate the value of this unique work, which will remain indispensable to all who are interested in Indian marine zoology and in coral reefs. Perhaps the best tribute that can be paid to it, as a whole, is conveyed in that accorded to one portion of it by Prof. H. Coutière, the author of a report in vol. ii., part iv., upon the Alpheidæ, a family of Crustacea frequenting coral reefs and other suitable localities in the tropics:—

"La collection comprend 76 espèces et variétés, soit près de la moitié des formes actuellement connues d'Alpheidæ, et, parmi ces formes, 48 sont nouvelles. Aucune expédition n'a jamais atteint, même de loin, un semblable résultat. Si la localité choisie s'est montrée exceptionnellement riche, il faut aussi que son exploration ait été conduite avec une méthode et une science de la recherche des espèces marines qu'on ne saurait trop mettre en relief."

Every naturalist who has worked along shores where corals grow is familiar with some members of the family Alpheidæ, for which a satisfactory English equivalent seems not to have been invented. These crustacea are so remarkable that a common expression calculated to convey some idea of their properties is to be desired, and the name of trigger shrimps may be suggested. Upon placing them in a glass jar, one is likely to be startled by a sudden report, often so loud as apparently to threaten the fracture of the vessel. The noise is made by the snapping of one of their pincers of peculiar construction.

Although mainly systematic, Prof. Coutière's memoir will be welcomed by those who take an interest in the forms of animal life, not only because of his method of treatment, but especially on account of the admirably clear illustrations, which are reproduced from the author's drawings on eighteen plates, besides text-figures. These are models of what such illustrations should be, and one shudders to think of the paper without them. There is something wrong with Figs. 127 and 128 on pp. 855–6, the letters of the former not corresponding with the description, and the number of joints in the shaft of the outer antennular flagellum of male and female respectively not coinciding with the statement in the text—small blemishes of no account to the specialist, who can endure much. This work does not include a bibliography, and such references as are given are not always to the point, *e.g. Ann. des Sc.* (6), 1899; the series should be (8) and the volume ix.

The same number (vol. ii., part iv.) contains the third instalment of Prof. Hickson's report on the Alcyonaria of the Maldives, with descriptions of fifteen (including two Briareidæ described previously) species of Gorgonacea and one Pennatulid. The depths at which the material was obtained ranged from 0–43 fathoms, generally between 20 and 30 fathoms; two specimens of the Pennatulid (*Pennatula murrayi*) were taken at 43 fathoms in the Suvadiva Lagoon. A general feature of many of the sublittoral Alcyonaria is their extreme variability.

Other papers to which space does not permit us to do justice beyond mentioning them are by Major Alcock on Paguridæ (hermit-crabs), recording twenty-six species, of which nine are new to the Indian Ocean, five new to science; Mr. L. A. Borradaile on Hydroids, twenty-three species; Mr. A. E. Shipley on two parasites; and Mr. W. L. Distant enumerates twenty species of Rhynchota.

The first supplement contains reports by Messrs. A. O. Walker (Amphipoda), J. Stanley Gardiner (Madreporaria), E. T. Browne (Scyphomedusæ), D. Sharp (Coleoptera), W. E. Hoyle (Cephalopoda), and R. Norris Wolfenden (Copepoda). Dr. Hoyle describes a rare squid, *Ancistrochirus lesueuri*, which has luminous organs; one specimen only, the second on record, was found floating dead off one of the atolls. Dr. Wolfenden, whose paper is illustrated by folding plates, compares the oceanic copepods of the Indian Ocean with those of the Atlantic, an intermixture of species between these two great oceans being hindered by the water barrier formed by the Agulhas Current; the author also points to an extraordinary difference between the Copepod fauna of the Maldive Group and that of the Gulf of Manaar, owing to the paucity of littoral forms in the former area.

The second supplement contains an article by Mr. R. I. Pocock (Myriopoda), an excellent systematic index, a subject-index, and Mr. Stanley Gardiner's concluding remarks. From his notes on the habits and distribution of the land animals, we learn that the mammals of the Maldives are three, the fruit bat or flying fox, *Pteropus medius* (not found in Minikoi), the musk shrew, *Crocidura murina*, and the rat, *Mus rattus*; the absence of insectivorous bats is noted as a singular deficiency. The study of the land fauna has confirmed his conclusion, previously based on geological grounds, "that the Maldives and Laccadives are recent lands."

As is known, Mr. Gardiner has crowned his labours in the Maldives by another expedition to the western part of the Indian Ocean, and when these results are made known the importance of his individual contribution to Indian oceanography will doubtless be fully appreciated.

The sumptuous monograph of the Indian Alcyonarians of the deep sea, by Prof. J. A. Thomson and Mr. W. D. Henderson, is a revelation of a wealth of new forms depicted in a manner which, for this class of illustration, is beyond praise. The authors are alive to the æsthetic possibilities of their subjects, and although these are to some extent prejudiced by inevitable *post-mortem* changes, enough remains to delight the eye and attest the beauty that is hidden in the depths of the sea. Of the eighty-six species included in the collection, sixty-one are new; only nine belong to the Alcyonacea (leathery corals, chiefly shallow-water forms); eight of these are new, and two of them are made the types of new genera. There are forty-one species of Gorgonacea ("sea-fans") and twenty-eight species of Pennatulacea ("sea-pens" or "sea-feathers"), thus displaying a very great contrast with the shallow-water fauna of the Maldives. Two genera, Sympodium of the Stolonifera and Umbellula of the Pennatulacea, contain a multiplicity of specific forms which the authors admit may be only mutations. In view of this possibility, it is hard to accept so many names on an equal footing with those of undoubted and striking types.

Several comparative tables of the species of various genera are introduced in the course of the work, and these should prove of great service to future investigators. This method of tabulation is the right one, and is capable of improvement until a degree of perfection is attained. In written descriptions it happens frequently that the most obvious distinction between allied species is a difference of verbiage. Such banalities can be eliminated from tables; thus it is not much to learn that whereas the axis of *Umbellula durissima* is "nearly cylindrical," that of *Umbellula dura* is "almost cylindrical." The quotation of an isolated example of this kind is not meant to detract in any way from the total value of the tables.

A special property of many deep-sea Alcyonarians is their viviparity. The authors have found embryos in eight different species belonging to the three principal sections, Alcyonacea, Gorgonacea, and Pennatulacea. A full bibliography completes the present monograph, and one dealing with the littoral forms is promised later.

MEDICAL MEDITATIONS.

Principia Therapeutica. By Dr. Harrington Sainsbury. Pp. xi+244. (London: Methuen and Co., n.d.) Price 7*s.* 6*d.* net.

IN the biological sphere, to attain by means of scientific analysis to generalisations of such a breadth as to justify the term of "Principia" is an arduous task, even for generations of men, and is one which is far beyond us at present. The attainment of principles can only be by the long and fallible ways of observation, verified by the experimental method; and—in medicine at any rate—we can claim to have surveyed and mapped out no very wide areas as yet. Now if this be true of pathology, of therapeutics it is grievously truer, although on the lines of pharmacology much "triangulation" is now going forward. It is almost needless to guard these remarks by adding that no one probably is more aware of these limits of our knowledge than the thoughtful writer of the book before us; he no doubt would be among the first to admit that his "Principia" are for the most part rather of the nature of ripe reflections on medicine—well-balanced cogitations by a wise, experienced, and instructed physician, regarding his art, as it were, from a height. Such thoughts obtain their generality rather by selection and proportion than by the slow accumulations of "induction." For our own part, we should have been disposed to prefer for this book some such a title as "Contemplations on Medicine."

Yet if we are indisposed to accept Dr. Sainsbury's mature reflections as "principia" in the sense of scientific theory, we are far from saying that it is useless to step thus backwards, or upwards, occasionally, so as to take more comprehensive glances of our science and art, and to delineate its larger features, so far as a slight sketch may go. By standing clear for a moment of the multiplicity of detail we gain a better sense of the proportions of the parts. The danger of this method is, of course, lest we mistake mere generalities for laws, dialectic for analysis of origins, and axioms of provisional service for verified and permanent conceptions. And it would be too much to say that Dr. Sainsbury has wholly escaped this danger; in some chapters his broad and detached way of looking at things is significant and illuminating, in others the attenuation of detail tends to vapidity, and thought is diluted until it becomes somewhat artificial and prosy. On the other hand, it may be just to say that no one could perhaps have penetrated farther in his way than Dr. Sainsbury does, and we have admitted that the change of attitude is needed occasionally to guide us and to give us wider bearings.

It would not be appropriate, then, to enter upon controversies with the author on matters of detail. It would not be difficult or unjust to do so, in many details, if the point of view were in itself more particular; but the author would be justified in answering that his reflections must be judged, not by items, but by the truth of the general point of view, and his answer would have weight. We forbear, then, from picking out from the joints of his edifice mortar which in not a few places seems to us to be unsound. Many a queried paragraph we may pass over in silence, as we must refrain from quoting many a happy one.

To turn to the larger aspects of the subjects, those general thoughts which the author had in view are often very well put; such as his conception of "compensation" as but part of the adaptation of stable moving equilibriums to their environments, so that cardiac "compensation," for instance, too often conceived with more than a spice of teleology, is a readaptation of the same general kind as immunity to bacterial and other poisons, and so forth. The whole of chapter vi. is interesting, perhaps the best in the book; the relative incidence of remedies in time is dwelt upon, and the potentialities of combinations of drugs—a practice in recent years much neglected—are fully discussed, their mutual enhancements or cross-purposes considered, and an explanation given of the chemical room left in the body for additional drugs as these may be in a solution saturated by one or more previously dissolved. Pp. 126–9, which deal with this part of the subject, are felicitous, and also the few pages following. Many sentences, too, are happily put, as, for instance, on p. 40:—"It may here be noted how it is that the organism as a whole secures its excretory stability, namely, by not carrying to the extreme the process of differentiation through which the higher types of tissue have arisen," &c. In another paragraph Dr. Sainsbury estimates in general terms the relative vigour of the communal and individual life of several parts. The chapter on diet, again, is good, especially the discussion on alcohol.

We must be forgiven if, in conclusion, we express the opinion that, in one respect at any rate, the author has not been watchful, namely, to counteract that tendency to flatness or dilution of thought which we have said is almost inseparable from speculative contemplations, and to endeavour to prevent prosiness and vagueness, by apt and penetrating phrases and instances. The quotations, which are made with some profusion, many of them bits of Latin, should have been fresh and "inevitable," but Dr. Sainsbury has not gone out of his way to seek for telling quotations. Almost all of them are well-worn "tags"; some are stale indeed. A common sentiment gains nothing by reiteration in Latin; *modus operandi* is no better than "mode of operation," and *non pane solo vivit homo* sounds to us better in our mother tongue. These points may receive attention in the new edition which the book deserves. The volume is well printed, and light in the hand.

T. C. A.

OPTICAL INSTRUMENTS.

Leitfaden der praktischen Optik. By Dr. Alexander Gleichen. Pp. viii+221. (Leipzig: S. Hirzel, 1906.) Price 5.60 marks.

Of the making of German optical text-books there is no end, and there are perhaps few which do not constitute valuable additions to optical literature. The present volume, however, does not pretend to furnish new material, and it is improbable that it will be found of any special interest to opticians in this country. It is, indeed, not easy to gather for what class of reader the work has been designed. The preface suggests that the mathematical knowledge assumed in the ordinary treatises on optical instruments is usually lacking to the practical optician, and that it seemed a not altogether useless task to explain the principles of the theory of optical instruments, their construction and design, on the basis of an acquaintance with mathematics not extending beyond the first elements of algebra. Thus should the practical optician be provided with matter he could digest and the student with a stepping-stone to the treatises aforesaid, not the least useful among which are the author's own "Lehrbuch der geometrischen Optik" and his text-books on special departments of optics.

It would seem to us, accepting the writer's own account of his intention, that the requirements neither of the student nor of the practical optician have been kept sufficiently clearly in view. It is probably rather to the amateur who wishes to acquire an intelligent appreciation of the main principles of construction of the more important optical instruments that the book will appeal. The practical optician is daily confronted with problems towards the solution of which he will here find little help, while the student who looks for an introduction to the subject will scarcely do well to acquire the elements of optics from a work in which the necessary mathematics are so entirely kept out of sight. For the general reader the volume presents many excellent features, yet even to him we would prefer to recommend Moritz von Rohr's admirable little book, "Die optischen Instrumente," which provides for the non-mathematician a very considerable amount of information in the smallest compass.

For the rest, the matter is carefully arranged and the explanations of technical points clearly and simply given. The usual portions of the subject are included—the elementary theory of mirrors, prisms and lenses, the optics of the eye, the microscope, telescope, and the photographic lens. There is a chapter also on stereoscopy, in which some of the modern developments are shortly treated. The variable power telescope receives rather more attention than is usual. Tables are given for the calculation of achromatic lenses and of prism combinations, and throughout the book attention has been paid to the furnishing of numerical data. These, however, might easily be rendered more complete—*e.g.* particulars as to the field of view obtainable at various powers in telescopes of different pattern would be of value. Complete data are provided for the construction of certain well-known combinations, direct-vision prisms, eyepieces, microscope objectives, photographic lenses, &c. The provision of numerical information is, indeed, the most characteristic feature of the book, and will render it of value for occasional reference to some who are already familiar with the author's presentment of the optical theory.

OUR BOOK SHELF.

Die Eisenindustrie. By Oskar Simmersbach. Pp. x+322. (Leipzig and Berlin: B. G. Teubner, 1906.) Price 7.20 marks.

IN German technical literature there are excellent exhaustive treatises on the metallurgy of iron, and students' manuals exist in abundance, but Mr. Simmersbach's work on the economics of the iron trade opens up an entirely new field. The leading principles and practices of the German iron trade are made clear, and a careful study of the information set forth cannot fail to prevent much waste of time and misapplication of energy in the conduct of business. The various chapters are well worthy of attentive study, and the book should find a place in the library of all who have any connection with the iron industry.

The first eight chapters give a concise introduction to the technology of iron and steel. They deal respectively with iron and its alloys, raw materials, blast-furnace practice, steelworks practice, rolling mills, testing of iron and steel, foundry practice, and the testing of cast iron and cast steel. The remaining seven chapters, dealing with the economics of iron and steel, are of greater interest. A general sketch of the importance of the world's iron trade is followed by chapters on the world's ore trade, the world's coal and coke trade, the world's pig-iron trade, the world's trade in castings, and the world's trade in malleable iron and steel. The final chapter deals with labour conditions and customs tariffs. The author takes an exceedingly optimistic view of the German coal and iron-ore resources. Germany is, he thinks, richer in iron ores than the rest of the Continental countries put together, and he explains the annual importation of more than six million tons of foreign ores as being the outcome of high railway charges. At the present rate of coal consumption there is, he believes, enough coal in Germany still unworked to last for 3520 years. These figures contrast strongly with his pessimistic views of the available resources of other countries. Prophecies as to the future of the world's iron trade are, however, of little moment.

The chief value of the author's work is in the abundance of admirably arranged statistical material regarding the present condition of the iron and steel industries, and in the evidence amply afforded of the manner in which science has superseded the old rule-of-thumb methods of carrying on operations at iron and steel works. A chapter on trusts, cartels, and syndicates would have been a useful addition to the work, and the absence of an index is to be deplored.

A Text-book of Fungi. By G. Massee. Pp. xi+427. (London: Duckworth and Co., 1906.) Price 6*s.* net.

THE fungi constitute numerically the most extensive group of plants, and at the same time they present the largest number of unsolved problems; this, too, despite the fact that, as the author says, our knowledge has increased by leaps and bounds.

Mr. Massee plunges at once *in medias res*, and proceeds to describe modern cytological developments, their legitimate and strained applications, and certain lines of inquiry pursued by Marshall Ward. Recent work has widened our knowledge of conidia, spores of various kinds, and other methods of reproduction. The author has introduced the salient facts both of sexual and asexual reproduction, but fails to offer a logical definition or a practical limitation of the terms spore, sporophore, &c. The chapter on sexual reproduction contains useful summaries of Blakeslee's account of the Mucorineæ, Thaxter's investigations of the Laboulbeniaceæ, as well as Dangeard's and Blackman's researches. The author's views on parasitism in fungi are set forth, and reference is made to experiments on similar lines by Miss Gibson and Mr. E. S. Salmon, the latter of whom has contributed the chapter on "biologic forms." Closely allied with the spread of disease, which provides the opportunity for noting the insidious danger of hibernating mycelium, is the subject of legislation. Mr. Massee enunciates his arguments, which are mainly to show that, unless it is exceedingly drastic, legislation to prevent the introduction of plant diseases through imported plants and seeds would be useless.

On the subject of classification, the opinion of the author as an acknowledged exponent is especially valuable, and the reader will find clear, and we think convincing, reasoning in favour of the acceptation of Brefeld's main groupings. The personal views on phylogeny appearing earlier in the book should be consulted in this connection. The treatment of the families is necessarily brief, but a good working basis for amplification is provided, and the last four sections, dealing with the anomalous order of Deuteromycetes, will be particularly useful to economic botanists.

The author claims to have provided an introduction to new lines of research. This is modestly expressed, for it will be found that, besides furnishing such an introduction, he has performed the additional service of discussing in a broad spirit their significance and interpretation; further, he has touched on most aspects of fungology, although not on the association of fungi in lichens, and has outlined the taxonomy of the group with a view to practical utility. In fact, Mr. Massee has supplied a serviceable and much required text-book on the present state of fungology which is embellished with numerous artistic and practical illustrations.

Douglas English Nature Books. No. 1, *One Hundred Photographs from Life of the Shrew-mouse, the Dormouse, the House-mouse, the Field-mouse, the Meadow-mouse, and the Harvest-mouse.* By Douglas English. Pp. 93. No. 2, *One Hundred Photographs of Bird Life.* By R. B. Lodge. Pp. 95. Illustrated (London: S. H. Bousfield and Co., Ltd., 1907.) Price 1s. each.

SINCE no less than sixty-four out of the ninety odd pages which go to form each of these volumes are devoted to reproductions of photographs of mammals and birds in their native haunts, the lover of animal life has a rich entertainment at a very small cost. As we learn from the introduction to the first, this series of books is intended for the pocket of the field-naturalist, and it is hoped that while the illustrations (which are almost beyond praise) will aid in the recognition of species, the letterpress will be of service alike in confirming previous observations and in suggesting new lines of inquiry. The series is intended to be comprehensive in scope. In the first part, which is devoted to some of the smaller British mammals, it is satisfactory to find a reversion to the use of popular names like water-rat, field-mouse, and shrew-mouse, in place of the spurious terms water-vole, field-vole, and shrew. In the second number Mr. R. B. Lodge gives one hundred photographs of bird-life, with appropriate notes. Since, however, the illustrations include species like the glossy ibis, little egret, and spoonbill, it is rather difficult to see what they have to do with the ordinary field-naturalist. R. L.

Gold Mining Machinery: its Selection, Arrangement, and Installation. By W. H. Tinney. Pp. xii+308. (London: Crosby Lockwood and Son, 1906.)

THIS book professes to be "a practical handbook for the use of mine-managers and engineers" to assist them in the "selection, arrangement and installation" of gold-mining machinery. Such a work properly executed would doubtless perform a useful function; but Mr. Tinney's production fails in its purpose, for it is out of date and superficial. For example, winding machinery, which should surely be one of the most important sections of a work such as this purports to be, is dealt with in seven pages of letterpress, and, as may well be imagined, the modern high-class winding engine finds no place in it. Deep winding, the greatest problem at present engaging the attention of the mechanical engineers of the Witwatersrand goldfields, is passed over in silence. Again, the electrical transmission of power, a subject of vast and ever-growing importance to the miner, is dismissed in four pages of letterpress.

It may well be asked, of what are the 300 pages of this book made up? The work appears to consist of a jumble of extracts from the note-book of the author (whose experience of the gold mines of the world would seem to have been somewhat limited), together with specifications of machinery makers, illustrated by a selection of photographs from their catalogues. To this *olla podrida* has been added a number of workshop receipts and various elementary tables, such as "the sizes of drawing paper," and formulæ for calculating the areas of a circle, a triangle, a square, &c., and the volume of a cube, a sphere, a cylinder, &c. One of the tables gives the "names, common and chemical," of a list of substances, beginning with "aqua fortis" and ending with oil of vitriol, and including such rare materials as chalk, iron pyrites, rust, slaked lime, salt, and soda.

Memories of the Months. Fourth Series. By the Right Hon. Sir Herbert Maxwell, Bart., F.R.S. Pp. x+319. (London: Edward Arnold, 1907.) Price 7s. 6d.

SIR HERBERT MAXWELL'S new volume will be welcomed by the many readers of his previous series of "memories." The ability to combine literary grace with scientific accuracy, and the power to interest and at the same time to impart useful information, is unfortunately rare, and we are grateful to Sir Herbert Maxwell for placing his gifts at the disposal of a large audience by means of these pages. Readers will be able to share with the author of the memories his "delight in the open field, the woodland, and the riverside," and if they prove willing disciples they may in time experience the joy of original observation for themselves—at least they will learn to study and appreciate the boundless beauties of nature.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

On the Relationship of Lemurs and Apes.

ACCORDING to the report published in NATURE (April 11, p. 574), Mr. H. F. Standing recently presented a memoir to the Zoological Society in which he described certain extinct lemuroids from Madagascar as being, "in many respects, intermediate between existing lemurs and monkeys," and, as the result of this interpretation of the anatomy of these animals, he expressed the view "that it was not possible to separate the Primates, as hitherto, into the two suborders Lemuroidea and Anthropoidea."

At the suggestion of Dr. A. Smith Woodward, Mr. Standing kindly sent me casts of the cranial cavities of three of the Prosimiæ found by him, and in January last I sent him a report in which their outstanding features and the inferences to be drawn from them were set forth. My conclusions not only lent no support to the above-quoted summary of Mr. Standing's opinions, but are in direct conflict with them. But I would not have deemed it necessary to repeat these statements, already made in my report (which I presume will be published along with Mr. Standing's memoir), had it not been for the fact that, since my report was written, further investigations (chiefly histological studies in the structure of the neopallium of Tarsius, Loris, Nycticebus, Perodicticus, Lemur, Propithecus, Hapale, Cebus, and Cercopithecus) have revealed important facts that enable me to speak more emphatically on the old problem once more raised for discussion by Mr. Standing, and also incline me to suggest a modification of my previously expressed views.

The evidence afforded by the cranial casts is very precise and unmistakable. One of them does not differ in any essential feature, excepting size, from the form exhibited by the brain in the living species of the genus Lemur; a second is an almost exact replica of the cranial cast of Indris; and the third, so far from affording any evidence of affinity to monkeys, presents highly specialised features, which enable us to place the animal (and also Nesopithecus, Megaladapis, and possibly Chiromys) within the fringe of the Indrisinæ. As these lemuroids are the most diversely modified members of the most highly specialised family of the Prosimiæ—which means that they are furthest removed from (and presumably have retained least resemblance to) the very early and remote ancestor from which both lemurs and apes could have sprung—it follows that these, the most aberrant and outlying branches of the prosimian phylum, are the least likely to supply us with any evidence bearing on the relationship of lemurs to apes; and the facts elucidated by the actual examination of these specimens quite bear out this *a priori* supposition.

I am the more anxious to make my position absolutely clear in regard to this matter for the reason that, some four years ago (Linn. Soc. Journal—Zool., vol. xxix., p. 83), in protesting against Hubrecht's suggested exclusion of all Prosimiæ (except Tarsius) from the Primates, I may have unduly minimised the differences in structure that indicate the wide separation of the Lemuroidea and the Anthropoidea.

The organisation of every part of the body proclaims the kinship of lemurs and monkeys, distant though it be; this has been so often summarised (see Earle, "On the Affinities of Tarsius," the *American Naturalist*, 1897, pp. 569 and 680) that it does not need repetition. I might direct attention to the fact that the lemurs are the only mammals that exhibit the true Sylvian fissure such as we find in the Anthropoidea or Simiæ; that the true central (Rolando's) sulcus is present in Perodicticus and in no non-Primate mammal, although there are distinct evidences in many prosimian families of the tendency toward the development of this caudal-limiting sulcus of the motor area; that the motor area presents histological features like those of the lowlier monkeys, and has a similar topographical distribution; that the calcarine sulcus and the distribution of the visual cortex (area striata) conform essentially to the Primate type, although in certain respects the structure of this cortex and its relation to sulci more nearly resembles the condition found in certain primitive Carnivora; and that the organisation of the other parts of the cerebral hemisphere and of the brain-stem and cerebellum resembles that of the corresponding parts of the brain in monkeys much more nearly than that of the Carnivora and Edentata, in which there are some analogies to the Prosimiæ.

But if the facts of cerebral anatomy establish the claim of the Prosimiæ to be included in the Primates, they afford equally emphatic evidence of the sharp line of demarcation between the diversely specialised suborders Lemuroidea (Lemures) and Anthropoidea (Simiæ) and the degraded rank of the former. In attempting to formulate the contrasts between these two suborders, Tarsius comes to occupy such an enigmatical position that it must be put into a category by itself, the suborder Tarsii (Gadow), the other Lemuroidea then forming the suborder Lemures (Hubrecht).

The Lemures are macrosmatic, and (excluding Megaladapis) have a sessile olfactory bulb, whereas the Simiæ are microsmatic, and have an elongated olfactory peduncle. Tarsius has a sessile olfactory bulb like the Lemures, and in form exactly like that of the Galaginæ and Lorisinæ, but it is much smaller than that of any lemur, and at the same time is bigger than that of a monkey.

The cerebral hemisphere in the Simiæ is prolonged backward to cover the cerebellum, carrying with it a diverticulum of the lateral ventricle to form a posterior cornu, the walls of which are composed to a large extent of very highly specialised striate cortex differing markedly in structure from the homologous area of other mammalian orders. In Lemures the occipital prolongation is not so extensive; there is no posterior cornu, and the cortex of the area striata approximates in structure to that of the Carnivora more nearly than to that of the apes. In Tarsius the extent of the occipital pole and its form most nearly resemble the condition found in the brain of the Galaginæ, but there is an extensive posterior cornu as in the apes, and the structure of the area striata presents a marked contrast to that of the lemurs, and resembles that found in Hapale and Cebus.

In the lemurs the frontal, temporal, and parietal association areas are much smaller than in monkeys.

The lateral hemispheres of the cerebellum exhibit a much greater expansion in the Simiæ than in the Lemures, although there is a very close resemblance between the patterns exposed in mesial section in the two suborders.

In many respects the structure of the brain in Tarsius departs widely from that of all the other Primates, both Lemures and Simiæ. Most of these features, such as the form and proportions of the corpus callosum and the architecture of the cerebellum, are indicative of a very primitive generalised condition, such as we find in the insectivore Gymnura.

All these considerations, and the mass of facts elucidated by Burmeister, Turner, Hubrecht, Mivart, Leche, Eugen Fischer, and the writer among many others, can, I think, find a rational explanation only by admitting that the Primates consist of three divergent phyla, which have all departed in varying degrees and in different ways from their original common ancestor, which must have been a creature in many respects like Tarsius, but more macrosmatic, and possessed of a smaller and less highly specialised visual cortex.

G. ELLIOT SMITH.

Radium and Geology.

Two points of special interest have come to light in recent investigations which I have made in connection with this subject.

(1) Typical rocks from the Simplon Tunnel contain quantities of radium considerably in excess of the average of igneous rocks. The Simplon rocks are altered sediments, for the most part, from Archæan to Jura-Lias age. There appears to be sufficient radium to account for the excessive temperatures met with in boring the tunnel, and the practical suggestion is allowable that engineers will do well to estimate the distribution of this substance before embarking on similar projects in the future.

The investigation suggests that radium, accumulating in great thicknesses of sedimentary deposits, may enter as a factor in mountain building by raising the temperature at the base of the accumulated mass. This would lead to a lessened resistance to compressive stress and pressure from beneath. In short, it will be for future investigation to explore how far radium (and uranium) in the surface materials has proved a source of *instability* in geological history, its transport by denudation being, in fact, not a transport of matter only, but a convection of energy.

(2) A sample of red clay from a depth of 2740 fathoms in the North Atlantic contained sixteen times as much radium as the average of igneous rocks as determined by the Hon. R. J. Strutt, and a specimen of globigerina ooze from a depth of 1990 fathoms in the South Atlantic about six times this average. These materials I owe to the kindness of Sir John Murray.

Here the question will arise, Whence all this radium? Sir John Murray's cosmic dust, of course, at once comes to mind, and, taking all the facts into account, I venture to regard these results as further evidence in favour of the extra-terrestrial origin of some portion of the radium we find upon the earth.

The above results are obtained by measurement of the emanation, with every precaution against error.

The point as to what constituent of the oceanic deposits is responsible for the radium is under investigation.

J. JOLY.

Geological Laboratory, Trinity College, Dublin, April 29.

THE ASTRONOMICAL AND ARCHÆOLOGICAL VALUE OF THE WELSH GORSEDD.

As a common term *Gorsedd* is used for "throne"; as a specific term it means (1) the stone circle, and (2) the bardic assembly at the circle. The proper Welsh for "throne" is *gorsedd-vaingc*, "*gorsedd*—seat or bench"; so the Welsh idea of a throne is the place of honour in a stone circle. That was once literally the case. Though the chief bard has always been the master of the Gorsedd ceremonies, the assemblies were held by the authority of the chieftain, lord, or king, and the business and festal features of the assembly were personally controlled by the lord of the land.

Perhaps the most satisfactory translation is "High Court." From the twelfth century to the present the Gorsedd has been the High Court of the Bards. We never hear of any other business transacted except matters that affected the bardic fraternity. But even such a circumscribed Gorsedd was never legal without the lord's authority.

There are many lines along which it would be easy to show the genuine antiquity of the Gorsedd traditions, and had I nothing more than this to say, I could with confidence invite archæologists to study them. When, however, Sir Norman Lockyer's "Stonehenge" came to my hand, some very obvious facts about the Gorsedd appeared at once to the point, and it has been my delight for the last six months to gather such facts together and apply to them the useful instructions given in the work mentioned. The present Gorsedd circle consists of twelve stones, 30° apart, with a larger stone in the centre. Outside, on the east, three stones are placed to indicate the solstices and equinoxes to an observer at the centre stone. A reader of "Stonehenge" would at once see that such an arrangement does not look very ancient. The silence of the bards about the February-May-August-November year suggested that something had been omitted in the instructions. All the old plans of a Gorsedd I have seen give 30° or so between the sunrise stones, and invariably the plans are contradicted by the verbal instructions accompanying them, in which a solstitial arrangement is insisted upon. Mr. T. H. Thomas, of Cardiff, to whom all Welshmen are grateful for what he has done towards setting the Gorsedd aright, kindly sent me a tracing of a Gorsedd plan preserved among the Iolo MSS. at Llanover, Mon.

It was the perfect plan that I had been searching for. It was accompanied by another, less perfect. As usual, the verbal explanations contradict the plans. In the perfect plan, which gives both the solstitial and the May years, the directions 30° or so north and south of east are stated to be the solstices, while no verbal explanation is given of the solstice stones. In the other plan the distance between the east stone and the winter solstice stone is stated to be "30 degrees south." Delightful blunders both!

Plan of a Gorsedd.

The plan was evidently prepared for the engraver, and the draughtsman signs his name as "T. Jones, Merthyr Tydvil, Sculpsit." The numbers given in the plan are not properly explained. A portion of the page is torn, and we have the fragmentary explanations:—"1 Alha—, 2 Alba (also underneath) Alb—, 3 Alban—, 4 y mai(n)—Cadlas neu Cylch C—.' Nos. 5, 6, and 7 are not explained. What Alban No. 1 represents is difficult to make out. In the above tracing I affixed No. 1 to the north stone, by way of directing attention to the fact that for a stone there we have an elaborated north sign. No. 1 was probably intended to mark the Alban Eilir and Elfed (the equinox stones). No. 2 fronts the Alban Hevin (summer solstice stones), but that name is written across the head of the May stones. No. 3 fronts the May stones, though on the margin it is "3 Alba—." No. 4 fronts the November stones, but across the head of that alignment is written "Alban Elfed," the bardic name for the autumnal equinox, while on the margin No. 4 is explained by words which seem to be names for the whole group of sunrise stones. The easternmost stone is described as "Alban Artban," the name of the winter solstice. Between the May and November alignments we have two names, one, "y meini gwynion neu'r Cylch Cyngrair," "the Holy Stones or the Stones of Testimony," the name, in fact, of the circle; the other name is "y Cyntedd," "the Court," the name of the space or gap formed on the east of the circle by the "sun stones." Accompanying another plan, in which names and measurements are also misplaced, we have the following explanatory remarks, which are perfectly correct:—

"The stones forming the circle are termed *White Stones* or *Stones of Testimony*—the circle itself is sometimes called the *white circle*.

"The middle stone, or altar, is termed *Maen Gorsedd*, i.e. *Presidial stone*.

"The stones pointing at the Equinoxes and Solstices are called *Stones of the Sun*. The Bards stand unshod and uncovered within the circle, the Presiding Bard, who must be of the *Primitive Order*, stands by the *presidial stone*. All the other Bards attend around, standing near the *white stones* or periphery of the circle."

This is the bard's English, in which language he used to hold his own in the presence of the great Pitt, Dr. Johnson, and the notabilities of his time. My references to the sources of these Gorsedd plans are "Llanover Iolo MSS., vol. x., p. 267, and vol. xix., p 160." "Holy," not "white," is the meaning of *gwyn* as applied to the Gorsedd circle.—J. G.

The writer, Edward Williams (Iolo Morgannwg), who died in 1826, did not quite understand the plans, but to his honesty as a copyist we are indebted for a very valuable document.

In what I venture to call the perfect plan, the place of honour is given to the May year, the solstitial stones taking a second place. This is the case still in Wales. The chief dates still in our rural life are May Day and All Hallows. The gap in the direction of the sunrise stones suggests a comparison with other circles which show a gap in that direction.

It is evident that our bards give us plans which they seem not to understand. They have not invented them. So far as I know, there is no megalithic monument in Britain exactly like a proper Welsh Gorsedd, that is, it is no copy of any existing monument. On the other hand, the similarity between it and existing circles is most striking. There is a circle of nineteen stones, with one stone much larger inside, at Boscawen-un, and nineteen is rather a common figure in such circles in Cornwall. A circle of twelve stones roughly divided the year into months, and one of twenty-four into "fifteen-nights," as the Welsh for "fortnight" signifies, with a gap left in the east to welcome the sun on the chief days of the year, for the nineteen stones are separated, except on the east, by 15°. I have noted that when the stones of a circle are separated, in the plans, by 30°, the circle is complete, as space is provided for a May-November alignment. But providing a splayed avenue for a solstitial arrangement necessitated a reduction in a circle of twenty-four stones to nineteen, and in the two plans I have referred to, where the circle consists of nineteen stones, there is no inner circle of twelve stones described. It is significant that in the conventional instructions the number of stones forming a Gorsedd circle is not definitely fixed. The most remarkable thing in the Welsh Gorsedd is its similarity to our prehistoric circles, while the evidence at no point suggests that it is a mere archæological "restoration" of the primitive circle.

Since the subjugation of Wales to the English throne, an all-round Gorsedd has never been practicable. The Tudor sovereigns issued commissions for Gorsedds, but with power only to set the bardic order aright. In the bardic traditions, however, we have descriptions of a Gorsedd as the High Court of Parliament of every State unit. The unit of government was the *cwmwd*, comot, corresponding roughly to some large country parishes. Places called Gorsedd, Eisteddva, Henllan, often Llan and Eglwys, were such local Gorsedds. There was also a High Court for all the units which formed a lordship or principality, and we read of stated places of inter-State Gorsedds, when Wales was divided into three principalities, namely, North Wales, South Wales, and Mid-Wales.

But such an all-round State Gorsedd became impossible about the time the straight history of Wales begins, just as the earliest codes extant of the Welsh laws take us back to the time when they were rapidly becoming obsolete. The bardic traditions, however, describe such impossible things, even to minute details. So the laws give us much of the history of Wales that is otherwise nebulous.

Even more than the ancient codes of Welsh laws, the bardic traditions of the Gorsedd are the most formally authenticated of any Welsh literature. Since the tenth century the former have had to take care of themselves, apparently, but the bardic traditions were always recited at every proper Gorsedd. From the twelfth century to the first quarter of the nineteenth we have accounts of a series of great Gorsedds (or Eisteddvod, the same thing), every one of which was convened for the chief purpose of re-codifying or otherwise dealing with the bardic traditions. The voluminous body of traditions in question grew out of such assemblies. There was usually one bard head and shoulders above the others, who, of his own accord or by request, would prepare a statement which would be approved at a Gorsedd convened by the lord, as at Caerwys by Queen Elizabeth, and become afterwards the law of the fraternity. After long intervals, and especially after great disturbances in civil government, such revising Gorsedds became necessary, and that they were held for such a purpose, in very adverse circumstances, witness the conservatism, persistence, and vitality which are still much in evidence in the Welsh bardic order. We have nothing so well and faithfully guarded in Welsh literature as our bardic traditions.

The very latest instructions which our present bards observe in erecting a Gorsedd circle were recorded at a time when some said the winter solstice was on December 9 and some on December 10. I mention this because some would have it that these instructions were invented by a Glamorgan bard about the beginning of the last century, who knew the solstice to occur on December 21!

True or false, there is no question of the formal authentication of these traditions, and that is a great step gained. But could these traditions be deliberate inventions after all, guarded and handed down by the bards as such? There is nothing to warrant such a remark. To invent such things the bards would have to be expert historians and archæologists. They were neither the one nor the other, and in their time scientific history and archæology were hardly in existence. Sometimes the bard-redactor indulges in history, and he always blunders in names and dates. But even the poor bits of history are found to be genuine traditions, and may be true enough except as to names, places, and dates. For instance, we are told that the bardic order, and every other order, was established by a man named Prydain (Britain), who was born on the vernal equinox, and every New Year's Day was Prydain's birthday. Students of Rome and Egypt will note this, though, I believe, some in the past have looked upon this tradition as a conclusive proof of the utter worthlessness of bardic history.

As to archæology, it is some study of that science which led me to look into these traditions for collateral evidence. The following are instances. We are told that Arthur caused the system of the Round Table (the Gorsedd, in fact) to be written on plates of tin and brass, and deposited at Gelliwig (Pendennis?) in Cornwall. I am not aware that such bronze tablets have been found there, and it is a mystery how the bards knew of such a medium of writing. But such plates have been found in ancient Gaul on which the Coligny Calendar is inscribed, dating about the beginning of the Christian era.

The bards tell us of an important festival which has wholly disappeared, except possibly in the form of "house-warming," the Hob Feast, *Gwyl Bentan*, "the feast of a fire back, which takes place when five fire back stones have been raised, so as to constitute a dwelling station."

There is one feature of the bardic lore that invites confidence apart from historical and archæological allusions. It is a fine unconsciousness, such as is never found, I believe, in faked, forged, or invented histories. It betrays itself in two ways. On the one hand, the necessity of proving or defending whatever history or tradition he records never occurs to the bardic scribe. From period to period we have simply a record, stamped by a Gorsedd authority, of accepted truth or sound lore. On the other hand, he never troubles himself about Druidism as such. He tells us, in passing, that there was something of the kind in the time of Julius Cæsar. Very seldom the term Druidism is used, and then not for what Cæsar knew as such, but for the actual teaching of the bards. He never troubles himself over the question of a Druidical succession from Cæsar's time to the present. It is over-consciousness in handling the bardic traditions that has worked havoc with them within the last century. Fortunately, however, our materials have a downward limit of date to the sixteenth century, before hardly anybody thought of arguing the matter.

Within the last fifty years a special effort has been made to "restore" the Gorsedd. Until lately its preservation was very much a local matter, in which the bards of Glamorgan have been most faithful. Now, however, it is a distinctly national institution.

JOHN GRIFFITH.

CLIMATOLOGY OF THE UNITED STATES.

PREPARED by Prof. A. J. Henry, under the direction of Prof. Willis L. Moore, chief of the United States Weather Bureau, a volume[1] of 1012 pages has recently been published dealing with the climate of the United States. This most valuable contribution to meteorological science will be welcomed by all who wish for the advancement of this subject, and the Department of Agriculture is to be congratulated on publishing in this form the climatic statistics for the different portions of the United States.

Americans are nothing if not practical, and the issue of the volume before us is an excellent example of this. Thus, in the introduction, we are told first that the "need of such a volume has been felt for some time, particularly within the Department." Further, and this is where Great Britain might take a hint with regard to furthering the agricultural needs of her colonies, "During the last few years the Bureau of Plant Industry has introduced a number of seeds and plants new to this country, as well as new varieties of plants and grains already well established. In order that the best results may be obtained, it is essential that the new plant or seed be placed in a climate closely resembling that of its original habitat. The Pomologist has likewise felt the need of more generalised climatic data than is afforded by the scattered publications of the Weather Service, and this is true in other lines of research that are being prosecuted by the Department."

The above quotation is another instance, if one is required, that the American Government carefully fosters the study of meteorology, and thereby increases its revenue.

The data on which the statistics here given are based may be said to be taken from three sets of observations. Thus the first is due to the Medical Department of the Army, the observations being made at military posts during the period 1820–1890. The second is the result of observations made by the cooperating observers of the Smithsonian Institution, and extends from 1849–1874. The third and last set is due to the Signal Service and the Weather Bureau, and commenced in 1870 and is continued up to date.

In spite, however, of the fact that several records cover a great number of years, only a few records exceeding fifteen years in length are inserted in this volume. The reason for this, as stated, is that it is only within the last ten or twelve years that uniformity, both in observing and recording climatological data, has been attained.

The book before us may be considered as divided into three sections. The first portion consists of an admirable summary of the main features of the United States climate (pp. 7–84), supplemented with numerous maps and charts. The second part (pp. 85–118) consists of general tables of temperature, humidity, and wind, followed by a list and map of the climatological stations which appear in the report. The remaining but greater portion of the volume (pp. 119–1012) is composed of the contributions of the district forecaster or section director of each State. This, as a rule, takes the form of a general description in words of the climate of the State as a whole, then a State summary in tabular form regarding temperature, frost, and precipitation, and, lastly, the monthly, seasonal, and annual means for temperature and precipitation for each station, together with such data as description of locality, instrumental equipment, and positions of instruments. When it be mentioned that no less than 690 stations are referred to, and the data for each station occupy a page, some idea of the amount of material dealt with can be obtained.

[1] "Climatology of the United States." By A. J. Henry. U.S. Department of Agriculture. Weather Bureau, Bulletin Q (Washington, 1906.)

Reference has been made above to Prof. Henry's admirable summary of the broader features of American climate. This portion of the work should be read with great interest, because it brings together in clear and concise language an account of the general conditions of atmospheric circulation which occur over this large stretch of country. Justice to this essay could only be done by occupying considerable space, so remarks will be limited simply to one or two points which seem to be of more special interest. The first of these describes the conditions which accompany "cold waves," which occasionally pass over the country and envelop it in Arctic weather. The fall of temperature to justify one of these waves must, as is stated, be at least 20° F. in twenty-four hours, except along the Gulf Coast, where a drop of 16° F. or more constitutes a cold wave. Cold waves follow in the wake of cyclones under the influence of which the temperature has risen. The lowest isotherms are nearly coincident with the highest reading isobars in the anticyclonic system which follows the cyclone. The isotherms, other than the lowest, only very generally follow the trend of the isobars, and spread much further south over the United States than the isobars would suggest. The cause of these cold waves is due, not merely to the prevalence of the cold north-west winds which follow the passage of the low-pressure area, but more particularly to the radiation from the ground in the clear dry air in the rear of the cyclone. The cold of radiation is communicated to a greater stratum of air, and the effect of solar radiation is reduced, since the surface layers are being constantly renewed by colder air from higher latitudes. With little horizontal air movement in the anticyclone, the night temperatures are low, and there is a tendency for this cold air to collect in valleys and basins. January, February, and March are the months in which the waves chiefly occur, and in the eastern part of the United States the average number a year is three or four.

Prof. Henry gives some very instructive maps illustrating the barometric and thermometric conditions during some of the more intense waves that have been recorded.

Hot waves, or "heated terms" as he calls them, are more briefly dealt with, and some idea of their effect on humanity may be gathered from the statement that "during the three weeks that ended August 22, 1896, there were 2036 known deaths in the United States directly attributable to sunstroke. Large as this number is, it doubtless falls far short of the actual number of cases."

In the same thorough way in which the above waves of heat and cold have been discussed, Prof. Henry deals with precipitation, sunshine, wind (including thunderstorms and tornadoes), &c. The concluding section is devoted to seasonal variations from year to year. It will be remembered that at the beginning of the present year, when Europe was enveloped in a cold wave, Iceland, with a much more northern latitude, was revelling in warm weather. Similar inversions occur in the United States. Thus we read that, during the severe weather of March, 1906, when temperatures 10° F. to 20° F. below zero prevailed in the northern Rocky Mountain region, including the southern portions of Alberta, Assiniboia, and Winnipeg, the weather in Alaska, far away to the north, was warm and pleasant, with temperatures above freezing in the lower Yukon Valley, and about freezing in the vicinity of Eagle (longitude 141° W.).

The primary object of the present work was to present in a form for easy reference comparative statistics for the different parts of the United States. This object has been very successfully attained in this volume so far as existing homogeneous observations allow, but the data for many stations will have to be revised when means can be formed for a greater number of years. Nevertheless, the volume is a valuable contribution to the meteorology of the portion of the world with which it deals, and will serve probably to stimulate the directors of some other meteorological services to bring together masses of existing material which are for the most part lying dormant.

DEDICATION OF THE CARNEGIE INSTITUTE.

THE trustees of the Carnegie Institute had permitted their European guests to select the steamers that suited them, and had taken quarters for them in the new and luxurious Hotel Belmont, 42nd Street, New York. On Wednesday morning, April 10, two special pulmans and a luncheon car were provided to take the party to Pittsburg, and one or two of the trustees were on board to welcome the guests and to make them known to one another. Amongst the party were Baron d'Estournelles de Constant and M. Paul Doumer, representing the Institut and various French universities; M. Leonce Benedite, director of the Luxembourg; and M. Camille Enlart, director of the Trocadéro Museum, Paris; their Excellencies T. von Moeller, Minister of State, and Lieut.-General von Loewenfeld, Adjutant-General, represented the German Emperor; Privy Councillor Dr. Koser, chief director of the Prussian State Archives and member of the Academy of Sciences, and F. S. Archenhold, director of the Treptow Observatory, represented scientific Germany; Sir Robert Ball, F.R.S., and Dr. Roberts, the Vice-Chancellor, represented the University of Cambridge; Dr. John Rhys represented Oxford University; whilst there were also present Sir Edward Elgar, Sir William Preece, F.R.S., and Dr. Chalmers Mitchell, F.R.S.

Continued snowstorms made it impossible to see much of the wild scenery of the Alleghenies, and the famous horse-shoe curve of the Pennsylvania Railroad was traversed in a regular blizzard. The party reached Pittsburg about 8 p.m., and at the Hotel Schenley, situated in the Schenley Park, a few yards from the Carnegie Institute, found assembled a very large number of Americans representing nearly all the scientific institutions and universities of the United States and from Canada, Principal Peterson and Dr. Bovey from the McGill University, Montreal, and Dr. Galbraith from Toronto.

The proceedings began on Thursday morning, April 11, with a reception of the guests in the founder's room by Mr. Frew, president of the board of trustees, who above all others has been responsible for the translation of Mr. Carnegie's generosity into the actual buildings. This was followed by a reception in the grand foyer of the institute, at which the guests were presented to Mr. and Mrs. Carnegie. After luncheon there was a procession of the guests in uniform or academic costume through lines of cheering students, from the hotel to the institute. At 2 o'clock nominally, actually about 3.30 p.m., the dedication took place. The Cambridge Vice-Chancellor delivered an "invocation," modelled on the university "bidding prayer"; Principal Rhys read a scripture lesson (Proverbs, iii., 9–27), Mr. Carnegie delivered a long address, and M. d'Estournelles de Constant and Theodor von Moeller presented official congratulations from France and Germany.

It was notable, and somewhat humiliating to the English visitors, how elaborately Germany had made official arrangements for showing the sympathy of its Government. At each function Germany was to the fore; there was a personal cable from the Emperor, the Emperor's high representatives appeared with their staff in brilliant uniform, and a special gift of German State records and Blue-books, and the formal return gift from Mr. Carnegie of a cast of Diplodocus, were only characteristic examples of the German activity. The high position and exquisite tact of Baron d'Estournelles de Constant, together with the public announcement made by him a few days later at New York, that the French Government had commissioned him to bestow the Grand Cross of the Legion of Honour on Mr. Carnegie, supported the prestige of France, but although the British subjects who were present ably upheld the position of England in their individual capacities, there was no one formally commissioned to represent the English Government.

On Friday, April 12, there was an informal reception at the technical institute, and a presentation of addresses in the large hall from the various universities and learned bodies throughout the world. There were in addition a number of addresses delivered in whole or in part by the European guests; Sir Robert Ball took as his subject "The Solution of a Great Scientific Difficulty," stating the difficulty in the old supposition that the contraction of its sphere could be the source of the energy radiated out by the sun, and suggesting that the presence of radium offered a solution. Sir W. H. Preece spoke on the connection between science and engineering, tracing the extent to which the art of the engineer had been indebted to the researches of pure science. Dr. Chalmers Mitchell discussed international cooperation in zoology, dealing specially with the necessity for unity in nomenclature and with progress in the international recording of zoological literature. In the evening there was a large banquet, and the proceedings ended on Saturday morning with the ceremony of the conferring of honorary degrees by the Western University of Pennsylvania. The English recipients were as follows:—LL.D., Sir Robert Ball, Sir Robert Cranston, Sir Edward Elgar, Dr. P. Chalmers Mitchell, Sir W. H. Preece, Dr. John Rhys, the Rev. Dr. E. S. Roberts, Dr. John Ross; Litt.D., Mr. C. Moberly Bell and Mr. W. T. Stead.

The Carnegie Institute, the area of which is nearly four acres, and the adjacent technical schools, which when completed will cover with their workshops and yards nearly thirty-two acres, are the "gifts of Andrew Carnegie to the people of Pittsburg," and are dedicated to "literature, science, and art." The total cost, together with a recent endowment for maintenance of more than a million pounds, has been about four million pounds. The management is vested in a board of trustees consisting of local representative men, under whom Dr. W. J. Holland is director of the museum, Mr. John W. Beatty director of the fine arts department, Mr. A. A. Hamerschlag director of the technical schools, whilst Mr. A. H. Hopkins is chief librarian. The exterior of the institute proper is unpretentious, the structure being of steel faced with grey sandstone in a simplified Corinthian style. The interior is a series of gorgeous halls and corridors in marble and gilding, decorated with a striking series of mural paintings by Mr. J. W. Alexander, a young American artist. The library contains special rooms for the reference collection, for the lending library, and for children, and at present consists of nearly 1,500,000 volumes, 800,000 of which find place in an eleven-story book-stack. There is a very large music-hall with a fine organ and a magnificent foyer. The fine arts department contains nine galleries, with a floor space of more than 44,000 square feet, and in addition a hall of sculpture and a hall of architecture. The galleries contain a good permanent collection, specially rich in the works of modern artists, with a special section for an annual international exhibition.

The museum, to which there is attached a fine lecture hall, an excellent special library, and a well-equipped series of research rooms, has a floor space of more than 100,000 square feet, arranged in three tiers, of open courts and galleries. On the ground floor there are special collections of gems and coins, particularly rich in specimens from China, India, and Korea, the gifts of John J. Lewis, William Thaw, and Mr. Carnegie. The main hall of the museum is devoted to mineralogy and geology. There is an almost complete collection of local minerals, and a fine series of huge relief maps of the district. The palæontological department is dominated by Diplodocus, but contains many other interesting specimens, in particular a very fine series of Oreodont mammals. The second floor contains galleries devoted to economic botany and to general zoology. There is a large and well-mounted showcase of Steller's sea-lions, and a capital group of Rocky Mountain goats. The bird series is as yet disappointing, but the arrangement of the galleries has only begun. The third floor is devoted to entomology, and Dr. Holland's fine collection of Coleoptera and Lepidoptera has now found a home worthy of its zoological importance. The chief assistants of Dr. Holland are Mr. Douglas Stewart, in the department of mineralogy; Dr. A. E. Ortmann, with P. E. Raymond, Earl Douglass, and O. A. Peterson, in palæontology; Prof. C. V. Hartman, in ethnology; Mr. O. Jennings, in botany; Mr. W. E. C. Todd, in ornithology; and Mr. H. Kahl, in entomology. The chief assistant in the setting up of fossils is Mr. A. S. Coggshall, whilst Mr. F. S. Webster is the taxidermist and Mr. Th. A. Mills the modeller. With such a staff and the ample endowments at his disposal, Dr. Holland has a magnificent opportunity of which he may be expected to take full advantage.

A full description of the technical schools would require many pages. In equipment and staff they are magnificent, and are adapted for the teaching of almost every form of the mechanical arts.

ARCHÆOLOGY AND THE ASSOUAN DAM.

A DESPATCH from the Earl of Cromer, just issued as a White Paper (Cd. 3397), deals with the question of increasing the water supply of Egypt by constructing a new dam or raising the present dam at Assouan. Notes are included by Sir William Garstin, Sir Benjamin Baker, Mr. A. L. Webb, and Captain Lyons, in which the various plans are considered. After examining all possible sites, the opinion expressed is that no alternative exists but that of raising the Assouan dam. Unfortunately, this means the almost complete submersion, during a portion of the year, of the temples at Philæ; and it is therefore important to know what the Egyptian Government intends to do with regard to the Nubian monuments affected by the proposed works.

Captain Lyons points out in his note that since in an arid climate the flood plains are almost the only region where civilisation has been able to develop, a thorough investigation of the monuments in the district to be affected should be made before the water-level is raised. His principal suggestions are summarised as follows:—

> An archæological survey of Nubia should be carried out, at the expense of the Government, and every effort should be made to render it as complete as possible. The different archæological societies in Europe should be invited to cooperate with the Egyptian authorities in this work, by sending representatives to assist in these researches. Wherever possible, the foundations of the monuments submerged should be reconstructed and consolidated, as was done in the case of the Philæ temples. Such repairs as may be considered necessary to insure the stability of their superstructure should also be undertaken. A thorough and complete examination of all the ancient sites, settlements, and cemeteries which will fall within the limits of the raised water-levels should be carried out, and drawings or photographs sufficient to preserve a complete record must be made by competent artists. Lastly, the results of these investigations must be published to the world.

Sir William Garstin does not hesitate to say that this programme will be adopted, and that "the funds necessary for such an object will not be grudged by the Government." If the raising of the dam is preceded by an exact scientific survey, archæology will benefit by an increase of knowledge, while Egypt will gain by an increase of water supply. There ought, however, to be a definite undertaking that the work will be carried out by the Egyptian Government in a reasonable time. We should be glad to know what has been done with regard to the complete archæological survey of the region already submerged. When the proposal was made in 1894 to build a dam at Assouan with its crest 114 metres above mean sea-level, the archæological societies of Europe protested against it in the strongest terms, and the result was the adoption of a modified scheme in which the crest of the dam is eight metres (26 feet) lower than that of the original project. This was of the nature of a compromise, and the Egyptian Government on its part undertook "to carry out an archæological and scientific investigation of the whole of Nubia."

From Captain Lyons's note in the present White Paper we understand that a topographical basis for such a survey has been prepared, but the systematic study of the submerged portion of the Nile valley, from an archæological point of view, has still to be made. As this is a matter for the Egyptian Government, the responsibility for the survey must not be thrown upon archæologists (who not only are not paid, but have to pay for their exploration), but should be borne by the Government.

By the scheme now proposed, the future maximum water-level will stand seven metres (very nearly 23 feet) higher than is the case at present, so that the dam now contemplated will have practically the same height as that of the original project against which archæological societies strongly protested. It is therefore desirable to insist that the promised investigations should be undertaken seriously by the Egyptian Government without delay, and that adequate provision be made for the systematic survey of the region. Unless all records of the earlier civilisation of the region are carefully and accurately collected and studied, as suggested by Captain Lyons, the claims of archæology are likely to be forgotten when the engineering scheme has been approved and the works are in progress.

MAY METEORS.

IN Spring months meteoric observers can hardly expect very productive results. The weather is often fine and pleasant, it is true, but meteors are usually scarce, and an average night will not present more than about four or five per hour. In 1886, during the month of May, I counted 127 meteors in twenty-five hours of observation. In 1903, May, I saw seventy-two meteors in $18\frac{3}{4}$ hours, and, if allowance is made for time engaged in recording paths, the deduced horary number was about five.

I have noticed that at this season of the year there are comparatively few meteors leaving definite streaks. In July (last half) and August there are, however, a large proportion of streak-producing meteors, but the majority of these are obviously Perseids belonging to the great July-August shower. Some years ago I counted out the number of meteors with streaks seen by me in June and July (1873–1901), and the relative figures were:—

June, of 252 meteors, thirty-one had streaks, proportion 8 to 1.

July, of 641 meteors, 141 had streaks, proportion $4\frac{1}{2}$ to 1.

It cannot be held that May offers any special inducement to meteoric observers, but some very interesting showers are visible. In the early part of the month there are the Aquarids, supposed to be connected with Halley's comet. At about the middle of May the Coronids are often active from radiants at about $231^\circ+27^\circ$ (near α Coronæ) and $246^\circ+31^\circ$ (ζ Herculis), and at the close there are the η Pegasids from $330^\circ+26^\circ$, maximum on May 30.

There are many other showers from Hercules, Draco, Libra, Serpens, Scorpio, &c. Fireballs are tolerably numerous during the month, and they are apparently directed from a number of different radiants.

This epoch is likely well to repay investigation, as it has never been amply studied in past years. More observations should therefore be obtained, so that the leading showers of the present day may be ascertained.

Though the majority of streams are probably of annual occurrence, a few of them are undoubtedly periodical, giving perhaps only one pretty rich exhibition once in a long series of years. The latter class of shower would escape notice unless observations were maintained with great assiduity and regularity. As an instance of a rich periodical shower of this kind, I may mention that on 1879 August 21–25 I witnessed the flight of fifty-six bright meteors from a radiant at $291^\circ+60^\circ$, near the star o Draconis, but though I frequently endeavoured to re-observe this display, it never returned except under a very feeble aspect.

W. F. DENNING.

NOTES.

THE annual conversazione of the Royal Society will be held at Burlington House on Wednesday next, May 8.

SIR JAMES DEWAR, F.R.S., has been elected a foreign member of the National Academy of Sciences, Washington.

THE Société chemique de France will celebrate its fifty years' jubilee by special meetings on May 16–18.

REUTER messages from Messina report that a violent eruption of Stromboli occurred at 10 p.m. on April 27. It was accompanied by a strong shock of earthquake, which shattered windows and caused other damage in the vicinity. The cable between the Lipari and Stromboli islands has been broken.

THE Meteorological Committee has appointed Mr. Ernest Gold, fellow of St. John's College, Cambridge, superintendent of instruments in the Meteorological Office, to the readership in dynamical meteorology established for three years from October 1. The readership is constituted from funds contributed by Dr. Arthur Schuster, F.R.S., and is tenable, under certain conditions, at any university in the United Kingdom.

THE exposition which is to be held at Berlin in connection with the fourteenth International Congress for Hygiene and Demography, on September 23–29, promises to be an interesting one. The fight against infectious diseases, principally colonial and tropical diseases, hygiene work of the State and municipality, especially the care of infants, provision of good drinking water, removal of waste, and the hygiene in schools, will be represented by many exhibits. In consideration of the importance of hygiene to private and public life, it has been resolved to keep open the exposition, which is to be held in the "Reichstag," to the end of September.

THE Destructive Insects and Pests Bill was read a second time in the House of Lords on Monday. The Bill is intended to grapple with several matters of importance to the agricultural world, and in particular with the disease called the gooseberry mildew. It provides that the Board of Agriculture may make such orders as are thought fit to prevent the introduction or spread of any particular insect, fungus, or other pest destructive to agricultural or horticultural crops, or to trees or bushes. The Bill gives the Board power to regulate the landing of plants and to authorise the removal or destruction of any diseased plant. Local authorities are empowered to pay compensation for any crops or trees so destroyed.

AT a special general meeting of the Geological Society, to be held on Wednesday, May 15, a new section of the bye-laws, providing for the election of women as associates, will be considered and voted upon. The first clause of the proposed new section reads as follows:—"Any woman who has distinguished herself as a geological investigator, or who has shown herself able and willing. to communicate to the Society original and important geological information, or who has exercised signal liberality towards the Society, and is desirous of being elected, provided she be a British subject, or be domiciled in the British dominions or their dependencies, may, subject to the provisions hereinafter contained, be elected an Associate, the number elected being limited to forty."

AT the second National Poultry Conference, to be held at Reading on July 8–11, the discussions have been arranged under six sections, dealing respectively with poultry farming and production, breeding, hygiene and disease, women and the poultry industry, education and research, and commercial subjects. Among papers to be read at the conference we notice the following:—the Mendelian laws and their application to poultry breeding, by Mr. C. C. Hurst; hybridisation experiments with Ceylon jungle fowl (*Gallus stanleyii*), by Dr. J. Llewellyn Thomas; the economic values of external characters, by M. Louis van der Snickt; parasitic liver disease in poultry, by Prof. F. V. Theobald; the influence of heredity upon the diseases and deformities of poultry, by Dr. H. B. Greene; methods of instruction in poultry-keeping, (*a*) in the United Kingdom, by Mr. F. W. Parton, (*b*) in Australia, by Mr. W. H. Clarke; results of experimental work, (*a*) in the United Kingdom—(*b*) in America, by

Prof. J. E. Rice. Full particulars of the conference can be obtained from the honorary secretary, Mr. Edward Brown, 12 Hanover Square, W.

The annual conversazione of the Selborne Society was held in the theatre and halls of the Civil Service Commission, Burlington Gardens, on Friday, April 26, and between five hundred and six hundred guests were present. Lord Avebury presided, and was supported by the Earl of Stamford and the Hon. Walter Rothschild. During the course of his presidential address, which dealt with the study and appreciation of nature, Lord Avebury said:—"To the wise and good, indeed, Nature is divine, but to understand her we must love her, we must feel that we are one with her. People often talk of the supernatural. This is, no doubt, mainly a matter of definition. To me, Nature is all-sufficient and all-covering. What they regard as supernatural seems to me either natural or non-existent. Whatever exists is part of Nature. It is not that those who hold these views wish to lower the so-called supernatural, but that those who hold the opposite opinion seem to us to limit and lower Nature. Nature is infinite. Every fresh discovery reveals new sources of wonder; every problem that is solved opens others. The telescope and microscope create for us new worlds; the spectroscope has answered questions which Comte thought were obviously beyond the range of human ken." During the evening Mr. E. J. Bedford, one of the first to apply photography to the study of birds, gave an illustrated lecture on "Bird Architecture." Among the exhibits were the original manuscript of Gilbert White's "Natural History of Selborne," and the original letters of Mulso to Gilbert White.

To vol. lxxxvi., part ii., of the *Zeitschrift für wissenschaftliche Zoologie*, Mr. W. S. Marshall, of Madison, Wisconsin, contributes an elaborate account of the development and structure of the cellular elements of the ovary in two species of insects, based on investigations recently conducted by himself in Berlin. The wasp known as *Polistes pallipes* forms the subject of the first paper, in which, after reviewing previous work, the author discusses the developmental history of the three types of cells—oöcytes, nurse-cells, and epithelial cells—throughout the whole or the greater part of their existence. In the second paper, where *Platyphylax designatus* is the species discussed, the author opens up newer ground, since very little is known as to the details of the developmental history of the Phryganeidæ.

We have received three publications from the Bergen Museum, the *Aarsberetning* for 1906, together with the third part of the *Aarbog* for 1906 and the first part for 1907. From the first of these we learn that attention continues to be directed to extending the educational value of the museum, especially as regards the fauna of the country, several new groups of Norwegian animals having been added to the exhibited series. In the third part of the *Aarbog* for 1906 Mr. J. A. Grieg continues his description of the echinoderms collected in the late cruise of the *Michael Sars*, dealing in this instance with the starfishes, while the bryozoans obtained on the same expedition form the subject of an article by Mr. O. Nordgaard in the issue for the current year. The stone-implements of western Norway are discussed by Dr. A. W. Brögger in the last-named part.

Prof. A. J. Ewart contributes to the Proceedings of the Royal Society of Victoria, vol. xix., part ii., a list of identifications of Australian plants, several of them being corrections of previously recorded names. A new genus of the Compositæ, Bellida, founded on a West Australian species, is described and figured. Two new species, *Daviesia mesophylla* and *Eriostemon intermedius*, are recorded, and the characters of *Romulea cruciata*, a native Irid known as onion grass, allied to *Romulea bulbocodium*, are noted.

In Florida the growers of citrus fruits are troubled with the whitefly, *Aleyrodes citri*. A Bulletin, No. 88, of the Florida Agricultural Station, prepared by Dr. E. W. Berger, deals with the methods of combating the pest. Special value is attached to the efficacy of fungi parasitic on the whitefly, of which a red fungus, *Aschersonia Aleyrodes*, a yellow species of Aschersonia, and a brown fungus are known. It is recommended to scatter spores of the fungi by spraying, or to introduce cultures on leaves or trees.

As a consequence of the shortage in the Indian jute supply, the Government of India delegated Mr. R. S. Finlow, attached to the Agricultural Department as a jute specialist, to ascertain whether new localities suitable as to soil and climate could be discovered outside the ordinary area of jute cultivation that lies along the lower courses of the Ganges and Brahmaputra rivers. In Mr. Finlow's report, issued as Bulletin No. 3 of the Agricultural Research Institute, Pusa, it is stated that jute growing promises to be successful in Bihar, where it will take to some degree the place of indigo. With regard to districts inspected in Madras, Bombay, and Central Provinces, the prospects are less certain, and it will be necessary to await the results of experimental cultivation.

No branch of botany received more attention from Prof. Errera and his pupils than the examination of organic compounds in plants. The late professor was therefore essentially qualified to prepare a practical course on the microscopical identification of such compounds in plant tissues. A small brochure, consisting of the notes on this subject drafted by him for the benefit of students taking botany for a doctorate in science at the University of Brussels, has been published by Dr. J. Massart. Some of the reactions are based on researches made in Brussels, others are taken from the writings of Macallum, Gilson, and Moll.

A general review of the evolution of scientific methods for improving the sugar-cane by hybridisation is presented in the paper published in the *West Indian Bulletin*, vol. vii., No. 4, under the joint authorship of Sir Daniel Morris and Mr. F. A. Stockdale. The possibility of raising seedling canes was authenticated by Harrison and Bovell in 1888; this was shortly followed by the production of numerous seedlings, some of which have proved greatly superior to previously existing strains. Success was thus obtained, but the results were quite fortuitous, and the parentage of the seedlings could not be determined. Finally, the somewhat difficult task of removing the anthers from young flowers and pollinating with pollen from a known type was performed by Lewton-Brain in 1904. The paper also furnishes an indication of future lines of work and a summary of results already obtained. Coloured illustrations of six of the best known West Indian varieties are given.

Up to the present time no deposit of coal has been discovered in the Sahara and in the whole of North Africa. An attempt to ascertain whether coal really exists to the south of Algeria has been made by Mr. E. F. Gautier, and the results of his explorations have been communicated to the Société d'Encouragement (Bulletin, vol. cix., No. 3) by Mr. A. Carnot. No trace of coal was found, but an extensive Carboniferous area was traversed between Figuig and In Salah, and it is possible that coal exists concealed beneath the vast Cretaceous plateaux.

AT the meeting of the Institution of Civil Engineers on April 16, papers were read on the Pyrmont bridge, Sydney, New South Wales, by Mr. P. Allen, and on the swing bridge over the river Avon at Bristol, by Mr. W. H. B. Savile. The Pyrmont bridge across Darling Harbour is 1210 feet long. There are three 30-feet openings in the Sydney approach for vehicular traffic to wharves, while on the Pyrmont side the Darling Island railway passes under a steel bridge of 25-feet span. Electric motive power is used for working the swing span and for roadway gates and for lighting, the whole being operated by one man from a conning tower in the centre of the swing span. The Bristol bridge, which is 600 feet long, carries a carriage road and a double line of the Great Western Railway. The main feature is the swing span, which is 202 feet 6 inches long, pivoted on a pier in the river.

THE current issue of the Transactions of the English Ceramic Society (vol. vi., part i.) shows that much useful work in the discussion of subjects relating to the clay-working industries is being done by the society, which meets at Tunstall, Staffordshire. The contents comprise seven original memoirs, four of which are written by Dr. J. W. Mellor, the hon. secretary of the society, and deal respectively with the determination of the amount of soluble salts in clays, excess air in firing kilns, the sulphuring and feathering of glazes, and the influence of high temperatures on porcelain pyrometer tubes. In the other papers, Mr. W. Burton reviews the different methods of recording high temperatures, Mr. W. F. Murray discusses the pottery oven of the future, predicting that gas firing, at present unknown in the earthenware trade, will fifty years hence be universal, and Dr. F. Shufflebotham deals with the hygienic aspect of the pottery industry.

THE Bureau of Science of the Government of the Philippine Islands publishes the *Philippine Journal of Science* in three sections, dealing with:—A, general science; B, medical science; and C, botany. The numbers in each section appear as rapidly as material is available, and the latest number to hand (A, vol. ii., No. 1) shows that the papers attain a high standard of excellence. There are four original memoirs, on the terpene oils of *Manila elemi*, by Mr. A. M. Clover; on the action of sodium on acetone, by Mr. R. F. Bacon and Dr. P. C. Freer; on a new subspecies of Philippine Cicindelidæ, by Mr. W. Horn; and on the proximate analysis of Philippine coals, by Mr. A. J. Cox. In the last-mentioned paper the author shows that the directions for coal analyses recommended by the American Chemical Society are inapplicable to certain Philippine coals. These coals are easily detected by the shower of incandescent carbon particles which are driven off when the sample is subjected to rapid heating. This mechanical loss can be overcome by expelling the volatile matter very slowly so that the escaping gases do not ignite. This smoking-off method approaches the conditions existing in a coke-oven.

AN interesting account of the Blue Grotto at Capri has been published by Mr. F. Furchheim, of Vienna, 2 Seilerstätte, District I., for private circulation. It is reprinted from the *Deutsche Rundschau fur Geographie und Statistik* (January), and deals with the changes which have taken place in the grotto, considered particularly in reference to variations of sea-level, from the times of the ancients down to the present day, as revealed by historic documents and references.

THE *Revue scientifique* (April 13) publishes an interesting account of graphic methods of calculation in the form of an inaugural address by Prof. Maurice d'Ocagne. As is well known, Prof. d'Ocagne introduced the method of "nomography," in which calculations are performed by drawing lines across a diagram with a ruler. His use of the method for solving algebraic equations is well known. That a piece of squared paper forms an excellent substitute for a slide rule when used in this way is so simple and obvious that it is surprising how often the fact is overlooked.

THE relations of science to questions of national interest forms the subject of a number of the papers in the current issue of *Science Progress*. Mr. James Johnstone discusses the international fishery investigations, and directs attention to the unsatisfactory position of fishery statistics, particularly in connection with Great Britain. The relationship of mining to science, in the hands of Mr. W. E. Lishman, forms the basis for further reflections on England's neglect of science. Dr. John Wade replies to Prof. H. E. Armstrong's attacks on our present medical curriculum; and Prof. Armstrong contributes an address on "The Opportunity of the Agriculturist," and draws a timely moral from the efficiency of the United States Agricultural Bureau. Mr. R. H. Biffen also shows the need of agricultural research in his paper on modern plant-breeding methods. Mr. Shipley, in his paper on the danger of flies, puts in one good word for the motor-car, which, with all its faults, affords no nidus for flies.

IN a paper contributed to the *Physical Review* for March, Mr. W. R. Turnbull discusses the forms and stability of aëroplanes. The author describes laboratory experiments made with planes and singly and doubly curved surfaces, and draws curves showing the lift, drift, and coordinate of the centre of pressure expressed graphically in terms of the angle of inclination. He rightly directs attention to the supreme importance of longitudinal stability. This is a factor which is apt to be neglected by practical aëronauts whose main thought is to build flying machines in the hope of winning prizes. The data in question will afford useful material so far as they go, for studying the stability of various types. This stability depends, however, on other factors also, such as the moment of inertia and the position of the centre of gravity of the proposed apparatus. Another interesting note was recently contributed to the *Comptes rendus* by Captain Ferber, dealing with the forms of propellers calculated to give the maximum efficiency.

MR. F. W. ASTON writes in reply to Mr. A. A. Campbell Swinton's letter, which appeared in NATURE of April 18 (p. 583), to say that when Mr. Swinton has the opportunity of comparing the full text of the Royal Society paper with his own results of 1898 he will recognise the wide dissimilarity of conditions, effect, and explanation between them. The mica mill referred to in the abstract is designed to show that inside the dark space, under conditions of moderate pressure and continuous current, the mechanical energy flowing towards the kathode in the path of the kathode rays is far in excess of that flowing in the opposite direction, a phenomenon which, under the conditions of Mr. Swinton's experiments—very low pressure and discontinuous current—is actually reversed.

REFERENCE was made in NATURE of April 4 (p. 543) to a paper by Mr. C. E. Moss on the "Geographical Distribution of Vegetation in Somerset." The paper is published by the Royal Geographical Society, but did not appear in the *Geographical Journal.*

A CORRESPONDENT asks for a reference to the latest discussion of the stadium of Eratosthenes and the official or Royal Egyptian stadium mentioned in a recent review in NATURE (April 11, p. 553). The information required will be found in "Griechische und römische Metrologie," by F. Hultsch (Berlin, 1882), and in Dr. Dreyer's "History of the Planetary System" (Cambridge, 1906).

A SECOND edition of "The Textile Fibres: their Physical, Microscopical, and Chemical Properties," by Dr. J. Merritt Matthews, of the Philadelphia Textile School, has been published by Messrs. John Wiley and Sons, of New York, and Messrs. Chapman and Hall, Ltd., in this country. The book has been re-written, and is intended to bring together all the material available for the study of the textile fibres. The price of the volume is 17*s.* net.

MESSRS. WITHERBY AND CO. announce the forthcoming publication of a limited edition of a work on "The Vertebrate Fauna of North Wales," by Mr. H. E. Forrest. The work will be a history of the mammals, birds, reptiles, amphibians, and fishes to be found in that part of Wales lying north of the Dovey Estuary, illustrated with plates depicting notable haunts of typical species, portraits of Pennant and other former recorders, and a coloured map of the district.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN MAY:—

May 1. 11h. Mars in conjunction with Uranus, Mars 0° 46′ S.
,, Mars. Apparent diameter = 12″·54.
1–6. Epoch of Aquarid meteors. Radiant 337° – 2°.
6. 10h. 31m. Minimum of Algol (β Persei).
16. 7h. 13m. to 10h. 27m. Transit of Jupiter's Sat. III. (Ganymede).
21. 12h. Jupiter in conjunction with Neptune. Jupiter 1° N.
26. 12h. 14m. Minimum of Algol (β Persei).
,, 16h. 6m. to 16h. 52m. Moon occults θ Libræ (mag. 4·3).

COMET 1907*b* (MELLISH).—An extension of the ephemeris given by Miss Lamson and Frederick, computed by Dr. Strömgren, appears in No. 4172 (April 20) of the *Astronomische Nachrichten*, and gives the calculated daily positions of the comet up to May 10. This object is now barely one-tenth as bright as when discovered, and, according to the elements, was nearest to the earth on April 10·98.

THE RING OF MINOR PLANETS.—Some very interesting facts are educed in a discussion, by Dr. P. Stroobant, which appears as an extract from the *Annales d'Observatoire Royal de Belgique*, vol. ix., part iii.; Dr. Stroobant's subject is the constitution of the ring of minor planets, and he considers the relative distribution, the masses, and the classification of the first 512 of these bodies. After giving a very abbreviated history of the discovery and study of asteroids, the paper discusses the *lacunae* in the grouping of the minor planets, and also the grouping in regard to their mean distances from the sun. A decided maximum occurs between the limits marked out by rings respectively 2·55 and 2·85 astronomical units from the sun, 199 of the asteroids considered revolving in this annulus.

From a discussion of the available data concerning the magnitudes and probable diameters of asteroids, it is found that nearly all the asteroidal matter is concentrated near to the middle of the ring in the neighbourhood of the mean solar distance of 2·7, whilst further analysis shows that, as a general law, the smaller asteroids are relatively less numerous in the richest zones. At the end of the paper Dr. Stroobant tabulates the 512 asteroids in order of their mean distances from the sun, and gives the mean movement, the mean distance, and other data for each.

POSITIONS OF PHŒBE, 1898–1904.—No. 3, vol. lx. (pp. 45–85), of the Harvard College Observatory Annals contains the measured positions of Phœbe, the ninth satellite of Saturn, during the period 1898–1904.

The places of the standard stars employed were taken from the C.P.D. for the epoch 1875·0, and, should greater accuracy be required, all the material for a second reduction is included in the present memoir; it will only be necessary for such a reduction to determine the places of the standard stars with greater accuracy.

OBSERVATIONS OF THIRTY-THREE VARIABLE STARS.—In Bulletin No. 110 of the Laws Observatory, University of Missouri, are published the preliminary results obtained from the observations of thirty-three variable stars, the light-curves and periods of which are as yet imperfectly known. The bulletin gives a list of the stars considered, with their places for 1855·0, followed by a brief discussion of the results yet obtained for each star. These results are compared with previously published elements, and in some cases the light-curves are reproduced.

THE ITALIAN PROMINENCE OBSERVATIONS, 1877–1883.—No. 5, vol. xxxvi. (p. 54, 1907), of the *Memorie della Società degli Spettroscopisti Italiani* contains a series of notes on the prominence observations made at Palermo and Rome from 1877 to 1883. These notes give the atmospheric conditions for each observing day, and brief remarks on any observation of especial interest, and should prove useful in any discussion of these valuable observations.

THE SPECTRUM OF MIRA.—A brief discussion of the spectrum of Mira, photographed at the Lowell Observatory on January 11, is published by Mr. V. M. Slipher in No. 3, vol. xxv. (p. 235, April), of the *Astrophysical Journal.* The region shown on the plate includes Hα, Hβ, Hγ, and Hδ, all of which are bright and increase in intensity in the order given. The series of absorption bands commences at λ 4584, possibly at λ 4463, and appears to extend beyond the region photographed, *i.e.* beyond λ 7000. Vanadium absorption is strongly represented. A comparison of this spectrum with that obtained by Stebbins, at Lick, in 1902, shows that Hβ (and probably Hα) was more intense during the more recent maximum. On the other hand, the series of dark bands appears to have been more intense, and to have extended further into the ultra-violet, in 1902.

THE HARVARD COLLEGE OBSERVATORY.—Prof. E. C. Pickering's report of the work done at the Harvard College Observatory during the year ending September 30, 1906, sounds a note of disappointment at the lack of financial support given to the schemes for astronomical work on well organised lines which he has formulated. The amount of meridian and photometric work accomplished was on the usual immense scale, and it is hoped that when the 60-inch Common telescope is completed the visual work will be greatly extended to the faintest stars.

On the Henry Draper memorial photographs Miss Cannon studied 691 stellar spectra and classified them. Three stars, H.P. 934, H.P. 3030 and +44°.3639, were found to show the second series of hydrogen lines. Mrs. Fleming also found numerous variable stars and stars having peculiar spectra on plates taken with the 8-inch Draper, the 8-inch Bache, and the 24-inch Bruce telescopes respectively. A great amount of work was also performed at the Arequipa station and at the Blue Hill Meteorological Observatory.

NORTH POLAR PROBLEMS.[1]

The deep North Polar Basin forms the northern termination of a series of depressions of the earth's crust extending north through the Norwegian Sea from the eastern side of the Atlantic, and dividing between the continental masses of the old and the new world. The eruption of the Jurassic basalts of Franz Josef Land and Spitsbergen may have had some connection with the sinking in of the North Polar Sea bottom, but the basin was probably to a great extent formed before that time. Newer volcanic rocks are not known hitherto from the edges of the North Polar Basin. On Bennett Island, De Long reports lava (or basalt), but we do not know its age.

It is most improbable that any block of land (horst) should have remained isolated in the middle of such a basin, surrounded by deep water on all sides, and without having any connection with the surrounding lands or continental shelves. It is, therefore, of essential importance to determine the edge of the continental shelf off the known coasts. But the edge of the North Polar continental shelf is only known exactly in two places—north-west of the New Siberian Islands and north of Spitsbergen—whilst in the region between these two places we know the deep sea to the north. In the remaining part of the North Polar Sea we know as yet very little about the edge of the continental shelf.

The rule that the continental shelves are generally much narrower outside high and mountainous coast than off flat and low lands holds good only where the mountain formations of the coast are in near relation to the trend of the coast and to the continental slope outside, and also where the mountainous coast is built up by primary rocks. This seems hardly to be the case on the northern coast of the American Arctic Archipelago and Greenland, although there are rather high promontories in some places. It is, therefore, difficult to say much about the extent of the continental shelf there. It is perhaps more the case along the north coast of Alaska, and therefore the continental shelf may possibly be narrower in that region; but even this is uncertain. The deeper soundings taken near the supposed edge of the shelf may simply indicate depths of submarine valleys, which may be numerous in this region, and many more and deeper soundings are required before we can say anything with certainty.

Dr. J. W. Spencer's conclusions as to the width of the continental shelf (*American Journal of Science*, vol. xix., No. 113, May, 1905), drawn from the great depths of the submarine fjords of the American Arctic Archipelago, are hardly well founded. Considerable depths of the submarine valleys and channels (fjords) do not point to a comparatively narrow shelf in regions where there has been glacial erosion. It ought also to be considered that, on the whole, the region of the American Arctic Archipelago exhibits geomorphological features which are exceptional. This region was probably near the heart of the great North American Ice age, and the land has been split up into islands and peninsulas, whatever the original cause of this dissection might have been.

It cannot, therefore, be said that the geomorphologic features of the known part of the Arctic regions exclude the possibility of a wide extension of the continental shelf, possibly with lands on it, into some parts of the Unknown North.

The Sea Currents and *the Drift of the Ice* seem to indicate that there is an extensive area of sea to the north of the *Fram's* track. Peary's experiences during his latest expedition also indicate that there is much sea to the north of Greenland. The ice-drift converges towards the opening between Greenland and Spitsbergen. Peary's observations of a rapid eastward ice-drift also indicate that there cannot have been much land to the east of his northward track; but as we do not know the depths over which Peary travelled, we cannot say much with regard to the possibility of land or continental shelf further north and east.

The drift of the *Jeanette* can hardly be said to indicate land to the north, as this drift was chiefly influenced by the winds.

My conclusions with regard to an actual current in the surface-layers of the North Polar Basin, pointing towards Franz Josef Land and Spitsbergen ("The Scientific *Fram* Report," vol. iii.), might seem to indicate that there was land to the north, and that the North Polar Basin is a long and narrow depression. For, owing to the earth's rotation, we might expect a surface-current of this kind to be deflected towards the coast on its right-hand side, *i.e.* towards the Greenland and American side. It is, however, probable that the winds and ice-drift in the unknown parts of the sea might have influenced the direction of our drift, and that therefore the results arrived at as to the direction of the current are not quite correct.

R. A. Harris's contention that the difference in the magnitude of the *tides* on Bennett Island and the coast of Alaska proves the existence of extensive land to the north is based on a much too scanty material of observations. On the northern coasts of Franz Josef Land I found a smaller tide than the *Jeanette* people on Bennett Island.

The possible differences shown by the *ice* in the Beaufort Sea, on the coast of Prince Patrick Island, north of Ellesmere Land and Greenland, and in the sea crossed by the *Fram*, cannot be said to point to the existence of land in the Unknown North.

The occurrence of *driftwood* on the northern coasts, and even on the floe-ice itself (north-west of Greenland), proves that this ice must have drifted across the unknown sea from Siberia or America. The great quantity of "*post-Glacial*" *driftwood*, found even at high elevations on the now ice-bound coasts in the north, points to a milder period in post-Glacial times with a more open North Polar Sea.

Methods of Exploration.—The drawback with sledge journeys across the Polar ice is that they do not give much opportunity of soundings and oceanographical work; but something could be done by a practical equipment. Determination of the edge of the continental shelf would be most important, but also some observations of the temperature and salinity of the deep-water strata of the deep sea beyond this edge would be of value.

A drift with a ship across the Unknown North from the sea north of Behring Straits or Western Alaska, and towards Greenland, would give important results, and could be done probably in five years, although the drift-cask of Bryant and Melville took nearly six years from Alaska to Iceland (from September 13, 1899, to June 7, 1905).

[1] Abridged from a paper by H.E. Dr. Fridtjof Nansen, G.C.V.O., read before the Royal Geographical Society on April 29.

SEISMOTECTONIC LINES.[1]

In studying the distribution of the towns and villages damaged by Calabrian earthquakes, Prof. Hobbs finds that they show a noteworthy tendency to grouping along series of essentially parallel straight lines (seismotectonic lines), which he believes are related to coast-lines, borders of mountain-masses, boundaries of geological formations, &c. The places most seriously damaged are generally situated at or near the intersections of indicated seismotectonic lines, while these lines often intersect lines of volcanoes (volcanotectonic lines) at volcanic vents. In the direction perpendicular to seismotectonic lines, he states that the destructive intensity of the waves falls off rapidly, having but little effect upon well-built houses more than a mile distant, except in the case of earthquakes of the first order of intensity. He therefore concludes that "the destructive violence of an earthquake is localised on vertical planes of fracture within the earth's crust; along which cracks the seismic waves are transmitted with the least loss of intensity."

The district chiefly affected by the Calabrian earthquakes is one in which the peculiar earth-sounds, known as brontidi, mistpoeffers, &c., frequently occur. Recent investigations by Cancani, Alippi, and others have shown

[1] (1) "On some Principles of Seismic Geology"; (2) "The Geotectonic and Geodynamic Aspects of Calabria and North-Eastern Sicily, a Study in Orientation." By William Herbert Hobbs. (*Beiträge zur Geophysik*, Bd. viii., pp. 219–362, and plates.)

that these sounds are closely connected with ordinary earthquake-sounds, and Prof. Hobbs finds that the Calabrian villages from which brontidi are reported are also those which have suffered most from disastrous earthquakes, and that they are ranged along the more prominent seismotectonic lines of the district.

In great detail Prof. Hobbs studies, not only the places damaged by the important earthquakes of 1638, 1659, 1783, 1894, and 1905, but also those at which numerous slight shocks were observed, for the latter, owing to their small disturbed areas, seem to be the most useful indices of the course of seismotectonic lines. The positions of more than 300 such lines in Calabria and north-eastern Sicily are estimated and drawn upon a series of maps, as well as the bearings of joint-planes, the trend of the volcanotectonic lines, and the distribution of brontidi.

It will be seen from this brief abstract that Prof. Hobbs's memoirs possess considerable interest. They are the result of extensive reading, and contain many useful references. But his wide generalisations seem to me to be based on insecure principles and insufficient data. Isoseismal lines, it is well known, are elongated in the direction of the originating faults, but the positions of a few places at which shocks are felt cannot determine a line of fracture. For instance, one of the British seismotectonic lines is located by the positions of four places, two of which are more than 200 miles apart. The seismotectonic lines revealed by the New England earthquake of 1870 are based on the positions of about a score of places distributed over an area reaching from Quebec to Newhaven, and on about a dozen apparent directions of the shock. When observed in houses, such directions are almost invariably perpendicular to the principal walls, but Prof. Hobbs assumes that they indicate that the shocks were transmitted along parallel seismotectonic lines. In Calabria, on the other hand, the damaged villages are so numerous that it would be strange if many of them were not collinear. Several of the seismotectonic lines plotted by Prof. Hobbs no doubt correspond with lines of fracture, but the existence of a very large number of his lines must, I think, be regarded as doubtful. Industrious as he has been in the collection of materials, he has tried within little more than a year to achieve results which the long-continued labours of many men might fail to establish.

C. DAVISON.

HYDRATES IN AQUEOUS SOLUTION.

A RECORD of researches which have been carried out by Prof. H. C. Jones with his students and confrères has recently been published by the Carnegie Institution.[1] The investigations which have been undertaken were to elucidate an observation made by Jones and Ota when studying the freezing points of solutions of double salts in order to ascertain whether in solution they remained as constituent molecules or were broken down. They found that concentrated solutions gave abnormally low freezing points, the molecular lowering of freezing point passing through a well-defined minimum as the concentration changed. Now according to the ionic theory as then expressed, the molecular lowering should decrease continuously as the concentration of the solution increased.

A very large number of solutions of salts, acids, and bases, and neutral organic substances have now been studied, and as a result it has been found that this excessive depression as the concentration increases is a general property of solutions. In order to explain this digression from the generally accepted rendering of the ionic theory, Jones postulates that "in solution a part of the solvent is combined with the dissolved substance and no longer plays the *rôle* of solvent, at least so far as the freezing point method is concerned."

By a determination of the freezing point, conductivity, and specific gravity of the solutions, it has been found possible to calculate approximately the total amount of water held in combination by the dissolved substance, and consequently the approximate amount combined with one molecule of the compound or of the ions resulting from it.

[1] "Hydrates in Aqueous Solution." By Harry C. Jones. Pp. viii+264. (Washington: Carnegie Institution, 1907.)

The theory proposed here differs from that suggested by Mendeléeff, who considered that such substances as sulphuric acid and calcium chloride form a few definite compounds with the water in which they are dissolved. But the present theory supposes that combination between the dissolved substance and water to be a general phenomenon. The compound forms, say, for example, calcium chloride, a complete series of hydrates extending from a few molecules of water to at least thirty, all the intermediate stages being represented.

The memoir commences with an introduction, in which the earlier work is reviewed and the freezing-point and conductivity apparatus used by the author are described. Then follows part i., dealing with the evidence for the existence of hydrates in aqueous solution and the approximate composition of the hydrates formed by a large number of electrolytes. The work here described was carried out by Getman and Bassett. Attention is directed to the effect of temperature on water of crystallisation, as bearing on the theory of hydrates in solution. It is shown that salts which on crystallisation contain water of crystallisation are able to combine when in solution at ordinary temperatures with a much larger quantity of water than they are able to bring with them out of solution on crystallisation. The results obtained are illustrated in many cases graphically by curves and in other cases by tables.

Part ii. is chiefly the work of Uhler, and deals with spectroscopic investigations. The spectrographic photographs which are given have been magnificently reproduced, and form quite a feature of the book. The colour changes produced, for example, by the addition of different salts to cobalt salts have been investigated quantitatively. That is to say, the absorption spectra of the substances, separately and when mixed in known quantities, have been observed with a direct-reading spectroscope, and thus the wave-lengths and absorption bands obtained. The special spectrograph which has been used to obtain the photographic record of the absorption bands is also described. The final section deals with non-aqueous solutions, the solution of substances in methyl and ethyl alcohol having been studied. The results seem to indicate that some substances at least, such as lithium chloride, bromide, and nitrate, combine to some extent with the solvent. However, this portion of the work is yet in its initial stage, and much yet remains to be done. We understand that the author is extending the work in this direction.

Altogether, the memoir is an extremely valuable contribution to the study of the subject, more especially in connection with concentrated solutions. It has often been urged, and with a considerable amount of truth, that the ionic theory is simply a specialised hypothesis, which is true only of dilute solutions. Prof. Jones has gone far to remove this reproach by broadening the basis of the theory and enlarging its scope. The publishers, the Carnegie Institution, must also be congratulated upon the splendid way in which the letterpress and diagrams have been got up.

F. M. P.

PRODUCTION AND DECAY OF MEDIÆVAL STAINED GLASS.[1]

THE earliest direct evidence as to the methods of mediæval glass-painting is contained in the treatise of Theophilus ("Diversarum Artium Schedula"), which dates back in all probability to the latter half of the twelfth century; here one finds detailed instructions for the making of the glass as well as for its formation into the flat sheets or "tables" in which it is required by the glass-painter.

This treatise makes it clear that at that time such window glass was for the most part made by what is generally known as the "muff" process. The process referred to is one of the three known methods of making window glass, namely:—

(1) Cast or plate glass, made by pouring molten glass on to a flat stone or metal slab.

(2) Muff or cylinder glass, in which the glass is worked

[1] Abstract of a paper read before the Society of Arts on March 13 by Mr. Noel Heaton.

into the form of a hollow cylinder by means of the blowpipe, which cylinder is subsequently opened out into a flat sheet.

(3) Spun or crown glass, in which a bulb-shaped mass of blown glass is converted into a disc by rotating it rapidly whilst in a plastic state.

The earliest known window glass, that of the Romans, was produced by the first of these methods; in fact, it has hitherto been supposed that the Romans knew no other way of making glass into sheets. A careful examination of the glass brought to light by the excavations at Silchester, however, leaves no room for doubt that the Romans were acquainted with the art of making blown window glass according to the "muff" process.

There are reasons for thinking that the making of window glass was not handed down from the Romans, but was re-discovered in the Middle Ages, and the author thinks it most probable (although evidence is too scanty to justify this as a statement of fact) that the glass of the earliest stained-glass windows, that is, those of the ninth and tenth centuries, was made in the same way as the cast window glass most generally employed by the Romans, this being the method that would most naturally suggest itself in the first place.

The composition of the glass described by Theophilus was quite different from that of the Romans, being produced, according to the treatise referred to, by heating a mixture of sand and the ashes of beechwood. It is probable, however, that the glass varied very considerably in composition at different times and in different places, owing to the impurity of the sand used and the varying nature of the wood ashes, which would in all probability be obtained by burning whatever species of timber came nearest to hand.

Considering these facts, mediæval glass would be expected to reveal on analysis a fairly complicated composition, and, whilst varying considerably, to show in general a richness in alkali (usually potash) and poorness in lime.

In order to obtain further information on this point, the author, in conjunction with Mr. Percy Williams, determined accurately the composition of some typical specimens of mediæval stained glass, of which a description is given in the paper. The following table is a summary of the results obtained:—

Composition of Mediaeval Glass.

Material	Sandiacre	Dale Abbey	Modern window glass
Silica	54·01	46·94	70
Phosphoric acid	4·18	4·11	—
Potash	13·20	16·96	15
Soda	1·70	0·12	
Lime	17·37	19·01	13
Magnesia	5·33	5·00	
Alumina	2·41	3·02	2
Iron	0·81	1·46	
Manganese	1·03	1·37	
Moisture due to decay	0·21	2·16	—

These results are of interest in several directions, chiefly, however, as revealing the presence of a considerable amount of phosphorus in the glass. The evidence this affords as to the making of the glass, and its effect on the nature of the glass, are discussed in the paper, and attention is directed to the disturbing influence this unlooked-for ingredient has on the process of analysis.

The importance of this point lies in the fact that if a partial analysis of the glass is made—with the view of determining the amount of alumina, for example—or if an analysis is attempted without the possibility of the presence of phosphorus being recognised, the results are liable to be seriously inaccurate. A summary of the method adopted by Mr. Williams for obtaining the analyses quoted follows, this being based on the removal of the phosphorus by silver carbonate.

The paper then passes on to discuss the phenomena of the decay of old stained glass in the light of the peculiar composition revealed by these analyses.

Mediæval glass decays in a very characteristic manner. Very commonly the glass becomes covered with little pits, for all the world like the worm-holes one often sees in an old oak cabinet.

The process of decay in glass is undoubtedly a parallel on a small scale to the change produced on a large scale by the action of time and weather on geological formations, such as chalk and sandstone—a combination of corrosion and internal change.

Corrosion of the surface of glass is produced by the long-continued action of moisture, which gradually extracts the

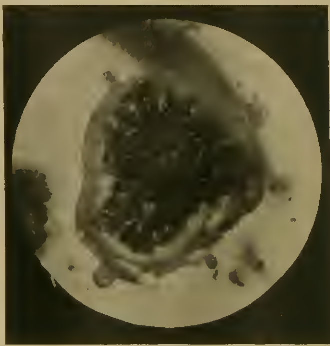

FIG. 1.—Photomicrograph of an area of decomposition in mediæval glass.

soluble silicates, leaving the insoluble silica in a thin film, the glass thereby becoming iridescent. Owing to the large proportion of lime it contains, however, mediæval glass does not become iridescent as the result of corrosion. On the extraction of the alkali by water this lime is left behind with the silica, and forms with it a hard, insoluble silicate of lime, which adheres to the corroded surface of the glass, forming an opaque scum or patina. In some cases this is so marked that the glass appears to be covered with a coat of cement.

The peculiar pitting of old stained glass is not, however,

FIG. 2.—Photomicrograph of similar structures produced experimentally in modern window glass.

in the author's opinion, due to corrosion at all, but to a change in the constitution of the glass. As is well known, glass changes its constitution and becomes crystalline if kept at a red heat for a length of time. What happens in a few hours when the glass is hot tends to take place on prolonged exposure to the atmosphere, with this difference, that when the glass is molten its molecules can freely move about, whereas when it is cold and rigid such freedom of movement is impossible; in consequence the definite formation of crystals cannot take place, and the result of the change is different. What happens is this. In the first place, molecules of the same kind tend to separate out from the homogeneous mixture and collect round a point, forming a centre of decomposition. Proceeding from this centre the glass is found decomposing into definite compounds in an ever-enlarging circle until it reaches a point at which the strain set up in the glass by this molecular movement results in a crack forming round the area of decomposition, and then the whole mass comes away, leaving behind it a little hole or pit in the surface of the glass.

Such are the two forces at work on the decay of glass—corrosion without and decomposition within—and, of course, they act simultaneously. As the pits are formed they are extended by corrosion, forming a resting place, in fact, for the water, until eventually the whole fabric of the glass is destroyed.

According to varying circumstances—the position of the window as affecting its degree of exposure, the climate in which it is placed, differences in composition and mechanical state of the glass—we get all sorts of variations in the precise effect of decay in particular instances.

It is a well recognised fact that glass containing a large proportion of earths, that is, lime, magnesia, and alumina, is especially liable to become crystalline. If, then, one is correct in thinking that the peculiar pitting of Gothic glass is due to a similar change of constitution, one would expect to find it excessively rich in these constituents, and we have already seen that this is, in fact, the case.

On the other hand, glass containing excess of alkali has an equally recognised tendency to go "blind," that is, to become covered with a film, due to corrosion. Finally, glass with a high content of silica, with earth and alkali equally balanced, may be looked upon as highly resistant in both directions. It is such glasses which decay slowly and with little tendency to devitrification, the surface being merely etched by corrosion, leaving the large proportion of silica in a coherent thin film, producing gorgeous effects of iridescence.

Besides the glass itself, a study of the materials used for producing the enamel with which the glass was painted to represent figures and subjects is a matter of some importance, which is fully discussed in the paper. After going thoroughly into the evidence afforded by those mediæval pay-rolls which have been preserved, dealing with the execution of stained-glass windows, the author comes to the conclusion that the enamel in question was prepared by making a fusible opaque black glass, technically known as "geet," probably because it resembled jet in appearance (the word jet being in writings of the period variously spelt jeat, ieat, geat, geet); this material would be used as a flux, and mixed with the oxides of iron and copper to make the paint. Experiment shows that an enamel prepared in this way is in every respect similar to that used in the finest examples of mediæval stained glass.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

AN exhibition illustrating a course of lectures on Japanese education given under the auspices of the University of London by Baron Kikuchi, will be opened on Tuesday next at the Victoria and Albert Museum (Indian Section), South Kensington. The exhibition will remain open until the end of June.

RECENT statistics published by the French Minister of Public Instruction give the number of students attending courses of instruction in French universities and higher educational institutions. The total reaches 38,197, of whom 3434 are foreigners—a number much larger than usual owing to the temporary closing of certain Russian universities. Of the native students, 1364 are women. The number of students at some of the larger universities are as follows:—Paris, 15,789; Lyons, 2783; Toulouse, 2675; Bordeaux, 2496; Nancy, 1841; Montpellier, 1752; Lille, 1560; Rennes, 1498; and Aix-Marseilles, 1269. The Paris students are distributed among the different faculties and schools as follows:—law, 7032; medicine, 3369; letters, 2413; science, 2022; and pharmacy, 953. The total number of French university men students include in the various departments of learning:—law, 15,427; medicine, 7501; letters, 4605; science, 5881; and pharmacy, 2224.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 15, 1906.—"On the Effect of High Temperatures on Radium Emanation and its Products." By Walter **Makower** and Sidney **Russ.** Communicated by Prof. A. Schuster, F.R.S.

In a previous paper it was shown that the activity of radium emanation sealed in a quartz tube is temporarily changed by subjecting it for a short time to temperatures between 1000° C. and 1200° C. From the results obtained it seemed probable that this change was not due to any alteration of the emanation itself, but rather to a change of activity of one of the more quickly decaying products of the emanation with which it is in equilibrium. To settle this point measurements were made of the rate of decay of the emanation when kept at 1100° C. Subsequently experiments were made on the effect of high temperatures on the active deposit collected on a platinum wire by exposure to the emanation.

The results obtained were:—

(1) The change in activity noticed when radium emanation is subjected to a high temperature is not due to any alteration in the emanation itself, since its time period is unaltered when it is maintained at a temperature of 1100° C.

(2) The change is due *either* to a change in radium B *or* C, since the activity of a mixture of these two substances can be changed by heating.

(3) The change is *probably* due to some influence of temperature on radium C. This conclusion is in agreement with the statement made by Curie and Danne.

In a note the authors discuss some recent observations made by Dr. Bronson which appear at first sight difficult to reconcile with the above conclusions. As a result of his experiments, Dr. Bronson concludes that there is no change of activity in radium even when exposed to temperatures of 1600° C.

It is, however, pointed out by the authors that there are several important differences between Dr. Bronson's experiments and their own, the most important of which is that Dr. Bronson measured the activity of the radium while hot, whereas they always allowed the active deposit to cool before making measurements. It is on this account that the authors consider that the results of Dr. Bronson and their own are not necessarily contradictory.

Zoological Society, April 9.—Dr Henry Woodward, F.R.S., vice-president, in the chair.—A collection of fishes made in the eastern watershed of the Transvaal by Captain G. E. Bruce, and presented to the British Museum: G. A. **Boulenger.** The collection contained specimens of eighteen species, of which several had not been previously recorded from the Transvaal, and five were new.—The osteology of the oligomyodian and diacromyodian Passeres: W. P. **Pycraft.** After referring to his previous contribution (published in the Proceedings) on the osteology of the eurylæmid and tracheophone Passeres, the author remarked that there seemed little room for doubt but that the diacromyodian and oligomyodian Passeres must be regarded as divergent branches of a common stem. The latter suborder included the Tyranniformes, Phytotomidæ, and Pittidæ, while the former embraced the remaining Passeres. In the present communication some fourteen families were described, and these were divided into four groups, Hirundines, Muscicapæ, Laniinæ, and Gymnorhinæ. This arrangement was based, not on osteological characters alone, but also on the evidence of pterylosis and certain wing-muscles. The author proposed to include the Vireonidæ with the Muscicapæ, and the Vireolaniidæ with the Gymnorhinæ. With this last group he proposed, tentatively at any rate, to include the Paradiseidæ, inasmuch as there seemed good reason for continuing to regard these birds as near allies of the Corvidæ.—Anatomy of a Bornean frog of the genus Megalophrys, with references to other genera of Batrachia: F. E. **Beddard.**—The winter habits of the greater horseshoe and other cave-haunting bats: T. A. **Coward.** This paper contained the results of observations made in the Somersetshire caverns, where at the end of December and beginning of January the author found that the bats were not in profound sleep, but moved in the caves and went into the open for food. This food, the author showed, was not all taken when the bats were in flight, but was usually devoured when the bats were at rest. The manner of feeding was described, and information supplied about the food of the greater horseshoe and the parasites which infested this species and the lesser horseshoe.

Anthropological Institute, April 16.—Mr. A. L. Lewis, vice-president, in the chair.—*Exhibit.*—A selection of specimens of flint from Cornwall: Mr. **Lewis,** Mr. **Warren,** Mr. **Kendall,** and Mr. **Chandler.**—Note on some Palæolithic and Neolithic implements from East Lincolnshire: S. Hazzledine **Warren.** The Neolithic implements described were found by the author *in situ* in an undisturbed section of the fen deposit of the East Lincolnshire coast near Skegness. The lowest bed seen in the district was Boulder-clay; overlying this there are patches of fluviatile gravel; above this, again, comes the old surface soil of the buried forest; then the peat by which the forest was destroyed, and above this, again, a succession of warp clays with some subordinate peat beds. The exact horizon at which the Neolithic implements occurred was in the old surface soil beneath the lowest peat bed. Besides the neoliths, the author also found a palæolith *in situ* in one of the patches of fluviatile drift gravel between the submerged forest above and the Boulder-clay below. One or two other palæoliths were also found which had evidently been derived from one of these patches of post-Glacial drift. Apart from discoveries in caves, this is the most northerly point at which Palæolithic implements have yet been found in this country in any river drift gravel.

Geological Society, April 17.—Sir Archibald Geikie, Sec.R.S., president, in the chair.—The toadstones of Derbyshire, their field-relations and petrography: H. H. **Arnold-Bemrose.** The district over which the toadstones are seen may be divided into three main areas of volcanic activity, between which there are no exposures of igneous rock:—(1) the north-western or Miller's Dale area; (2) the south-eastern or Matlock area; (3) the south-western or Tissington area. In each of these areas there are lava-flows, bedded tuffs, and volcanic vents, and in the Miller's Dale and Matlock areas several intrusive sills. In the Miller's Dale and Matlock areas the igneous rocks are, with the exception of the Hopton vent, entirely in the Mountain Limestone, but in the third area they are mostly in the Yoredale Shales, and lava plays only a subordinate part. In the Miller's-Dale area the upper lava is the thicker, and extends over a greater district than the lower, while in the Matlock area the converse is true. In the former area the lavas are separated by about 150 feet of limestone, in the latter by about 80 feet to 100 feet. The upper lava of Miller's Dale is on a lower horizon than the lower lava of Matlock, and the limestone above it contains at least two bands of interbedded tuff. The lavas are vesicular and amygdaloidal in structure, and often very much decomposed. They contain olivine, augite, and felspars, magnetite, and iron-oxide; the felspars are often present in two generations. The sills are, for the most part, ophitic olivine-dolerites, and pass from a very coarse-grained dolerite through the intervening stages into a fine-grained dolerite or basalt; they are similar in structure to certain Tertiary dolerites. The toadstones have all been mapped on the 6-inch scale, and petrological accounts of the different rocks are furnished.—Data bearing on the age of Niagara Falls: Prof. J. W. W. **Spencer.** The author has been engaged in investigations for a monograph on Niagara Falls, to be published by the Geological Survey of Canada. Soundings at all the points of great changes in the gorge have been successfully undertaken; borings were put down for the exploration of buried valleys, and instrumental surveys made of the original river-banks and the physics of the stream. The mean recession of the crest-line of the falls is found to be 4·2 feet a year under existing conditions, and this rate has approximately obtained for 227 years. But this rate will not give the age of the falls, on account of former great variations in the volume of the river and in the height of the falls themselves. The chief change in volume of water depends on the fact that originally Lake Erie alone was discharged over the falls, when the supply of water was only 15 per cent. of the present discharge. Lake Ontario, too, stood at a higher level, and thus the cutting-back from Queenstown to Foster's Flats was effected with a small water discharge and, at first, a low head. After an uplift, which raised the crest of the fall considerably above Lake Ontario, a slight depression followed which "drowned" part of the lower gorge. This cutting is calculated to have taken 35,500 years for a distance of 14,400 feet. Above Foster's Flats the sudden widening indicates the inflow of the other lakes into Erie, greater water discharge, and greatly increased rapidity of recession. The changes in height of the falls and resistance of the rocks are examined in detail, and the small influence of pre-Glacial filled channels estimated. The whirlpool is on the site where the recession broke down the partition separating the head of the Whirlpool-St. David's buried gorge, and began to empty out the contents of this valley. The cutting with the full power of the water of the four lakes varied at times according to the height of the fall, and is calculated to have occupied only 3500 years for the cutting-back of about four miles above the head of Foster's Flats. Thus the entire age of the falls is given as 39,000 years.

Royal Meteorological Society, April 17.—Dr. H. R. Mill, president, in the chair.—Phenomenal rainfall in Suva, Fiji, August 8, 1906: R. L. **Holmes.** This is an account of a very remarkable fall of rain which occurred during a thunderstorm at Suva, the capital of Fiji, on the night of August 8. Unfortunately, the exact amount had to be, in part, estimated, owing to the observer failing to measure the fall at intervals during the night. Very little rain fell before sunset, but from 6 p.m. it continued a ceaseless downpour until sunrise the next day. At 10 p.m. the assistant found the gauge overflowing with 12·50 inches of rain in it. Four hours later, at 2 a.m. on August 9, the gauge was again overflowing, and at 6 a.m. it was overflowing once more, that is, three times in twelve hours. Very little rain fell after 6 a.m. These measurements show more than 37 inches, without taking into account the overflowings, which are an unknown quantity. As the gauge was 25 feet above the ground, Mr. Holmes is of opinion that the rainfall should be increased by about 11 per cent., so that the total fall must have been fully 41 inches in about thirteen hours, which he thinks surpasses anything that has been recorded in any other part of the world in so short a space of time.—Temperature around the British Islands in relation to the Gulf Stream: R. **Strachan.** This paper was based on observations made in the year 1906 which have been published by the Meteorological Office. Around the British coasts the temperature of the air was lowest in February and highest in August; the temperature of the sea corresponded to these epochs with slight interruptions, having been lowest in January for the west and central, in March for the south, and highest in September for the north and in July for the east, positions. The water in the Strait of Florida was about 30° warmer than the sea at the north of Scotland.—Weather regarded as a function of climate: L. C. W. **Bonacina.**

MANCHESTER.

Literary and Philosophical Society, March 12.—Prof. W. Boyd Dawkins, F.R.S., in the chair.—The occurrence and significance of symbiotic corpuscles in the lower animals: Dr. F. W. **Gamble** and Dr. F. **Keeble.** The paper described the occurrence of symbiotic coloured corpuscles in the bodies of lower animals. It dealt in detail with a single case, that of the simple turbellarian worm

Convoluta roscoffensis, and discussed the evidence for describing the green cells of the animals as an "infection" by a flagellated vegetal organism. The nature and life-history of this organism were described, and the significance of the association of the organism and of the animal Convoluta was discussed.—Bones of the great auk from Funk Island, Newfoundland: F. **Nicholson.** The bones exhibited were those of the now probably extinct species of bird, the great auk, or gare-fowl, *Alca impennis* of Linnæus. There were seven bones in this collection, consisting of:—one base of skull, one clavicle, one sacral vertebra, two right humeri, two right tibiæ. The bones have been presented to the Manchester Museum at the Victoria University.

March 26.—Mr. Francis Nicholson in the chair.—An apparent case of gaseous absorption caused by the action of a few milligrams of radium bromide on the sides of a glass tube containing the radium: T. **Thorp.** At first there was an expansion, but later on, as the glass turned purple, a contraction took place to less than the original volume. Further investigations are being made, the results of which will be communicated to the society.—A collection of fishes, batrachians, and reptiles made by Mr. S. A. Neave in Rhodesia, north of the Zambezi, with field notes by the collector: G. A. **Boulenger.** Thirteen species of fish, one of which (*Barilius neavii*) was described as new, seven batrachians, and forty-four reptiles were obtained. The localities, dates of capture, and native names of the various forms were given in the paper.—A new class of organo-metallic compounds. Trimethylplatinimethyl hydroxide and its salts: W. J. **Pope** and S. J. **Peachey.** No alkyl compounds of metals belonging to groups 1 and 8 of the periodic table have hitherto been described. The authors find that the chlorides, or in some cases the oxides, of iron, cobalt, nickel, ruthenium, rhodium, palladium, osmium, iridium, and platinum, belonging to group 8, and of gold, belonging to group 1, react vigorously with magnesium methyl iodide. Trimethylplatinimethyl iodide, $(CH_3)_3Pt.I$, is formed by the action of platinic chloride dissolved in ether upon magnesium methyl iodide in ethereal benzene solution; after treating with water and extracting with benzene, the benzene solution yields the new compound on evaporation. On boiling for several hours with silver hydroxide in a moist mixture of benzene and acetone, it is converted into trimethylplatinimethyl hydroxide, $(CH_3)_3Pt.OH$. Trimethylplatinimethyl nitrate, $(CH_3)_3Pt.NO_3$, obtained by dissolving the hydroxide in nitric acid, crystallises in colourless plates, and is freely soluble in water. On adding an alkali chloride to its aqueous solution, trimethylplatinimethyl chloride,

$$(CH_3)_3Pt.Cl,$$

is precipitated. This salt crystallises from chloroform in colourless rhombic dodecahedra belonging to the cubic system. In a similar manner a number of other salts have been prepared, including the bromide and the cyanide; the latter is hydrolysed on heating with caustic potash with evolution of ammonia.

April 9.—Mr. Arthur McDougall in the chair.—Further notes on the adventitious flora of the sandhills of St. Annes-on-the-Sea: C. **Bailey.** The author summarised his observations on the alien plants which had appeared during his five years' residence at St. Annes-on-the-Sea. The number of these aliens was quite worthy of a large ballast-discharging port; altogether between forty and fifty species have occurred, as represented by herbarium examples exhibited at the meeting.

Paris.

Academy of Sciences, April 22.—M. A Chauveau in the chair.—Primitive tuberculosis of the lungs and bronchial and mediastinal ganglia communicated to young cattle by the ingestion of tuberculous virus of human origin: A. **Chauveau.** Tubercle of the lungs can arise directly from the ingestion of human tubercle virus by the digestive organs, and this is not necessarily accompanied by tuberculous lesions of the intestines, although such may sometimes be the case.—The earthquakes of April 15, 18, and 19, 1907, recorded at Paris: G. **Bigourdan.** The records of April 15 indicate that the epicentre was at a distance of 8500 kilometres to 9000 kilometres, about the distance from Paris to Mexico. It is known that there was a disastrous earthquake in Mexico on this day.—The direct hydrogenation of the isocyanic esters: Paul **Sabatier** and A. **Mailhe.** The vapours of ethyl isocyanate, carried off in a current of hydrogen in excess, were passed over a column of reduced nickel maintained at 180° C. to 190° C. The gases issuing from the apparatus contained a little ammonia and carbonic acid, but neither methane nor carbon monoxide. The chief product of the reduction was methylethylamine, small quantities of ethylamine, diethylamine, and triethylamine being also present. With phenyl isocyanate a little aniline was obtained, but the main product was diphenylurea.—Concerning the spectroheliograph: G. **Millochau.** On a question of priority as to the use of a second slit by M. Deslandres.—Differential equations of the second order and first degree the general integral of which has fixed critical points: B. **Gambier.**—Equations with reciprocal integrals: C. **Popovici.**—The theorem of Nernst and liquid chains with identical extremities: J. **Guyot.** An extension of the work of Negbauer and Nernst on solutions of binary electrolytes formed of univalent ions to solutions of electrolytes of polyvalent ions. The experimental results are compared with the figures calculated by Planck's method.—Positive light and Melde's experiment: P. **Villard.**—The phosphorescence of the rare earths: J. **de Kowalski** and C. **Garnier.** To the nitrate of calcium or strontium is added a weak solution of the nitrate of the rare earth (praseodymium, neodymium, erbium, or samarium), the whole precipitated as carbonate, and the latter heated to a red heat with sulphur. The proportions of rare earth giving a maximum phosphorescence were determined in each case.—The phosphorescence of manganiferous calcium compounds: L. **Bruninghaus.**—The triboluminescence of substances containing zinc: Adrien **Karl.**—Some complementary observations concerning a property of platinum amalgam discovered by M. Henri Moissan: Paul **Lebeau.** The property of platinum amalgam of forming a stable emulsion seems to be peculiar to that metal. Instead of shaking the amalgam with water, the author used a 5 per cent. solution of gelatin, capable of solidifying on cooling. Sections were taken of the solidified mass with the view of studying its microscopical structure.—Remarks on the constitution of the copper alloys: Léon **Guillet.**—A new silicide of tungsten, Si_2W: Ed. **Defacqz.** The new silicide is formed by the action of amorphous tungsten upon copper silicide (containing 50 per cent. of silicon) at the temperature of the electric furnace; the same compound is obtained by reducing a mixture of tungstic anhydride and silica with aluminium in the presence of sulphur.—The condensation of sodium derivatives of acyloines of the fatty series with acetic esters: L. **Bouveault** and René **Locquin.** The authors have given the name acyloines to compounds of the type

$$R.CH(OH).CO.R.$$

—Ethylidene-imine (aldehyde ammonia) and hexaethylidene-tetra-amine: Marcel **Delépine.** The author has previously given reasons for supposing that aldehyde-ammonia is not $CH_3.CH(OH).NH_2$, as usually supposed, but the hydrate of $(CH_3.CH:NH)_3$. In confirmation of this view the present paper describes the preparation and properties of the trinitroso-derivative.—The detection and estimation of ammonia in monomethylamine and the more volatile fatty amines: Maurice **François.** By the usual method of a Nessler's reagent of defined compositinn, two parts of ammonium chloride in 1000 of methylamine hydrochloride can be detected with certainty. A quantitative method is developed on this basis.—The composition and analysis of wolfram and hübnerite: Paul **Nicolardot.** A scheme for the rapid analysis of tungsten minerals, permitting of the determination of all the constituents.—The differentiation of the tissues of the stem and frond of Equisetum: C. **Queva.**—The experimental genesis of vital processes: J. **Kunstler.**—Some remarks on the food of the sardine: Casimir **Cépède.**—The functions of the hypophysis and the pineal gland: M. **de Cyon.**

Calcutta.

Asiatic Society of Bengal, April 3.—Specimens illustrating the fauna of certain brackish pools in the delta of the Ganges: Dr. N. **Annandale.** This fauna has become isolated recently, probably within the last half-century, and presents many features of interest. It includes typical fresh-water Entomostraca, as well as two cirripedes (*Balanus amphitrite* and *B. patellaris*), the larvæ of a mosquito (*Anopheles rossii*), numerous fresh-water fish and molluscs, a hydrozoon (*Irene ceylonensis*), and an actinian (*Metridium schillerianum*). The last is probably the most interesting form now occurring in the pools, as it appears to have undergone a very distinct change, both in structure and in habits, since it was described by the late Dr. F. Stoliczka thirty-nine years ago.—Note on the absorption of gases, vapours, and substances from solution by solids and amorphous substances: Dr. M. W. **Travers.** In this note attention is directed to the physical character of such phenomena as the absorption of moisture by organic materials. It has usually been considered that such absorption must be attributed either to surface condensation or to solid solution. It appears, however, that substances which absorb gases or vapours are invariably amorphous, and as amorphous substances must be referred to the liquid rather than to the solid phase, the use of the term solid solution is not permissible. It is the author's opinion that such phenomena as the absorption of water vapour by cotton or jute involve the formation of a simple solution, the supposed solid phase consisting really of a substance in the liquid phase, but possessing a high viscosity. The law of distribution in this particular case is exponential instead of linear, but it tends to become linear as the temperature rises.

DIARY OF SOCIETIES.

THURSDAY, May 2.

Royal Society, at 4.—Election of Fellows.—At 4.30.—The Spontaneous Crystallisation of Binary Mixtures. Experiments on Salol and Betol: Prof. H. A. Miers, F.R.S., and Miss F. Isaac.—On the Variation of the Pressure developed during the Explosion of Cordite in Closed Vessels: Prof. C. H. Lees, F.R.S., and J. E. Petavel.—Space described in a Given Time by a Projectile moving in Air: A. Mallock, F.R.S.

Society of Arts, at 4.30.—The Applicability to India of Italian Methods of Utilizing Silt: Sir Edward C. Buck, K.C.S.I.

Linnean Society, at 8.—The Fauna and Flora of Abyssinia compared with Those of West Africa: Prof. E. B. Poulton, F.R.S.—(1) Report on the Marine Biology of the Sudanese Red Sea (Communicated with an Introduction by the President); (2) Formation of the Shone Cliff near Alexandria; (3) Recent History of the Coral Reefs of the North-West Shores of the Red Sea: Cyril Crossland.—Polyplacophora collected by Mr. Cyril Crossland: E. R. Sykes.—On Chelonethi (Pseudoscorpions) from Asia and Australia: C. J. With.—Note on the Function of the Spiracle in certain Elasmobranchs: A. D. Darbishire.—*Exhibits*: (1) Probate of the Will of Richard Anthony Salisbury; (2) Manuscripts of Dr. W. J. Burchell, Presented to the University of Oxford by Francis A. Burchell, Rhodes University College, Grahamstown, Grand-nephew of the Great Naturalist and Explorer: Prof. E. B. Poulton, F.R.S.

Chemical Society, at 8.30.—(1) The Chemical Action of Exradio, Part I., Action on Distilled Water; (2) The Chemical Action of Exradio, Part II., Action on Copper Salts in Solution. Preliminary Note: Sir W. Ramsay.—Freezing Point Curves of the Menthyl Mandelates: A. Findlay and E. M. Hickmans.—The Constitution of Homo-eriodictyol. A Crystalline Substance from Eriodictyon Leaves: F. B. Power and F. Tutin.—The Relation between Valency and Heats of Combustion. Preliminary note: G. Le Bas.

Institution of Electrical Engineers, at 8.—The Use of Wooden Poles for Overhead Power Transmission: C. Wade.

FRIDAY, May 3.

Royal Institution, at 9.—Dexterity and the Bend Sinister: Sir James Crichton-Browne, F.R.S.

Geologists' Association, at 8.—The Igneous Rocks of the Bristol District: Prof. S. H. Reynolds.—The Carboniferous Limestone Sections of Burrington Combe and Cheddar: T. F. Sibly.—Recent Researches in the Lower Carboniferous Rocks: Dr. A. Vaughan.

SATURDAY, May 4.

Royal Institution, at 3.—Scientific Work in the Sea-Fisheries: Prof. W. C. McIntosh, F.R.S.

MONDAY, May 6.

Society of Chemical Industry, at 8.—The Works Chemist as Engineer: O. Guttmann.

TUESDAY, May 7.

Royal Institution, at 3.—Stimulation, Luminous and Chemical: Prof. William Stirling.

Zoological Society, at 8.30.

WEDNESDAY, May 8.

Society of Arts, at 8.—The Production of Coke and its Application in Domestic Fires: Paul Schlicht.

THURSDAY, May 9.

Royal Society, at 4.30.—*Prelable Papers*: The Anatomy of the Julianiaceæ considered from the Systematic Point of View: Dr. F. E. Fritsch.—The Ascent of Water in Trees, Second Paper: Prof. A. J. Ewart.—Increase in the Complement-Content of Fresh Blood-Serum: Dr. J. Henderson Smith.

Royal Institution, at 3.—Spectroscopic Phenomena in Stars, (1) Chemistry: H. F. Newall, F.R.S.

Institution of Electrical Engineers, at 8.—Telephonic Transmission Measurements: B. S. Cohen and G. M. Shepherd.

Iron and Steel Institute, at 10.30 a.m.—Presidential Address.—Electrically Driven Reversing Roller-Mills: D. Selby-Bigge.—(1) Steel Making from High Silicon Phosphoric Pig Iron by the Basic Bessemer Process; (2) Steel Making from Pig Iron containing Chromium, Nickel, and Cobalt: A. W. Richards.—The Use of Steam in Gas Producer Practice: Prof. W. A. Bone and R. V. Wheeler.

FRIDAY, May 10.

Royal Institution, at 9.—Recent Excavations on Forum Romanum, and the Forum Ulpium: Signor Comᵉ Giacomo Boni.

Physical Society, at 8.—Stereoscopy with long Base-line illustrated on the Screen: Dr. T. C. Porter.

Royal Astronomical Society, at 5.

Malacological Society, at 8.—The Pairing of *Limnaea peregra* with *Planorbis corneus*: W. D. Lang.—Notes on *Achatina denisoni*, Reeve, and *Achatina magnifica*, Pfr.: E. A. Smith.—Review of the New Zealand Acmæidæ, with Descriptions of New Species and Sub-species: Henry Suter.

Iron and Steel Institute, at 10.30 a.m.—Sentinel Pyrometers and their Application to the Heat Treatment of Tool Steel: H. Brearley and F. Colin Moorwood.—Induced Draught with Hot-air Economisers for Steel-Works and Blast-Furnace Boilers: A. J. Capron.—The Influence of Process of Manufacture on Some of the Properties of Steel: F. W. Harbord.—The Distribution of Sulphur in Metal Ingot Moulds: J. Henderson.—The Ageing of Mild Steel: C. E. Stromeyer.—Carbon-Tungsten Steels: T. Swinden.—The Nomenclature of Iron and Steel: Report of a Committee of the International Association for Testing Materials.

SATURDAY, May 11.

Royal Institution, at 3.—Scientific Work in the Sea-Fisheries: Prof. W. C. McIntosh, F.R.S.

CONTENTS.

THURSDAY, MAY 9, 1907.

IS THE ELECTRONIC THEORY OF MATTER LEGITIMATE?

Electrons, or the Nature and Properties of Negative Electricity. By Sir Oliver Lodge, F.R.S. Pp. xv+230. (London: George Bell and Sons, 1906.) Price 6s. net.

AT the present time there are few more absorbing topics among physicists and chemists than the electron and its relation to matter, and none on which a more complete mystification exists. A book on the subject by so illuminating and inspiring a publicist as Sir Oliver Lodge is therefore doubly acceptable at the present time.

A few words on the existing situation may be of general interest. It will be recalled that the researches in optics on the one hand, culminating in the discovery and elucidation of the Zeeman effect, and in the phenomena of the Crookes's tube on the other, resulting in the isolation of the free electron and the measurement of its constants by J. J. Thomson, made the scientific world familiar with the conclusion that the same electron or atom of negative electricity is *an* ultimate constituent of all atoms, and possesses, in virtue of the magnetic field it creates in motion, inertia which, though small, is definite and indistinguishable in ordinary circumstances from the inertia possessed by ordinary matter. There is little that would to-day be generally considered as controversial in these two conclusions. On the contrary, the researches which have led to them have received the unstinted admiration of all. But upon these conclusions are based others, concerned, not with the nature of electricity, but of matter, in the highest degree controversial and speculative, which regard the electron as the universal unit out of which all matter is essentially built up, and mass as an electromagnetic phenomenon due to a vast assemblage of constituent electrons grouped together in stable configurations constituting the atoms. This view of atomic structure was developed by J. J. Thomson in two papers (*Phil. Mag.*, December, 1903, and March, 1904). He regarded the atom as composed of a uniform sphere of positive electrification containing an electrically equivalent number of electrons revolving in regular motion about the centre, and showed that according to the numbers of the electrons periodic sequences of properties of the systems would occur strikingly similar to the periodic sequences in the properties of the atoms of the actual elements themselves.

One of the most enthusiastic supporters of the universal extension of the electronic theory to explain the properties of matter has been Sir Oliver Lodge himself, who saw in the instability, natural to a system constituted of electrons in constrained motion, due to the external radiation of energy that must be supposed to take place, a possible cause of radioactivity and of the observed disintegration of the radioactive elements. Some few months ago, however, J. J. Thomson (*Phil. Mag.*, June, 1906) published the results of an investigation into the actual number of electrons existing in an atom of matter by three independent methods, which led to the uniform and unexpected conclusion that the number of electrons is of the same order as the weight of the atom in terms of that of hydrogen as unity. Since then it may be safely said that no one has known quite what to think with regard to the electronic theory in its application to material phenomena, and the present book, from the pen of a writer to whom so often in the past the student has looked for light and leading in difficult places, will therefore be opened with curiosity and read with eagerness.

The effect of the profound changes which have come over the subject in the last few months is evident in the preface, where we read:—

"A proof that the atom of matter is essentially composed of such electrons, and that its mass, too, is of purely electromagnetic nature, is lacking; the electromagnetic theory of Matter . . . must be regarded for the present as no better than a working hypothesis. It is a hypothesis of stimulating character, and of great probability, but its truth is still an open question that is probably not going to be speedily closed."

The extract may be said to give the keynote to the treatment in the book. It is evident that the writer himself has not lost confidence in the ultimate triumph of the electron theory in its universal aspect, and although he is aware of, and does not attempt to minimise the magnitude of, the recent difficulties which have arisen, his enthusiasm is still undamped. In a chapter towards the end of the book, devoted to a consideration of some of these difficulties, he himself describes the recent paper of J. J. Thomson, to which reference has been made, as "the most serious blow yet dealt at the theory, at least in its simpler and cruder form" (p. 194); and again (p. 151), "it has tended to reduce the whole subject to a state of exaggerated uncertainty." But his final conclusion is (p. 200):—

"The most exciting part of the whole is the explanation of matter in terms of electricity, the view that electricity is, after all, the fundamental substance, and that what we have been accustomed to regard as an indivisible atom of matter is built up out of it; that all atoms—atoms of all sorts of substances—are built up of the same thing. . . . But it must be remembered that although this solution is strongly suggested it is not yet a completed proof. Much more work remains to be done before we are certain that mass is due to electric nuclei."

No excuse need be offered for dwelling on this side of the book, for the attitude of the leading exponents to the recent developments of the electronic theory of matter is topically the most interesting to the scientific reader at the moment. But attention must not on that account be diverted from what is, after all, the main subject of the book, not the nature of matter, but that of electricity. The major part is devoted to an admirable and inspiring treatment of those solid results of experiment and analysis elucidating the nature and properties of negative electricity, which have led to the establishment on a firm basis of the atomic theory of electricity. It is only the last third which is devoted to the speculative and controversial side in which the electron becomes also a material conception replacing the "*urstoff*" or "protyle" of earlier similar speculations. Some of the points touched upon in the text are treated at greater length in a series of appendices, but no index has been furnished, which is a decided omission.

Of the chapters presenting special features of interest may be mentioned chapter ix., which is largely concerned with the size of the electron and its power of penetrating matter, the effects of a collision between electron and atom, and the ratio of the distribution of the energy of collision between heat and X-rays; chapter xi., which deals with the magnetism of light, and affords a very clear exposition of the nature of the action, which "has opened up a new branch of physics, a new department, as it were, of atomic astronomy, with atoms and electrons instead of planets and satellites"; and chapter xiv., which contains a full treatment of the experimental work of Kaufmann on the high-velocity β-ray electrons expelled by radium. In chapter xv. no less than five alternative views of the constitution of the atom are considered, which emphasises, to use the author's own expression, the "painfully indefinite character" of the theory applied to matter. Exception must be taken to chapter xviii., entitled "Summary of other Consequences of the Electron Theory," which begins with a section headed "Radioactivity" (!). Now this is surely unfair to a great and independent experimental subject, because not only has radio-activity taught us something really definite and fundamental about matter as distinguished from electricity, but also it has at the same time furnished, for example, in the penetrating power of the α and β rays, the most damaging evidence against the possibility of an electronic constitution of matter.

Sir Oliver Lodge's well-known forceful and attractive style is always in its element in dealing with the conquests achieved in physical science, but the concluding passage is something of the nature of a parting shot at the reader.

"Especially must the inner ethereal meaning both of positive and negative charges be explained: whether on the notion of a right-and-left-handed self-locked intrinsic wrench-strain in a Kelvin gyrostatically-stable ether, elaborated by Larmor, or on some hitherto unimagined plan. And this will entail a quantity of exploring mathematical work of the highest order."

To explore the inner ethereal meaning of this right-and-left-hander elaborated by the author demands a brain of unquestionable gyrostatic stability.

Having dealt with the author's book as the exposition of his views of the nature of electricity and matter, and having first fully acknowledged the debt the reading public owe to Sir Oliver Lodge for the leading part he has taken in the public work of advancing and expounding the new doctrines, it may not be considered ungracious to touch a little less enthusiastically than the author does on certain aspects of the new theories themselves here so powerfully advocated.

Without in the least wishing to minimise the importance of the part played by imagination and hypothesis in experimental science, the question may fairly be asked whether these persistent efforts to "simplify" matter and reduce it to a single fundamental existence have a place in the legitimate scientific thought of the present day, or whether they are not a continually recurring phase of an apparently innate primitive mental aspiration, the origin of which is to be sought, not in the phenomena themselves, but in the predilections of the human brain. The rule that where one conception suffices it is superfluous to use more than one may be fully granted. But it is surely still something of a mental luxury to believe that these ideas of the essential unity of matter and its ultimate reducibility to a single type, which exist deep down in the most ancient mythologies, and may be said to form part of the common stock of original ways of thinking, have as yet any other than this foundation. Matter continues to be experimentally incomprehensible, and as recent work in radio-activity has shown, the possibilities of its complexity are far from exhausted by the eighty or more recognised elements. The attempts, for example Prout's hypothesis, to reduce matter to one common basis testify rather to the aspiration for that kind of explanation which to our ideas seems appropriate. It is undoubtedly satisfying to picture all matter as built up of some one unit, because an ingrained bias exists in the mind towards the simplest possible origin of phenomena. There is, however, evidence that our natural subjective impressions of what is fit and appropriate are, when they are traced to their source, derived in the first place from an insufficient study of the operations of Nature, which fuller knowledge usually dispels. It is, of course, possible that with the even fuller knowledge of the future some such doctrine as a connection between what is mentally harmonious and what is physically true may transpire, and the doctrine find a legitimate place in the theories of pure physics. But for the present the supporters of the electronic theory of matter have to show that they have not allowed their enthusiasm to betray them into an attitude of mind which belongs rather to the past than to the future of scientific thought.

FREDERICK SODDY.

THE COLONISATION OF VIRGINIA.

The Generall Historie of Virginia, New England, and the Summer Isles, together with the True Travels, Adventures and Observations, and a Sea Grammar. By Captaine John Smith. Two vols. Vol. i., pp. xxxiii+396; vol. ii., pp. xix+330. (Glasgow: James Maclehose and Sons; London: Macmillan and Co., Ltd., 1907.) Price 25s. net.

AT the time of writing (April) the warships of the Powers are gathered together in Hampton Roads to honour the tercentenary of the founding of the Commonwealth of Virginia, and the Jamestown Exposition (held at Norfolk) will soon be opened for all the world and his wife to come and see what Virginia can show them after three hundred years of existence, in spite of the grievous calamity of forty years since. What the warships of the other Powers have to do with the celebration is not quite clear; one would have thought that this would have been a domestic event to be celebrated by the navies and peoples of the United States and Great Britain alone. For there was no foreigner, barring a recalcitrant Dutchman or two, concerned in the settling of Jamestown and the creation of Virginia in the fair land of Wingandacoa, in the year of grace 1607.

For although Wingandacoa had been discovered by the emissaries of Sir Walter Raleigh, and its name changed to "Virginia" by "Her Maiesties Grace" in honour of her glorious self, in 1584, it was not until 1607 that the permanent settlement was made, and called Jamestown in honour of the "Solomon" who now presided over the destinies of the British nation. It was odd that the name of his tobacco-hating majesty should have been given to the first capital of the country which has always produced the bulk of the obnoxious weed!

With the expedition which set sail from Blackwall in December, 1606, came Master John Smith the redoubtable, who bore for his arms the three Turks' heads granted to him by Sigismundus Bathory, "by the Grace of God Duke of Transilvania, Wallachia, and Moldavia, Earle of Anchard, Salford, and Growenda," in commemoration of his great exploit in the service of that prince, when, "with his sword, before the towne of Regall, in single combat he did overcome, kill, and cut off" the heads of three Turkish champions. In memory of which exploit the three isles off the American coast called the "Turks' Heads" were also named by Master John Smith himself. Smith was a man of the most indomitable energy and determination, as his fellow-voyagers to Virginia, Mr. Edward-maria Wingfield and the rest, soon found; and it was not very long before the hero of the Turks' heads was in full command of the colony, very much for its good, and Wingfield and Smith's enemies returned to England to sow the seeds of opposition which eventually made the position of the masterful governor untenable.

Smith himself tells the story of his work in his remarkable "Generall Historie," of which Messrs. Maclehose have issued the present admirable reprint just at the right moment, when the tercentenary of the founding of Jamestown is being celebrated in Virginia. Egotistical the book is, but when he wrote it Smith was smarting under the undeserved reproach of the enemies that his energy had made for him, and his purpose was to assert to the world what he had done, and to show, what none will gainsay, that but for him the Commonwealth of Virginia would never have been securely founded. Enemies he may well have made, for he called a spade a spade, and could not suffer a fool gladly; the gentlemen of the Virginia Company at home were roundly trounced in his despatches to them for their foolish desires for non-existent gold, when all that Virginia could give them was fish, tobacco, and a little copper; and why not raise revenue and gain honest profit from fish and tobacco? says he. Rough with the natives he was said to be, but that is the way of the pioneers, and we can see from many passages in his book that Smith was really a most kindly man, and liked the "salvages." We know in our own time how accusations of roughness to "natives" are made against men of the type of Smith by people whose knowledge of foreign lands is derived from books and their own brains, and have never themselves come into personal contact with the less civilised races in their own home. Of his truly scientific quality of observation and deduction Smith's book is eloquent proof; he knew what he was talking about. But that he was tactless and undiplomatic in dealing with his own fellows, however well he may have understood the natives, is equally evident. And the man who knows, but is impatient and tactless in trying to drive others to realise his knowledge for their own good, often sees his work torn from him before he can complete it. This was the case with Smith, who never returned to Virginia after he left it, wounded and discouraged, in 1609. To New England he went, and had much to do with the constitution of the northern colony; but though during the rest of his life he never wearied in strenuous advertisement of the Virginian settlement, he did not re-visit it.

The picture of the people of Wingandacoa which Smith gives us is well known. Powhatan the "mighty emperour" and his werowances or chiefs; Pocahontas his daughter, who saved Smith's life when he was a prisoner and her father would have tortured him to death, that Pocahontas who, after Smith left, married Master Rolfe, came to England, was presented at Court, and died when leaving to re-visit her home; the marvellous incidents of Smith's imprisonment and the discoveries of himself and his men; his descriptions of all these have been known to many generations of lovers of tales of adventure, and have furnished much material to the modern writers of them. Yet to read Smith's own narrative again, with its naïf comments on men and things, its quaint spelling, and its Wegg-like "droppings into poetry," by himself and his friends, mostly very bad and merely inserted "seeing there is thus much Paper here to spare, that you should not be altogether cloyed with Prose"—is always amusing, and in the present year most interesting. So we may thank Messrs. Maclehose for their reprint, which includes, besides the timely "Generall Historie," also Smith's story of his own adventurous life in other lands than America, and his very curious "Sea-Grammar," which may well have supplied Swift with some of the material for his utterly unintelligible description of a storm in Gulliver's "Voyage to Brobdingnag"!

The book is a handsome one, and the paper and type have an air of archaism which well suits the subject. Smith's own maps are reproduced, and the famous portrait of Pocahontas, called "Matoaka alias Rebecca filia potentiss: princ: Powhatani Imp: Virginiae," or "Emperour of Ananoughkomouck, *alias* Virginia," besides the original illustrations of Smith's adventures among the "salvages."

THE LIFE-WORK OF AN EMINENT METEOROLOGIST.

Gesammelte Abhandlungen aus den Gebieten der Meteorologie und des Erdmagnetismus. Von Wilhelm von Bezold in Gemeinschaft mit A. Coym. Herausgegeben vom Verfasser. Pp. viii+448; illustrated. (Brunswick: F. Vieweg and Son, 1906.) Price 14 marks.

PROF. VON BEZOLD'S position as the late head of the Prussian Meteorological Institute suffices to make the publication of his collected works on meteorology and terrestrial magnetism an event of importance. His papers on electricity and physiological optics remain apparently to be dealt with. In preparing the present work for press, he had the assistance of Dr. Coym, formerly of the Meteorological Institute. The collection includes twenty papers; in some, slight alterations have been introduced and some notes have been added.

Only the earliest paper, written in 1864, represents von Bezold as himself an observer. It treats of the phenomena visible after sunset, especially of what von Bezold terms the "Purpurlicht." An appendix refers to recent authorities, and especially to the effect of volcanic ejecta on the richness of the phenomena.

The next three papers deal with the frequency of thunderstorms. It is explained in an appendix, pp. 83-90, that much of von Bezold's writings on this subject seemed of too local interest to reproduce. In the first paper, after dealing with statistics from a number of stations—mostly in central Europe—von Bezold decides in favour of a connection between thunderstorm and sun-spot frequency. His conclusion on p. 59, repeated in the last thunderstorm paper, p. 82, is that thunderstorm and auroral frequency follow opposite courses, thunderstorms being least frequent in years of sun-spot maximum, when auroras are most numerous. This conclusion must be regarded with some reserve.

In the next paper, dealing with sun-spot data from Bavaria and Württemberg, von Bezold considers the evidence favourable to the reality of a twenty-six-day period in thunderstorms. A footnote dated 1905 qualifies this, pointing out that it would be natural to look for the source of a twenty-six-day period in the sun, and as it is probable that the seat of greatest activity in the sun changes its position, the twenty-six-day period will naturally change its phase, and so be recognisable only in statistics covering a comparatively short period. This seems the same position as has been taken up in the case of magnetic storms by Maunder, who, however, finds a period of about 27¼ days. The reality of a period the phase of which alters in an indefinite way is rather a difficult matter to decide.

The third of the thunderstorm papers suggests an extraordinary increase in damage by lightning in Germany. In Bavaria the percentage of (insured) houses struck by lightning was fully six times as great in the decade 1893–1902 as in the decade 1833–1842. Von Bezold appears to accept the increase as proved all over Germany. Other German authorities, it may be added, have expressed some doubts as to the true significance of the insurance statistics; the phenomena may not be purely meteorological.

Papers v.–ix., pp. 91–220, form a group devoted to the thermodynamics of the atmosphere. The elementary portion of air contains moisture which may be wholly gaseous, or partly condensed in raindrops, in snow, or in hail. Also the air element resembles a compartment of a train in that its original occupants may leave it at intermediate stations, whilst new occupants may come in. Change of state in the water contents implies evolution or absorption of heat, and the five papers aim at tracing the various possible modifications and identifying them with the phenomena of cyclones, anticyclones, Föhn winds, and so on. The reader to whom German presents difficulties will find an English translation of the first three papers of the group in Prof. Cleveland Abbe's "The Mechanics of the Earth's Atmosphere"; he must, however, be on his guard against misprints. The present reprint contains some fresh notes, and shows some alterations, *e.g.* on pp. 123 and 125, dealing with cyclonic and anticyclonic phenomena. These thermodynamical papers represent a product which the typical English meteorologist will contentedly deny himself. If, however, the Cambridge mathematical meteorologist ever comes into being, he ought to read these papers as part of his preliminary education. If he reads them critically in the light of recent meteorological knowledge he will—whether he agrees wholly with the author or not—have done a good deal to qualify himself for profitable research in the dynamics of the atmosphere.

Papers x.–xv. are also in the main theoretical, but they contain information from balloon ascents as to temperature and moisture in cyclonic and anticyclonic weather at different seasons of the year. Paper xvi. gives statistics from various sources as to the mean annual values of temperature, pressure, rainfall, and cloud round parallels of the earth. To obtain zones of equal area, the author takes as parameter the *sine* of the latitude. This paper leads naturally to xvii., the first of four papers, pp. 371–448, devoted to terrestrial magnetism, in which von Bezold considers what he calls the "isanomalies" of the magnetic potential, *i.e.* the departures from the mean value round a parallel of latitude. Paper xviii. deals with what the author calls the *normal* earth's magnetism. Paper xix. treats of the foundations of the Gaussian theory as based on the vanishing of line integrals taken round areas on the earth's surface, and discusses the diurnal variation, in the light of Prof. Schuster's variation potential, and its representation by vector diagrams.

The final paper advocates the taking of magnetic observations round a parallel of latitude, which von Bezold suggests might pass through the south of England. To a magnetician familiar with the Gaussian analysis and with Schuster's work on the diurnal variation, von Bezold's contributions to the subject will appear to be rather a matter of definitions and identifications than of original ideas. To those, however, who have a difficulty in grasping the physical significance of abstruse mathematics, they may serve a useful purpose, provided it be clearly understood that anything like a complete treatment of the diurnal variation requires a careful study of the influence of the season of the year as well as the relation to sun-spot frequency. The proposal advocated by von Bezold and others to effect a line integration round a parallel of latitude ought before its adoption to receive careful consideration from the side of atmospheric electricity. It should be remembered that the earth-air currents required to invalidate the hypothesis embodied in the Gaussian potential are not transient currents varying with the hour of the day or with the weather—such currents could only modify the magnetic diurnal inequality or cause irregular disturbances—but currents of practically constant value and direction over large areas.

Since the above was written, science has had to mourn the death of the distinguished author, Prof. von Bezold, a fact already announced to the readers of NATURE (February 21, p. 397).

CHARLES CHREE.

THE COLLOIDAL THEORY OF DYEING.

The Chemistry and Physics of Dyeing. By W. P. Dreaper. Pp. viii+315; illustrated. (London: J. and A. Churchill, 1906.) Price 10s. 6d. net.

WHEN it is remembered that dyeing has become a highly scientific process, it is somewhat strange to note what a small part theoretical considerations have played in the practical development of the art, a fact no doubt largely due to the lack of definite knowledge of the chemical constitution of textile fibres. Most manuals of dyeing have been written for practical ends, and have devoted small space to the consideration of the various theories of dyeing which have been put forward, since, as before remarked, these have helped but little in the practical solution of dye-house problems. Our knowledge of the nature of fibres has, however, now reached a point when it is undoubtedly of value that the scientific dyer should make himself acquainted with this side of his subject, and recent work on the nature and properties of colloids certainly appears to throw much new light on the intricate nature of dyeing processes.

It has, of course, long been known that one and the same kind of fibre acts differently towards various dyes, and that dyestuffs may be classified into groups on the basis of this differentiation. To a considerable extent this grouping is found to correspond with fundamental similarities in the chemical constitution of the dyes, and this broad fact has lent strong support to the chemical theory of dyeing.

The older theories of dyeing could be broadly classified into two groups, those assuming a chemical reaction between fibre and dye, and those in which dyeing phenomena are explained by the physical properties of the reacting bodies. To a great extent these theories are antagonistic, and yet upholders of each are able to put forward incontrovertible facts in their support. It is, however, far from satisfactory to have to assume that similar phenomena can be explained in one case by a certain theory and in a second by an opposite theory, and the time is ripe for a wider view which shall embrace and reconcile all well-established facts concerned with dyeing processes. How far the colloidal theory of dyeing is successful in doing this may be gathered from a perusal of the book under review. Much of the experimental work mentioned lacks precision, and the various researches are somewhat detached, but the present knowledge of colloidal conditions and functions, incomplete as it is, throws much light on earlier work, and from further work in this direction a satisfactory explanation of dyeing processes may eventually emerge. In the past many difficulties, in regard to dyeing theory as in other directions, have arisen from an attempt to draw a hard and fast line between chemical and physical action, and the blending of the two may be considered as the characteristic feature of the reactions of colloids.

The book is arranged in twelve chapters, of which the first is devoted to a historical introduction, which might with advantage have been considerably extended. The properties and reactions of fibres, dyes, mordants, and assistants are dealt with in chapters ii.–v. Chapter vi. contains an excellent summary of the recent work on the properties of colloids. Chapter vii. gives facts in support of the old mechanical theory of dyeing which reached its final development in the solid solution theory of van 't Hoff and Arrhenius, which was applied to dyeing processes by O. N. Witt. Chapters viii. and ix. give a similar summary of facts supporting the chemical theory of dyeing. Then follows in chapter x. an attempt to show the application of the colloidal theory, and in this the incompleteness of the evidence becomes apparent, though as a suggestive contribution it is very interesting. A chapter on the action of light on dyeing operations and dyed fabrics appears to have little connection with the central theme of the work.

The many inaccuracies in the book lay it open to a good deal of minor criticism. For example, on p. 14 several of the formulæ are altogether inexplicable. On p. 33 it is stated that Bancroft divided dyes into *subjective* and adjective, the term used by Bancroft being *substantive*. A fair summary of the work of various investigators is usually given in the text, but it is often difficult to ascertain at what point the summary ends and the author's comments begin. There is thus some danger of injustice to one or other. Since both centigrade and Fahrenheit thermometric scales are used in the book, some confusion arises in the frequent cases where a temperature figure is given without indicating which scale it refers to. Amongst mis-spelt authors' names may be mentioned Verquin for Verguin, Pokorng for Pokorny (several times), Prager for Perger, Brand for Brandt, Boettinger for Böttiger, and Hirst for Hurst.

The general plan of the book is excellent, and the author's work, though somewhat unequal, is on the whole very satisfactory. The production of such a book would have been impossible a few years ago, and it marks a distinct advance in the linking up of one of the most ancient arts with modern scientific theory, and shows a common ground where the practical dyer, the chemist, and the physicist may meet. Its study will well repay all students of dyeing and those practically engaged in the textile trades who have been able to keep in any way abreast with recent work. WALTER M. GARDNER.

THE WAYS OF WILDFOWL.

Practical Wildfowling. A Complete Guide to the Art of the Fowler, with Descriptions of the Various Birds usually met with. By W. J. Fallon. Second edition, revised and greatly enlarged. Pp. 248; illustrated. (London: L. Upcott Gill; New York: Chas. Scribner's Sons, 1907.) Price 6*s*.

THE new edition of Mr. Fallon's useful little handbook of practical wildfowling has been brought up to date, and a considerable amount of new matter and many new illustrations have been added. Thoroughly to enjoy his sport the wildfowler must be a good field naturalist, and this little work aims, *inter alia*, at making easy the identification of those species of birds he is most likely to meet with. The enjoyment of wildfowling lies not only in killing, but in seeking to kill by pitting one's endeavours and skill against the cunning and wariness of the fowl. Unlike pheasants and partridges, they cannot be brought over the guns. Herein lies the essence of the sport, and hence the absolute necessity of understanding the life-habits and peculiarities of the various kinds of wildfowl.

With the first part of this excellent manual, which deals fully with the guns, boats, ammunition, and other outfit and accessories necessary for the pursuit, we are not immediately concerned, but pass on to the chapters on the art of wildfowling, for therein much may be learned about the habits of some of the shyest of birds. To be a successful wildfowler, a man must have an intimate knowledge of the birds' ways and behaviour under the varying conditions of time, tide, and weather. He must also be able to identify the fowl, not only when in hand, but when at a distance. His skill in handling the gun will avail him little if he cannot distinguish a jack snipe from a sandpiper, curlews from gulls, or ducks from divers, for all these and others must be attacked with a different strategy. To know birds, when at a little distance, by some peculiarity of motion, shape, or flight, is a great part of the fowler's craft, for the tactics adopted to secure one kind of duck may be quite inadequate in the case of some other species of this family. He must be familiar, too, with the food and the feeding-ground of the various ducks, geese, and shore birds in order to know where they may be found, and at what time of the day or night.

Naturalists, indeed, are indebted to the wildfowler for much that they have been able to record as to the habits of various wildfowl; and as Mr. Fallon essays, and very successfully, to instruct the tyro in all these things, his book appeals strongly to the field naturalist. In this part of the book the subject is treated under the heads of wild swans, wild geese, wild ducks, and shore birds, and the plan adopted is to describe each species of these groups likely (or even possible, for the rare kinds which *may* turn up any day are included) to be met with, and then to deal with the various methods of approaching and shooting them.

The identification of the different species is rendered more easy by the introduction of some very life-like figures, while in reading about the way to get at them we find ourselves learning a good deal about their individual peculiarities. In going through the book we come upon many good notes and original observations on the food and feeding habits of geese, ducks, and shore birds, and would instance the interesting remarks on the grain-feeding habits of the pink-footed goose. Many another out-of-the-way scrap of natural history, too, can be gleaned; for example, the curious habit of sheldrakes choosing as a nesting site the straw stacks which are placed in the fields as shelter for the cattle in some marshy districts. If we were disposed to be critical, we might suggest that the curlew sandpiper should not be described as of similar plumage to the dunlin, and that the white patch on the lower part of the back, so conspicuous when the former bird is flying, is a mark distinguishing the two species. Also that it is not up to date to say that a clutch of knot's eggs does not exist in any collection; not that this matters to the wildfowler. There have been many books written on wildfowling since the days of Hawker, but it is doubtful whether any of them give so much information in so small a compass as this little handbook. There is a good index, and we cannot withhold a word of especial praise from the delightful picture with a heron in the foreground.

O. V. APLIN.

OUR BOOK SHELF.

Hypnotism and Suggestion. By Edwin Ash. Pp. 134. (London: J. Jacobs, 1906.) Price 4*s*. net.

IN the preface the author tells the reader that the objects he had in view in writing this book were to explain the technique of experimental hypnotism and suggestive therapeutics, and at the same time to endeavour to divest the subject of the air of mystery with which it is popularly invested. In an introductory chapter he briefly alludes to certain general questions connected with hypnotism. He considers that telepathy is at present "non-proven," and, further, he does not believe in a "magnetic force" for curative purposes.

The author carefully describes the methods employed in the production of hypnosis, and the earlier and later phenomena to be observed when this condition is brought about. He discusses the various stages of hypnosis, and points out the difficulties of arranging an accurate classification. In considering the use of hypnosis for surgical anæsthesia, he recognises its limitations, and although he fully realises its value, nevertheless, from the practical standpoint, the difficulty of producing it rapidly and deeply is a serious objection in the way of bringing it into general use. Post-hypnotic influence forms the subject-matter of another chapter, and its possible relationship to criminal acts is referred to. Dr. Ash agrees with many observers that suggestions which are incompatible with the moral sense of the subject are in most cases at once rejected. Nevertheless, it must be admitted that if it is possible by means of hypnosis to suggest crime to a person whose moral sense is defective, then this is a factor which might become of vast importance if hypnotic suggestion ever became a remedy of general use.

The author gives an interesting chapter on "suggestive therapeutics," and in it he shows the power of suggestion of one mind upon another, and even in the same person the influence of the conscious mind upon the subconscious. He believes that Christian science is largely a system of auto-suggestion.

Dr. Ash strongly urges that there should be introduced into the medical curriculum a compulsory course of psychology and lectures on the principles of "suggestive therapeutics." We cordially agree with the former recommendation, for it is lamentable to find the ignorance that still exists regarding the normal mind, and some knowledge of this subject is a matter of growing importance, both from the evolutionary and dissolutionary standpoints.

For those who wish to learn some of the practical points regarding hypnosis and suggestion, Dr. Ash's book will be found most helpful, for although it is small it contains much information.

Domaine de Tervueren—Arboretum—Types de Forêts des Régions tempérées représentés dans leur Composition caractéristique. By Ch. Bommer. Pp. 211. (Brussels: Imprimerie F. and L. Terneu, 1905.)

THE site of the above arboretum was generously given by the King of the Belgians to the people. At the time of the gift His Majesty expressed the opinion that it was very useful, not to say indispensable, to create or to preserve open spaces with natural decoration near large towns, both from an æsthetic and hygienic point of view. M. Ch. Bommer was entrusted with the task of laying out the arboretum, and this he has evidently done in a scientific and practical manner. The various plots or groups have been formed to illustrate the principal types of vegetation in the temperate zone of the old and new worlds. Even the bushes and herbaceous plants characteristic of these zones have been added to complete the picture, thus very clearly illustrating the characteristics of the various species and their geographical distribution. The arboretum also forms an excellent centre for testing the acclimatisation of exotic trees. We have also in the above book a detailed account of the individual species which includes synonyms, size, habit, general characteristics, and uses of wood, &c. Numerous photographic plates are included illustrating various groups and points of general interest. Plans of the arboretum and maps showing the geographical distribution of the species are given at the end of this very useful and interesting book.

Elementary Science for Pupil Teachers. Physics Section by W. T. Clough. Chemistry Section by A. E. Dunstan. Pp. vi+183. (London: Methuen and Co., 1907.) Price 2s.

PUPIL teachers who have opportunities of doing practical work will, if they perform the experiments in this book and follow the guidance it gives, obtain sound preliminary ideas of physics and chemistry. The physics section comprises the measurement of lengths, areas, volumes, and masses, simple hydrostatics, and an introduction to the study of heat. The chemistry section covers the subjects arising from a careful study of air, water, and other common substances. The volume is on the whole attractive, but the smaller of the two types is likely to try the eyes of readers.

A First Geometry. By W. M. Baker and A. A. Bourne. Pp. viii+128+vi. (London: George Bell and Sons, 1907.) Price 1s. 6d.

WITH the exception of a dozen theorems at the end, this book is a simple course of experimental geometry designed to familiarise young pupils with fundamental geometrical conceptions by setting them to draw with mathematical instruments and to construct simple models for measuring angles and constructing plans. The lessons are interesting, and arranged in a manner that shows the authors to be well acquainted with the needs and capabilities of beginners.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Radium and Geology.

PROF. JOLY'S interesting discovery (NATURE, May 2, p. 8) that typical rocks in the Simplon Tunnel contain quantities of radium considerably in excess of the average of igneous rocks raises a question. From Mr. Strutt's investigations it appears that the average content of igneous rocks would be sufficient to account for the ordinary temperature gradient in the earth's crust were it due to radium. It seems, therefore, that, if the temperature was so caused, the gradient in the Simplon Tunnel ought to have been higher than the average, viz. 1° F. for between 50 feet and 60 feet. But, in fact, as beneath other mountains, it was considerably lower. In NATURE, October 27, 1904, it is stated that the temperature of the rocks in the advanced gallery was 108° F. where the cover was 7005 feet. This gives 1° F. for 92 feet. In the St. Gothard Tunnel it was 1° F. for 102 feet, and in the Mt. Cenis Tunnel 1° F. for 100 feet. That the gradient in the Simplon Tunnel, though low, was somewhat higher than in the other two was probably caused by the spring 23° hotter than the rock, which brought up heat from a lower level. I think I have shown in my "Physics of the Earth's Crust," chapter xvi., that these low gradients can but very slightly be attributed to the convexity of the surface.

Is not, therefore, the result of Prof. Joly's examination of the Simplon rocks rather unfavourable than otherwise to the hypothesis that the heat of the earth's crust is due to radium? O. FISHER.

Graveley, Huntingdon, May 4.

Ethnological Notes on the Aboriginal Tribes of New South Wales and Victoria.

A REVIEW of the above work appeared in NATURE of May 31, 1906 (vol. lxxiv., p. 100), to which I wish to reply briefly. The review opens by saying that my works "have either been ignored or dismissed in a footnote by experts such as Dr. Howitt and Prof. Spencer." Whilst the reviewer was quite aware of the obscure "footnote," he was quite silent regarding my reply to it, dated June 27, 1905.[1] The opinions of the two men named do not perturb me, but when such an injurious statement appears in the "thunderer" of scientific journalism, I crave fair play and the right of reply.

[1] The Queensland Geographical Journal, vol. xx., pp. 73-75.

For nearly forty years I have practised as a land surveyor in Australia, and through my professional duties I have been much in contact with the aborigines over all the eastern half of this continent. In my youth I became fascinated with the study of local ethnology, and my enthusiasm has never flagged since, so that I can claim to be no tyro in the science. Having had exceptional opportunities of studying my subject on the spot, I claim a little consideration. More than one hundred of my contributions have already been published by various scientific societies in Australia, England, France, Prussia, Austria, and the United States, so that my work has met with some appreciation. I mention these few facts about myself, not egotistically, but as *bona fides*, because Australia is so far removed from the centre of scientific civilisation that a quiet worker is apt to be overlooked unless he presents his credentials.

Now, as regards the "ignoring" referred to by the reviewer. Dr. Howitt does not mention me in his book published in 1904, but he reports, at p. 92, the names Kulpuru and Tiniwa as phratries of the Yantrawanta tribe. He omits to say, in fine he "ignores," that I reported these same phratry names in 1899,[1] and again in 1900.[2] At p. 138 he says that "Tiniwa is the same as Kararu and Kulpuru as Matteri," but he "ignores" that I reported this self-same equivalence in 1900.[3] At p. 107 he stumbled across the word Mukulu (my muggulu), which he mistook for a phratry name instead of a blood division, a thing he had apparently never heard of. At p. 211, in speaking of the Wiradjuri sociology, he says that Ippai can marry Matha as well as Kubbitha, but he "ignores" my report to the same effect in 1896, eight years before.[4]

Then again, in his account of the Dora ceremony (my Toara or Doara), at pp. 599–606, Dr. Howitt "ignores" that I described that rite in January, 1900.[5] If he did not avail himself of my work, which appeared four years earlier than his, then there is a wondrous agreement in our details.

And yet again, Dr. Howitt at p. 44 gives a sketch-map showing the habitat of certain tribes in South Australia, but he "ignores" that I published substantially the *same* map in 1900,[6] four years earlier. In comparing the two maps and the explanatory letterpress accompanying mine we observe a marvellous coincidence. Many other examples could be cited, but exigencies of space force us to pass them over for the present.

I do not particularly object to all the above instances of "ignoring," because they have the effect of confirming the accuracy of my earlier reports; my objection applies to the damaging way in which reference is made to them in NATURE.

Regarding Prof. Spencer's "footnote," I refer your readers to my reply thereto in the Queensland Geographical Journal, vol. xx., pp. 73–5. No doubt he was very much cut to find that I had forestalled him by describing the eight sections of the Wombaia (his Umbaia) tribe in 1898;[7] that I had dealt with the Binbingha sociology in 1899;[8] and that I had reported the sociology of the Chingalee in 1900,[9] with a comprehensive map showing the location of these and other tribes. The publication in 1901 of my "Ethnological Notes on the Aboriginal Tribes of the Northern Territory"[10] probably increased his irritation and disappointment.

Fault is found in the review with my statement that nothing important has been added to our knowledge of the Kamilaroi organisation since the time of Ridley and Bridgeman. I beg to repeat that Ridley showed that Ippai married Kubbitha or Ippatha, and that there were totems with female descent. He also gave many illustrations of the intermarriages of the four divisions. Bridgeman stated that certain pairs of sections had a phratry name as well. I am still of opinion that nothing new or important had since been added by anyone until I reported the Blood and Shade divisions. The reviewer mentions Dr. Howitt's book, but his work is merely confirmatory of the previous reports of Ridley and Bridgeman.

It is stated in the review that Mrs. Langloh Parker's phratry names are identical with my Blood divisions; such is not the case, because she mistook the names of the Blood divisions for the phratries. I have known the Yuāleai (Mrs. Parker's Euahlayi) tribe for many years, and have been through most of their country. When publishing a grammar and vocabulary of their language in 1902[1] I stated that their social organisation and initiation ceremonies are the same as those of the Kamilaroi, thus anticipating much of Mrs. Parker's book, which did not appear until 1905.

Much more could be added, but it is thought that enough instances have been given to show that in original research among the Australian blacks I have often been first in the field; that probably my published results have been used and "ignored" by others; and, above all, that my work will stand the most rigorous criticism.

I have explained to the editor of NATURE the cause of the delay in my replying to the review in question.

IF I have done Mr. Mathews an injustice in my notice of his book, I can only express my regret for it and offer such reparation as a statement of my present view of the matter may make.

In directing attention to the fact that Mr. Mathews is ignored by Dr. Howitt and Prof. Baldwin Spencer, I merely stated a fact; if I had seen his reply I would have mentioned it. As to the reason why he is ignored I know nothing; a closer examination of Mr. Mathews's contributions than I had at the time of writing the notice been able to make leads me to think much better of his work; his readiness to acknowledge and withdraw his errors is worthy of the highest praise; and if his work is ignored solely on the ground that it is untrustworthy, it seems to me that this readiness is a sufficient reply to his critics. If there are further reasons, it is for Mr. Mathews's fellow-workers in Australia to state what they are. I personally have never heard of any further reason, and it seems to me that we in England are entitled to have one, if one exists. I may add that in my recent work, "Kinship and Marriage in Australia," I quoted Mr. Mathews as freely as any other author; at the same time, I have expressed dissent from some of his inferences.

Mr. Mathews makes good in the foregoing remarks his claim to priority on many points. His discovery of the "blood" divisions, of which Dr. Howitt knows nothing, seems to me especially important. In order to realise exactly what the situation is, we need a complete genealogy of a tribe for several generations back, showing both phratry, class, blood, and totem names of each individual. If Mr. Mathews can provide this material we shall owe him much; failing that, I hope it may be possible for some trained anthropologist, familiar with the modern genealogical method, to investigate the matter. I may add that Mr. Mathews has invited me to verify in person all the statements in his works which he bases on his own observations; this in reply to the review which called forth the above protest is surely a guarantee of good faith. I much regret that no money is forthcoming in England for anthropological work; if the financial part of the business could be settled, I would gladly accept Mr. Mathews's offer.

Nothing was further from my mind than to hurt Mr. Mathews's feelings, and if my notice was somewhat sharp in tone, I must plead in excuse the somewhat emphatic self-assertion of the passages I quoted. I hope that any future criticisms of mine will be such as to call for no protest on Mr. Mathews's part.

FRENCH EXPERIMENTS ON RIVETING.[1]

A STUDY of the most elementary form of connection used by the engineer may not appear to offer anything in the way of novelty or scientific value, as a contrivance at once so old and so simple as a rivet seems at first sight not likely to afford much scope for an investigation considered as a unit apart. Indeed, the chief interest has rather been in the grouping and arrangement of rivets, and the analysis of their behaviour under stress when assembled in the various joints and connections used by engineers in boilers, bridges, and the like. In the present instance the author, keeping strictly to the simpler problem, has produced a memoir of great interest.

In the early pages the ordinary processes of hand riveting are described, and a series of measurements and photographs, after the manner of Marey, shows in an interesting way that the well-known preference of the striker for the full swing of the hammer for long-continued effort as compared with the short swing and greater number of blows is an instinctive solution of the problem of obtaining the maximum effect for the effort exerted.

Fig. 1.—Composite photograph of a smith and striker for one swing of the hammer.

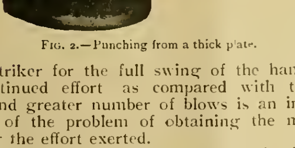

Fig. 2.—Punching from a thick plate.

The section following traces the growth of riveting machinery, and describes the characteristic effects produced when steam, air, or water is employed as the working fluid. Specimens of riveting obtained from various types of machines are noteworthy as showing that the shank of the rivet does not, as a rule, bear against the plates, and that eccentricity in the rivet head is common even in the most favourable circumstances. The essential difference between riveting by hand and that produced by a riveting machine is made clear by photographs of sections of rivets at different stages of their formation, the surfaces being prepared by polishing and etching in the usual way. The superficial effect of a blow, as compared with the squeeze of the pressure machine, is apparent in all the illustrations shown in the memoir.

The interesting question of the pressure required to produce the head of a rivet is taken up, and the various circumstances which influence this are the subject of much experimental study. These include the influence of temperature, the chilling of the metal by the die, the influence of the time in which the head is formed, and the effect of an excess of material in the shank, whereby waste material is squeezed up and forms a ring round the rivet head proper.

In addition, the diagrams drawn by the recording gear give precise information as to the work done on the rivet when the time of formation of the rivet-head is varied; they also show the effect of the cooling in drawing the plates together.

A detailed examination of the strength of the rivet gives special attention to the behaviour of the head and the way it ruptures under stress, and as a result a form of head is recommended having a radius of 0.86 the diameter of the rivet and a height of two-thirds the diameter.

The author, all through, has made great use of photographs of sections of pieces of material, but without magnification, and it seems possible that this side of the investigation would have yielded still more interesting results if it had included a detailed examination of the sections under the microscope.

As an instance of this, the accompanying figure shows the well-known form of punching produced from a thick plate, in which the characteristic sharp edge appears near the middle of the depth. Sections of such punchings would be well worth examining under the microscope, and, in fact, the possibilities of further research, with the microscope pressed into service, seem well worth consideration.

BIG GAME PRESERVATION.

A BLUE-BOOK containing correspondence relating to the preservation of wild animals in Africa was issued at the close of 1906, and sets forth ten years' official work in the British Empire, and in the dominions of other European nations in Africa, for the preservation of wild animals.

The Blue-book is not a satisfactory example of careful printing. It is extraordinary that before being issued, apparently from the Colonial Office, the proofs should not have been submitted to a zoologist for revision and correction. The names, in

Latin and in the vernacular, of beasts and birds are constantly disfigured by printers' errors of a childish description.

So far back as 1890 a movement began in Great Britain in favour of preserving wild life in lands under British control rather than allowing it to be exterminated by ruthless shooters. To some extent this movement was inspired from the United States. The creation of the National Park of the Yellowstone district, which was to lead to the formation of a "paradise" for the nearly extinct bison, bears, prongbuck, deer, and wolves of central North America, suggested to several sportsmen-naturalists of Great Britain similar preserves in tropical lands, especially in Africa. Of course, long antecedent to that, British naturalists had at last induced the State to legislate for the preservation of the scanty remains of the British fauna, and although our measures in this respect are still woefully inadequate, and a limited and old-fashioned class is allowed to push certain forms of sport at the expense of the wild fauna of these islands, still we have saved much; and in some districts of Great Britain birds and the smaller mammals really form constant and charming features in the landscape.

The great invasion of Africa, however, which began in earnest in 1890, directed public attention to the coincident slaughter of big game which everywhere accompanied the pioneering parties of the British. Just as Great Britain had been the greatest sinner in the slave trade, and was consequently the greatest and most enthusiastic among abolitionist nations, so her people, having gone far beyond any other nationality in the destruction of wild beasts and birds, are now foremost (though the United States is running almost neck and neck) in the world-movement for the preservation from extinction of all but the most harmful animals. We are rapidly appreciating the principle that just as "man does not live by bread alone," so we cannot be contented æsthetically with beef, mutton, poultry and pheasants, with cereals, tubers and cabbages, but that to complete the interest of our lives we must have beautiful wild things around us to admire and study; there must be a niche in our society for the rhinoceros, the lion, the tiger, and even the wolf. The hippopotamus and the walrus cannot be allowed to die out completely, still less the elephant. With improved methods of travel and rapid sea transit, we want to be able to contemplate birds of paradise, alive and well, in their New Guinea setting, and not see them in women's hats. A flock of flamingoes should be looked upon as a commercial asset of real value in Mediterranean lagoons or on West Indian beaches.

The leaders of this movement in Great Britain were mostly of the "converted-burglar" type—men like Selous, E. N. Buxton, Alfred Sharpe, and Lord Delamere—who, having had glorious sport with the rifle and killed specimens of all the great or rare beasts of Africa from north to south, had gradually transferred their interest from the mere passion of pursuing and killing to the contemplation of life-habits, to the study of the living animal. Photography—especially with the telephotographic lens was a potent agent in their reformation. Mr. E. N. Buxton especially has grown to grace, and led others with him up the pilgrims' way, through the new sport of snapshotting. An unconscious disciple of Mr. Buxton's has been Herr Schillings, whose beautiful study of wild life in East Africa ("With Flashlight and Rifle") has done much to advance the cause of game preservation in those regions. A very great share, however, in this important movement has been taken—perhaps unknown to the author himself—by Mr. J. G. Millais His book, "A Breath from the Veldt," published in 1895, was an epoch-making work. Many date their conversion to the new gospel from the days in which they first studied Mr. Millais's work. Though a sportsman of the truest type (and sport in this sense means far more than mere accurate shooting with rifle or gun), Mr. Millais realised himself, and taught those who gazed at his pictures, that it was far more profitable to our enjoyment and education to *watch living creatures alive* and study their habits with accuracy than to kill them and stuff their dead bodies.

How far the official world is in earnest about big-game preservation—in our own or any other Governments—it is difficult to say, there being so much humbug about the attitude of all Governments towards questions of art, science, and morals. Officialdom, as represented by Ministers that come and go, has taken a certain amount of tepid interest in the preservation of the African fauna. Some of the permanent officials (as distinguished from the parliamentary), like Sir Clement Hill, have displayed a praiseworthy persistency in pressing this matter on the attention of Secretaries of State, Governors of Colonies, and Commissioners of Protectorates. Sir John Kirk and the late Herr von Wissmann worked hard in the same direction. Sir Charles Eliot during his Commissionership in East Africa gave practical effect to regulations which had sometimes fallen into abeyance; the writer of this review (together with Sir Alfred Sharpe) between the years 1892 and 1901 created a number of game reserves in British Central-, British East Africa, and Uganda, the reserves ranging from an area of thirty to several thousand square miles in extent.

The policy of "game reserves" has been called much into question at different times by settlers and tourists. Settlers in regions adjoining these reserves complain that the wild game harbours the tsetse-fly, or that lions and leopards stray from the area of the reserve and become dangerous to the inhabited regions outside. Tourists, especially those who are naturalists and judicious sportsmen, complain that the "game reserve" (at any rate in Somaliland and parts of the Sudan) simply becomes a "game *preserve*" for the military officers on duty in those regions. On the other hand, if there is no special "national park," "paradise," or region set apart for the unfettered existence of wild beasts and birds, then, as Africa becomes opened up, an almost complete destruction of wild life ensues. Regulations may be framed and printed, but to attempt rigidly to enforce them is to incur constant friction, and even serious trouble, with Europeans and natives, both of whom are more or less reckless about "shooting for the pot" or destroying any creature that may threaten their crops or livestock. It has seemed to the present writer that the only real solution of this difficulty is to create and enforce game reserves—to set aside relatively large areas here and there in Africa which are not particularly well adapted for cultivation or settlement, but which may nevertheless offer features of great picturesqueness or interest, and thus become national parks where live creatures of every description are allowed to lead an unfettered life. But, naturally, in creating these game reserves the writer has not intended that their sanctity should be infringed by anyone with a gun—official or non-official. Many specially protected beasts or specially reserved areas are relieved of protection when a very distinguished or influential applicant applies for exemption from the regulations. The present writer would have the sanctity of these reserves rigidly adhered to; on the other hand, he would not attempt to enforce too drastically the preservation of game in the settled districts *outside* the reserves, though he would do everything in his power to discourage the needless killing of any beast, bird, reptile, or even insect that was not markedly harmful to the interests of man. Creatures of extraordinary beauty or interest, like the tiger, lion, moose, or elephant, should be allowed considerable latitude, and the State should compensate the cultivator or the passing tourist for annoyance because of the general interest felt by the community in the splendid development of these remarkable mammals.

The writer of this review deeply regrets that no efficient steps have been taken to create on a small scale national parks within the limits of Great Britain and Ireland for the preservation of wild life under wild conditions. He pointed out several years ago how admirably adapted for such a purpose is Achill Island, off the west coast of Ireland, a place which is fortunately still a refuge for many of the rarer and more interesting British birds.

H. H. Johnston.

THE INTERNATIONAL UNION FOR CO-OPERATION IN SOLAR RESEARCH.

A MEETING of the International Union for Co-operation in Solar Research will be held in Meudon, near Paris, during Whit-week, and a provisional programme of the proceedings has been sent to those who have accepted invitations to attend. The meeting will open on May 20, when formal business will be transacted in the morning. In the afternoon it is intended that all new proposals for joint work shall be submitted to the meeting, so that members will have an opportunity of privately discussing the desirability of adopting the proposals before a final decision is taken towards the end of the week.

The mornings of Tuesday and Wednesday, May 21 and 22, will be spent in receiving the reports of the committees appointed at the Oxford meeting in 1905. It is understood that Prof. Pérot is ready to submit his measurements of the wave-length of the red cadmium line, and that his results are in such good agreement with those previously obtained by Michelson that the meeting probably will be able to adopt finally a primary standard of wave-length. Other reports deal with the observations of sun-spot spectra and the organisation of the systematic application of the spectroheliograph to solar work. A question of interest to which several members of the union have given considerable attention consists in fixing the best methods of measuring the areas of flocculi. This matter has been under consideration at some of the American observatories, as well as at the Solar Physics Observatory at South Kensington and at the University Observatory, Oxford, so that an interesting and fruit-bearing discussion may be expected. On Tuesday evening, Dr. Janssen, the president of the congress, will give a banquet to the members at the Hôtel d'Orsay, in Paris, and on Wednesday afternoon Prof. Julius will demonstrate in the physical laboratories of the Sorbonne some of his experiments on anomalous dispersion. Arrangements have also been made to visit the Observatory of Paris in the same afternoon.

It is hoped that the scientific work of the meeting will be concluded on Thursday, May 23, and an excursion to the Château de Chantilly has been arranged for the Friday. A formal business meeting on Saturday, May 25, will bring the meeting to a close.

UNIVERSITY NEEDS AND THE DUTY OF THE STATE.

THE Chancellor and Vice-Chancellor of Oxford University have just appealed through the medium of the Press for at least 250,000*l.* to enable our oldest university to meet the demands that are made upon it by the ever-expanding requirements of modern learning. This appeal, coming so soon after a similar plea for a million and a half pounds, put forward recently by the Duke of Devonshire on behalf of the University of Cambridge, again brings into prominence the general question of the place of the university in the modern State and the duty of a Government in relation to the financial needs of institutions of higher learning.

In both cases appeals are made to the generosity of the wealthy public, and there is no suggestion that any responsibility attaches to the Government for the comparative poverty of these universities, in which Englishmen profess to feel great pride. The Oxford Chancellor and Vice-Chancellor, indeed, say of the needs of their university:—"In this country it is of no avail to look to the State for the satisfaction of those requirements; and it is to private generosity that the appeal must in consequence be made." It will be instructive to examine this attitude of mind towards one of the gravest questions confronting the nation at the beginning of the twentieth century, to analyse the appeals made in the light of recent experience, and to compare the results obtained with the experiences of university authorities in other great countries of the world.

In February last, in his letter to the public asking for a million and a half pounds for the University of Cambridge, the Duke of Devonshire reviewed the bequests, benefactions, and gifts received by the university since 1899, when the Cambridge University Association was formed at Devonshire House to promote the re-endowment of Cambridge University. From the sums received from our men of wealth the association was able to transfer to the university a total amount of 115,000*l.* In other words, during the seven years in which private generosity was being trusted to provide adequate means for the multifarious demands of a great university, an annual sum of about 16,430*l.* was forthcoming. That is to say, if private generosity could be trusted to display itself equally lavishly throughout so long a period, it would take more than ninety years to collect the million and a half pounds in which the University of Cambridge stands in pressing need to-day.

Similar particulars of a precise kind are not forthcoming in the case of Oxford, but it is, fortunately, possible to form some idea of the demands which are to be made upon private generosity to meet existing needs as enumerated by persons in authority in the university. The present appeal is for 250,000*l.*, and the letter signed by the Chancellor and Vice-Chancellor states two significant facts in connection with it. First, the ordinary university accounts for 1905 showed a balance of 5*l.* 17*s.* 6*d.*, and in 1906 there was "a further improvement, but the increased revenue is already allocated or pledged, and it is obvious that little more can be done in this way." Secondly, the constituent colleges contribute annually to university and academic purposes some 40,000*l.* An article was published in Nature on July 6, 1905 (vol. lxxii. p. 231), in which a detailed account was given of the needs of Oxford University, drawn up by the professors and heads of departments, and in the article an estimate was made of the capital outlay and the annual income required to meet the needs enumerated. The scheme outlined on that occasion was of a more ambitious character than the present, and involved an expenditure of more than half a million pounds; and for its effective execution an annual income of about 93,000*l.* was demanded. It seems clear, therefore, that in order to establish the University of Oxford on a scale commensurate with modern requirements—supplementing its existing departments and providing accommodation and equipment for the study of branches of knowledge of recent development—there must be found, in addition to a very substantial increase in the capital outlay, a further 50,000*l.* a year by way of income.

If it is supposed that the response made by our men of wealth particularly interested in Oxford will be on something like the same scale as that with which the appeal of the Cambridge University Association was met, it is not difficult to form a good working idea of the length of time which will be required to provide, from this source, sums of money enough to make it possible to place Oxford University in a position to invite comparison with the great universities of other countries.

The fact is, if we are to rely entirely upon private generosity to secure for this country the advantages of an adequate number of universities, planned, equipped, and financed on a scale liberal enough to meet modern needs, our chances of obtaining a supply of places of higher education comparable with that in Germany and the United States are small indeed. The vital importance of higher education in the international competition for imperial and industrial supremacy is conceded by all competent judges; and yet our statesmen hesitate to decide that what is so much worth having is worth paying for. In this country we cannot depend upon private effort to put matters right.

In his presidential address to the British Association in 1903, Sir Norman Lockyer reminded us that our universities and other institutions of higher instruction are as much a line of national defence as our Army and our Navy. The national responsibility, so far as the efficiency both of Navy and Army is concerned, is fully recognised by all political parties, and there is little difficulty in meeting the enormous financial demands which such efficiency in the services entails. As Sir Norman Lockyer pointed out, other countries are building universities even faster than they are building battleships; are, in fact, "considering brain-power first and sea-power afterwards." It is a saddening reflection how long it takes British statesmen to appreciate facts which have long been fully grasped by other nations. To leave to private enterprise the provision of necessary funds for the endowment of universities and research is as foolish as it would be in these days to relegate to private patriotism the duty of finding the money for the equipment of a modern army and an up-to-date navy.

What is the view of these matters taken in the United States? A recent publication[1] gives illuminating particulars as to the relative amounts provided in the United States for certain State universities, by the State on one hand and by private benefactions on the other. It is well to state here parenthetically that the bulletin deals only with State universities; there are, in addition, many other American universities—including Harvard, Yale, and others, the names of which are household words—which are not dealt with by the writer of the report. But the statistics provided supply ample information as to the share taken by the State in the encouragement of higher education in the United States. Details are available concerning forty State universities, but it will be sufficient for the purposes of comparison to refer to a quarter of them only. The amounts stated are approximate in every case. The University of South Carolina has received from Government support a total of 511,000*l.* and nothing from private sources. The University of Indiana has received from the former source 500,000*l.* and from the latter 20,000*l.* Corresponding numbers in the case of the other universities selected are:—University of Michigan, 1,281,000*l.* and 164,000*l.* respectively; University of Iowa, 705,000*l.* and 11,000*l.*; University of Wisconsin, 1,321,000*l.* and 18,000*l*; University of Illinois, 1,290,000*l.* and 5000*l.*; University of Minnesota, 1,072,000*l.* and 40,000*l.*; University of Nebraska, 761,000*l.* and 14,000*l.*; University of Columbus (Ohio State), 976,000*l.* and 56,000*l.*; University of Texas, 758,000*l.* and 30,000*l.* respectively.

Speaking generally, the reliance placed upon private benefactions for the provision of university education in the United States is small compared with what the Government is expected to do. Moreover, during the last decade there has been a steady increase in the amount received from the Government by American State Universities. The Western Universities in the United States may be taken as an example. The total annual amount received from Government sources by these ten State universities during the last decade shows a substantial increase of about 600,000*l.* The annual amount thus received by the University of Michigan has increased from 45,000*l.* to 87,700*l.*; that by the University of Missouri from 25,500*l.* to 73,000*l.*; by the University of Iowa, from 20,300*l.* to 85,900*l.*; by the University of Wisconsin from 62,600*l.* to 159,300*l.*; by the University of Kansas from 21,000*l.* to 60,400*l.*; by the University of California from 63,400*l.* to 135,600*l.*; by the University of Illinois from 28,900*l.* to 165,000*l.*; by the University of Minnesota from 40,000*l.* to 69,000*l.*; by the University of Nebraska from 14,000*l.* to 71,000*l.*; and by the University of Colorado from 17,300*l.* to 28,000*l.*

The semi-official bulletin from which the figures quoted have been taken leaves no doubt as to the results of American experience. To quote a remark which follows the figures we have cited, "the State University which has attempted to combine the policy of public service with the policy of appeals for private support has fallen between the two." Speaking of the eight institutions which represent the strong State universities of the Central West States, the bulletin remarks: these institutions "have received somewhat less than five per cent. of their total support since their foundation from private sources, and this support has come in the main to a few institutions."

University authorities in the United States may well smile when they read the opinion of the Chancellor and the Vice-Chancellor of the University of Oxford:—"In this country it is of no avail to look to the State" for the satisfaction of University requirements.

The same principle is conceded generously in Germany. An article, published in NATURE on March 12, 1903 (vol. lxvii., p. 433), showed that the ordinary total income of all the German universities, excluding Jena, was for the year 1891–2 about 939,000*l.*, of which nearly 709,000*l.* was derived from State funds.

Surely the lesson of these facts is plain to the least reflective citizen. The future struggles for supremacy among the nations of the world will be contests between minds, and muscles will be at a discount. The nations which have sacrificed present luxury in order suitably to train their young men by attendance at modern universities will reap the

[1] "Bulletin of the Carnegie Foundation for the Advancement of Teaching." No. 1. (Published by the Foundation, March, 1907.)

advantages of their forethought and prescience; and those countries which, content with ancient prestige and former prowess, have neglected their duty to higher learning and have left their universities to languish on the doles of patriotic benefactors will sink into subsidiary places, and their part for the future will be to serve the men of brains with whom they have had to contend on such unequal terms.

SCIENCE AND THE EMPIRE.

IT was a happy idea which resulted in the association of the British Empire League and the British Science Guild to pay honour to the Colonial Prime Ministers during their visit to this country. The cooperation of men of science with statesmen whose special work is to govern and develop the constituent parts of the Empire can result in nothing but increased national efficiency, and the presence of Sir Wilfrid Laurier, Mr. Deakin, Sir Joseph Ward, Sir William Lyne, Mr. F. R. Moor, and Mr. T. Bent at the banquet held on May 2 is a gratifying sign that the need for applying the methods of science to affairs of State becomes year by year more fully recognised. The banquet provided the only opportunity the Prime Ministers have had of meeting men of science and others interested in the progress of knowledge and desirous of introducing the scientific spirit into the administration of Imperial affairs.

Lord Derby occupied the chair at the banquet, and about 260 guests were present, including many men of science and distinguished representatives of the Imperial service and administration, and of law, art, and other departments of intellectual activity. Mr. Haldane, who was to have represented the united interests of the British Empire League and the British Science Guild, was, unfortunately, unable to be present; and his place was taken by the Vice-Chancellor of the University of Oxford, Mr. T. H. Warren, who, in supporting the toast of "Our Guests," proposed by Lord Derby, referred to the relation of universities to the Empire and national progress as follows:—

Why do the universities and the educational interests wish to add their greeting to those which have been pressed, I am afraid, in overwhelming and almost surfeiting measure, on those distinguished men who have crossed the ocean to visit us? I can assure them that no welcome can be more warm, but that is not enough. I think it is because we feel that to the instinctive and intuitive welcome which has manifested itself so spontaneously from every portion of English society we have some little to add. We feel that learning and science have something to say to Empire. We feel that, more and more, nowadays scientific training and thorough study of history, of the science of history and of sociology, is necessary to the proper carrying out of every great enterprise, and that Empire is one of the greatest enterprises on which man, intrepid man, has advanced. The student of history sees, or thinks he sees, a development, an evolution in the political as in the animal kingdom. The family, the clan, the city, the kingdom, the Empire, as they unravel themselves in the long series of sequences, need a corresponding advance in trained and educated intelligence. Now, we in our universities, and in the learned societies study these questions in the abstract. It is our duty and privilege in the insulated detachment, in the clear and calm life of academic tranquillity, to study these problems, and to try to find the solution of them; to study economic problems apart from the bias and prejudices of party and of commercial interest, and to study science in that spirit of disinterested devotion which, after all, I think Sir Norman Lockyer will agree with me, in the long run has the promise of this world, and, in a sense, of the other—of the world alike of truth and the world of success. But universities have now, not only an abstract, but a personal part to play. It is their privilege to bring together, and their duty to bring together, the brightest minds, at the most impressionable age, of those who will be in the future the leaders, whether in thought or in action, of the Empire. The university has had in the past a great part in bringing our leading men together in their early days and giving them common sentiment and common loyalty and knowledge of each other. May it not be so still more in the future on a wider scale and in a wider way? I hope that the universities, and the learned societies, and the educational establishments of this country feel, I believe I can say they do feel, that they have new and extended duties. Already Oxford and Cambridge, and the old universities of which I have spoken, realise that they are not only universities of a kingdom, but universities of an Empire. In future, no doubt, other universities of the Empire more and more will play their part—the universities of Montreal, of Melbourne, of Sydney, of New Zealand, and of the Cape. They, too, will have their traditions and their opportunities. There will be special opportunities of science and of learning, a special atmosphere and special surroundings in one place more than another, and I look forward to the time when students and professors will pass to and from one university to another. Meanwhile, let us make the beginnings, let us attack at once this great future which lies before us, let us take those steps which are now possible and promising. Let us use every opportunity of getting to know and to understand each other, and then I think that this great gathering of 1907 will prove not less fruitful in the scientific, and in the learned, and in the academic, than it has proved and is proving in the political and social sphere.

The toast was responded to by Sir Wilfrid Laurier, the Hon. Alfred Deakin, and Sir Joseph Ward. In the course of his remarks, Mr. Deakin said:—

Of all the meetings which we have been able to attend this has perhaps the most distinctive character. Never before in my experience have we seen blended the two sections of an Empire League of patriotism united to a body of scientific men whose immense abilities, whose sterling achievements, are the pride of the last century and the promise of this, and who are content to descend from those exalted heights, in which they unravel the mysteries of the universe, to find themselves perplexed by the truisms of politics. And if, as has been suggested, this union be typical, surely it is most fortunate, and certainly most necessary. If there is anything on this earth in human action which is casual and empirical, which is go-as-you-please and happy-go-lucky, it is the British Empire. Exactly how it came to be, precisely what it is, and what on earth it is going to be, no scientific prophet can tell. On the other hand, we have the men of science, calm and luminous, rigid and regular—I mean in their professional studies—aiming above all things at method, at principle, at organisation, the last three things we seem incapable of introducing into our Empire. And yet, though imperceptible, though unchangeable, there are manifest forces of cohesion, which even the finest instruments cannot measure, which keep this Empire as an Empire together. There are a series of rudimentary, of imperfect, of catch-as-catch-can organisations, by means of which, in some mysterious manner, this unwieldy, this gigantic and inexplicable combination, manages to survive. Surely we shall yet be found willing to sit at the feet of our scientific teachers and to endeavour, at all events at the outset, to acquire that knowledge in scientific manner, and by scientific methods, which shall enable us to appreciate, in the first place, the vast, the incalculable natural resources which are at present in our possession under the Flag—the means of utilising these instruments of material power for the benefit of our race. That appears to me to be the task of Empire, the task of scientific conquest of its physical, and shall we not be bold and say, ultimately of its political problems? The Empire rests upon the individual citizen—the individual citizen that has great capacity for service, providing you permit him to have access to these means of knowledge, to that stored-up wisdom of the ages, to these lessons and teachings which science can place in our hands. By these means we annihilate distance and draw the Empire together. By these means we enable them to conquer the wilderness and still carry with them the necessities of civilisation. By these means, in the tiniest hamlet, we plant almost first the schoolhouse to which the children go, and, when the principle of a scientific system of education is really in practice, the Empire will be marching indeed. Therefore I hail to-night, sir, the presence here of the intellectual men who are representatives of the scientific movement, and their blending with the British Empire League I take as one of the happiest auguries of our future.

NOTES.

The managers of the Royal Institution have awarded the Actonian prize of one hundred guineas to Madame Curie, as the author of the essay "Recherches sur les Substances Radioactives."

Sir William Ramsay, K.C.B., F.R.S., has been elected an honorary member of the Academy of Sciences of Christiania; and the Società italiana delle Scienze (known as the Society of the Forty) has conferred upon him the Matteucci gold medal for 1907.

The North Sea Investigation Commissioners will be entertained by the Corporation at the Guildhall on Friday, June 14, the Lord Mayor presiding. The Fishmongers' Company will give a dinner in their honour on the previous evening at Fishmongers' Hall.

The Government of Chili has appointed Count de Montessus de Ballore, of Abbeville, France, to institute a seismological service of the first rank. This action on the part of the Chilian Government is, says *Science*, a direct result of the disastrous Valparaiso earthquake of last August. The service in question will, at the beginning, include one station of the first rank and three of the second.

Prof. Ira Remsen, president of the Johns Hopkins University, has been elected president of the National Academy of Sciences, in succession to Mr. Alexander Agassiz. The vacancy thus created in the vice-presidency has been filled by the election of Dr. C. D. Walcott, secretary of the Smithsonian Institution. Sir James Dewar, F.R.S., Prof. A. R. Forsyth, F.R.S., Prof. D. Hilbert (Göttingen), and Prof. J. C. Kapteyn (Gröningen) have been elected foreign associates of the academy.

The University of Geneva will celebrate with appropriate pomp and circumstance the 350th anniversary of its foundation, which falls in 1909. We learn from the *British Medical Journal* that a committee has been appointed to arrange for the proper solemnisation of the festal rites, to which representatives of foreign universities will be invited. The "Academy," founded by John Calvin in 1559, retained that title until 1798. It was afterwards erected into a university, and reached its full development, with faculties of theology, law, physic, philosophy, and science, in 1873.

Reuter reports that the Observatory of Catania and Etna has issued the following statement:—"The activity of Mount Etna is increasing. The mouth at the base of the central crater is emitting vapour and small incandescent stones. On May 4, at 11.10 a.m., another mouth of smaller dimensions opened and threw up boiling lava. At the observatory the sound of an almost continuous eruption has been heard up to May 6. At Nicolosi a reddish vapour was seen rising from the volcano."

The professors of the National Museum of Natural History of Paris have decided to open an international subscription with the object of offering a worthy tribute to the memory of Lamarck, by erecting his statue in the Jardin des Plantes. Subscriptions may be sent to Prof. Joubin, at the National Museum of Natural History, Paris. The committee has decided to offer to all subscribers of not less than twenty francs a reproduction in heliogravure of an authentic unpublished portrait of Lamarck, which was painted for his family by Thévenin in 1801. To all subscribers of not less than 200 francs a plaster cast of the bust of Lamarck by the sculptor Fagel (to whom is entrusted the execution of the proposed monument) will be presented. The scheme has already received distinguished support, and a comprehensive committee comprising representative men of science of all nationalities has been formed. Among the list of the committee we notice the names of Sir John Evans, K.C.B., Sir Archibald Geikie, Prof. Ray Lankester, and Sir John Murray, K.C.B.

The New York Academy of Sciences will celebrate on May 23 the 200th anniversary of the birth of Linnæus. The anniversary celebrations will begin at the American Museum of Natural History with an exhibition of American animals known to Linnæus. Letters concerning the anniversary received from scientific societies will be read at the beginning of the morning session, and afterwards an address on North American geography in the time of Linnæus will be delivered by the president of the American Geographical Society. Dr. J. A. Allen has been invited to speak on Linnæus and American zoology. In the afternoon there will be an exhibition of American plants known to the Swedish naturalist, and an address on Linnæus and American botany will be given by Dr. Per Axel Rydberg. A bronze tablet in memory of Linnæus, a gift to New York from the Academy of Sciences, will be unveiled at the bridge—which is to be dedicated to Linnæus—over the Bronx River in Pelham Parkway, between the Botanical Garden and the Zoological Park. Numerous addresses will be delivered in connection with the unveiling ceremony. In the evening, at the museum, the director of the museum of the Brooklyn Institute will deliver an address on Linnæus and American natural history. The various meetings will be open to the public.

We have to acknowledge the receipt of a copy of the first part of a memoir on the caterpillars of French Lepidoptera ("Les Premiers États des Lépidoptères Français"), by Prof. C. Frionnet, of the College of Natural Science at St. Dizier. The memoir is being published in the *Mémoires* of the Society of Letters, Sciences, &c., of St. Dizier, the first part, which deals with the caterpillars of butterflies, being dated 1906. Unfortunately, there are no illustrations.

In a report on Antarctic birds collected by the *Scotia* Expedition contributed to the *Ibis* for April, Mr. Eagle Clarke has added four species—the Arctic tern, the blue petrel, the short-winged petrel, and Hutton's sooty albatross—to the nine previously recorded from within the Antarctic circle. Petrels and their relatives are attracted, it is suggested, so far south by the extraordinary abundance of food to be found immediately north of the ice-barrier, some of these visitors making their appearance in autumn after the breeding season, while others may be non-breeding birds which spend the whole summer in the South Antarctic. That the Arctic tern, after breeding in the far north, should visit the opposite pole is a most remarkable fact.

In reference to a suggestion that Fair Island, an outlying member of the Shetland group, is specially favoured by migratory birds, Mr. Eagle Clarke, in a paper published in the April number of the *Annals of Scottish Natural History*, points out that we should rather consider the island specially favourable to the observer. Despite the number of trained observers, the writer considers that "we in Britain see only an infinitesimal number of the migrants which visit our shores: far fewer than is generally supposed, and this is especially the case on the mainland." In addition to recording, for the first time, the red-rumped swallow as a visitor to the British Isles, Mr. Clarke was fortunate enough to observe a number of rare birds, several of which were previously unknown to visit the Shetlands.

AMONG rare birds recorded in Norfolk by Mr. J. H. Gurney in his ornithological report for 1906, published in the April number of the *Zoologist*, are five glossy ibises, which made their appearance on Breydon Broad on September 3. It is believed that three birds of the same species, killed shortly afterwards in Ireland, together with one shot in Sussex, represented this flock. Immediately following the ibises came a flock of thirteen red-headed pochards, which settled on Breydon, where they were soon destroyed. The movements of these birds were connected, in the author's opinion, with a wave of heat which occurred at the same time. A pelican and a couple of flamingoes were also among the summer arrivals, but the latter appear to have been birds which escaped from Woburn, and there can be little doubt that the former had likewise been in captivity. The occurrence on the coast of an example of a bulbul, *Liothrix lutea*, may apparently be accounted for by the fact that a number of these birds were turned out at Woburn.

THE Journal of the Society of Arts for December 14, 1906, contains a paper read before the council of the National Fruit-growers' Federation by Mr. C. H. Hooper, on fruit-growing and bird-protection. The paper is also in course of publication in the *Gardener's Magazine*, of which the issue for April 20 contains the first instalment. It is satisfactory to see that Mr. Hooper speaks his mind plainly, without any attempt at special pleading for species which are notoriously harmful; and while admitting that birds are, on the whole, beneficial to the agriculturist and horticulturist, advocates the relentless destruction of certain kinds and a restriction of the numbers of others. Another author has already advocated the most stringent measures for the extermination of sparrows, wood-pigeons, and stock-doves as being distinctly injurious, and pleaded in favour of permitting, or rather encouraging, the taking of the eggs of the chaffinch, greenfinch, and bullfinch. Mr. Hooper, in addition to reducing the numbers of the species just named, urges that in fruit-growing districts it may be absolutely essential to kill off a percentage of blackbirds, starlings, and even missel-thrushes, thrushes, and rooks. On the other hand, hawks, owls, and strictly insectivorous birds of all kinds should be religiously protected. A few more straightforward and outspoken addresses of this description, and there would perhaps be less nonsense talked and written about the duty of encouraging and protecting birds even where they are eating the unfortunate gardener and farmer out of house and home.

IN a paper read before the Epidemiological Society, Colonel Bruce, F.R.S., details recent researches into the epidemiology of Malta fever, showing that goats' milk is the principal source of infection. One-third of the cases of Malta fever in the Navy could be traced to residence in the Royal Naval Hospital, Malta, but since the use of goats' milk has been prohibited not a single case has occurred there.

THE making of models of microscopic objects by means of wax reconstruction plates has taken a recognised place in morphological, embryological, and pathological research. The cutting out of the plates by means of a scalpel, the usual method, has disadvantages, and Mr. Mark has devised an electric wax-cutter in which a platinum wire, electrically heated and mounted in a sewing machine, performs the work expeditiously and efficiently (Proc. Amer. Acad. of Arts and Sciences, xlii., No. 23, March).

IN the *Bio-Chemical Journal* for April (ii., No. 4) Mr. Lovatt Evans discusses the catalytic decomposition of hydrogen peroxide by the catalase of blood. His experiments suggest that the reaction velocity may be explained by the hypothesis known as the "active system" theory, first suggested by Prof. Adrian Brown and subsequently by Prof. Armstrong. Dr. Maclean describes experiments on the influence of kreatinin in modifying certain reactions of sugar in urine, and Dr. Spriggs discusses the excretion of the same substance in pseudo-hypertrophic muscular dystrophy. Messrs. Bearn and Cramer detail observations on zymoids, substances present in enzymes which have the property of combining with the substrate without the power of destroying it, and obtain evidence of their existence in pepsin, rennin, emulsin, and takadiastase. Mr. Coleman describes the effect of certain drugs and toxins on the coagulation of the blood.

A PRELIMINARY list of higher fungi collected by Mr. N. M. Glatfelter in the vicinity of St. Louis during a period of eight years is published as vol. xvi., No. 4, of the Transactions of the Academy of Science of St. Louis. Of about five hundred species enumerated, the majority are basidiomycetes. The determinations authenticated by Prof. C. A. Peck include twenty new species.

AN account of an instruction camp organised by Mr. J. A. Leach for members of the Field Naturalists' Club in Victoria appears in their journal, the *Victorian Naturalist* (March). The camp was pitched at Mornington, on the eastern shore of Port Phillip Bay. Each day was devoted to the study of one or other branch of natural history under the direction of special leaders, and lectures were arranged in the evening. The reports of the excursions made each day and the evening lectures are printed in the journal.

THE reports of the director and other Government officials connected with the Royal Botanic Gardens, Ceylon, are published as a consecutive series, beginning with No. 20, in vol. iii. of the *Circulars and Agricultural Journal*. Mr. T. Petch, in his report as Government mycologist, refers to a number of fungi infesting tea bushes; of these, a new species, *Massaria theicola*, producing a stem-disease, is under examination, also the horse-hair blight, generally attributed to *Marasmius sarmentosus*. The most serious outbreak of fungal disease was caused by a Phytophthora growing on the fruits of Para rubber trees, inducing decay and rot. The disease spread rapidly during the rains in June, and seemed likely to cut short the supply of seed, but was checked by the dry weather in July. The most dangerous insect pests mentioned by Mr. E. E. Green were the tortrix, *Capua coffearia*, and shot-hole borer, *Xyleborus fornicatus*, both pests of the tea plant; a leaf-rolling caterpillar was fortunately restricted to the Funtumia rubber trees. Mr. Green also alludes to experiments for introducing the *eri*-silkworm, *Attacus ricini*, and European bees into Ceylon.

THE importance of a closer alliance between science and industry was again strongly emphasised by Sir Alfred Jones at Liverpool on April 8, when, at his invitation, a number of prominent men of science and commerce met at a luncheon given in honour of Mr. Herbert Wright, the author of a valuable work on the rubber industry. Mr. Wright gave a brief account of the progress and methods of rubber cultivation in the British Empire, quoting, as an example of the benefits accruing from the adoption of scientific methods, the enormous advances made by the industry in the Indo-Malayan area during the past decade. Ceylon alone, in a few years' time, may be expected to produce some 5000 to 7000 tons of rubber annually, and our other possessions in the East are developing similarly.

IN the Transactions of the Royal Society of Canada (vol. xii., pp. 267–288) Dr. R. W. Ells gives some useful notes on the mineral fuel supply of Canada. He shows that in the western half of the Dominion the supplies of mineral fuel are practically inexhaustible. The analyses of these coals show that their quality is greatly superior to that of those now mined in the Pacific States of the American Union.

THE Transactions of the Institution of Engineers and Shipbuilders in Scotland (vol. l., part vi.) contain a suggestive paper by Mr. R. Royds on the most economical mean effective pressure for steam engines. He appends a bibliography of papers dealing with the steam-engine problem, all of which are based upon direct experimental evidence. These should be studied by all concerned with the generation of motive power.

THE demolition of the Great Wheel at Earl's Court, which for twelve years has formed so conspicuous a feature in the London landscape, is now completed. The work, which is described in detail in *Engineering* of April 26, has been one requiring the exercise of much ingenuity in the devising of safe methods of procedure. The wheel was a pin-jointed structure 300 feet in diameter, weighing, with the cars in position, 1000 tons, whilst the two standards on which it was mounted weighed 400 tons more. The whole structure was demolished in less than six months, which, considering that every rivet had to be sawn through, as every nut was completely set in rust, reflects great credit on all concerned.

THE address delivered by the president, Mr. T. Hurry Riches, to the Institution of Mechanical Engineers on April 25 forms a valuable work of reference on rolling stock and the machinery used in railway engineering, its value being enhanced by the seventy-six illustrations accompanying it depicting the locomotives and rolling stock of the railways of Great Britain at the present time. It is evident from these illustrations that modern requirements are gradually bringing the locomotives on the railways more and more into accord with one another when the work to be done is similar.

AN interesting set of models, showing the development of the rack-rail locomotive from Blenkinsop to Abt, has lately been placed on view in the mechanical engineering collection of the Victoria and Albert Museum. The models, which are described in detail in the *Engineer* of April 26, comprise Blenkinsop's original model of the Middleton colliery locomotive of 1812, and models, made at the museum to a scale of 1 to 16, of the Fell centre rail engine of 1867 for the line over the Mont Cenis, of Riggenbach's system of a ladder-rack midway between the running rails (1874), and of Abt's improved form of rack (1882). The three models are admirably adapted for the use of engineering students, and throw much light on a somewhat complex subject.

THE new island in the Bay of Bengal, referred to in Admiral Field's letter in NATURE of February 28, is the subject of a detailed account, by Lieut. E. J. Headlam, R.I.M., in the April number of the *Geographical Journal*. By the courtesy of the editor we are permitted to reproduce one of the illustrations, which gives a good idea of the general appearance of this mud-bank. An illustration to some notes on the San Francisco earthquake, by Jacques W. Redway, in the same number, gives a very good idea of the ploughed land along one of the faults, where this shows at the surface as a belt of shearing instead of as a simple fracture.

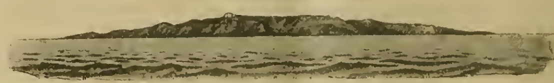

FIG. 1.—General appearance of the new Island in the Bay of Bengal from the eastward, at a distance of about half a mile.

Photo.] [*R. S. Holway.*

FIG. 2.—The San Francisco Earthquake: Ploughed land along the earthquake rift.

IN a letter to NATURE of February 14 (p. 368) Mr. Charles G. Barkla described experiments which indicated that nickel must have an atomic weight of about 61·3 instead of the value 58·7 generally accepted by chemists. This result, which is confirmed in a letter just received from Prof. B. Walter, of Hamburg, is based on the law that the secondary Röntgen rays from a chemical element have a specially high penetrative power with regard to the material from which they originate; for other elements this specific penetrative power falls off proportionately as the atomic weight of the element differs from that of the substance producing the rays. Prof. Walter points out, however, that the general properties utilised by Mr. Barkla as a basis for his considerations were in the main published by him in the year 1905 (*Annalen der Physik*, Bd. 17, p. 561; *Fortschritte auf dem Gebiete der Röntgenstrahlen*, Bd. 8, p. 297). Referring to the fact that Mr. Barkla does not accept a specific power of penetration such as Prof. Walter suggested, but holds the opinion which was generally accepted previously, that a selective absorption takes place, Prof. Walter says that this assumption is shown in his papers to lead to contradictions in the case of the *primary* Röntgen rays. In his opinion, it cannot be correct in the case of the *secondary* rays, because the phenomena in question become all the more apparent for these rays the *thinner* the absorbing laminæ be made. According to Mr. Barkla's conception, exactly the opposite should be true.

Whilst cuprous chloride and bromide have long been known, the existence of cuprous sulphate has been recognised mainly as a disturbing factor in the copper voltameter. Owing to the formation of this salt, the copper deposited on the kathode is liable to be partially redissolved $Cu+CuSO_4 \rightleftharpoons Cu_2SO_4$, causing the deposit to be too light; on the other hand, if the cupric solution has been saturated with metallic copper, the deposit is too heavy, since twice as much copper is deposited per coulomb from the cuprous as from the cupric salt. The recent experiments of Foerster and Blankenberg (*Berichte*, xxxix., 4428–4436) have added much to our knowledge of this salt. By enclosing ammonium cupric sulphate with metallic copper in sealed tubes they were able to ensure the formation of a large proportion of cuprous sulphate, and actually succeeded in isolating a double salt of the formula $Cu_2SO_4,4NH_3,H_2O$. When quite dry, the salt can be kept for some weeks in sealed tubes, but it is immediately decomposed by dilute sulphuric acid, giving rise to metallic copper and cupric sulphate. It is of interest to note that a solution containing initially 0·05 mol. $CuSO_4$, 0·05 mol. NH_3, and 0·15 mol. $(NH_4)_2SO_4$, became quite colourless when saturated with metallic copper, and when electrolysed gave a kathode deposit 55 per cent. greater than that obtained from a cupric solution in series.

A popular article upon the planet Saturn and its system, by Mr. E. V. Heward, appears in the May number of the *Fortnightly Review*.

Excellent work is being done by the Central Technical College Old Students' Association, the official organ of which, the *Central*, forms a very creditable addition to periodical engineering literature. In the current issue (vol. iv., No. 11) there are original articles on the construction of a new railway, by Mr. A. C. Cookson, and on electrical test-shop measurements, by Mr. Percy Good.

We have received from Mr. C. Baker, of High Holborn, London, an advance proof of his new quarterly catalogue of second-hand scientific apparatus. The list contains particulars of more than a thousand separate items, and is worth examination.

OUR ASTRONOMICAL COLUMN.

Comet 1907*a* (Giacobini).—No. 4173 (p. 336, April 27) of the *Astronomische Nachrichten* contains a new set of elements for comet 1907*a*, computed by Miss Lamson, in which the time of perihelion passage is given as March 17·66. A daily ephemeris, calculated by Prof. Kreutz and based on these elements, is also given, and extends to May 22. The comet is at present apparently travelling very slowly and nearly due north in the northern limits of Orion, its computed positions for May 9 and May 22 respectively being α=6h. 11m., $\delta=+14° 7'·4$ and α=6h. 14m., $\delta=+17° 5'·8$. The brightness of this object is now about one-quarter of that at the time of discovery, when it was of the eleventh magnitude.

The Temperature of the Sun.—An excellent popular description of the apparatus and methods by which MM. Millochau and Féry determined the solar temperature during 1906 is given by the former observer in *La Nature* (No. 1770, p. 338, April 27). As previously recorded in these columns (see Nature, No. 1932, p. 40, November 8, 1906), the observations were made at Meudon, Chamonix, the Grands Mulets, and the summit of Mont Blanc during July and August last. The instrument used was the pyrheliometric telescope devised by M. Féry in 1902, and described and illustrated in the paper under notice. Essentially it consists of a reflecting telescope, having a mirror of 103 mm. diameter and 80 cm. focal length, in the focus of which is placed a thermoelectric couple, which is connected with a galvanometer reading directly to about one-hundredth of a millivolt. The couple is composed of two wires, one of iron, the other of constantan, soldered together at their point of intersection, the joint being covered with a carefully blackened, very small and very light disc. A bent eye-piece, placed behind the reticule bearing the couple, enables the observer to direct the telescope to any desired portion of the solar disc. The results obtained gave a temperature of 5663°, absolute, for the centre of the solar disc, considering the sun as an ideal black body, or, as M. Guillaume terms it, an "integral radiator." Correcting this value for the probable absorption in the solar atmosphere, M. Millochau obtains 6130° absolute as the effective temperature of the sun's interior.

Photography of the Infra-red Solar Spectrum.—In No. 14 (p. 725, April 8) of the *Comptes rendus* M. Millochau records some results he has obtained in the photography of the infra-red region of the solar spectrum. The plates employed were specially prepared by plunging them for about ten minutes into distilled water to which several drops of acetic acid had been added, then into a saturated alcoholic solution of malachite green, and finally washing and drying them. They were then rendered much more sensitive by exposing them for 30 seconds at a distance of 75 cm. to a 4 candle-power electric lamp, according to the method suggested by Major-General Waterhouse in 1875.

With plates thus prepared the solar spectrum was photographed, in the region 0·750 μ to 0·950 μ, on such a scale that one Angström unit=0·1 mm., the photographs showing that the structure of the A band in the solar spectrum is identical with that of the B band. Another photograph showed the Z band resolved into lines.

A plane-grating spectrograph of 3 cm. aperture and 60 cm. focal length was employed, and with this apparatus the A band, under good conditions, could be photographed in ten, and the extreme region in thirty, minutes.

The Orbit of α Draconis.—The following elements have been found for the orbit of α Draconis from spectrograms secured at the Dominion Observatory, Ottawa, by Mr. J. S. Plaskett:—period=51·42 days, ϵ=0·322, ω=20°·3, m_0=294°, T=1906 July 11d. 4h., velocity of system=−18·4 km. per sec.

In No. 2, vol. i. (March–April) of the Journal of the R.A.S. Canada, where the above is published, Mr. Plaskett also gives a very interesting description of the methods employed in adapting a Brashear universal spectroscope to the requirements of line-of-sight spectrography.

RUSSIAN GEOGRAPHICAL WORKS.

THE labours of the great Prjevalsky have been continued by his lieutenants and others who participated in his explorations of Central Asia, and we have already mentioned the achievements of Mr. P. K. Kosloff. Mr. V. I. Roborovsky conducted an expedition, under the auspices of the Imperial Russian Geographical Society, largely along previous lines, during 1893–5, and the records are published in three volumes, viz.:—(1) the report of the head of the expedition; (2) that of his assistant, Mr. P. K. Kosloff; and (3) embodying the scientific results. We have received the three parts of the first volume, (*a*) from Tian-Shan to Nan-Shan; (*b*) Nan-Shan and Amne-Matshin; and (*c*) from Amne-Matshin to Zaisan. Elaborate preparations were made, and the best procurable instruments were placed at the disposal of the expedition. It is interesting to note that Messrs. Vladimir and Eugene Prjevalsky, brothers of the pioneer, cooperated with Mr. Roborovsky and furnished some instruments used on former occasions. A halt was made at the tomb of Prjevalsky, on the shore of the lake Issik-kul, near Prjevalsk, where a requiem was held. It was found that camels, valuable for arid desert transport, suffer severely in cold and damp regions, whereas yaks are most at ease in mountain travelling.

The sands of Kum-tag cover a legendary city of vice, destroyed beneath a shower of sand, one righteous man escaping, as in the case of the cities of the plain. At Sa-tshzhoy the expedition met with M. Splingaerd, a Belgian in the Chinese service, whose knowledge of the Chinese and their life is probably unique after many years' residence. Gold is found in the mountains near the Sa-tshzhoy oasis, of which unscrupulous advantage is taken by officials and citizens to the detriment of the revenue. The Shan-rdi lama, visited by the party, previously thought that Russians and English were the same people. Mongols and Tanguts call every European a Russian. The Tanguts, who seem to live by cattle-lifting, are dreaded by the Chinese and Mongols, and more than once attempted to raid the expedition. A chapter is devoted to the social and marriage customs of the Tanguts, with whom polyandry is rife and the expression "illegitimate" has no meaning. The Mongols showed Mr. Roborovsky a large portrait of Genghis khan, whose re-appearance is expected before long. Marriage among the lamas is prohibited in most Buddhist countries, but is regarded lightly at Tsaidam, where many lamas settle. The city of Luktshun and the Chantu people form the subject of a long chapter. A preparation of stags' horns is a feature of Chinese medicine. Wild stags are said to feed on a mythical herb which no man can find, giving them special strength and vigour. The horns are cut, dried, and smeared, then taken as a tonic by men who feel their powers decay. "Three days' weeping" is a strange remedy for scorpion bite, suggested by a Sart named Abdurahman. Sickness of men and beasts seriously hindered progress, and sympathy will be felt for the courageous leader, whose breakdown led to an earlier return from exploration and delay in publication of these volumes. Elegant phototypes of scenery add to their interest, together with meteorological and botanical observations.

In the first issue of the Transactions of the Imperial Russian Geographical Society for 1906 appears a lengthy and interesting illustrated article by the botanist Mr. V. I. Lipsky, author of "The Flora of Central Asia," on his journeys in Russian Turkestan (Tian-Shan) in 1903. Travelling was difficult, and many hardships had to be surmounted, including locusts and piercing cold. Part of the journey was "by Dunganin," *i.e.* the Dunganins are a tribe of Chinese Mussulmans who have settled in Russian territory, and gain a living by horse transport of goods and passengers. Though progress is slow, it is not unpleasant, and these people bear a high reputation for honesty. The Aksai country resembles the better-known Pamir region. Mr. Lipsky records the fact as remarkable that in the mountain lake Tshatir-kul, at a very high level, he found specimens of *Zostera marina*. This article concludes with some notes on the Kirghiz, in whom the author found strong Little Russian characteristics, both in customs and songs. Kirghiz women enjoy greater freedom than the rest of their Mussulman sisters, and attract involuntary attention when walking unveiled in the streets of Tashkend. In the same issue Mr. O. A. Shkapsky describes two journeys to the mountains of the Tashkend district. After inspection of the mountain pastures, where cattle are reared for the Ferghana and Tashkend markets, he attaches great economic importance to their more detailed survey, both as regards the food of the cattle and the customs of the breeders. Mr. Y. Edelstein contributes notes on the glaciers of the ridge of Peter the Great, where he marked indications for the guidance of future observers. There is also a translation of Prince P. Kropotkin's memoir of M. Reclus, and a memoir of Baron F. von Richthofen by Mr. K. Bogdanovitch. About twenty-five pages are occupied by a bibliography of Russian geographical literature, indicating a prolific output.

Fig. 1.—Murman Biological Station of the St. Petersburg Society of Naturalists.

Mr. Y. S. Edelstein made a geological excursion in the autumn of 1903 in the south-eastern districts of Mukden (Shentszin) province, including the Sin-tzin-tin, Feng-huang-chen, and Liao-yang districts, and has published a detailed account of his investigation of a semicircular route from Mukden to Liao-yang. He collected specimens of rocks and soil, but the outbreak of war prevented him from bringing these home. In consequence, Mr. Edelstein could only offer general deductions and a map of the broad features of the immediate areas through which his route lay. His justification for the publication of details more meagre than he could have wished is the increased interest attaching to Manchuria, and the fact that the Mukden province has been unvisited by geologists since Richthofen. In the early chapters of his work he traces his progress step by step, and sums up general conclusions in the final chapter. Mr. Edelstein thinks that serious gold-mining enterprise would be amply rewarded, but hitherto the Chinese have neither suspected the presence of gold in pyrites nor understood how to extract it. Without entering into particulars, he observes that there is a great future for this industry in Liao-dun. While there are no large coal areas like that of the Don basin, there is ample for local needs, while silver and lead veins were worked when this region was under Corean sway. Marble, copper, and asbestos are also reported, and the Chinese obtain sulphur from pyrites. Considering that the expedition was accomplished within one month, there is reason to believe that a wide field of profitable research and future mining operations has been revealed by Mr. Edelstein's skilled labours.

No. 18 of the reports of the Zoological and Zootomical Cabinets of St. Petersburg University forms a very interesting report by Mr. K. M. Derjugin on the Murman Biological Station, a centre of activity for six years in the Kola gulf and peninsula. Previously, the station was on the Solovetsk Islands, and the band of naturalists came into contact, not free from misunderstanding, with the authorities of the famous monastery. The station consists of a main building with laboratories, library, museum, and aquarium; living quarters; houses for attendants; shed and dock, with ice-house; engine-house and workshop; pavilion above a granite basin; and small harbour, with fresh- and salt-water channels. The *Orca*, a small sailing vessel of Norwegian type, is used for cruising and exploration. The fauna resembles that of Spitsbergen, especially on its western side. The journey from Archangel, we learn, presents great interest and variety for the naturalist. In his enumeration of species of plankton, Mr. A. K. Linko remarks that a vast amount of material in the northern seas has not yet been studied, and promises future reports. The work contains tables of observations, records of temperature, plans and sketches, and a library catalogue.

Mr. V. V. Markovitch has described a botanical excursion from Ossetia to Colchis, including the sources of the rivers Ardon and Rion. His first chapter opens

Fig. 2.—Wood growing horizontally out of permanent snow mounds.

with an account of the great mountain range at different seasons, and of the gaudy sun-tints. The people of Ossetia, whose characteristics are respectively modified by proximity to Georgians or Kabardians, are generally grouped under the heads of Irontsi, Tualtsi, Digortsi, and Tagaurtsi, the central point being Alagir. As it was known that this region possessed silver-lead ore, and the Tsar Nicholas I. desired that the Russians should depend upon their own resources for lead in time of war instead of upon imports, this mining centre was established under the direction of the engineer Ivanitzky. This energetic official also started a nursery and fruit garden, the success of which has been so marked that the term "Alagirsky" denotes the highest type of fruit throughout the Caucasus. Passing along the Ossetian military road, traces of every geological period may be observed, including Palæozoic slates, but fossils are rare. Alagir itself is on the site of a huge glacier from the main crest of the Caucasus. Long experience convinced Mr. Markovitch that there is no marked difference between the northern and southern slopes of the Caucasus, but a gradual transition, and having received material support from the highest botanical authorities he was encouraged to study transitional forms. The most convenient time of year for exploration of the Ossetian mountains appears to be the end of July and the beginning of August, though botanists would need to go a little earlier. Throughout Ossetia sacred trees are found, into which pilgrims throw offerings of money and other gifts. This pagan survival is adapted to Christian saints' days, especially to the festival of the popular St. George, celebrated in November. A main conclusion of Mr. Markovitch's survey is that the differences between people living side by side on a limited area are greater than those in the flora, while in Russia the contrary is the case. Ossetians and Imeritians, who live together, are entirely distinct, while there is much similarity in neighbouring peoples along European frontiers. Contrary to former suppositions, the flora of the Colchis region varies very slightly from that of the northern Caucasus.

THE TEMPERATURE OF THE NORTH SEA.[1]

In a Blue book just published dealing with hydrographical work done in connection with the International Investigation of the North Sea, I have included a paper on some methods and results of hydrographical investigation, or, as it might perhaps have been more correctly termed, on some methods of representing hydrographical results.

We have from the work of our own vessel, the *Goldseeker*, quarterly observations at numerous stations in the northern part of the North Sea, and also monthly or six-weekly observations at some twenty other stations off the east coast of Scotland as far to the eastward as 1° east. At these stations, some fifty in all, we have observations at all depths, both as to temperature and to salinity. In addition to this work of our own, we receive from a large number of passenger captains frequent observations as to temperature and a smaller number of samples for the determination of salinity, taken at the

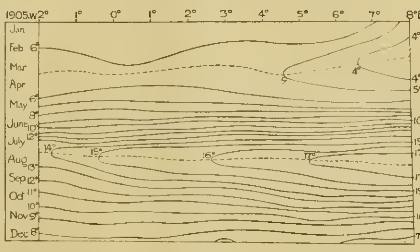

Fig. 1.

surface along many important routes crossing the North Sea. In the present paper temperature-phenomena alone are dealt with, and the results are based mainly upon our own work with but little attempt as yet to include or correlate the work of our foreign colleagues.

From a large number of observations such as we receive, from our own vessel and from the captains of liners—observations made at varying dates, and, in the case of the voluntary observations, at shifting points along particular lines—it is necessary in the first place to obtain, by interpolation, approximate data for given dates and localities. These data may then be diagrammatically represented in various ways.

Fig. 1 is a diagram of surface temperatures on the route from Leith to Hamburg, from January to December, 1905. It is constructed on a method devised some sixty years ago by Lalanne. The coordinates are time and distance along the given line, and over these coordinates are superposed contour lines, or "isopleths," representing temperature. It will be seen that from this diagram we can read at a glance many things; we see, for instance, that in early summer and late autumn there is little or no difference of temperature all the way, while, on the other hand, about March the sea gets gradually colder and about August gradually hotter as we travel eastward towards the

[1] Abstracted from the Second Report (Northern Area) on Fishery and Hydrographical Investigations in the North Sea and Adjacent Waters, 1904-1905 [Cd. 3358]. (1907.)

German coast. We easily see the extent of difference in seasonal range of temperature, which near our own coast runs from less than 6° C. to more than 13° C., at 2° east

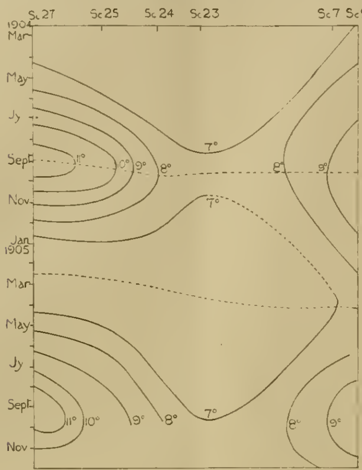

FIG. 2.

from less than 6° C. to more than 15° C., and off the German coast from less than 4° C. to more than 17° C. We notice next how comparatively slow are the changes of temperature when near the minimum in winter and the maximum in summer, and how rapid in spring and autumn when near the middle of the rise and fall, and we also perceive that the fall takes place somewhat slower than the rise, for the isopleths are less crowded in autumn than in spring. Lastly, we may discern that lines joining the cusps of the closed curves, in other words, the lines of minimum and maximum, tend to run somewhat obliquely across the chart, and that the maximum at least is definitely later as we approach the Continental coasts. Similar charts for various other routes show essentially the same phenomenon, and those drawn from the Scottish coast in the direction of Norway tend to show the influence of land at both ends of the route, the range of temperature being least in the middle.

Similar diagrams may be drawn for any given depth, and Fig. 2 is so drawn for a depth of 100 metres on a line from Buchan Deep, near Aberdeen, to the Viking Bank between Shetland and Norway. In this diagram we see that as we leave the coast the temperature-isopleths diminish rapidly in number, until in the neighbourhood of our station xxiii. (about 59° 40′ N., 0° 40′ E.) the seasonal change is only from something less to something more than 7°; but as we go further north we come again to a region of larger temperature variations, where the maximum is considerably higher and the minimum not quite so low. We notice also a retardation of dates, the maximum not being attained until well on in September.

Another series of diagrams, of a kind that has been more frequently employed, and notably by Dr. H. R. Mill in his work on the Clyde sea area, shows temperature plotted by means of isopleths over coordinates representing time and depth. While the former diagrams showed temperature changes along a line of stations during successive months, but for one depth only, these diagrams show the changes at all depths during successive months, but at one point of space only.

These and other methods of representing sea temperatures by means of diagrams may be supplemented by the use of empirical formulæ. The rise and fall of surface temperature at a given point is a very simple wave that can be suitably expressed as a sine-curve. In the periodic temperature-function

$$f(\theta) = A_0 + A_1 \sin(\theta + e_1) + A_2 \sin(2\theta + e_2),$$

&c., θ is an angle increasing in proportion to the time, A_0, A_1, A_2 are constants expressed in degrees centigrade, and e is a phase angle of which each degree signifies approximately one day in advance or arrear of our starting point, namely (since we are dealing with monthly means), January 15. If we submit an annual series of temperature observations to harmonic analysis, we find that the first sine-factor differs but little from the actual curve, while the third and following factors are entirely negligible. If we deal with mean temperatures at a given point over several years, we find the simple sine-formulæ still more closely applicable. Thus, for the surface temperatures at Abertay, taking the mean of ten years, 1893–1903, we obtain the formula $f(\theta) = 8{\cdot}43 - 4{\cdot}32 \sin(\theta + 60°)$, and find that results calculated from this formula for the middle points of the successive months differ in no case by so much as half a degree centigrade, and by a mean difference of only one-fifth of a degree centigrade, from the means of the observed temperatures for the said months. If we were to apply the next factor of our harmonic formula $[+0{\cdot}29 \sin(2\theta + 49°)]$ we should obtain calculated results showing a maximum discrepancy from observation of about a quarter of a degree, and a mean discrepancy of one-tenth of a degree.

After repeated trials of this kind we come to the conclusion that the sine-formula is a safe representation of the annual wave of temperature change. That it is a highly convenient one is obvious, for, in the first place, it gives us at a glance the three essential factors of the phenomenon, the mean temperature (A_0), the range or half-range of temperature (A_1), and the phase (e_1), which last we may briefly describe as the mean retardation of maximum and minimum. Furthermore, it enables us to compare these three factors very easily for a series of adjacent stations or for successive years. Thus if we work out our formula for points a degree of longitude apart on the route from Leith to Hamburg we obtain a table of which the following is a part:—

Table of Harmonic Constants for Surface Temperatures. Leith to Hamburg.

Long.	1904 A_0	1904 A_1	1904 e_1	1905 A_0	1905 A_1	1905 e_1
W. 2	8·90	4·18	51	8·86	3·07	56
1	9·20	4·18	50	9·24	3·09	56
0	9·48	4·39	51	9·55	4·24	56
E. 1	9·45	4·49	52	9·62	4·50	59
2	9·45	4·88	51	9·62	4·70	61
3	9·50	5·47	52	9·62	5·10	62
4	9·70	5·70	49	9·76	5·45	61
5	9·81	5·60	48	9·98	5·73	58

This orderly succession of constants may then anew be transferred to diagrams, as in Fig. 3. Similar data may

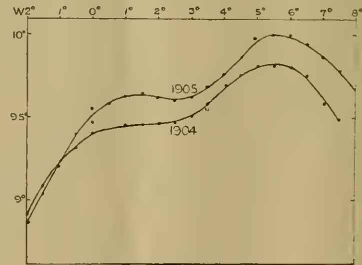

FIG. 3.

also be transferred to charts, of which a series is printed in the report.

Lastly, if it be granted that a sine-curve approximately represents the actual succession of temperatures, we may modify our diagram of the annual wave by substituting for it a circle (Fig. 4), on which time and temperature may be read together. The centre of the circle is at a height above the base-line proportionate to the mean temperature, the radius is proportionate to the half-range, and when we shall have marked upon the circle a date-

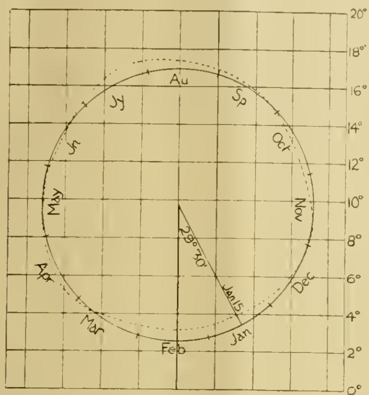

Fig. 4.

mark having reference to the phase, the temperature at a given date will be proportional to the perpendicular that falls on the base from a corresponding point of the circle. By superposing a number of such circles, or, better still perhaps, by combining them at proportionate distances in a solid model, we may represent all the various changes from point to point.

D'Arcy W. Thompson.

MAYA HIEROGLYPHS.[1]

By way of encouraging the study of ancient documents having reference to the early history of the Mayas, the museum committee on Central American research purpose publishing translations of the more important papers that have appeared in connection with the deciphering of the Maya hieroglyphs. The most recent issue of this series is a translation of Dr. Förstemann's commentary on the Maya MS. in the Royal Library of Dresden, generally known as the Dresden Codex. The figures of the original manuscript may be known to students from the admirable reproductions due to Lord Kingsborough (London, 1831), and for the proper appreciation of the value of Förstemann's commentary, these plates or some other facsimile should be consulted. Without such assistance Dr. Förstemann admits that his description is of little value, and even with this aid, the book will scarcely be intelligible without some previous knowledge.

It is very much to be regretted that the committee has not seen its way to give some indication of the process by which the figures have been conjecturally deciphered, and to enable us to assign the degree of trustworthiness that can be placed on the suggested readings. This information is the more necessary, because research on Maya hieroglyphs is confined to a few experts, and the explanations that are now accepted cannot be regarded as final. We may confidently assert that these MSS. to some extent represent encyclopædias of astronomical or astrological lore, but, at the same time, it must be admitted that they include subjects of very diverse origin, the meaning of which is still obscure.

[1] Papers of the Peabody Museum of American Archæology and Ethnology, Harvard University Commentary on the Maya Manuscript in the Royal Public Library of Dresden. by Dr. Ernst Förstemann. Translated by Miss Selma Wesselhoeft and Miss A. M. Parker. (Cambridge, Mass.: Published by the Museum, 1906.)

The key of the whole is the Tonalamatl. This is a period of time, determined by the combination of the numerals 1–13, with twenty different signs indicating as many days, consequently giving rise to a period of $20 \times 13 = 260$ days. The number 20 was the base of the ancient Mexican numerical system, and it was natural that for the measurement of time a count of twenty days should form the first unit of a higher order. The 13 is not so easily explained. Apparently it may be compared with a period analogous to our week. Such a period was but little suited for chronological purposes, since it was neither directly based on astronomical observation nor was it the expression of any uniform recurring motion in time. Yet, by its divisions and references to natural objects, such a calendric system was destined to become a useful artifice in the hands of the priestly caste for supporting forecasts and giving force to divination. Consequently, the chronological importance of the MS. merges into the astrological, and we find mixed up with the pictures figures representing gods, one of whom is delineated no less than 141 times, and several others who recur with greater or less frequency. It seems not impossible, therefore, that hidden under these symbols we have the essential part of the religious conception of the Maya peoples in a tolerably complete form; but, unfortunately, any connection between the figure of the god and the principle it represents remains vague and undetermined. The accounts of the Spanish authors regarding the mythology of the Mayas correspond very slightly with these figures of gods, and since all other conjectures respecting their significance are very dubious, the deities can only be safely and temporarily defined by alphabetical designations. Dr. Paul Schellas suggested this method of distinguishing, without describing, any particular deity, and this plan has been wisely followed by Dr. Förstemann in his commentary.

We may now ask whether the planets have been identified with greater certainty? The first reference to a planet is made in connection with "an inverted figure of a person in a squatting attitude, the head surrounded by stars, and a sign on the back, which may be a suggestion of the Sun glyph. In this figure I see the planet Mercury, and I believe that the planet's retrogression (which lasts 17–18 days) or disappearance into the light of the Sun during this week is the subject of this passage." The evidence, to those unused in the exercise of a vivid imagination in such matters, does not seem overpoweringly strong. The retrograde motion of Mercury, though variable in length, has a longer duration than seventeen to eighteen days. There is the suggestion of forced agreement here, but if we are to understand the time during which the planet remained invisible between the evening and the morning appearance, the construction is not impossible. But if it were the intention of the scribe to record such phenomena, it is difficult to understand why such symbols do not occur with some approach to regularity.

The references seem to be a little less obscure in the case of Venus. The author exhibits a series of numbers the law of formation of which, unfortunately, is not given in this treatise, which indicate that the Mayas were aware of the approximate equality of five synodic periods of Venus to eight solar years. Assuming the length of the solar year as 365 days, and the synodic period of Venus 584 days, 2920 days include both periods. This number occurs repeatedly. The author takes a further step, which also seems warranted. In a manner comparable with that by which the cycle of 7980 Julian years is determined, he proposes to bring in the Tonalamatl of 260 days by connecting it with the number 37,960 days. This number occurs in various combinations, and is equal to 146×260 (Tonalamatl), 104×365 (solar year), 65×584 (Venus, synodical period). This combination is sufficiently remarkable, and still more noticeable is the recurrence of higher numbers running into millions, in which it seems possible to trace this factor. But a very rigorous examination of the manner in which these numbers are formed is necessary before it can be concluded that they bear but one interpretation. It must also be remembered that the synodic period of Mars, taken at 780 days, is equal to precisely three Tonalamatls.

But if the instances of allusion to planetary periods are remarkable, the omissions are not less so. The explanation that Dr. Förstemann offers for the absence of reference to Jupiter or Saturn in these hieroglyphs is that their synodic periods are too nearly equal to the solar year. This can scarcely be regarded as a satisfactory explanation. But still more curious is the small attention paid to the moon. It is true that the writer traces a reference to the synodic period of $29\frac{2}{3}$ days, but the effort strikes one as rather forced, and the reference is by no means so prominent as in the case of Venus. There is, too, no mention of eclipses. In one passage Dr. Förstemann finds an allusion to clouds, and one need be very cautious how he disagrees with the opinion of so distinguished an expert. But it seems scarcely likely that such ordinary phenomena as clouds should be referred to, in what is evidently the production of considerable labour, intended for a permanent record. This omission is the more strange if we accept Dr. Seler's view that the Maya documents declare an advance on the Mexican pictorial writings, and possess greater accuracy, indicating more elaborate computation. For in a Mexican MS., Codex Vaticanus, No. 3773, we have a distinct reference to the sun being devoured by a jaguar, and causing or explaining a solar eclipse (Kingsborough, iv., 22).

The commentary offers many other instances in which ingenuity and resource are exhibited in deciphering or in assigning meanings to these pictures, but here we can oo no more than express our admiration of the patience and skill, which have solved so many enigmas and offered so many interesting suggestions.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The Robert Boyle lecture for 1907 will be delivered by Prof. Karl Pearson, on "The Scope and Importance to the State of National Eugenics," on Friday, May 17, at 9 p.m., in Balliol Hall.

The Herbert Spencer lecture for 1907 will be given by Mr. Francis Galton, on "Probability, the Foundation of Eugenics," in the Sheldonian Theatre on Wednesday, June 5, at 2.30 p.m.

Mr. C. G. Douglas, formerly Demy of Magdalen College, has been elected to an official fellowship in natural science at St. John's College.

Cambridge.—During their visits to England, it is proposed to confer the degrees of Doctor of Law upon the King of Siam and Prince Fushimi.

At a congregation to be held in June, the degree of Doctor of Science, *honoris causa*, will be conferred upon Sir Clements R. Markham, Colonel Sir T. H. Holdich, and Sir T. R. Fraser, professor of materia medica and of clinical medicine in the University of Edinburgh.

Prof. Hughes has been nominated to represent the University at the celebration of the centenary of the Geological Society of London in September.

Mr. A. D. Imms, Christ's College, has been appointed professor of biology at Allahabad University.

Prof. Nuttall will deliver his inaugural lecture in the anatomical lecture theatre on Wednesday, May 22, at 4.30 p.m.

An exhibition of 50*l.* a year tenable for two years is offered by the governing body of Emmanuel College to an advanced student commencing residence at the college in October. Application should be sent to the Master of Emmanuel not later than October 1.

The professorship of agriculture is vacant by the resignation of Prof. Middleton. The title of the professorship will in future be "The Drapers Professorship of Agriculture." The election of a professor will take place on Saturday, June 1, at the University Offices, St. Andrew's Street. Candidates for the chair are requested to communicate with the Vice-Chancellor of the University on or before Thursday, May 23.

The Mercers' Company lectures on "The Internal Media of the Body and their Relation to the Tissues" will be given in the physiological department of University College (University of London) by Prof. E. H. Starling, F.R.S., on Fridays at 5 p.m., commencing Friday, May 10. These lectures are open to all students of the London medical schools, and to medical men on presentation of their cards.

In the course of some remarks at the annual dinner of the Institution of Mining and Metallurgy on May 3, Mr. R. McKenna, M.P., President of the Board of Education, referred to the new Imperial College of Science and Technology, and said he hopes that a year hence it will be in a state of flourishing existence. He announced that this week it will be his duty to petition the King for a charter for the new college. The Bessemer memorial fund now amounts to 13,000*l.* or 14,000*l.*, and it is hoped that the amount will rapidly be increased to 30,000*l.* or 40,000*l.* The very best equipment the world can produce is needed for the Royal School of Mines, which even without such facilities has created a world-wide reputation for itself.

In the House of Commons on Monday, Mr. Murray Macdonald asked the Prime Minister whether, in view of the recent and prospective increased expenditure upon the improvement and development of State-aided education, of the importance of connecting it more closely with the universities, and of the fact that more than twenty-six years had elapsed since the last public inquiry into the universities and colleges of Oxford and Cambridge was held, he would appoint a commission to examine into the desirability of amending the existing enactments with regard to the finances, emoluments, and government of these universities. In reply to the question, Sir H. Campbell-Bannerman said:—I am disposed to agree with my hon. friend that the conditions of the universities are ripe for a thorough and comprehensive inquiry, but I am not disposed to add, at the present moment, to the number of Royal Commissions already existing.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 28.—"On the Dispersion in Artificial Double Refraction." By Dr. L. N. G. **Filon.** Communicated by Prof. F. T. Trouton, F.R.S.

It is well known that glass compressed unequally in different directions behaves like a temporary crystal. If T_1, T_2 be the principal stresses in the wave-front, τ the thickness of glass traversed, then the relative retardation of the two oppositely polarised rays is $R=C(T_1-T_2)\tau$. C may be called the "stress-optical coefficient" of the glass.

The experiments described were undertaken in order to find out how C for borosilicate glasses varied with the colour of the light used and with the composition of the glass.

Polarised light was passed through a combination of glasses under flexure optically equivalent to a slab under uniform stress. It was then analysed by a Nicol and spectroscope. The spectrum was crossed by a dark band whenever R = integer multiple of λ. The measurement of λ then gave R and C.

It is found that, on the whole, the dependence of the stress-optical coefficient on the colour is very well expressed by the empirical formula

$$\left(\frac{C}{C_0}-1\right)\left(\frac{\lambda}{\lambda_0}-1\right)=1,$$

C_0, λ_0 being constants. This gives a hyperbolic law.

In certain glasses, however, systematic deviations from this law exist. These deviations are local in character, and their study suggests a strong analogy with the effect of absorption bands on the dispersion in single refraction.

With regard to the effect of chemical composition, it appears that an increase in the percentage of B_2O_3 increases C_0; an increased percentage of K_2O probably decreases C_0. λ_0, on the other hand, seems roughly independent of the composition, so that, for the glasses examined, the curves of C plotted to λ differ only in their scale; the dispersion increases with the stress-optical coefficient.

Chemical Society, April 18.—Sir William Ramsay, K.C.B., F.R.S., president, in the chair.—The magnetic rotation of hexatriene, $CH_2 : CH.CH : CH.CH : CH_2$, and its relationship to benzene and other aromatic compounds, also its refractive power: Sir W. H. **Perkin.** Hexatriene was found to have the rotation 12·196, which, when reduced by 0·982, the constant due to the effect of ring formation, gives 11·214 for benzene as against 11·284 actually found for benzene. This indicates that benzene contains three contiguous unsaturated groupings (Kekulé's formula), and that these have substantially the same values as in open chain compounds.—Aromatic azoimides, part i., *p*-hydroxyphenylazoimide: M. O. **Forster** and H. E. **Fierz.** The properties of *p*-hydroxyphenylazoimide were described and compared with those of camphorylazoimide.—Measurements of the velocities of saponification of the *l*-menthyl and *l*-bornyl esters of the stereoisomeric mandelic acids: A. **McKenzie** and H. B. **Thompson.** *l*-Bornyl *d*-mandelate is saponified more quickly than *l*-bornyl *l*-mandelate. The bornyl esters are more quickly saponified than the menthyl esters.—The constituents of the essential oil of American pennyroyal. Occurrence of a dextro-menthone: M. **Barrowcliff.** The oil has been found to consist of (1) an undetermined phenol; (2) *l*-pinene; (3) *l*-limonene; (4) dipentene; (5) *l*-methyl-3-*cyclo*hexanone; (6) pulegone; (7) *l*-menthone; (8) *d-iso*menthone; (9) a sesquiterpene alcohol; (10) esters of formic, acetic, octoic, decylic, and salicylic acids, and the ester of a dibasic acid of the probable formula $C_8H_{14}O_4$, together with formic, butyric, octoic, and decylic acids in the free state.—Studies in the camphane series, part xxiii., oximes of camphorylsemicarbazide and camphorylazoimide: M. O. **Forster** and H. E. **Fierz.**—The action of ethyl oxalate on thioacetanilide and its homologues: S. **Ruhemann.**—The action of tribromopropane on the sodium derivative of ethyl acetoacetate: T. E. **Gardner** and W. H. **Perkin,** jun.—Indican. Preliminary notice: A. G. **Perkin** and W. P. **Bloxam.** A process is described for the isolation of the glucoside from Indigofera leaves, and it is shown that the indican from *I. sumatrana* is identical with that from *I. arrecta*.—Cupric nitrite: P. C. **Rây.**—The action of hydrogen peroxide on potassium cyanide: O. **Masson.** The products of the action are potassium cyanate and potassium and ammonium carbonates.—The reaction between calcium carbonate and chlorine water: A. **Richardson.**—The density of hydrogen chloride: R. W. **Gray.** The highest value obtained for the weight of a litre of the gas at 0° and 760 mm. in London was 1·64091 grams, and the lowest 1·64026 grams. The mean value, corrected to lat. 45°, is 1·6397 grams, which is practically identical with the value 1·6398 grams found by Prof. Guye.—Di-iodocamphor: J. E. **Marsh** and R. de J. F. **Struthers.**—Acyl-ψ-derivatives of iminothiocarbamic acid and their isomerides: A. E. **Dixon** and J. **Taylor.**

Institution of Mining and Metallurgy, April 18.—Prof. W. Gowland, president, in the chair.—A visit to the goldfields of Orenburg, Russia: F. H. **Hatch.** Notes of a journey recently made through the district, with a brief review of its physical characteristics, the occurrence of gold in alluvials and quartz, and the systems of mining adopted.—The McMurtry-Rogers process for desulphurising copper ores and matte: communicated by T. C. **Cloud.** A description of this process as carried on at the Wallaroo Works. It consists in calcining sulphide ores containing a large proportion of silica or siliceous material in converters fitted with blast-pipes and air-holes, thereby allowing a strong current of air to pass through the charge; an important part of the process is the preliminary "swamping" of the ore and the materials to be treated with water.—The ironstone of Cleveland: A. E. **Pratt.** A brief account of the Cleveland ironstone beds, which produce 40 per cent. of the iron ore raised in this country. The author described the geology, mining, and calcination methods pursued at leading mines, with practical notes on the working of the Cleveland kiln.—Laboratory crucible and muffle furnaces: G. T. **Holloway.** An illustrated description, accompanied by a complete specification, of furnaces erected in the author's own laboratory.

PARIS.

Academy of Sciences, April 29.—M. A. Chauveau in the chair.—A suspended collimator giving the position of the zenith: G. **Lippmann.** A vertical collimator carrying a very fine hole in its focal plane is suspended by a very flexible spring in such a manner that it is perfectly free to oscillate in a vertical plane. The suspending spring is formed of steel ribbon, 1/20th of a millimetre thick, 1 cm. wide, and 20 cm. long. The system is damped by a set of plates dipping in oil, and ceases to oscillate in two minutes. The apparatus is not sensitive to slight earth tremors, and the luminous image returns to exactly the same spot even after violent shocks.—The representations of an integral by a sum of ten or twelve squares: G. **Humbert.**—The direct hydrogenation of allyl compounds: Paul **Sabatier.** The vapour of allyl alcohol in a current of hydrogen carried over reduced nickel maintained at a temperature of between 130° C. and 170° C. gives nearly pure propyl alcohol, the only impurity being a trace of propionic aldehyde. Reduced copper at 180° C. produces the same reaction, but both the yield and the quality of the product are inferior.—Observation of the eclipse of the sun of January 14, 1907, at the Observatory of Phu-Lien, Tonkin: G. **Le Cadet.** An account of visual observations, actinometric measurements, and barometric changes during the partial eclipse.—The distances of the satellites of Uranus and of Jupiter: Émile **Belot.**—The analytical nature of the solutions of certain partial differential equations of the second order: Charles **Goldziher.**—The development of hyperelliptic functions in trigonometrical series: Z. **Krygowski.**—The surfaces developed by a circular helix: E. **Barré.**—The most general representation of the equation of nomographical order 3 by a conical nomogram: Maurice **d'Ocagne.**—The sharp edge integrator: M. **Jacob.** This form of planimeter is capable of dealing with important questions arising from the equations of Abel and Riccati, and presents especial interest from the point of view of artillery.—The action of a horizontal aërial current upon a vertical vortex: Bernard **Brunhes.**—The direct determination of the absolute value of the electric charge of a monovalent electrolytic ion: H. **Pellat.** It has been shown by Townsend that the electric charge carried by a gaseous ion is the same as the charge carried by a monovalent ion during electrolysis; J. J. Thomson has determined the first of these two quantities, thus giving the second indirectly. In the present note a method is given for measuring the charge carried by a monovalent electrolytic ion without assuming any of the properties of gaseous ions. The numerical results are of the same order as those furnished by the Thomson-Townsend method.—The dielectric constant of ice and of water in the neighbourhood of 0° C.: F. **Beaulard.** It is found that the dielectric constant of ice is of the same order of magnitude as the square of the refractive index; the constant for water near 0° C. is about double that of ice.—An apparatus for measuring the rate of consumption of petrol in motors: M. **Krebs.** An acknowledgment of priority for a similar apparatus invented by M. Parenty.—The acoustic efficiency of the telephone: Henri **Abraham.** Leaving cases of resonance out of account, the best telephone does not transmit more than one-thousandth part of the energy which it receives to the line.—A new microscope and its applications to stereoscopic photomicrography: A. **Quidor** and A. **Nachet.**—The limit of inflammability of mixtures of ether vapour and air: O. **Boudouard** and H. **Le Chatelier.** Referring to a paper on this subject published recently by J. Meunier, the authors point out that they anticipated these results ten years ago.—Researches on the compressibility and vapour pressure of mixtures of methyl ether and sulphur dioxide; the formation of a compound between these two bodies: E. **Briner** and E. **Cardoso.** Data are given proving the existence under strong compression of a compound having the composition $(CH_3)_2O,SO_2$. The critical temperature and pressure of this compound were measured.—The temperature of formation of the carbides of strontium and barium: Morel **Kahn.** The reduction of baryta and strontia by carbon can be realised at a temperature near that of the fusion of platinum, with formation of the corresponding carbides.—The preparation and properties of a new variety of chromium: Binet **du Jassonneix.** At a high temperature copper dissolves about 1·6 per cent. of chromium, and this separates out during cooling in the form of a spongy mass. The chromium can be isolated by dissolving away the copper in nitric acid.—The limit to the proportion of silicon which can be taken up by copper: Em. **Vigouroux.** In the presence of lead, bismuth, or antimony, silicon in excess reacts with the copper only to form a copper silicide, the maximum percentage of silicon taken up being about 10 per cent.—The higher oxides of rubidium: E. **Rengade.** By the regulated action of oxygen upon rubidium, evidence is obtained of the formation of a black oxide intermediate between the dioxide and the peroxide, and of a composition approximating to Rb_2O_3.—The isomeric dioximidosuccinic acids: A. **Wahl.**—The dibromides of the allyl phenolic ethers; the formation of cyclopropanols: MM. **Tiffenau** and **Daufresne.**—The bitterness of milk: MM. **Trillat** and **Sauton.** The bitterness of milk, as of cheese, is produced whenever contamination occurs with any organism capable of producing both aldehydes and ammonia, or by several species of organisms, some of which are capable of producing ammonia, others aldehydes.—The presence of sympathetic ganglia situated below the spinal ganglia; microsympathetic and hypo-spinal ganglia: G. **Marinesco** and J. **Minea.**—The nephro-poïetical activity of the fœtal kidney: P. **Carnot** and A. **Lelièvre.**—The mode of action of sodium salicylate on the uric excretion: Pierre **Fauvel.** Salicylate of soda does not increase the amount of uric acid or xantho-uric products, but only exerts a modifying action on the secretion.—The discovery of a human jawbone in a Quaternary breccia: A. **Favraud.**—The relations between glacial erosion and fluvial erosion: Jean **Brunhes.**—The movements of sands along the coastline: M. **Thoulet.**

DIARY OF SOCIETIES.

THURSDAY, MAY 9.

ROYAL SOCIETY, at 4.30. The Anatomy of the Julianiaceæ considered from the Systematic Point of View: Dr. F. E. Fritsch.—The Ascent of Water in Trees, Second Paper: Prof A. J. Ewart.—Increase in the Complement-Content of Fresh Blood-Serum: Dr. J. Henderson Smith.—On the Periodic Variations of the Nile Flood: E. B H. Wade.

ROYAL INSTITUTION, at 3.—Spectroscopic Phenomena in Stars, (1) Chemistry: H. F. Newall, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Telephonic Transmission Measurements: B S. Cohen and G. M. Shepherd.

IRON AND STEEL INSTITUTE, at 10.30 A.M.—Presidential Address.—Electrically Driven Reversing Roller-Mills: D Selby-Bigge.—(1) Steel Making from High Silicon Phosphoric Pig Iron by the Basic Bessemer Process: (2) Steel Making from Pig Iron containing Chromium, Nickel, and Cobalt: A W. Richards.—The Use of Steam in Gas Producer Practice: Prof. W. A. Bone and R. V. Wheeler.

MATHEMATICAL SOCIETY, at 5.30.—Rational Expression of the Invariants of a Quintic by Means of Three: Dr. H. F. Baker.—Secular Stability: Prof. H. Lamb.—A Lemma connected with Fourier's Series: F. J. W. Whipple.

FRIDAY, MAY 10.

ROYAL INSTITUTION, at 9.—Recent Excavations on Forum Romanum, and the Forum Ulpium: Signor Comᵉ Giacomo Boni.

PHYSICAL SOCIETY, at 8.—Stereoscopy with long Base-line illustrated on the Screen: Dr. T. C. Porter

ROYAL ASTRONOMICAL SOCIETY, at 5.—On the Presence of Tin in Stellar Atmospheres: J. Lunt.—Tables to Accompany Mr. Innes's Paper on Computation of Secular Perturbations: F. Robbins —Note on Certain Photo-visual Objectives: W. J. S. Lockyer.—On the Variable Stars *RV* and *RX Andromedae*: A. Stanley Williams.—Note on Le Verrier's Tables of Saturn: A. M. W. Downing.—Note on the Range in Brightness at Maximum of Long-period Variables: H. H. Turner.—An apparent Influence of the Earth on the Numbers and Areas of Sun-spots in the Cycle 1889–1901: Mrs. A. S. D. Maunder.—Some Notes on the Classification of Long-period Variables: H. H. Turner.—*Promised Papers*: Distribution of Prominences in Latitude in the Year 1906: John Evershed.—Description of the 30-inch Reflector recently erected at the Helwan Observatory, Egypt: J. H. Reynolds.—Note on the Spectrum of α Orionis: H. F. Newall.—Observations of Jupiter's Sixth and Seventh Satellites from Photographs taken with the 30-inch Reflector in 1906–7: Royal Observatory, Greenwich.—Recent Work at the Kodaikánal Observatory: Prof. Michie Smith.

MALACOLOGICAL SOCIETY, at 8.—The Pairing of *Limnaea peregra* with *Planorbis corneus*: W. D. Lang.—Notes on *Achatina denisoni*, Reeve, and *Achatina magnifica*, Pfr.: E. A. Smith —Review of the New Zealand Acmæidæ, with Descriptions of New Species and Sub-species: Henry Suter.

IRON AND STEEL INSTITUTE, at 10.30 A.M.—Sentinel Pyrometers and their Application to the Heat Treatment of Tool Steel: H. Brearley and F. Colin Moorwood.—Induced Draught with Hot-air Economisers for Steel-Works and Blast-Furnace Boilers: A J. Capron —The Influence of Process of Manufacture on Some of the Properties of Steel: F. W. Harbord.—The Distribution of Sulphur in Metal-Ingot Moulds: J. Henderson.—The Ageing of Mild Steel: C. E. Stromeyer.—Carbon-Tungsten Steels: T. Swinden.—The Nomenclature of Iron and Steel: Report of a Committee of the International Association for Testing Materials.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Consideration of the Patents and Designs Bill, 1907.

SATURDAY, MAY 11.

ROYAL INSTITUTION, at 3.—Scientific Work in the Sea-Fisheries: Prof. W. C. McIntosh, F.R.S.

MONDAY, MAY 13.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—An Expedition from the Niger to the Nile: Lieut. Boyd Alexander.

VICTORIA INSTITUTE, at 4.30.—Recent Discoveries in Palestine and Syria: Dr. Ernest W. G. Masterman.

TUESDAY, MAY 14.

ROYAL STATISTICAL SOCIETY, at 5.

ANTHROPOLOGICAL INSTITUTE, at 8.15.—Exhibition of Australian Specimens and Photographs recently received from Dr. Ramsay Smith, of Adelaide: Prof. D. J. Cunningham, F R.S.—Dolls: N. W. Thomas.

WEDNESDAY, MAY 15.

SOCIETY OF ARTS, at 8.—Trypanosomiasis or Sleeping Sickness: Dr. H. W. G. Macleod.

ROYAL METEOROLOGICAL SOCIETY, at 4.30.—The Standard Rain Gauge, with Notes on Other Forms: Dr. Hugh Robert Mill.—On a Method and Apparatus for Measuring Fog Densities: J. W. Lovibond.—Note on a Balloon Struck by Lightning, April 11, 1907: Colonel J. E. Capper.—Account of a Remarkable Excavation made by Lightning in Peat-earth on August 2 or 3, 1906: J. Nevin and A. S. Herschel, F.R.S.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Diffraction Rings due to a Circular Aperture: Prof. A. W. Porter and P. F. Everitt.—An Improved Vertical Illuminator: E. M Nelson.

GEOLOGICAL SOCIETY, at 8.—The Origin of certain Cañon-like Valleys Associated with Lake-like Areas of Depression: F. W. Harmer.

THURSDAY, MAY 16.

ROYAL INSTITUTION, at 3.—Spectroscopic Phenomena in Stars, (2) Motion: H. F. Newall, F R.S.

CHEMICAL SOCIETY, at 8.30.—The Relation Between the Crystalline form and the Chemical Constitution of Simple Inorganic Substances: W. Barlow and W. J. Pope.—Experimental Investigation into the Process of Dyeing: J. Hübner.—Some Derivatives of *p*-Pyranol allied to certain Derivatives of Brazilein and Hæmatein, Preliminary Communication: W. H. Perkin, jun., and R. Robinson.—Mixed Semi-ortho-Oxalic Compounds: G. D. Lander.—The Mechanism of Bromination of Acylamino-compounds, Preliminary Notice: J. B. Cohen.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Present State of Direct Current Design as Influenced by Interpoles: F. Handley Page and Fielder J. Hiss.

DEVELOPMENT OF THE HUMAN EMBRYO.

Handatlas der Entwicklungsgeschichte des Menschen. By Prof. Julius Kollmann. Part i. Pp. viii+340 figures, many of them printed in several colours, with a brief explanatory text. (Jena: Gustav Fischer, 1907.) Price 13 marks.

THOSE who wish to see at a glance a truthful and graphic representation of our present knowledge concerning the conception and development of the human body will find it in this hand-atlas by Prof. Kollmann. Here is a museum rather than a book, a museum in which specimens illustrating nearly all stages of development have been judiciously collected from the best sources—many of them from the shelves of the author's own museum—and represented by all the skill of modern pictorial art, a brief description being given of each specimen to supply the place of a catalogue. Altogether, this work will contain 800 figures illustrating stages in the development of the human body.

Five-and-twenty years ago our knowledge of the human embryo, if not a complete blank, was almost a complete series of blanks. When the late Prof. His published his great monograph on the early human embryo in 1882, he was able to find accounts of only ten specimens belonging to the first month of development, these accounts being, for the greater part, imperfect descriptions of the external appearances of poorly preserved embryos. The rapid progress which has made the production of this hand-atlas possible was the result of the application of a new method by which the minute and exceedingly delicate embryo could be cut, fixed, sectionised, and accurately reconstructed on a magnified scale. The reconstructional method gave embryologists an easy means of mutual exchange; by a reconstructed model it became possible to show accurately in five minutes what had been acquired by five months of labour. The method of reconstruction by wax plates is usually ascribed to Prof. Born, but the late Prof. G. B. Howes claimed the invention for Mr. E. T. Newton, who applied it to the reconstruction of the brain of insects before 1878. This laborious method has never appealed to the English anatomist; hence we find that not one of the forty-four specimens which Prof. Kollmann uses to illustrate the stages of development in the first and second months was prepared in England; the reconstructed models of which illustrations are given were made in the laboratories of Germany, Switzerland, and America. Yet the method by which progress has been attained was first used in England; nor were human embryologists lacking in England in the early days, for when Prof. His began his great work he counted that of the late Prof. Allen Thomson amongst the best. How far we have lost preeminence in this subject may be seen from the fact that in the 340 illustrations used in the first part of this atlas, only one is the work of a British anatomist, and that is a diagram published a good many years ago by Sir William Turner, of Edinburgh.

It has always been the habit to utilise our knowledge of the developmental history of the domestic animals to fill in the blanks in the history of human development. That is now unnecessary except for the first week; Leopold's ovum represents the earliest stage of human development, and it is probably in the seventh or eighth day of growth. The fertilisation and segmentation of the human ovum have not yet been seen, but it is highly improbable that they will present any peculiar features. To supply this blank, Prof. Kollmann reproduces the excellent illustrations of the fertilisation of the mouse's ovum given by Sobotta, and those of the segmentation of the ovum of the dog and bat depicted by Bonnet and van Beneden. The author also realises the great value of comparative embryology as a key to the more obscure processes of human development, and draws freely on the work of van Wijhe, Flemming, van der Stricht, Hertwig, Froriep, Stöhr, and Schauinsland. Abnormalities of development are also illustrated.

There was a general expectation that a complete knowledge of the phases of embryonic development would give a key to the origin and past history of man. That expectation has not been fulfilled. If to some extent developmental phases do recapitulate certain generalised stages of evolution, yet so blurred are they, so much are they modified by the conditions of fœtal growth, that they give us no certain knowledge. In the excellent series of models which the author uses to illustrate the transformations at the end of the first month and beginning of the second one can see the gill arches and cleft appear and then disappear, the tail bud out and then become suppressed. But even in these early stages it is to be seen that the brain is planned on a large scale; Prof. Kollmann reproduces side by side a human embryo in the second month of development with that of an ape (*Macacus cynomolgus*) in a corresponding phase; superficially they look wonderfully alike, especially as regards their limbs, but the human head, if the same in type, already shows a distinct difference in form and proportion. It is too soon to say how far embryology may yet throw light on the relationship of man to other Primates. We know practically nothing of the embryology of the anthropoids which are most closely related to man. Thanks to the labours of Selenka, which are freely used by Prof. Kollmann, we know a good deal of the early history of one anthropoid, the gibbon, and in it the process by which the ovum becomes embedded in the uterus is identical to that in man and differs from that of the common ape. That was to be expected from what is known of their anatomy. It is possible, too, that the investigations which are being made in America by Mall, Bardeen, and Lewis on the later stages of the development of the human embryo—the formation of the bones and muscles of the limb and trunk—may give definite bearings as to man's relationship to other Primates. All the present evidence for the solution of such problems has been brought together and made available for those who are interested in this subject by Prof. Kollmann. The price of the hand-atlas is so low that one marvels how the venture can be made to pay.

THE PROBLEM OF CRYSTALLISATION.

An Introduction to Chemical Crystallography. By P. Groth. Authorised translation by Dr. Hugh Marshall, F.R.S. Pp. xii+123. (London: Gurney and Jackson, 1906.) Price 4s. net.

IN providing for English-speaking readers a translation of Prof. Groth's "Einleitung in die chemische Krystallographie," Dr. Marshall has performed a task of great utility, the value of which is no doubt enhanced to many in this country by the references to abstracts and papers in the Journal of the Chemical Society added by him. In preparing the translation he has kept closely to the original, but not so slavishly as to mar the literary style.

The question as to the precise nature of the constitution of unorganised matter, including as it does the problem of the phenomenon of crystallisation and the relation between the chemical composition and the crystal structure, has since the time of Lucretius, and even earlier, been the subject of no little speculative thought, much of which has necessarily been abortive because the knowledge derived from experiment was not sufficiently far advanced to act as a check on the correctness of the various theories propounded. The past century has, however, seen a vast increase in the store of facts relating to the characters of mineral substances, and chemists have, particularly in recent years, recognised the importance of determining with precision the crystallographical properties of the salts prepared by them in the laboratory. For many years past Prof. Groth has been engaged in the preparation of a complete digest of the physical properties of all crystallised substances. The first of the four volumes in which that work will appear was reviewed in NATURE of April 4 (vol. lxxv., p. 529). To that colossal work this small volume forms an introduction.

In a remarkably brief compass, and with all his customary lucidity of exposition, Prof. Groth has summarised the state of our knowledge at the time of writing. After a short discussion of the possible varieties of crystal structure, he proceeds to consider the main subject in its various aspects. Polymorphism deals with the various modifications displayed by the same substance, such as, to take the best-known instance, sulphur, and the nature of the transition between them. The next chapter is concerned with morphotropy, or the comparison of the crystal structures of chemically allied substances, such as, for instance, the aromatic compounds. Isomorphism is a particular case of morphotropy, in which the change in composition leaves the structure almost unaltered. The last chapter treats of molecular compounds, which, however, cannot be differentiated from isomorphous mixtures.

So vigorous is the growth of this subject that, even though various alterations have been embodied in the translation which were necessitated by the publication of investigations during the short interval that elapsed between the dates of appearance of the original and the translation, further revision is demanded by still more recent material. Of primary importance is the simple yet fundamental theory of close-packing put forward by Mr. Barlow and Prof. Pope in a paper read before the Chemical Society in November last.

We may commend this introduction to all who are interested in this important subject, and especially to chemists in this country, to whom we hope it may reveal the advantages of a study of crystallography, a branch of science of which they are said to be neglectful.

PHYSICS FROM MANY POINTS OF VIEW.

(1) *First Year's Course in Practical Physics.* By James Sinclair. Pp. viii+124; illustrated. (London: George Bell and Sons, 1906.) Price 1s. 6d.

(2) *Theoretical and Practical Mechanics and Physics.* By A. H. Mackenzie. Pp. xvi+112; illustrated. (London: Macmillan and Co., Ltd.; New York: The Macmillan Co., 1906.) Price 1s.

(3) *Junior Experimental Science.* By W. M. Hooton. Pp. viii+260; illustrated. (Cambridge: University Tutorial Press, Ltd., 1906.) Price 2s. 6d.

(4) *Text-book of Mechanics.* By Louis A. Martin, jun. Vol. i. Pp. xii+142; with diagrams. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1906.) Price 5s. 6d. net.

(5) *The Tutorial Physics.* Vol. v. Properties of Matter. By C. J. L. Wagstaff. Pp. iv+251; illustrated. (Cambridge: University Tutorial Press, Ltd., 1906.) Price 3s. 6d.

(6) *Practical Physics.* By W. R. Bower and J. Satterly. Pp. xi+399; illustrated. (Cambridge: University Tutorial Press, Ltd., 1906.) Price 4s. 6d.

(7) *The School Magnetism and Electricity; a Treatise for Use in Secondary Schools and Technical Colleges: based on Potential and Potential-gradient.* By Dr. R. H. Jude. Pp. vi+403; illustrated. (Cambridge: University Tutorial Press, Ltd., 1906.) Price 3s. 6d.

(8) *Mechanics Problems for Engineering Students.* By Frank B. Sanborn. Second edition, revised and enlarged. Pp. viii+194; illustrated. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1906.) Price 6s. 6d. net.

(9) *A First Course in Physics.* By Dr. R. A. Millikan and Dr. H. G. Gale. Pp. viii+488; with illustrations. (Boston, New York, Chicago, and London: Ginn and Co., n.d.) Price 5s. 6d.

ANYONE who thinks that the existing supply of text-books in mechanics and physics is quite sufficient is neglecting to make an adequate estimate of the extremely varied conditions under which teachers and pupils work. There was never a time when so much teaching was being done as now. Elementary school, high school, public school, technical school and college, each is developing on different lines, with the result that each feels the need of a text-book written specially to suit its work. Besides these, there is the cramming school, the main object of which is to get a man "through" an examination; this also has its special aims and needs, and seeks to satisfy them. Those of us who are ceasing to be young fared very differently in our day from the modern student. A few leading text-books we had from which to select; after reading these we were encouraged at once to study the more simple of original papers and treatises. In this way we were led early to view science in the making, and ever since we have valued the independent spirit which this mode of training infused into us. Granting the increased facilities for absorption (it is amazing what some of our junior students "know"), it yet remains to be seen whether the present mode of boiling down science into a sort of intellectual pemmican will turn out better scientific men. Meanwhile, the flow of text-books continues, each written to meet some want. The above are some that we have received.

(1) In this first course in practical physics an attempt is made to provide for pupils in day schools, evening schools, and pupil teachers' classes a course which is not too difficult for young students, but which contains all that is really essential. The description of the experiments is not surrounded by any theory, the author's opinion being that this should be given by the teacher—at any rate in the first year. The course is a very simple one, consisting of exercises in the measurement of length, area, volume, mass, relative density, pressure of air, and of a few experiments in heat. The instructions given seem to be very clear in the main, and the order of experiment is quite logical.

(2) The text-book by Mr. Mackenzie is intended for artisans in evening schools. These belong to a class of student which has not been sufficiently catered for up to the present. A volume like this is an effort to provide something suitable for preparing them to benefit more fully from the instruction given them in the principles underlying their trades.

The course laid down is wholly experimental.

"Although instructions on the carrying out of experiments are given in detail, the students are not told as a rule what they are expected to see or what conclusions they should draw."

No previous experience of laboratory work is expected. The range covered is the same as in No. 1. We recommend this volume as a very suitable introduction to the rudiments of the subject.

(3) "This book has been written in order to supply a want," viz. a work containing approximately all that is required by the syllabuses in experimental science set for the Oxford and Cambridge junior local and Central Welsh Board junior examinations. It is primarily meant to help the teacher by providing the material required for revision. The subject-matter includes hydrostatics, mechanics, heat, and chemistry. Each experiment is prefaced by a short theoretical account which will add value to the book, and each chapter ends with a set of questions. There is not much room for originality in such a volume—the conditions laid down in producing it tend to preclude originality. The descriptions, so far as they go, appear to be clear, and provided a student actually does the described experiments are probably sufficient. We regret to see the phrase "whole pressure" alluded to in a modern text-book; still more do we regret to see it defined as the total force tending to deform a body.

(4) Mr. Martin's "Text-book of Mechanics" deals only with statics; the kinematics and kinetics are to follow in a second volume. For such an elementary book sufficient care is not always exercised in connection with fundamental illustrations. The necessity of a strong push to displace appreciably a large ball of iron hung up by a string indicates its great *weight*, and not its great mass. The difficulty of displacing it *quickly* depends on its mass. It is not usually true to say that "two bodies of equal mass moving with equal and opposite velocities will on impact (collision) come to rest." Even two equal lead balls will not behave in this way. Force is defined in the introduction as rate of change of momentum; no attempt is made to connect this definition with the use of the word force in the body of the book. Putting aside, however, this incompleteness of logical treatment, the volume may be considered a useful summary of elementary rules regulating the equilibrium of bodies. The last third of the book consists of chapters on graphical statics with applications to stresses in members of framed structures. These chapters will be found to be useful in teaching technical students, for whom they are primarily intended. There is no calculus employed, although it will be used extensively in the companion volume, which is nearly ready for the press.

(5) "Properties of Matter," by Mr. Wagstaff, is a somewhat more ambitious work, since it is intended to include all that is usually required for a pass degree; it therefore deserves a stricter examination. We must point out that Borda's metre has long been obsolete; the same remark applies to Borda's kilogram. The work of the Bureau International seems to be little known to writers of text-books. The author deserves credit for attempting to introduce vitality into his subject by outlining various attempts to "explain" matter. However, is not Osborne Reynolds's interesting granular theory now discredited? Also, is there not some doubt about the possibility of explaining all mass as being electromagnetic? We think that the selection of problems has been very well made, and the treatment is very clear. A proof is given of most of the theorems stated, and this is usually sufficient for those who intend to proceed only to a pass degree. Suggestions, of course, might be offered in many ways. The experiment on a stretching wire is most easily made with a wire of copper. With a thin wire the whole course of the extension up to the breaking point can be obtained with small loads, and the amount of permanent extension is much more considerable than with steel. We think that some idea of the nature and character of rolling friction should be included. Were this done, an explanation could also be given of the incompleteness of the working out of the problem of the disc rolling down an inclined plane. The solution given (the usual one, by the way) involves perpetual motion of the disc when once started on a horizontal plane, for its acceleration would be zero. The fact is that if the friction be represented by a single force it cannot be represented

at the same time as acting at the point of contact between the disc and the surface.

(6) In the "Practical Physics" of Messrs. Bower and Satterly we have a course intended for matriculated students. No previous knowledge of experimental physics is assumed, however, and hence the handbook is a complete elementary manual of the subject. Great pains have evidently been taken to secure efficiency, and the result is a text-book which merits great praise. Both the writers have had considerable experience in practical work, and, moreover, have the ability to impart the results of this experience to others. The volume is profusely illustrated with sketches, which will prove of great use to teachers who are obliged to make their own apparatus. Most of the experiments are intended to be performed in a properly equipped laboratory; certain of them are designed to be performed at home. The latter have been arranged so as to keep the cost of performance low, but at the same time merely trifling experiments have been avoided. These experiments form part of the complete course, and are meant to be done in a laboratory, if not at home.

(7) In spite of the considerable merit of the preceding manuals, we turn from them to Dr. Jude's elementary treatise and peruse it with some sense of exhilaration. It is only a school book, containing "all of the subject that is required for the London University Matriculation," though not written to the syllabus of any examination; but from first to last there is an originality of treatment which makes it interesting reading even to one who is *blasé* in the reading of text-books. Our only doubt is whether it is not too thorough for such examinations as that named; a wise teacher will know, however, how to benefit by it himself, and at the same time to temper it to the more junior boys without sacrificing the thoroughness. According to its subtitle, it is based on "potential and potential-gradient," notions which even university students sometimes find it hard to grasp. The fallacy of the old theory of "free and bound" charges is exposed, and this exposure is made much more effective than is customary. It is shown that when a conductor is under electric induction, the amount of electricity which runs out of the conductor on earthing is not in general equal to that which resided beyond the neutral line before the earth connection was made. In the case of a sphere under the action of a point-charge placed at a distance of four times the radius from the centre, the so-called "bound" charge is less than one-fifth of the induced charge when the sphere is earthed. A matriculation pupil will not understand the mathematical quotations in respect to this point, but these quotations will serve to keep many a teacher on the right path. This example indicates the thoroughness characteristic of the volume. The diagrams are numerous, and, in general, are good, but it is certainly with regret, and also with some surprise, that we see certain familiar lines-of-force diagrams doing duty once more. A moment's reflection should persuade anyone that a diaper pattern between two north poles (p. 206) hardly does justice to the lines as pourtrayed by iron-filings, imperfect though these are. Still less does it do justice to the true lines of force between two such poles. The figure for two opposite poles (Fig. 94) should also be replaced by a much more satisfactory one. We do not wish to conclude the notice of the book by an adverse criticism, however slight. It has given us great pleasure to read through it, and we hope that this pleasure will be felt by very many more.

(8) The collection of mechanics problems made by Mr. Sanborn is a second edition of a book prepared for engineering students. The aim has been to present many practical problems, together with brief definitions and solutions of typical problems, to help the student to follow George Stephenson's advice to his son Robert: Learn for yourself, think for yourself, make yourself master of principles. It is illustrated with process-work cuts in the new manner, presumably with the object of adding interest to a mere collection of problems. Whenever these cuts illustrate a definite point, their inclusion acquires a real value. In some cases the moral is somewhat hazy. The frontispiece of an engine belching black smoke on an up-grade on the Pennsylvania Railroad at Tyrone seems somewhat superfluous, especially as the camera, having seized the wrong perspective, has given the lines a down-grade rather than an up-grade appearance. In other cases, where, for example, it is a dipper dredge which is depicted in full working order, the picture is necessary to the proper understanding of the problem on the opposite page. There is a novelty about the choice of problems which we very much appreciate. The utility of the book would be enhanced if more of these problems were worked out in detail. With regard to provision of answers, a middle ground has been taken in giving them to about half the questions. The answer to a problem is not the principal thing from the standpoint of education, though it of course becomes very important when it forms the basis of a monetary transfer. The one feature of the book which we fail completely to understand is the order in which the questions are arranged—work, force, motion. Is it possible that it is intended that the exercises should be performed backwards?

(9) "A First Course of Physics," by Drs. Millikan and Gale, "has grown out of the actual needs of the elementary work in Physics in the University of Chicago, particularly in the University High School." The aim has been to give "a simple and immediate presentation in language which the student already understands, of the hows and whys of the physical world in which he lives." It must not be understood from this quotation that we have here merely a compilation for the amateur reader; the volume is a genuine text-book for schools. We think that in the choice of matter and in its treatment the authors have been successful. Not the least valuable feature is the large number of excellent portraits of physicists, old and new, from Aristotle to Galileo, Maxwell, and J. J. Thomson; these will help to stimulate the budding genius. In the section on image formation the method of wave-curvature has been adopted. We agree that in the elementary treatment of images there is advantage in this method; at the same time,

we do not see in what respect the representation of waves by their wave-fronts is associated with less fiction than what the authors refer to as "the time-honoured fiction of rays." Whether the wave is represented by its front or its normal is a question merely of convenience or lucidity. The fiction which affects both equally consists in regarding the wave as a simple spherical one, and when the question is the higher one of the deviation from sphericity, we think the advantage lies all on the side of the method of rays. We conclude by wishing this volume all success; it deserves to be widely read.

THE PRINCE OF ENTOMOLOGY.

Les Débuts d'un Savant Naturaliste. Le Prince de l'Entomologie. Pierre-André Latreille à Brive de 1762 à 1798. By Louis de Nussac. Pp. vii+264. (Paris: G. Steinheil, 1907.) Price 5 francs.

THE subject of this memoir was the natural son of Baron d'Espagnac, and some doubt exists as to the exact date and place of his birth; his biographers, however, are agreed in giving the former as 1762, and Brive, in the department of Corrèze, as the place where he first saw the light of day. He was educated at Brive and at Paris, took orders in 1781, and eight years later became a fully ordained priest. The Revolution altered the ecclesiastical future of Latreille, for in 1793 he was arrested on the charge of neglecting to take the oath of allegiance to the new Government, was thrown into prison, and sentenced to exile in Cayenne in company with other recalcitrant priests.

Latreille was saved from this fate by the influence of friends and by a fortunate accident, the story of which is of considerable interest. On the wall of his cell, which he shared with an invalid prisoner, Latreille, who was already an expert entomologist, found a specimen of a beetle that he recognised as new to science; the surgeon attending the invalid observed Latreille's excitement, and on discovering the cause of it asked if he might give the specimen to a scientific friend, M. Bory. Next day the surgeon brought back word that M. Bory was unable to identify the new beetle, and Latreille, perceiving that he was dealing with a brother entomologist, sent him the message:—"Vous lui direz que je suis l'Abbé Latreille, qui va aller mourir à la Guyane avant d'avoir publié son 'Examen des Genres de Fabricius.'" Steps were immediately taken to free the captive, and he was literally snatched from the ship bearing the exiles to Cayenne; the ship subsequently foundered off the French coast, and all hands were lost. Latreille, in his classic work on insects and crustaceans, describes the insect that was the means of his salvation as *Necrobia ruficollis*, and details the circumstances of its discovery; in his "Genera crustaceorum et insectorum" he apostrophises it as "Insectum mihi carissimum," and a representation of it is carved on the bust of the great entomologist in the museum at Brive with the inscription "Necrobia ruficollis Latreillii salus anno MDCCXCIII.

After these adventures Latreille returned to Brive, and tranquilly resumed his entomological studies. The end of the eighteenth century in France was marked by the immense stimulus given to the scientific study of agriculture; societies for the encouragement and advancement of agriculture sprang up everywhere, and met with official sanction and help. Experiments on the cultivation of all sorts of crops were carried out, new agricultural machines were invented and tested, efforts were made to combat insect pests, and the methods of other countries were studied. In fact, France more than a century ago had arrived at a stage in agricultural progress which the modern Englishman may well envy. To-day an industrious peasantry, firmly rooted to the soil, is the prop and mainstay of France, and who can doubt that their existence is largely due to the work of those early agricultural societies, called into being themselves by the revulsion of feeling against a tyrannical and effete landed aristocracy? The cry of "Back to the Land" is only heard in those countries where the needs of agriculture are regarded by legislators with languid indifference.

In a milieu of eager and scientific inquiry a man like Latreille was bound to make his mark; he was appointed professor of natural history at Brive, and in 1798 was elected a member of the Institut National des Sciences et des Arts of France. During these years he was in active correspondence with Fabricius, to whom he owes his title of *Princeps Entomologiae*, with Olivier, Bosc d'Antic, and other entomologists of the day, and he was personally known to the Paris zoologists, the great Cuvier, Duméril, Daubenton, and Lacépède. Several of his letters are quoted by M. de Nussac, and these alone show, even if we had not his published works to convince us, that Latreille possessed the true Frenchman's power of generalisation and ability to seize on characters of prime importance for systems of classification. In 1796 Latreille published at Brive his first great work, "Précis des Caractères génériques des Insectes," which earned for him the plaudits of the entomological world of the day; it was followed by "Essai sur l'Histoire des Fourmis de la France," and shortly afterwards Latreille migrated to Paris to take up a post in the Natural History Museum. There his biographer leaves him, but promises a second volume on his subsequent career; M. de Nussac will find it difficult to write a more interesting volume than his first.

R. S.

OUR BOOK SHELF.

The Steam Turbine as Applied to Marine Purposes. By Prof. J. H. Biles. Pp. vii+126. (London: Charles Griffin and Co., Ltd., 1906.) Price 6s. net.

PROF. BILES delivered the Keith lectures before the Royal Scottish Society of Arts in Edinburgh during the spring of 1906, and as only a condensed summary of the lectures was published by the society in its monthly journal, while many requests were made to the lecturer for complete copies of the lectures, he decided to publish them in book form.

Before dealing with the special form of turbine most suitable for marine purposes, the author gives a condensed and useful account of the development of the turbine from the time of Hero to the present day. In the second chapter the main features in the design of marine turbines are discussed, and then a detailed account is given of the method of blading the turbine drum and casing. In a convenient table at the end of this chapter the author gives in detail the sizes of the blades and their spacing for the H.P., L.P., and astern turbines of an ocean liner. The next chapter is well illustrated, and the reproductions of photographs, taken at various stages in the process of building a large set of marine turbines, will do much to make the non-technical reader familiar with the more important details in turbine construction. The thermodynamic principles which govern the design of turbines are then briefly touched upon, and their application illustrated by the calculations, necessary in determining blade dimensions for a channel steamer, being fully worked out. The success of the marine turbine is so entirely dependent on the efficiency of the propeller to which it is connected that it was most desirable that Prof. Biles should in these lectures discuss fully the theory and design of the screw propeller as employed in turbine vessels; the important and complete series of experiments carried out at the United States Navy Tank at Washington are admirably summarised; the results are illustrated by graphs, and their application to the design of a propeller which has to work under any given set of conditions is clearly explained.

The book concludes with a summary of all the trustworthy information at present available as to the comparative economy of turbine and reciprocating marine engines, and it is worth pointing out that, judging from the performances of certain cross-channel steamers, the considerable economy of the turbine-engined steamer which is shown during the preliminary trials is apparently not maintained in active service, though the author has every confidence that this loss in economy, which he considers is due to cavitation, will eventually be overcome.

T. H. B.

A First Year's Course in Geometry and Physics. By Ernest Young. Parts i. and ii. Pp. viii+101. (London: George Bell and Sons, 1907.) Price 1s. 6d.

THIS satisfactory first year's course of work in geometry and physics recognises fully the desirability of making the introductory lessons in mathematics and science as practical as possible. The author is an experienced schoolmaster who understands the need of setting young pupils to do things for themselves if they are really to understand the subjects under consideration. Though there is little that is novel in the methods adopted, the book provides an abundance of well graduated exercises suitable for boys of twelve to thirteen years old.

New Geometry Papers. By Rupert Deakin. Pp. 103. (London: Macmillan and Co., Ltd., 1907.) Price 1s.

THE recent changes in teaching geometry have rendered Mr. Deakin's "Rider Papers on Euclid" of little use in most schools, and the present book is intended to serve a similar purpose under the new conditions. The papers are graduated and arranged in order of difficulty, while hints are provided on the method of solving riders. The collection should prove useful as a supplement to the school text-book of geometry.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Name of the Cave Horse.

IN the paper on the derivation of the horse in the April number of the *Quarterly Review*, to which reference was recently made in NATURE, Prof. J. C. Ewart expresses the opinion that the wild Mongolian horse, commonly known as Przewalski's horse, is identical with the horse depicted by the prehistoric inhabitants of La Madelaine Cave, in the Dordogne. The same view is even more emphatically expressed by Dr. E. L. Trouessart in the Bulletin of the Paris Museum (1906, p. 453). No mention is made by either writer of any change in nomenclature involved in this identification.

In the Phil. Trans. for 1906 Sir R. Owen described the prehistoric horse of the cavern of Bruniquel (Tarn et Garonne) as *Equus spelaeus*; and although he estimated the height of the animal at 13½ hands, it is practically certain that it was really much less, as he was not aware of the relatively large size of the molars in the Mongolian horse.

Now it can scarcely be doubted that the small prehistoric horse of the Bruniquel cave is identical with the one depicted by the prehistoric hunters of La Madelaine, and as there is equally little doubt that both are merely races of *Equus caballus*, the name of the La Madelaine horse is *Equus caballus spelaeus*.

Hence, if Messrs. Ewart and Trouessart are right, it is also the title of the wild Mongolian horse, the name *Equus przewalskii* dating only from 1881. It is true that there is a possibility that a name given by Hamilton Smith to a horse supposed to be from Tatary may antedate both *spelaeus* and *przewalskii*, while *Equus fossilis*, dating from 1836 or 1846, may possibly be identical with *spelaeus*. Nothing certain can, however, be affirmed with regard to either of these points.

The name *E. c. spelaeus* for the La Madelaine horse certainly cannot be ignored, but it seems inadvisable that it should be made to supersede *E. c. przewalskii*, especially when the wide separation in time and space between the types of the two is taken into consideration. A way out of the difficulty may be found in a refusal to admit Messrs. Ewart and Trouessart's absolute identification of the fossil with the living form, and to regard them as distinct, although closely related, races, when they will stand respectively as *Equus caballus spelaeus* and *Equus caballus przewalskii*.

I may add that I cannot agree with Prof. Ewart in regarding the skull of Przewalski's horse as conforming to the type in which the face is bent down on the cranial axis. On the contrary, it is more or less of the straight type, in common with the prehistoric horses of Europe. The bent type seems to me characteristic of domesticated breeds, especially thoroughbreds and Arabs, and as it also occurs in the fossil Indian *Equus sivalensis*, my suggestion that Arabs and thoroughbreds are descended from that species, while the ordinary "cold-blooded" European horses trace their origin to the "Przewalski," is strongly confirmed. In a short time I hope to put skulls of the two types on exhibition in the Natural History Museum, so that visitors can judge for themselves on the point at issue.

R. LYDEKKER.

The Enigma of Life.

IN the review of my book "The Evolution of Life" in NATURE of May 2 (p. 1), "J. A. T." admits his inability to "point out precisely where my experiments are fallacious," and says he does "not know what to answer unless it be that the sterilisation was inadequate, or that the preparations were contaminated before the photographs were taken." But the adequacy of the sterilisation, in accordance with all existing knowledge, is fully shown in the book: and, as for the last suggestion, it seems really absurd when "J. A. T." was told that the organisms removed from the tube were received on a sterilised slip, covered with a sterilised cover-glass, and were there photographed almost as soon as they were found.

That he should not be convinced, however, by my "final decisive experiments" is only what might be expected when he says, in excuse for not himself repeating my simple experiments, "we regard archebiosis as so great a miracle that we do not expect to see it repeated," thus implying a disbelief even in its occurrence in the past. I certainly could not hope to convince anyone, by my experiments, who disbelieves in the natural origin of living matter on this earth when its crust became sufficiently cool to permit of such an occurrence.

Then, "harking back to heterogenesis," "J. A. T." refers to my belief in the origin of Otostoma from the Hydatina egg, and it is what he says on this subject that tempts me, in the main, to write this letter.

He says I was good enough to show him "the mummy of an Otostoma reposing within the egg-case of Hydatina. *There can be no doubt about it.*" These latter words, which I have italicised, are of some significance in reference to previous doubts expressed by many persons; but in the former statement Prof. J. Arthur Thomson (for your reviewer evidently affects no concealment of his identity) has certainly said too little. I showed him, not one specimen of Otostoma only, but about fifty specimens of this rare ciliate, either within egg-cases of Hydatina or lying among them. As he says, he thought it a result of parasitism, notwithstanding all the evidence against this view; and he left me with the expressed intention of investigating the subject himself. He now says that he, and also Dr. John Rennie, "watched many ova of Hydatina. But neither the expected nor the unexpected happened." From which I deem it quite possible, judging from the great rarity of Otostoma, that neither of them may even have seen one of these ciliates among the Hydatina eggs which they were watching. Yet I have taken some hundreds of Otostomata from my experimental pots. One may be permitted to smile at the puerile suggestion that, because Dr. John Rennie saw two infusorians moving within a split Hydatina egg-case, that kind of thing, which may be commonly enough seen, can at all explain my repeated observations with details and photographs concerning the origin of Otostoma from the egg of the rotifer. Yet it is with such a suggestion that "J. A. T." dismisses the subject.

Still, his attitude in regard to this question is much the same as it is concerning archebiosis, seeing that he has previously said concerning it (NATURE, February 25, 1904):—"There are some things that one must see for oneself, and even then one would not believe them." I, however, have seen this transformation, marvellous as it is, on so many occasions that I find no possible room for doubt as to the reality of its occurrence. Parasitism, I maintain, is out of the question, because no minute germs of ciliates are known; because of the extreme rarity of this particular great ciliate; and, above all, because it is the whole substance of the egg which becomes transformed within the unruptured egg-case, and because no movement can be seen until *the whole mass* begins slowly to revolve and speedily issues as a great embryo ciliate—which in its free state attains a bulk two or three times as great. Full evidence in support of this is to be found in my work "The Nature and Origin of Living Matter," chapter xiii., and in the Proceedings of the Royal Society, vol. lxxvi., B, pp. 385–392. H. CHARLTON BASTIAN.

Radium and Geology.

IN his letter in NATURE of May 9 (p. 31) the Rev. O. Fisher raises a point of wide interest, but one which admits at the present moment of little more than the suggestion of fresh hypotheses and the destructive criticism of old ones.

Sediments rich in radium involve *prima facie* parent rocks capable of supplying the necessary uranium. Failing this explanation, we must, I think, assume that the uranium is derived from an extra-terrestrial source. Neither hypothesis is at the present moment capable of proof. Much will turn upon (among other things) our final estimates of the quantities to be accounted for.

With the concluding portion of Mr. Fisher's letter I regret I am not able to concur. Many predictions, based on the best knowledge available, were made of the temperatures which would probably be encountered in boring the Simplon Tunnel. Geologists and engineers both arrived at results much below those which were afterwards observed. That of Heim was 38°–39°. That of Stockalpen (formerly head engineer of the north boring, St. Gothard) was 38°, &c. The highest predicted temperature—then criticised as quite excessive—was that of the "Ingenieur-Geolog" Stapff, which was 47° C., but the actual temperature reached was 55° C. (see papers by Ed. Sulzer-Zeigler and by Prof. H. Schardt in the *Verhandlungen der schweizerischen naturforschenden Gesellschaft*, July–August, 1904). This will give a considerably higher gradient than that reckoned by Mr. Fisher, more especially as the highest temperatures were by no means coincident with the greatest overlying mass.

Nor do I think the facts will admit of explanation by hot springs coming from below. Prof. H. Schardt, perhaps the highest authority on the subject, in a contribution to the journal cited above, states that the region of highest temperature was characterised by abnormal dryness of the rocks, and to this fact (the *absence* of circulating water) and the horizontality of the strata he ascribes the specially elevated temperature.

Mr. Fox, in the article in NATURE of October 27, 1904 (vol. lxx., p. 628), to which Mr. Fisher refers, states that the ordinary gradient of 1° F. in 70 feet is insufficient to account for the great heat, and suggests a volcanic source.

Trinity College, Dublin, May 13. J. JOLY.

The Relationship of Lemurs and Apes.

IN NATURE of May 2 Dr. Elliot Smith has referred to a memoir presented by me to the Zoological Society on "Recently Discovered Sub-fossil Primates" from Madagascar. On the evidence supplied by the brain-casts of three of these fossils, Dr. Elliot Smith takes exception to my conclusion that certain of these extinct Prosimiæ are in many respects intermediate between the extant Malagasy lemurs and the true monkeys.

I have nowhere in my memoir maintained, as Dr. Elliot Smith seems to imply, that, *so far as their brain-conformation is concerned*, these recently discovered sub-fossil lemurs form a distinct link between the existing genera and monkeys. On the contrary, I have emphasised the fact, insisted on by Dr. Elliot Smith himself, that many of them show evidence of marked retrogressive changes in their brain-structure; and I have pointed out that, just because of this *retrogressive specialisation*, it is the condition of the brain which, of all characters, is least likely to afford satisfactory evidence of close affinity between the Malagasy lemurs and the Old and New World monkeys. I will not anticipate the suggestions which I make in my memoir as to the possible causes which have brought about this curiously degenerate condition of the brain of these Malagasy lemurs, nor is it possible here to give in detail the facts and arguments on which I base my conclusion that, *in spite of this brain degeneracy*, these recently discovered fossils do, in fact, afford strong evidence that they, in common with their extant allies, are descended from ape-like ancestors. A detailed study of these fossils and a comparison with their nearest living relatives, on the one hand, and with various genera of Old and New World monkeys on the other, has convinced me that most of the so-called *lemuroid* characters of the extant Malagasy lemurs have been secondarily acquired, and that, taken as a group, the characters which differentiate the Malagasy lemurs, recent and extinct, from the monkeys are so few and (with the possible exception of brain-structure) so unimportant as not to justify their retention in a separate suborder.

A satisfactory discussion of the subject seems, however, hardly possible until the publication of the two memoirs by Dr. Elliot Smith and myself describing in detail the fossils themselves. H. F. STANDING.

South Kensington, May 9.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY.

THE draft of the Charter for the incorporation and government of the Imperial College of Science and Technology to be established at South Kensington has now been laid on the table of the House of Commons. It provides for the appointment of a governing body which, when complete, will consist of forty members, each member holding office for a period of four years. The governing body will be constituted in accordance with the recommendations of the Departmental Committee which reported in January, 1906. When complete, it will consist of forty members, of whom six will be appointed by the Crown, four by the President of the Board of Education, five each by the University of London, the London County Council, and the City and Guilds of London Institute, two by the Royal Commissioners for the 1851 Exhibition, one by the Royal Society, four by the professorial staff of the college, and eight by various technical societies, viz. one each by the Institutions of Civil Engineers, Mechanical Engineers, and Electrical Engineers, the Iron and Steel Institute, the Institution of Naval Architects, the Society of Chemical Industry, the Institution of Mining Engineers, and the Institution of Mining and Metallurgy. The President of the Board of Education will summon the first meeting of the governing body, which will be deemed to be constituted on the occasion of that meeting. The governing body will meet at least four times a year, and will publish a report of its proceedings annually. It will be permitted to delegate powers to an executive committee and to other committees, provision being made for the possible inclusion on any of these committees, except the executive committee, of non-members of the governing body. The governing body will in this way be able to secure the advice of independent experts, including persons with practical experience of industrial requirements. Advisory boards may also be appointed with the same object in view.

The purposes of the Imperial College will be to give the highest specialised instruction and to provide the fullest equipment for the most advanced training and research in various branches of science, especially in its application to industry, and to do all or any of such things as the governing body consider conducive or incidental thereto, having regard to the provision for those purposes which already exists elsewhere. For these purposes the governing body will carry on the work of the Royal College of Science and the Royal School of Mines (at present under the direct control of the Board of Education), and may establish colleges or other institutions or departments of instruction. Any institution or department so established, and, subject to the fulfilment of certain conditions, the Central Technical College of the City and Guilds of London Institute, will become integral parts of the Imperial College. The special conditions attaching to the affiliation of the Central Technical College have for their object to secure for the college a certain measure of independence. The college, which will in future be known as the City and Guilds College, will be managed—subject to such powers of general supervision, direction, and control as are reserved for the governing body of the Imperial College—by a committee of management appointed for the purpose by the City and Guilds of London Institute, to which committee the governing body of the Imperial College will add five additional members; and the Institute will continue to exercise its privilege of awarding the diplomas of Associate and Fellow. As already announced by Mr. McKenna, the Royal School of Mines will retain its name, and the governing body of the Imperial College will award the diploma of "Associate of the Royal School of Mines" to any student who completes the prescribed courses to the satisfaction of the governing body. Subject to agreement with the authorities of any college or other institution, the governing body may by resolution recognise that college or institution or any department thereof as being in association with the Imperial College, but no such resolution will be valid or operative until allowed by His Majesty in Council. Power will be reserved to His Majesty in Council to amend or add to the provisions of the Charter, and in particular to declare and define more precisely the purposes and scope of the Imperial College in relation to matters appertaining to the biological sciences, and to make such provision in reference thereto as may appear expedient.

As regards the connection between the Imperial College and the University of London—a matter which has been fully discussed during the past year—it is proposed that, pending the settlement of the question of the incorporation of the Imperial College with the University, the college shall be established, in the first instance, as a "school" of the University. It is expected that an inquiry by Royal Commission, which has been suggested by Mr. McKenna, will be necessary before this question of incorporation can be decided. In the meantime, the governing body of the college will be directed to enter into communication with the University with regard to the coordination of the work of the college with the work of the University and its other schools, and for the purpose of carrying out or facilitating such coordination the governing body may enter into such arrangements either by way of transferring or exchanging departments of instruction or otherwise, and upon such terms as may be agreed upon between the governing body and the University.

The resources which are at present available for the purposes of the Imperial College are considerable. In the first place, there are the buildings and equipment of the Royal College of Science, including the new chemical and physical laboratories, which have cost nearly 300,000*l.* The Royal Commissioners of the 1851 Exhibition have resolved to appropriate certain portions of their estate at South Kensington for the purposes of the college. The late Mr. Alfred Beit bequeathed 50,000*l.* and 5,000 preferred shares of 2*l.* 10*s.* each in De Beers Consolidated Mines (total value about 135,000*l.*) to be applied for the purposes of the "College for Technology (including Mining and Metallurgy) in connection with the University of London." Lord Rosebery, in a letter to *The Times*, published on June 29, 1903, announced that Messrs. Wernher, Beit and Co. had offered to place a sum of money in the hands of trustees to be applied as a contribution towards the cost of building and equipping an institution at South Kensington for advanced technology, and that further offers of the same kind had been made by other public-spirited London citizens. The Bessemer memorial fund, which will probably amount to not less than 20,000*l.*, will be devoted in whole or part to the Royal School of Mines. As regards income, the Treasury has consented to place in the Estimates a grant of 20,000*l.* per annum in respect of the cost of the staff and of laboratory expenses of the Royal College of Science and the Royal School of Mines. The London County Council, which in the past has not contributed generously in aid of higher technological work, may be expected to avail itself gladly of the opportunity of developing such work in London which the establishment of the Imperial College will afford, especially in view of the fact that the Council is now under a legal obligation to consider the educational needs of its area, and may supply or aid the supply of higher education. The Council on

July 21, 1903, considered Lord Rosebery's letter, to which reference has already been made, and placed on record its opinion that, when certain conditions had been complied with, the Council would be well advised to contribute out of the money annually placed at its disposal under the Local Taxation (Customs and Excise) Act of 1890 a sum not exceeding 20,000*l.* per annum towards such part of the work described in Lord Rosebery's letter as fell within the statutory definition of technical education. Although the conditions are now entirely changed, there is no reason to suppose that the annual contribution of the Council to the college will be less than that suggested four years ago. The Board of Education will pay the fees for its selected scholars, and the fees payable by other students will amount to a considerable sum. It is expected that the resources of the Central Technical College will also be available. The total expenditure on this college for buildings, fittings, &c., has exceeded 130,000*l.*, and the current expenses of the college (about 15,000*l.* per annum) are met by the fees of students and a subvention from the City and Guilds of London Institute. The total value of the land, buildings, equipment, and capital available for the Imperial College (including the Central Technical College) will certainly exceed one million pounds.

The assets in the way of teaching staff and students also deserve mention. The teaching staff of the colleges includes such well-known men of science as Profs. Tilden, Callendar, Perry, Watts, Gowland, Cox, Ayrton, Armstrong, Dalby, and Henrici. At the Royal College of Science and the Royal School of Mines the total number of students is about 300; a high standard for entry is not at present demanded, and the proportion of students preparing for university degrees is comparatively small; but a large number of able students are entered at the college under the Board of Education system of national scholarships for science students. At the Central Technical College the number of regular students is about 375; the test for admission is approximately equivalent to London Matriculation, and a fairly large number of students are reading for London degrees as internal students of the University.

THE BUTTERFLIES OF INDIA.[1]

THE second volume of Colonel Bingham's important work on the butterflies of India includes the Papilionidæ and Pieridæ, and five out of the seven subfamilies into which the author divides the Lycænidæ "provisionally . . . on the structural characters of the imago or perfect insect." These subfamilies are Gerydinæ, Lycæninæ, Curetinæ, Liphyrinæ, Poritinæ, Theiclinæ, and Arhopalinæ, of which the last two stand over until the next volume. The tables and descriptions are very carefully drawn up, and the illustrations, both coloured and uncoloured, the latter often representing venation, legs, and other important structural characters, are worthy of high praise. Some of the text-figures of large species are reduced. The transformations, broods, habits, flight, scent, stridulation, &c., of various butterflies are also fully discussed, especially the curious relationships between Lycænidæ and their larvæ and ants and aphides. We notice, however, that references to the transformations of common European species have generally been omitted; we are not certain whether this is done to save space (for it might have been thought hardly necessary to repeat information to be found in every European book on butterflies) or because Indian records of the transformations of these particular species happen to be wanting.

[1] "The Fauna of British India, including Ceylon and Burma." Published under the Authority of the Secretary of State for India in Council. Edited by Lieut.-Colonel C. T. Bingham. Butterflies, vol. ii. By Lieut.-Colonel C. T. Bingham. Pp. viii+480; plates xi–xx. (London: Taylor and Francis, 1907.)

Notwithstanding the care with which the book is written, we notice an occasional oversight; for instance, the range of the genus Colias is incompletely given, as it is found in Lapland, South Africa, and other localities which would seem to be excluded by the wording of the paragraph. Perhaps the newest and most interesting observation in the book is that recorded by Colonel H. J. W. Barrow, R.A.M.C., who observed a Lycænide (*Allotinus horsfieldi*) "milking" an aphis in the same manner as if the butterfly had been an ant (p. 287, Fig. 73). The description of the tentacles of the larvæ of *Curetis bulis* (p. 445) is also quite original and very curious, as is also the long account of the carnivorous larva of the very anomalous *Liphyra*

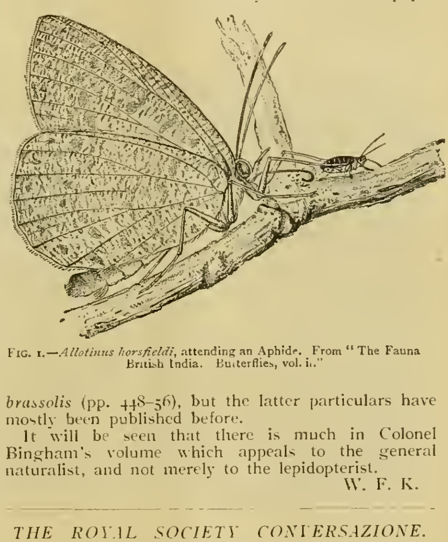

FIG. 1.—*Allotinus horsfieldi*, attending an Aphide. From "The Fauna British India. Butterflies, vol. ii."

brassolis (pp. 448–56), but the latter particulars have mostly been published before.

It will be seen that there is much in Colonel Bingham's volume which appeals to the general naturalist, and not merely to the lepidopterist.

W. F. K.

THE ROYAL SOCIETY CONVERSAZIONE.

THERE were numerous interesting exhibits at the Royal Society conversazione on May 8. The guests were received by the president, Lord Rayleigh, and included representatives of many departments of intellectual activity.

During the evening, demonstrations were given in the meeting-room of the Society by Mr. Louis Brennan, C.B., Dr. C. G. Seligmann, and Dr. Hele Shaw, F.R.S. Mr. Brennan explained the principle and action of his mono-railway by means of a working model. On his system each vehicle is provided with automatic stability mechanism which endows it with the power of maintaining its equilibrium upon a single rail laid upon the ground, either while standing still or travelling at any rate of speed, notwithstanding that the centre of gravity of the vehicle is above the rail, and that wind pressure, centrifugal force, or the movement of passengers or displacement of load may tend to upset it. This mechanism consists of two gyroscopes, revolving in opposite directions, and their precession, by being accelerated, produces a restoring couple at right angles to the rail. The same principle is applicable to motor-cars, flying-machines, and other structures.

Dr. C. G. Seligmann gave a kinematograph exhibition of native dances taken during the course of the Daniels ethnographical expedition to British New Guinea. The demonstration by Dr. Hele Shaw was on the subject of aërial gliding. During the last few years a large number of experiments have been made in connection with aëroplanes and machines for soaring and gliding. Dr. Shaw gave a brief account of the work of Lilienthal, the Wright Brothers, and others, and summarised the present state of our knowledge on the subject.

Two exhibits of particular interest were apparatus of pure iridium and rhodium and of fused silica by Messrs. Johnson, Matthey and Co., Ltd. This firm has succeeded in producing iridium and rhodium of such extreme purity as to render these hitherto practically unworkable metals so malleable as to enable their being used for the manufacture of such apparatus as basins, tubes, and flasks. These metals, having a very high melting point, and being almost unattacked by acids, should prove of great value in chemical research. The scientific work of which the process of manufacturing apparatus of fused silica is the outcome was carried out by two English men of science about ten years ago; unfortunately, as so often happens in these cases, its commercial importance was first recognised in Germany, and its production on an industrial scale commenced, little or nothing of a similar nature being attempted at home. Messrs. Johnson, Matthey and Co. have now taken up the original process, and by suitable modifications to meet industrial requirements are enabled to place this material upon the market at a price which can no longer be considered prohibitive. The apparatus is manufactured from the purest silica obtainable. At a high temperature this substance melts, and yields a viscid liquid which can by suitable means be fashioned into apparatus having all the appearance of ordinary glass, as is shown in the accompanying illustration. The apparatus possesses many properties which are likely to render it of great service both to science and to industry; *e.g.*, it can be made white hot and plunged into water, or otherwise rapidly cooled, without any danger of cracking; it is quite unattacked by water or acids, while ordinary glass under similar conditions is appreciably dissolved.

Transparent Silica Apparatus.

In the subjoined summary of the official catalogue of the exhibits, those on related subjects have, so far as possible, been grouped together.

Mr. H. R. A. Mallock, F.R.S.: Instrument for recording by photography rapid changes of pressure in the air, such, for example, as are caused by the wave produced by an explosion.—*The Director of the Meteorological Office:* Model of the neighbourhood of the winter quarters of the National Antarctic ship *Discovery*, 1902–4.—*Dr. W. J. S. Lockyer:* Cloud studies. The pictures exhibited represent some of the first results secured in attempting to photograph cloud forms during the past year. After some trials it was found that by the use of yellow screens (×10 for summer and ×5 for winter) and an ortho-process plate, sufficient contrast was obtained without undue length of exposure. No difficulty was experienced in photographing either heavy "cumulus" cloud or very elevated "cirrus."—*Solar Physics Observatory, South Kensington:* (1) Stellar spectrograms. (*a*) Bellatrix. (*b*) Rigel, (*c*) Sirius, (*d*) ε Ursæ Majoris, (*e*) Capella. (2) Spectroheliograms. Two series showing the development of the large spot of March (5–17), 1907. (3) Recent photographs of British stone circles, &c., in Cornwall.—*Commander Chetwynd, R.N.:* Improved liquid compass. In the compass exhibited the diameter of the card is considerably smaller than that of the bowl, the proportion being three-quarters, so that the edge of the card is substantially outside the influence of that ring of damping fluid which, on altering the ship's course (or whilst turning the compass bowl), adheres to and is drawn round by the inner surface of the bowl. The edge of the card being so far from the inner surface of the bowl on which the lubber's line is usually marked, a special lubber's mark or pointer is introduced projecting horizontally from the bowl on a level with the card. The extremity of this pointer, filed to a fine point and being in close proximity to the edge of the card, obviates all possibility of error of parallax in reading the course, without in any way causing a disturbance of the card.—*Mr. H. Cunynghame, C.B.:* A detached gravity escapement. The object of this escapement is to cause the impulse on the pendulum to be given by means of a light arm which falls by the action of gravity, and is hence independent of the force of the train, and to provide that the release of the train that winds up the arm is not derived from a blow by the pendulum, but of the arm itself.

Prof. W. E. Dalby: Working models, illustrating the balancing of a two-cylinder gas engine and a locomotive.—*Prof. A. G. Ashcroft:* Lecture table testing machine.—*Colonel R. E. Crompton, R.E.:* Crompton's measuring machine, combining accuracy with rapidity in working. With this measuring machine, which has been designed for observing length differences due to the heat treatment of specimens of steel, measurements of objects from 1 inch to 6 inches long, not differing among themselves more than a quarter of an inch, can be made and entered on the test sheet at the rate of one per minute. The accuracy obtainable is greater than 1 in 200,000.—*Mr. S. G. Brown:*

Relay working of long submarine telegraph cables. The apparatus consists of (1) an automatic transmitter, the movements of which are governed by means of a perforated tape, and originate the signals sent into an imitation cable; (2) a relay, receiving the signals at the other end of the line, and actuating an automatic perforator by which a duplicate of the originating type is reproduced at the relay station for re-transmission on another cable.—*Sir James Dewar, F.R.S.:* The Crookes radiometer—motion arrested in very high vacua, &c. (1) Experiments showing the cessation of radiometer action in very high vacua, made by charcoal cooled in liquid hydrogen or liquid air, even when the instrument is subjected to the concentrated radiation of an electric lamp. (2) Radiometer filled with helium at atmospheric pressure, which is inactive to a charcoal liquid-air vacuum, but becomes active in a charcoal liquid-hydrogen vacuum.—*Mr. W. Duddell, F.R.S.:* Persistent electric oscillations. The oscillations are produced by the method of the "musical arc." In this method a direct-current arc is shunted with a circuit consisting of a condenser and a self-induction in series. The frequency of the oscillations can be varied by altering either the capacity or the self-induction in the shunt circuit. The oscillograph records exhibited show the variations in the potential difference and current when the oscillations are produced. To obtain powerful oscillations at very high frequencies, the arc may be placed in hydrogen gas as employed by Paulsen. In the apparatus shown the arc burns in coal gas, and *no magnetic field* is used to blow out the arc. Experiments in magnetic induction, tuning, and discharge *in vacuo* are easily demonstrated with persistent high-frequency oscillations. The persistent oscillations are of special use for energising the transmitter in wireless telegraphy, as they permit better syntony or tuning to be obtained.—*Mr. W. A. Douglas Rudge:* The action of radium and other salts on gelatin culture medium. Radium, barium, strontium, and lead salts, when placed in contact with gelatin culture medium, give rise to a kind of cellular growth, which is due to the formation of an insoluble precipitate with the sulphuric acid usually present. Radium salt added to the medium from which the sulphuric acid has been removed causes no growth, but the addition of a soluble sulphate produces a growth at once. Analyses of the growths obtained with radium salts show that they are composed of barium sulphate.

Messrs. R. and J. Beck, Ltd.: (1) New diffraction wave-length spectroscope. This instrument comprises a Thorpe replica diffraction grating with a collimator and slit. The observing telescope swings on an axis which passes through the grating, parallel with the lines. The motion is by means of a micrometer screw which reads the sine of angle of rotation direct, thus giving on its divided milled head the wave-length in A.U. (2) The "isostigmar" photographic lens on optical testing bench.—*Mr. A. Kershaw:* A new visual method of measuring the speeds of photographic shutters.—*Mr. Ulrich Behn:* (1) The flame tube. A simple apparatus capable of indicating very small changes of air-pressure. It consists of a short metal tube with wide outlets, at which, after the tube is connected with the gas main, the gas is lighted. It shows, if one end is raised a few millimetres, the decrease of atmospheric pressure with height by the changes in size of the flames. The tube is capable of various applications. (2) Demonstration of the theory of microscopic images. (3) An indirect method of measuring the temperature of liquid-air baths. (4) A short glycerine barometer. This consists of an air thermometer of the old Italian type, the bulb of which is kept at zero by means of ice in a Dewar vessel.—*Dr. J. T. Bottomley, F.R.S., and Mr. F. A. King:* Experiments with vacuum gold-leaf electroscopes on the mechanical temperature effects in rarefied gases. The apparatus consists of a "radium clock" and various types of vacuum electroscopes. The vacuum electroscopes are set up to show the effects of radiations from sources of heat and light upon gold leaves hanging within highly exhausted enclosures. The gold leaves of the vacuum electroscope diverge when illumination of any kind falls upon them, and stand permanently apart when placed in bright daylight. By suitably manipulating such sources as a spirit flame, candle, or Nernst lamp near the electroscope, forces, which vary in direction and magnitude from point to point within the enclosure, are generated, and cause the leaves to be twisted into curious shapes. The gold leaves will remain in this contorted condition for a considerable time after the exciting cause has been removed.—*Dr. J. R. Milne:* A special camera for the purpose of automatically recording the readings of the scale of any instrument.—*Messrs. Pilkington and Gibbs, Ltd.:* A heliochronometer which gives Greenwich mean time by a simple direct solar observation. It comprises devices for adjustment in latitude, longitude, level, and azimuth, and is self-correcting for the equation of time.

The Cambridge Scientific Instrument Co.: (1) Prof. Féry's self-contained radiation pyrometer. The pyrometer utilises the heating effect of the "total radiation" from a hot body, focussed as an image of that body by means of a concave mirror. It differs from the already known Féry radiation pyrometer in being entirely self-contained, the image falling upon a minute bi-metallic flat spiral (Breguet spiral). This becomes partially uncoiled as its temperature rises, and a light pointer attached moves over a dial divided to give direct (centigrade) temperature readings. (2) Universal portable electrometer, designed by Mr. C. T. R. Wilson, F.R.S. A gold-leaf instrument with very small capacity and fused quartz insulation, suitable for work on atmospheric electricity, radio-activity, &c., and self-contained, with means for standardising the readings, which are very steady even in a fairly high wind.—*Mr. Joseph Goold:* Vibration experiments with steel plates and six bars tuned accurately to 400, 500, 504, 600, 700, and 800 vibrations per second.—*Dr. Otto Schlick, and Messrs. Swan, Hunter, and Wigham Richardson, Ltd.:* Working models illustrating the action of the Schlick gyroscope in steadying ships at sea (see NATURE, April 11, p. 561).—*Dr. Robert Knox and Mr. G. Pearce:* Skiagraphy of the human subject; examples illustrating the advantages of reduction in exposure. The instruments employed to produce skiagraphs, with exposures varying from one to seven seconds, consist of a powerful induction coil yielding a greatly intensified secondary current, worked in conjunction with an electrolytic interrupter directly from high-tension electric light mains. The core of the coil consists of transformer plates. The primary is of a much larger wire than usual, and has more turns. The secondary is smaller than usual. The X-ray tube is provided with a heavy anode to withstand the current. In series with the X-ray tube, a rectifier is placed to render the current unidirectional.

The Thermal Syndicate, Ltd., Wallsend-on-Tyne: Pure fused silica ware. The articles consist of pure silica, and are manufactured by an electric furnace process at a temperature of about 2000° C. The material is highly refractory, and possesses a very low coefficient of expansion (about 1/17th of that of glass), and in consequence it is able to resist sudden and extreme changes of temperature without cracking. It is unaffected by practically all acids, is an excellent electric insulator, and retains its insulating properties even at high temperatures. The specimens show that it is possible to produce a brilliant lustre on the surface of the material.—*Dr. F. D. Chattaway, F.R.S.:* Copper mirrors deposited upon glass from aqueous solution. In the mirrors exhibited, the copper had been deposited upon the glass by reducing cupric oxide by an aqueous solution of phenylhydrazine in presence of potassium hydroxide, which accelerates the action to a remarkable extent. The mirrors are equal in brilliancy and uniformity of surface to silver mirrors, and on account of the colour of the copper are much more beautiful.—*Hon. C. A. Parsons, F.R.S.:* Photographs of microscopic diamonds obtained from pure iron heated in a carbon crucible in an electric furnace and rapidly cooled. Scale, 150 diameters.—*Prof. J. Perry, F.R.S.:* British Association Album, meeting in South Africa, 1905. Two copies of an album prepared by Mr. Eustace Calland from photographs selected from those taken by members of the British Association.

Marine Biological Association of the United Kingdom: Marine algæ and their reproduction. A small representative collection of sea-weeds from the Plymouth district exhibited to illustrate their different habits of growth and reproduction.—*Prof. E. Ray Lankester, F.R.S.:* (1) Metamorphosis of the eel. Series of specimens showing the transformation from the marine larva or Leptocephalus of the common eel into the fresh-water "elver" and young eel. Also a series showing the metamorphosis of the conger eel. (2) Specimens of Cephalodiscus. Specimens of *Cephalodiscus nigrescens* and *Cephalodiscus hodgsoni* obtained by the *Discovery* in the Antarctic Ocean, and *Cephalodiscus gilchristi* obtained by Dr. Gilchrist in the Cape Seas. Also the original Cephalodiscus (*Cephalodiscus dodecalophus*) obtained by the *Challenger* in the Straits of Magellan in 1876, for comparison with the above newly discovered species. (3) Coloured cast of the tile-fish. The tile-fish was first discovered in 1879 in about 100 fathoms in the North Atlantic, and was expected to become a regular marketable fish. In 1882 a vast destruction of the tile-fish took place, owing, it is supposed, to a chilling of the part of the sea which it inhabited, and millions of the dead fish were found floating on the surface of the ocean. It was feared that the fish had become extinct, but since 1892 specimens have been caught in fair numbers. This cast was prepared and coloured by the authorities of the National Museum at Washington. (4) Specimen of the okapi. The specimen is an immature male, obtained by Major Powell Cotton in the Ituri Forest, Congo State. The bony horns have not yet penetrated the skin as they do in adult animals. Special interest attaches to this individual, in that Major Powell Cotton was able to examine the recently killed body and determine the sex. The specimen has been presented by Major Powell Cotton to the Natural History Museum, which already possesses the complete skeleton of the same individual.

Dr. F. A. Dixey: Seasonal dimorphism in butterflies. It has recently been established, partly by observation, but mainly by the experiments of Mr. G. A. K. Marshall, that in many tropical and subtropical species of butterflies which produce two or more broods in the course of the year, the broods differ in appearance according to the season at which they emerge. In several of these cases the difference is so extreme that the seasonal phases of the same insect have received different specific names, and have even been considered to be widely separated from each other in the systematic series. In some instances it has been found possible to transform one seasonal phase into the other by artificial means. Similar phenomena have long been recognised in certain European Lepidoptera (butterflies and moths), but it is only lately that experimental proof has been obtained in the case of tropical forms such as those exhibited.—*Prof. E. B. Poulton, F.R.S.:* The female forms of the African *Papilio dardanus*, the most remarkable example of mimicry hitherto discovered. Mr. Roland Trimen, F.R.S., first showed (in 1870) that these diverse forms were the females of a single species with a non-mimetic male. His evidence was not confirmed by the final test of breeding until 1902, when Mr. G. F. Leigh, of Durban, bred a single family containing males and two of the female forms. After other partial successes Mr. Leigh succeeded, in the autumn of 1906, in breeding the single family exhibited. It was bred from a female of the second form, and contains fourteen males, and examples of all the female forms known in South-East Africa: eight of the first, three of the second, and three of the third.—*Colonel Bingham:* Pupa of *Binsitta barrowi*, Bingham, with photograph of moth and pupa, and a coloured drawing of the head of a tree-snake (*Lycodon aulicus*, Linn.). *Binsitta barrowi*, Bingh., is a rare moth belonging to the family Tineidæ, lately discovered by Colonel Waller-Barrow at Maymyo, a hill station near Mandalay, Upper Burma. Colonel Barrow found the moth just issuing from the chrysalis, and noticed at once the curious resemblance of the latter to the head of a snake. When the chrysalis is looked at from in front, the likeness to the head of *Lycadon aulicus*, Linn., a bird-eating snake, is at once perceived.—*Mr. Fred Enock:* Ovivorous parasitic Hymenoptera (Mymaridæ).—*Prof. Charles Stewart, F.R.S.:* Selected specimens from the Museum of the Royal College of Surgeons, England.—*Mr. H. St. J. Donisthorpe:* The inhabitants of British ants' nests.—*Mr. W. Woodland:* Microscopic preparations illustrating the development of the plate-and-anchor spicules from the soft tissues of *Synapta inhaerens* and *S. digitata*.—*Mr. H. B. Fantham:* Microscopic preparations of *Spirochaeta* (*Trypanosoma*) *balbianii* from the crystalline style and intestine of the oyster.—*Prof. A. Dendy:* (1) The "pineal eye" in the New Zealand lamprey (Geotria) and in the tuatara (Sphenodon). (2) Reissner's fibre in the brain and spinal cord of Geotria.—*Mr. R. I. Pocock:* Example of the skins of English domestic cats. English domestic cats, whatever their colour may be, and whether they belong to "Manx," "Persian," or "ordinary" breeds, are shown by their pattern of stripes to be referable to two distinct kinds, known as the "striped" and "blotched" tabbies. The striped tabby appears to be the scarcely modified descendant of the European and North African wild cats. The origin of the blotched tabby is unknown.

Mr. R. H. Biffen: Hybrids of wheat and barley.—*Prof. W. B. Bottomley:* Fixation of nitrogen by leguminous and other plants.—*The Director, Royal Botanic Gardens, Kew:* (1) *Welwitschia mirabilis*, Hook. f. (Gnetaceæ), south-west tropical Africa. (2) *Acanthosicyos horrida*, Welw. (Cucurbitaceæ), western tropical Africa. (3) Labrador lichens. A striking feature of the Labrador lichens is their similarity to those of northern Europe. *Platysma nivale*, *Cetraria islandica*, *Bryopogon jubatum*, and species of Stereocaulon so abundant in Norway and Sweden, flourish equally well in Labrador, whilst, just as in Lapland, *Cladonia rangiferina*, the "reindeer moss," covers vast areas. (4) Figures of remarkable new or rare plants (exhibited by Mr. W. Botting Hemsley, F.R.S.). (5) Figures of African terrestrial Utriculariæ (exhibited by Dr. Otto Stapf).

Prof. John Milne, F.R.S.: Records of recent large earthquakes. (1) Jamaica earthquake; (2) San Francisco earthquake; (3) the so-called Valparaiso seismogram (see NATURE, February 21, p. 403).—*Rev. R. Ashington Bullen:* Cable broken by the Jamaica earthquake of January 14, 1907. The cable had remained intact for twenty years. It rested on a muddy bottom in a depth of 700 fathoms, about seventeen miles south of Kingston. The probability is that here it crossed the line of a geological fault.—*The Director of the Imperial Institute:* (1) Igneous and metamorphic rocks of northern Nigeria. Typical specimens collected during the course of the mineral survey of northern Nigeria now in progress in connection with the Imperial Institute. (2) Tinstone from Bauchi, northern Nigeria, and tin smelted from it. (3) New or exceptional minerals from Ceylon. (4) New vegetable products of hitherto unknown composition.—*Mr. C. Carus-Wilson:* (1) Crystallised granite. A remarkably fine mass of Cornish granite in which the mineral constituents had crystallised out around the walls of a large cavity. (2) Musical flint nodule from the chalk near Faversham. The specimen is 21 inches long, and emits a loud metallic ring when struck at the thin end.

Mr. F. J. Lewis: The succession of plant remains in British peat mosses. All the Scottish and north of England peat mosses show a definite succession of plant remains. Detailed investigations have been carried on in twenty-four districts, from Westmorland to the Shetland Islands, and the geographical distribution of the successive strata ascertained. The evidence so far shows that two distinct arctic beds and two distinct forest beds occur in the peat, and these features are so regular and spread over so wide an area that the alternation must be due to climatic changes during early post-Glacial times.—*Mr. H. F. Standing:* Recently discovered sub-fossil Primates from Madagascar. The chief interest of these relates to the light which they throw on the origin of the extant Malagasy lemurs. They show these latter to be descended from ape-like ancestors, and that many of their so-called "lemuroid" characters have been secondarily acquired. Some of the recently discovered species are of gigantic size, showing evidence of various retrogressive changes, notably in the frontal region of the brain. One of these gigantic extinct Prosimiæ (Palæopropithecus) was probably aquatic. Its brain indicates certain affinities with the aye-aye, that curious aberrant rodent-like "lemur" from the Malagasy forests.—*The Director, British Museum (Natural History):* Mandible of Tetrabelodon from the Loup Fork formation (Lower Pliocene), Nebraska, U.S.A. This specimen shows that the primitive mastodons, with a long chin and lower tusks, reached North America before their final extinction.

(Exhibited by the Keeper of Geology.)—*Prof. H. G. Seeley, F.R.S.:* Skull of a South African saurischian (*Erythrosuchus africanus*). The remains were collected by Dr. R. Kannemeyer in 1897. They were displaced, and in unusual confusion. The matrix has been entirely removed by Mr. Richard Hall, of the British Museum, but portions are missing, so that the skull has not been reconstructed as yet. The whole skeleton indicates a new division of this order of animals.

Mr. W. Dale: A cordoned bucket or cist of bronze, "Halstatt" type, early Iron age of Europe, late Bronze age of Britain, *circa* 700 B.C., found at Weybridge, Surrey, April, 1907, at a depth of 10 feet, in sinking a shaft for the pier of a bridge close to the river at the new motor track. The bucket is of north Italian manufacture, and is similar to specimens found at Halstatt and in other parts of Europe as far as Hanover, but never before in Britain. It has quite recently been proved that some brooches, in museums and private hands, found in England, must have come from north Italy in the early Iron age of Europe. On the strength of this, it has been asserted that there was commerce between Europe and Britain as early as 700 B.C., and the theory is confirmed in a remarkable way by the discovery of this bucket. The British Museum Catalogue figures a Halstatt bucket (Fig. 30, "Guide to Early Iron Age") exactly similar. The workmanship of the handles is the same as that of the ancient torques.—*Mr. Rowland G. Hazard:* Arrow heads and spear points from North America, Egypt, and Japan.—*Sir Benjamin Stone, M.P.:* History pictures of Egypt. These views are a selection from the series of photographs taken by Sir Benjamin Stone during the recent winter season. The series of about 800 views shows the aspect of Egypt and the Soudan at the present time.

NOTES.

WE regret to learn that Dr. Alexander Buchan, F.R.S., the distinguished meteorologist, died on Monday, May 13, at seventy-eight years of age.

AT the Chemical Society on Thursday, June 13, Prof. J. B. Farmer, F.R.S., will deliver a discourse entitled "Some Borderline Problems in Botany."

M. LE CHATELIER has been elected a member of the Paris Academy of Scences in succession to the late Prof. Moissan.

THERE will be a reception at the Linnean Society on June 7 in celebration of the 200th anniversary of the birth of Linnæus. The principal exhibits will be of objects associated with or belonging to Linnæus, such as letters, manuscripts, and objects of natural history.

PROF. E. RAY LANKESTER has left for the Continent with the view of studying the specimens of the okapi in the museum of the Congo Free State at Tervueren, near Brussels, and in other collections.

DR. J. HALM, assistant at the Royal Observatory, Edinburgh, has been appointed first assistant at the Cape Observatory, in succession to Mr. S. S. Hough, F.R.S., who was recently promoted to succeed Sir David Gill as H.M. Astronomer at the Cape.

THE fifteenth "James Forrest" lecture of the Institution of Civil Engineers will be delivered by Dr. Francis Elgar, F.R.S., on the evening of Tuesday, June 18, his subject being "Unsolved Problems in the Design and Propulsion of Ships." The fourth engineering conference will be held on June 19–21, commencing each day at 10 a.m., and the annual conversazione on the evening of June 20 at the Royal Albert Hall.

WE are informed that Prof. H. F. Osborn has returned to New York from Egypt, where he accompanied and superintended an expedition to search for remains of the fossil vertebrates of the Fayum for the museum he represents. He took with him a staff of trained collectors, who have been left in Egypt for some time longer to continue the work of collecting. As the result of such expert collecting, a number of remains of the smaller mammals have, we believe, been obtained, which should prove of great interest.

AN interesting undertaking is that of a party now at Seattle on the way to study seismic and volcanic conditions in the Aleutian Islands. One of the fifty-nine volcanoes in these islands was reported active last March. The expedition is headed by Prof. T. A. Jaggar, of the Massachusetts Institute of Technology, and includes Prof. H. V. Gommere, of the University of California, and Dr. Van Dyke, of San Francisco.

ON May 11 the Lowell Astronomical Expedition to the Andes sailed from New York. Its main object will be the observation of Mars in July. The site for the observations will be selected next month, probably either in the high Andes of Peru or in the desert regions of northern Chili. The work is in charge of Prof. David Todd, director of the Amherst College Observatory, Mass., who will be accompanied by Mrs. Todd. Mr. E. C. Slipher, also of Amherst, will be responsible for the photographic side of the expedition, and Mr. Albert G. Ilse, of the firm of Alvan Clark and Sons, of Cambridge, Mass., will be chief mechanician and instrument maker. The appointments of the *personnel* of the expedition have been made by Prof. Percival Lowell, who is himself working at present at Flagstaff, Arizona.

THE Cardiff public telescope and observatory are proving a decided success. During the last few weeks, in response to an appeal from Mr. Albert Taylor, a large number of teachers in the locality have applied for permission to use the instrument. The attendance of the general public also has been such as quite to warrant the corporation in the expense to which it went in connection with the observatory.

ON Thursday next, May 23, Sir James Dewar will commence a course of three lectures at the Royal Institution on "Chemical Progress—Work of Berthelot, Mendeléeff, and Moissan." The Friday evening discourse on May 24 will be delivered by Prof. J. A. Fleming, on "Recent Contributions to Electric Wave Telegraphy," and on May 31 by Mr. A. H. Savage Landor, on "Recent Journey Across Africa."

THE Gypsy Lore Society, which was first formed in 1888, and has lain dormant since 1892, is to be revived under the presidency of Mr. David MacRitchie. On July 1 next it is proposed to issue the first number of a new series of the society's quarterly journal, the publication of which ceased with the termination of the activities of the association in 1892. The society aims at enrolling every amateur of gypsy philology, folk-lore, and ethnology, and every student of Sanskrit and Indian languages. The society will be conducted on a purely honorary basis—neither writers nor officers being paid. Interested persons should communicate with the hon. sec., Mr. R. A. Scott Macfie, 6 Hope Place, Liverpool.

THE annual report of the Ray Society, read at the annual general meeting on May 9, stated (*inter alia*) that part iii. of the "British Annelids," by Prof. W. C. McIntosh, F.R.S., is now in the press, and will be issued for the present year, and that there is a sufficient number of monographs waiting their turn for two volumes per annum to be issued for several successive years if the funds of the society will permit. The officers and council for the ensuing year were elected, Lord Avebury being re-elected president; Dr. F. DuCane Godman, F.R.S., treasurer; and Mr. John Hopkinson, secretary. The new members of the council elected were Sir Charles Eliot, K.C.M.G., and Mr. C. D. Soar.

Mr. G. R. Dunell, whose death on Sunday last, at fifty-nine years of age, we regret to have to record, was the author of many articles and reports on engineering subjects in the columns of Nature. For the past twenty-five years or so, Mr. Dunell's life was devoted almost entirely to literary work connected with engineering and industry; and his wide knowledge and lucid style gave his articles a distinctive character unusual in technical description. Formerly he was a frequent contributor of articles to the *Times*, but in recent years most of his work was done for *Engineering*. His last contribution to our columns appeared on April 11, and dealt with the gyroscopic apparatus for steadying ships described at the recent meeting of the Institution of Naval Architects. Mr. Dunell was a familiar figure in the engineering world, and his death will be sincerely deplored by all who knew him.

The Catania Observatory states that at 7.40 p.m. on May 10 Stromboli burst into violent eruption, throwing masses of stone, ashes, and lava towards the eastern portion of the island, which is inhabited, and causing fires in several vineyards. The eruption was preceded by loud rumblings. Mount Etna is also in a state of activity. Large columns of thick vapour have issued from the cone of the volcano and spread over the surrounding country. On the evening of May 10 slight earthquake shocks were reported at Belpasso, Nicolosi, and Viagrande.

A special meeting of the proprietors of the London Institution, Finsbury Circus, was held on May 8 to consider a proposed scheme of re-building, having for its objects "such an increase of revenue as would enable the committee to carry out the objects of the charter on a wider basis than at present, and at the same time to give improved accommodation to the proprietors." The scheme provides for the removal of the present lecture theatre and smoking room, thus rendering vacant 10,612 superficial feet of land, to be let on a building lease for eighty or ninety years. The alterations would include a new theatre, a storage room for 200,000 volumes, refreshment and other rooms, and the dividing of the present reference library into a reading room, small lecture room, and a committee room. The cost is estimated to be about 15,600*l*. Strong criticism of the scheme led to the adjournment of the meeting for four weeks.

The ninetieth annual meeting of the Société Helvétique des Sciences Naturelles will be held at Fribourg on July 28–31. The first day will be devoted to preliminary matters and to a social gathering of visitors. The inaugural address will be delivered on July 29 by Prof. Musy, and afterwards Prof. Mühlberg will lecture on the subject of the supposed condition of Switzerland and neighbouring regions during the five Ice ages, interglacial periods, and the return of the last glaciation. Dr. John Briquet and Prof. Zchokke will speak on the post-Glacial immigration respectively of flora and fauna into Switzerland. The subject of the utility of an international atlas of erosion will be discussed by Prof. E. Chaix, and a lecture will be delivered by Prof. Jean Brunhes on glacial action. The following day will be devoted to sectional meetings, and a joint meeting of the geological, botanical, and zoological sections. The centenary of Agassiz will be celebrated on the concluding day, when discourses will be delivered by Profs. de Girard and Th. Studer. The Swiss Geological, Botanical, Zoological, and Chemical Societies, and the Physical Society of Zurich, will hold their annual meetings at Fribourg on the same days.

The twelfth annual congress of the South-Eastern Union of Scientific Societies will be held at Woolwich on June 12–15 under the presidency of Prof. Silvanus P. Thompson, F.R.S. The following papers will be read:—Goethe as a naturalist, Dr. Treutler; geology of Woolwich and district, W. Whitaker, F.R.S.; an experiment in cooperative field-work in botany, Prof. Oliver; the antiquity of *E. caballus* in Europe, with special reference to remains found in Kent, W. H. Griffin; xerophytes, Mrs. W. Plomer Young; concretionary types, forces, and evolution, G. Abbott; the storage and use of rain-water for domestic purposes, G. F. Chambers; how to make our local societies more efficient, H. Norman Gray; and local archæology, W. T. Vincent. Excursions, weather permitting, are planned to Well Hall, Eltham Palace, and Avery Park; Charlton Camp and Pits and Greenwich Park; the Royal Arsenal, R.A. Institution and Rotunda; Lessness Abbey, and Crayford Pits. There will be a reception by the Mayor (Alderman Squires, J.P.) and a congress museum. These meetings, &c., are open to members and associates of the South-Eastern Union. Mr. B. C. Polkinghorne, Woolwich Polytechnic, is the local secretary, and the hon. general secretary is the Rev. R. Ashington Bullen, Englemoor, Woking, from either of whom programmes and tickets can be obtained.

Madreporian corals from the coast of French Somaliland form the subject of a paper by Mr. T. W. Vaughan published as No. 1526 of the Proceedings of the U.S. Nat. Museum (pp. 249–266). As the collection was obtained just outside the mouth of the Red Sea, it is of special interest for comparison with the coral-fauna of that sea on the one hand, and of the East African coast on the other.

"Convergence" in animals is illustrated in an article contributed by Dr. O. Rabes, of Magdeburg, to the April number of *Himmel und Erde*. An interesting figure of a rorqual-embryo with teeth is reproduced from a paper by Dr. W. Kükenthal. Among the other illustrations, exception may be taken to one which revives the myth of the flying frog, and to a second in which the Ganges dolphin is represented with a relatively huge eye.

A revision of the genus Spilanthes, prepared by Mr. A. H. Moore, is printed as vol. xlii., No. 20, of the Proceedings of the American Academy of Arts and Sciences. The genus belonging to the order Compositæ is chiefly distributed over the American continent, but also occurs in the tropical regions of the old world. The author identifies about forty species, of which twelve are new to science.

According to a paper by Mr. J. Henderson, of which the first portion appears in vol. iv., No. 2, of the University of Colorado Studies, the land and fresh-water molluscs of Colorado have been greatly neglected by naturalists. Although the land-snails are for the most part small, water-snails and pond-mussels abound in almost every stream and piece of water, even at high elevations.

A paper by Dr. S. A. Forbes on the local distribution of certain Illinois fishes, forming article eight of vol. vii. of the Bulletin of the Illinois State Laboratory of Natural History at Urbana, is noteworthy on account of the seven exquisitely coloured plates of so-called "darters" (Etheostominæ) with which it is illustrated. In article nine of the same serial Dr. Forbes discusses from a similar point of view (that is to say, the relations of interaction between organisms and their animate and inanimate surroundings) the results of an ornithological traverse of Illinois in autumn. The predominance of European (we fail to see why they should be specially referred to as English) sparrows in certain districts and situations is very noteworthy.

The series of "ichnites" in the geological department of the British Museum (Natural History) has just been enriched by the addition of two large slabs of Triassic sandstone from Storeton, Cheshire, displaying labyrinthodont and reptilian foot-prints. Some remarkably well-preserved casts of the foot-prints of "Chirotherium," together with other much smaller ones referred to the reptile Rhynchosaurus, and likewise others of an unknown reptile, are displayed. Both slabs are the gift of the owners of the Storeton quarries. Important additions have likewise been made to the series of exhibits illustrating the development of eels and the nature of the food of well-known food-fishes. In one jar are displayed a number of specimens from the Gulf of Messina, presented by Prof. Grassi, showing various stages in the development of the larvæ of the conger-eel and their final evolution into young congers, while alongside are shown a mass of elvers recently taken in the Severn, and a few young eels from the Thames. The fishes of which the food is illustrated are the plaice, the turbot, and the sole, the exhibits being specially instructive on account of the remarkable difference existing between the nutriment of the turbot on the one hand and that of the plaice and sole on the other. The turbot, for instance, seems to subsist entirely on other fishes, including immature clupeoids and flat-fish and sand-lance. Excepting that young sand-lance are eaten by the first and very small dabs by the second, plaice and soles, on the contrary, subsist on an invertebrate diet, including lug-worms, echinoderms, crustaceans, and tellinas and other small bivalves.

Considerable interest attaches to a paper, by Mr F. W. True, just issued as No. 1694 of the quarto series of Publications of the Smithsonian Institution, on an imperfect cetacean skull obtained in 1847 from the Eocene Marl of the Ashley River, near Charlestown, South Carolina. In the same year appeared a brief account of it, with plates, by Mr. M. Tuomey, who referred it to Zeuglodon, and two years later it was named *Z. pygmaeus* by Prof. J. Müller, of Berlin. Soon afterwards the specimen came under the notice of Prof. L. Agassiz, who caused a lithographed plate to be prepared, with the lettering *Phocodon holmesi*, Agass. For some reason this plate was never issued, and in 1895 Prof. E. D. Cope referred the specimen to a new genus, under the name of *Agorophius pygmaeus*. Despite the fact that the specimen, when figured in the plate made for Agassiz, had a single Squalodon-like tooth remaining in the maxilla, a suggestion was made that the species might be an ancestral form of rorqual. Were this confirmed, it would have been a matter of much importance, and Mr. True has therefore been well advised in publishing the original plate. In his opinion, Agorophius is a squalodont, although differing in cranial characters from Squalodon itself. The European so-called *Squalodon ehrlichii* of Van Beneden has, however, a broad rostrum recalling the Carolina genus, and it may be that this imperfectly known form is a connecting link between Squalodon proper and Agorophius.

Several matters referred to in the report for 1905 of Mr. M. Kelway-Bamber, a Government chemist at the Royal Botanic Gardens, Ceylon, published as vol. iii., No. 24, of the Circulars and Agricultural Journal, are of scientific as well as practical interest. The problem of establishing a connection between the mineral ingredients of the tea plant and the quality and strength of the tea is under investigation, with a prospect of obtaining definite results. From a study of the methods of preparing Oolong tea in Formosa, it is concluded that the quality and characteristics are due to an aroma produced by faint oxidation in drying and a slight scorching during roasting of the leaf, as well as to the mild decomposition caused by a fungus, and it is suggested that the fungus acting on the legumin in the leaf produces flavouring bodies similar to the action of moulds in cheese. The report also contains hints on the distillation of camphor and citronella oil.

An article in the *West Indian Bulletin*, vol. vii., No. 4, deals with the manufacture of citrate of lime, as an article for export to take the place of concentrated lime juice. The project was brought to the notice of planters in the West Indies by Dr. F. Watts, who has published information on the production of citrate of lime in Sicily, and given public demonstrations on the process of manufacture. The commercial outcome is seen in the shipments first made from Dominica in 1906, and also from Montserrat. In the same number Mr. W. R. Buttenshaw compiles some facts on the distribution of plants from the various botanic stations in the West Indies to indicate the valuable service rendered in this connection. Incidentally he refers to the popular practice of observing Arbor Day, and mentions that palms, principally the cabbage palm, *Oreodoxa oleracea*, and the royal palm, *Oreodoxa regia*, are commonly chosen for planting, often, too, the mahogany or the white wood, *Bucida Buceras*.

The principal article in the last issue (No. 4) of the Kew Bulletin, contributed by Mr. J. S. Gamble, treats of the gutta-percha trees in the Malay Peninsula. After reviewing the species belonging to eight genera of the Sapotaceæ found in Malaya, the author concludes that the only important tree is *Palaquium Gutta*, known as "Taban Merah," with its variety oblongifolium, "Taban Sutra"; three other species, *Palaquium Oxleyanum, Palaquium obovatum*, and *Payena Leerii*, afford a second-rate gutta, and cultivation is being restricted to these four species. The lists of new plants from the herbarium comprise a decade of orchids, mostly from Asia, determined by Mr. A. N. Rolfe, and exotic fungi from India and elsewhere, identified by Mr. G. Massee. Supplementing the information given in the first two numbers of the Bulletin for this year, Mr. T. A. Sprague confirms the distinction between Dubouzetia and Tricuspidaria, and offers a revision of the former genus.

The second part of the nineteenth volume of the Proceedings of the Royal Society of Victoria contains some interesting papers on the biology and geology of Australia. It begins with the eighth of Mr. Frederick Chapman's valuable "Additions to the Palæontology of Victoria"; in this number he describes some interesting new Silurian ophiurids. He also describes a new Cypridina from Hobson's Bay. Mr. J. A. Leach directs attention to the value of surface tension in the formation of canyons, a factor hitherto neglected. There is also a contribution to the flora of Australia, describing new or little-known plants, by Prof. A. J. Ewart, who holds the double appointment of the new chair of botany at Melbourne University and botanist to the Government of Victoria.

In the Records of the Geological Survey of India (vol. xxxiv., part iv.) Mr. R. R. Simpson describes the Jaipur and Nazira coalfields, Upper Assam. The measures are of Middle Tertiary age, and the coals closely resemble in appearance those from the Makum area, but they are somewhat inferior in quality. They burn readily, with considerable flame and great heat. The amount of workable coal exceeds 20 million tons in the Jaipur field and 35 million tons in the Nazira field. The Dikhu River area is the most suitable for the establishment of a colliery. The accompanying view on the Dikhu River, with the Bor Jan landslip in the background, shows the nature of the ground, which is covered by virgin forest with a dense thorny undergrowth presenting the maximum of difficulty to penetration. The difficulties of transport could probably be overcome by means of an aërial wire-rope tramway. Mr. Simpson also has a note on the Makum coalfield between the Tirap and Namdang streams. Other papers in the same issue are on the Kabat anticline near Seiktein, Upper Burma; on the asymmetry of the Yenangyat-Singu anticline, Upper Burma; and on the northern part of the Gwegyo anticline, Upper Burma, by Mr. E. H. Pascoe; and on *Breynia multituberculata*, an undescribed species from the Nari of Baluchistan and Sind, by Mr. E. Vredenburg.

Photo. [*R. R. Simpson.*

View on Dikhu River; the Bor Jan landslip in the background.

Dr. Eredia, assistant in the Meteorological Office at Rome, has undertaken a laborious and useful work in discussing the frequency of wind direction in various parts of Italy from the observations contained in the Annals of that office. Part i. refers to the winds of Piedmont, and deals with monthly and seasonal values for various stations. Speaking very generally, winds from the south-west quadrant predominate in winter, while in summer they are south-westerly in Upper, and north-easterly and south-easterly in Lower Piedmont; in spring and autumn no very marked predominance is exhibited.

In the Bulletin of the Moscow Imperial Society of Naturalists, Nos. 1 and 2, 1906, Dr. E. Leyst completes his valuable series of statistical investigations of optical phenomena. The results deduced from observations at seventy stations, and including in the aggregate 1308 years, show that the phenomena have a yearly and secular range, and that solar coronæ are observed about five times less frequently than lunar coronæ; the maximum of the yearly range occurs in spring, and the minimum about July. The coronæ are seen more frequently inland than near the sea coast.

At the request of the seventh International Geographical Congress, the Danish Meteorological Institute has for some years past published in its year-book of nautical meteorology valuable details, accompanied by monthly maps (April–August), of the state of the ice, compiled from logs of ships and other sources. The summary for 1906 shows that, as the winter 1905–6 was comparatively mild over Spitsbergen, Barents Sea, and the Kara Sea, and severe over Greenland and parts of Arctic America, the conditions of the ice were consequently favourable in the former region and unfavourable in the latter; in Barents Sea the conditions were especially favourable, while in the Greenland Sea the ice-belt was broader, and off Labrador drift-ice was more frequent, than usual. All things considered, it is expected that the conditions in 1907 will be rather favourable along the coasts of Greenland, and less so around Labrador and Newfoundland. The most important events of the year in the Arctic regions were the accomplishment of the North-West Passage by Captain Amundsen and the attainment of latitude 87° 6′ N. by Commander Peary.

The revised edition of the Institution of Electrical Engineers Wiring Rules, which has been recently issued, contains a good many alterations and a great deal of rearrangement. The rules apply only for voltages up to 250 volts, the Board of Trade rules being appended and used for the higher pressures. The standard for copper conductors is now that of the Electrical Standards Committee instead of Mathiessen's standard, as in the past. Insulation tests are also modified in that the "bending" test has been omitted, though an increase in the length of time for which the pressure test is applied takes its place. This is a distinct advance, as the danger of mechanical rupture was always present when bending cables of any size, and was in very many cases an unnecessary strain on the cable. Bare conductors also are allowed under special conditions. Switches of more than 5 amperes at 125 volts when placed in cases are to have their cases lined with asbestos. Dynamos and motors are now placed under separate headings, but transformers are no longer kept separate, being under a combined heading with resistances and choking coils. At the end of the rules the Electrical Standards Committee's standard for the resistance and weights of copper conductors is defined as follows:—"A wire one metre long and weighing one gramme having a resistance of 0·1539 E.S.C. standard ohms at 60° F." In addition to the Board of Trade rules for voltages from 250 volts to 650 volts, the Home Office

Regulations for Mining Work are also attached. The revised rules are certainly an improvement on the previous edition, and the rearrangement and enlargement under the different headings tend to simplify them greatly.

The May issue of the *Westminster Review* contains an appreciative unsigned article on the life and work of the late Prof. Marcellin Berthelot. This biographical notice, in addition to its references to Berthelot's achievements in science, provides much interesting information concerning his private life and his services to France in administrative matters.

OUR ASTRONOMICAL COLUMN.

A Nebulous Background in Taurus.—In No. 3, vol. xxv. (p. 218, April), of the *Astrophysical Journal*, Prof. Barnard discusses the apparently nebulous background shown on some excellent photographs of a region in the constellation Taurus, of which two reproductions are given.

The vacant lanes among the Milky Way stars in Ophiuchus suggest from their appearance that not only are they due to the absence of stars, but that they are really darker than the rest of the sky, that is, they are probably channels in a substratum of nebulous matter. The recent photographs obtained by Prof. Barnard show that lanes of this nature are undoubtedly in a substratum of some kind, and not merely a subjective effect of contrast in a region otherwise densely packed with stars.

The region dealt with is comprised between the limits α=4h. 0m. to 4h. 34m. and $\delta=+24°$ to $28\frac{1}{2}°$, well to the east of the Pleiades, and shows numerous narrow, vacant lanes, one of which is singularly well defined, and extends for some 26m. in R.A. Another feature is a large space, nearly devoid of stars, but containing a large nebula which seems to suggest the possible existence of a larger nebula of which the outlying portions are dead or non-luminous, and therefore absorb the light of the stars behind them.

The White Spot on Jupiter's Third Satellite.—Referring to the white spot near the north limb of Jupiter's third satellite, observed by Senor José Comas Solá in November, 1906 (see Nature, No. 1942, p. 281, January 17), Prof. Barnard directs attention to the fact that he observed the same, or a similar, spot some fourteen years ago, and that, as in Senor Solá's observations, it was only seen when the satellite was *following* Jupiter. This leads to the assumption that this feature cannot be a true polar cap in the sense of its being at the pole, or it would be seen with equal facility in all parts of the satellite's orbit. Further, if this white spot is an extra-polar marking, and is only visible in certain points of the satellite's orbit with respect to the earth, it indicates that Jupiter's third moon, like the earth's satellite, always keeps the same face towards its primary.

During the observations of 1893–4, Prof. Barnard saw a similar spot at the south limb of the fourth satellite when that body was near superior conjunction (*Astronomische Nachrichten*, No. 4173, p. 327, April 27).

The Meteorite from Rich Mountain, North Carolina.—The results of a minute examination of a portion of the meteorite which was seen to fall at Rich Mountain, Jackson County, North Carolina, "about June 20, 1903, at 2 o'clock in the day," are given by Messrs. Merrill and Tassin in an abstract (No. 1524) from the Proceedings of the U.S. National Museum (vol. xxxii., pp. 241–244, April 18).

The portion examined seemed to be the nose of a larger mass, and weighed 668 grams. Metallic iron particles project from the crust, and seem to have resisted the frictional heat of the atmosphere better than did the silicate portions. Chemical analysis showed about 7 per cent. of iron, nearly 47 per cent. of olivine, about 4 per cent. of troilite, and about 40·7 per cent. of insoluble silicates. Copper was apparently absent, and, among the compounds, chromite was not found, whilst a relatively large amount of graphitic carbon was present.

Comet 1907*b* (Mellish).—In No. 4174 (p. 347, May 3) of the *Astronomische Nachrichten*, Prof. Berberich directs attention to the great similarity between the elements of the orbit of comet 1907*b* and those of the bright comet of 1742 as published in vol. clxxii. (p. 105) of the same journal.

Prof. Barnard has discovered an image of this comet on a plate taken on April 13, the day before the object was found by Mr. Mellish, and a number of other American observations are also recorded for April 14, 15, and 17 in the same journal.

The Orbits of Four Double Stars.—Recently determined orbits of the systems of ξ Scorpii, Σ 2173, Σ 3121, and μ^2 Herculis are given by Dr. Doberck in Nos. 4169–70 (p. 257, April 17) of the *Astronomische Nachrichten*. The orbits were determined by successive corrections by the least-square method, and the computed places are compared with all the available observational results; ephemerides extending to 1926 are also given. The periods given by the final elements for each of the above stars are 45·12, 46·20, 35·38, and 44·20 years respectively.

The Discovery of Variable Stars.—The value of the new method of discovering, photographically, variable stars, by superposing a negative and a positive copy of a similar negative taken at a different epoch, is illustrated in Circular No. 127 of the Harvard College Observatory. A plan has been started whereby the whole of the sky, as photographed on the Harvard Map of the Sky, will be systematically examined for variables, and the present circular deals with two regions already examined by Miss Leavitt; eight new variables were found in the one region and six in the other. A comparison of the results with those previously obtained shows that apparently all the bright variables exhibiting conspicuous changes in these two regions have now been discovered.

The Radiant Point of the Bielids.—From observations made at Stockholm in November, 1904, Dr. Karl Bohlin finds the radiant point of the Bielid shower, epoch November 21·33 (M.E.T.), to have been $\alpha=+26°\ 2'$, $\delta=+44°\ 10'$ (1900). The record of the observations and discussion of the results appear with a chart, in No. 2, vol. viii., of the *Astronomiska Iakttagelser och Undersökningar å Stockholms Observatorium*.

IRON AND STEEL INSTITUTE.

The annual meeting of the Iron and Steel Institute was held at the Institution of Civil Engineers, Westminster, on May 9 and 10. The proceedings opened with the Right Hon. Sir James Kitson, Bart., M.P., past-president, in the chair, who explained that the president, Mr. R. A. Hadfield, having attended to present an address on behalf of the institute at the dedication of the building given by Mr. Carnegie to American engineering societies, was unable to return to England in time for the meeting.

The report of the council, which was read by the secretary, Mr. Bennett H. Brough, showed that the past year had been one of exceptional activity and progress. The membership of the institute amounted to 2052, and the joint meeting with the American Institute of Mining Engineers resulted in the presentation of so large a number of papers that it was found impossible to compress the minutes into the usual two volumes, and two extra volumes were issued. The report by the treasurer, Mr. W. H. Bleckly, showed that the financial prosperity of the institute is a matter for congratulation. The receipts amounted to 6610*l.*, and the expediture to 5915*l.*

The first act of the new president, Sir Hugh Bell, Bart., on taking the chair was to present the Bessemer gold medal to Mr. J. A. Brinell, the eminent Swedish metallurgist.

In his presidential address, Sir Hugh Bell gave a sketch of the iron trade in the last hundred years, the subject being chosen from the fact that the life of his father, Sir Lowthian Bell, begun in 1816 and ended nearly ninety years later, almost covered the period reviewed. The address is a work of conspicuous literary merit, and its value is enhanced by the addition of a carefully compiled chronological table of the more important events connected with iron and steel during the century. A vote of thanks to the president for his address was eloquently proposed by Sir W. H. White and seconded by Mr. Schneider (Le Creusot).

The first paper read was by Mr. D. Selby-Bigge (Newcastle-on-Tyne), who described the latest application of electricity to reversing rolling-mills of high power. The first mill of this kind was started on July 27 last at the Hildegarde Works, at Trzynietz, in Austrian Silesia. The mill is of 10,350 horse-power, and is provided with the Ilgner arrangement of fly-wheel converters. The discussion was well sustained, and the rival claims of electricity and steam were ably urged.

The secretary announced that Carnegie research scholarships had been awarded by the council to C. A. Edwards (Horwich), J. A. N. Friend (Germany), D. M. Levy (Bradford), A. M. Portevin (France), A. K. F. Hiorth (Norway), and B. Saklatwalla (India and Germany). For research work carried out during the past year, medals were awarded to E. F. Law (London) and Dr. O. Stutzer (Freiberg in Saxony). The reports of these two candidates, and the reports of P. Breuil (Paris), W. H. Hatfield (Sheffield), and Dr. Guillet (Paris) were found to be of sufficient merit to warrant their publication in full in the journal of the institute.

Two papers were read by Mr. Arthur W. Richards describing processes he has adopted at the works of Messrs. Bolckow, Vaughan and Co. for the manufacture of steel from high-silicon phosphoric pig iron by the basic Bessemer process, and of high-class steel from pig iron containing chromium, nickel, and cobalt.

Prof. W. A. Bone, F.R.S. (Leeds), and Mr. R. V. Wheeler (Warrington) read a lengthy paper on the use of steam in gas-producer plant. The experiments were made with a Mond gas-producer plant with the view of determining the influence of variation in the proportions of air and steam in the blast upon the composition of the gas, its suitability for furnace operations, and upon the general and thermal efficiencies of the producers. The quality of the gas obtained, though always good, steadily deteriorated as the steam saturation temperature was raised beyond 65°. An investigation of the thermal efficiency showed that the use of steam beyond that required to saturate the air blast at 60° was not attended by any increased economy of working, but rather the reverse. If, however, a gas producer be regarded primarily as an apparatus for ammonia recovery, then undoubtedly it should be worked with the highest steam saturation temperature consistent with the production of combustible gas.

The paper read by Mr. F. W. Harbord (London) is a valuable addition to technical literature. For many years it has been recognised that steels made by different processes, although practically of the same composition, varied in their tensile strength, hardness, and other physical properties, and it has been generally admitted that basic Bessemer steel was softer than acid Bessemer, and basic open-hearth softer than acid open-hearth steel. Mr. Harbord's paper gives for the first time systematic experimental results defining these various differences over a wide range of carbon content. He shows that if engineers wish to obtain rails of equal hardness from the basic open-hearth that they have been accustomed to from acid Bessemer steel, they must permit the manufacturer to increase the percentage of carbon to give the required hardness, as otherwise, although the rails may satisfactorily pass all the usual tests required by the specification, there will soon arise, under the conditions of heavy train-loads now customary, serious trouble due to spreading heads and undue wear. American engineers, in their standard specifications, have already recognised the importance of this, and they vary their rail specifications according to the process of manufacture.

A paper on the ageing of mild steel was read by Mr. C. E. Stromeyer (Manchester). The idea that steel might go through an ageing process has been scouted, but from the tests described the conclusions to be drawn are that certain steels do possess ageing qualities, that some steels tend to improve with time, others to deteriorate; and that as yet the process which gives results which are most in harmony with practical experience is to plane the edges of two samples, to nick them with a specially prepared chisel, and then to bend one sample at once and the other after waiting some weeks or after boiling.

Mr. A. J. Capron (Sheffield) read a paper on induced draught, with hot air economisers, for steel works and blast-furnace boilers. Briefly, the system consists of induced draught in combination with hot air economisers, which utilise the waste heat from the boiler in heating the air required for combustion. A fan is placed at the base of the chimney and draws the gases, as they come from the boiler, through a series of tubes which form a heating-box or hot air economiser. The system has already been adopted at several iron and steel works, and is found to result in considerable economy of fuel and absence of smoke. There is also the advantage that no high chimney is required.

A paper on the distribution of sulphur in metal ingot moulds was contributed by Mr. J. Henderson (Stockton-on-Tees). The question of the distribution of sulphur in ingot moulds made of hæmatite pig iron was recently brought to his notice by the fact that several large moulds were alleged to contain an excessive percentage of sulphur out of all proportion to the sulphur contents of the pig iron from which the moulds were made. The fact that much more sulphur is generally found in the tops of ingot moulds and other large castings is, or should be, well known to all ingot-mould makers and users. Yet in spite of this it is evident that some steel makers drill the tops of the moulds in order to ascertain the sulphur contents, and on the results so obtained condemn the moulds as unfit for use in the open-hearth furnace for melting purposes when they are scrapped. Such a method of sampling is manifestly unfair, as the results obtained by the author show that the excessive sulphur does not go deeper than the first inch, and that after the second inch there is no reason to find fault with the composition of the mould.

A paper on sentinel pyrometers and their application to the annealing, hardening, and general heat treatment of tool-steel was contributed by Mr. H. Brearley (Riga, Russia) and Mr. F. C. Moorwood (Sheffield). An indicator which can, in most cases, be placed exactly on the spot the temperature of which is required to be ascertained may occasionally be more serviceable than a fixed pyrometer of a more expensive type which registers the temperature of its immediate vicinity only. By making the indicators from materials which clearly melt at or above a definite temperature, and, after melting, also continue to show when the temperature falls to or below that point, a simple means is discovered which may claim a place amongst instruments of precision. The authors suggest that, for this purpose, no more suitable materials could be adopted than well-chosen salts of the metallic oxides.

In a paper on carbon-tungsten steels contributed by Mr. Thomas Swinden (Sheffield), a research is described having for its object an investigation of the influence of varying percentages of carbon in the presence of a constant percentage of tungsten.

Reports on research work carried out by holders of Carnegie research scholarships were also presented. Mr. P. Breuil (Paris) gave the results of a systematic investigation of copper steels from the point of view of their industrial application. Mr. W. H. Hatfield (Sheffield), in a research on cast iron, found that there is undoubtedly occasionally a great variation in the strength of cast irons of the same composition as cast; that this variation does not appear to follow any distinct rule with regard to the temperature of the casting operations; that a difference in mechanical tests is generally accompanied by a difference in the microstructure; and that the inequalities of the metal can be rectified by judicious heat treatment, *i.e.* the irregularity need not persist after heat treatment, at any rate under certain conditions. Dr. O. Stutzer (Freiberg, Saxony) gave the results of an elaborate investigation of the genesis of the Lapland iron ore deposits, showing that the phosphoric magnetite deposits of north Sweden are all associated with plutonic rocks of the syenite family, and that they have been formed in a magmatic manner, and, indeed, either as magmatic separations *in situ* or as erratic magmatic segregation. Pneumatolysis has also had considerable influence in the formation of these ores.

Mr. E. F. Law (London) dealt with the non-metallic impurities in steel. His paper is the result of an examination of more than one hundred steels. The impurities have been considered as consisting of five in number, namely, iron sulphide, manganese sulphide, iron silicate, manganese silicate, and iron oxide. Iron sulphide very rarely occurs in commercial steels, and is therefore not considered at length. Manganese sulphide is always present in steel, and is usually harmless. The only instance in which it has been found to exert injurious influence on the quality of the steel is when it segregates with phosphide of iron in the form of "ghosts." Silicates of manganese and iron are frequently found in steel, and are highly injurious to the quality of the metal. In large forgings they sometimes occur in considerable masses, but in rolled steel they are distributed throughout the mass. In either case they are responsible for many failures. No indication of their presence is afforded by ordinary commercial means, and they can only be detected under the microscope. Oxide of iron frequently occurs in Bessemer steel. It occurs in a finely divided state, and there is evidence that it is soluble in steel. As a general rule, steels which on pickling evince a tendency to blistering are high in oxygen. The effect of hydrogen on steel containing oxide is discussed, and experiments were made with the view of determining the temperature at which the oxide is reduced. The results of these experiments tend to show that the oxide is reduced at 100° C. Iron oxide differs from other impurities present in its electrical behaviour, and the influence of this difference on the corrosion of iron and steel is discussed. It has been found that the presence of oxide accelerates corrosion, and corrosion of welded iron affords an illustration of this action. Other instances of the effects of the presence of oxide may be found in the pitting of boiler plates and tubes.

The last paper on the programme dealt with the nomenclature of iron and steel. This is the report of an influential committee of the International Association for Testing Materials which was presented by Prof. H. M. Howe (New York) and Prof. A. Sauveur (Harvard) at the Brussels congress of that association. It was then proposed that the report be submitted to the Iron and Steel Institute for consideration, and the secretary will be pleased to receive written comments for publication in the journal.

The meeting concluded with the usual votes of thanks to the Institution of Civil Engineers, proposed by the president and seconded by Sir John Alleyne, and to the president, proposed by Mr. G. Hawksley and seconded by Mr. Saladin (Le Creusot).

On Friday evening the annual banquet was held, with the president in the chair. Four hundred members were present, and the speakers were the Austrian Ambassador, the Swedish Minister, Sir James Kitson, Mr. Yves Guyot, Admiral Sir Cyprian Bridge, Sir C. E. Howard Vincent, Lord Justice Fletcher Moulton, and Mr. Robert Hammond.

CHIMÆROID FISHES.

A MEMOIR on "Chimæroid Fishes and their Development," by Prof. Bashford Dean, has been issued as Publication No. 32 of the Carnegie Institution of Washington. It begins with a short review of the researches in comparative anatomy and palæontology, which led to the view that chimæroid fishes are the most primitive vertebrates or the least modified descendants of the ancestral cranium- or jaw-bearing vertebrate; that, although shark-like, they are nevertheless widely distinct from the shark; and that altogether they represent a lower plane in piscine evolution.

Admitting the importance of the grounds on which these conclusions were based, Prof. Dean refers to the incomplete nature of the evidence. The material at the disposal of investigators was inadequate for the solution of the great morphological problems involved, and especially embryological material was extremely scanty or absent. The author himself failed for several years in his efforts to obtain satisfactory materials, until his attention was directed by President Jordan to the vicinity of the Hopkins Marine Laboratory at Monterey as a promising locality for collecting *Chimaera colliei*. Under the guidance of a Chinese fisherman, Ah Tack Lee, who not only possessed a perfect knowledge of the Chimæra grounds, but proved to be a keen observer of the habits of the fish, the author obtained hundreds of specimens of the adult fish and of ova. Such of the latter as were not required for immediate examination were placed in a case, which was then sunk, attached to a buoy, in water of about five fathoms, to obtain the much needed series of developmental stages.

After having given an account of the habits and mode of propagation of the Californian Chimæra, the author enters into a full description of its egg and capsule in comparison with the ova of other Chimæroids. This is followed by a detailed account of the various stages of development of the embryo and of the post-larval growth of the fish. Next the relationships of fossil Holocephales are considered. In the chapter on organogeny, the discussion of the obscure problem of the development of the dentition and of the homologies of its component parts in living and extinct forms will be studied with particular interest.

Anatomical, embryological, and palæontological evidence, then, appears to the author to be unmistakably in favour of Chimæroids being widely modified rather than primitive forms. The recent forms retain less perfectly the general characters of the ancestral gnathostome than do living sharks. On the other hand, they have retained several characters of their Palæozoic Selachian ancestors which modern sharks have lost. The ancestral Holocephali diverged from the Selachian stem near or even within the group of the Palæozoic Cestracionts, and the many features of kinship retained by the recent Chimæroids and Cestracionts distinctly point at this line of evolution.

The memoir is illustrated by 144 excellent text-figures and eleven plates.

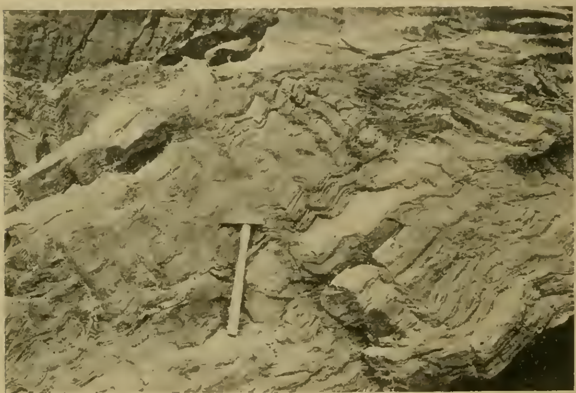
BRITANNIC GEOLOGY.

FEW teachers have utilised the study of our own islands to greater advantage than Dr. Joseph H. Cowham, of the Westminster Training College. For thirty years past he has led his pupils over the varied country south of London, and the present writer is one of those who became pleasantly acquainted at an early date with his interest in scenery and his keenness for the details of a landscape. Dr. Cowham has published in "The School Journey" (Simpkin Marshall, pp. 80, price 1*s.*) an account of his methods, illustrated in the country between Croydon and Godstone; Mr. G. G. Lewis, a former pupil, describes an excursion in the Greenwich and Woolwich area; and Mr. T. Crashaw, another pupil, shows how a class may study erosion and deposition in river-courses on the banks of the Calder, in Lancashire. These expeditions appear to be wisely accepted as part of the regular school curriculum, instead of being relegated, as sometimes happens, to the holidays. Their effect in bringing together teacher and taught is rightly insisted on, and cannot be exaggerated; and the feeling is early engendered that the class-instruction in geography relates to something real and natural, which any eye can see and any willing brain can comprehend.

It is to such teachers, and to their pupils in later years, that the long-established Geologists' Association especially appeals. In part x. of its Proceedings (November, 1906, Stanford, price 1*s.* 6*d.*) Mr. R. S. Herries describes the geology of the Yorkshire coast between Redcar and Robin Hood's Bay, which was the scene of the long excursion of 1906. Especial interest here attaches to the estuarine representatives of the Middle Jurassic series, with *Equisetum columnare* "found upright in the sandstones as it originally grew," and to the zoning of the Lower Jurassic by the abundant ammonites. The valuable "Sketch of the Geology of the Birmingham District," by Prof. Lapworth, with a contribution on petrology by Prof. Watts and one on the glaciers by Mr. W. Jerome Harrison, has now been reprinted from the Proceedings of the Geologists' Association for 1898 (Cornish Bros., Birmingham, pp. viii+104, price 2*s.* net), and will serve as a guide for generations of students in the Midlands. The region includes exposures of the famous Permian boulder-beds (pp. 60–64), on which we should now like the opinion of some South African geologist.

The Geological Survey of the United Kingdom, which is intent on bringing the knowledge of our own islands up to date, issued two memoirs, with accompanying colour-printed maps, at the close of 1906. In one, Mr. W. A. E. Ussher describes the country between Wellington and Chard (Memoirs of the Geological Survey, "Explanation of Sheet 311," pp. vi+68, price 1s. 3d.). The map, Sheet 311 of the new series, centres in the interesting watershed of the Black Down Hills, where the streams running south and west have cut through a plateau of Cretaceous rocks into the underlying Trias. The westward extension of the Selbornian beds (largely of Albian age) beyond the Rhætic and Jurassic, and their striking unconformity with these earlier strata, form interesting features in the map. The "clay with flints" appears for the first time in this region as "in part Eocene." The difficulty of selecting colours for superficial deposits which will suit all areas of our complex island is seen in the resemblance between "valley gravel and rainwash" and Triassic strata. In the index, however, this resemblance is greater than in the actual map. In the memoir we touch the work of many previous writers, including De la Beche and Fitton, and have the advantage of the views of Mr. Jukes-Browne on the correlation of the Cretaceous series.

In the second memoir ("Explanation of Sheet 346. The Geology of the Country near Newquay," pp. iv+132, price 3s.), Messrs. Clement Reid and Scrivenor describe an area in which the interest ranges from the Pliocene outlier of Saint Agnes to partly abandoned tin and copper mines. The close relation between the lodes and the metamorphic aureole of intrusive granite is at once obvious on the map. The economic section and appendix, the latter by Mr. D. A. Macalister, justly occupy forty-eight pages of the memoir. The granite cuts rocks of Lower Devonian age, which are now coloured on the map in tints of grey. The old familiar brown colour appears in the area of beds, now known to contain Pteraspis, near St. Mawgan, above which undoubtedly marine strata prevail. Interesting veins containing axinite are described by Mr. Flett in association with certain intrusive greenstones. They are attributed to "pneumatolytic" action, such as promoted the formation of tourmaline in other places, and are thus connected with the intrusion of the granite. These garnet-axinite-augite-epidote veins are held to have occurred where lime-silicates or patches of impure carbonate of lime were provided by the greenstones. The post-Carboniferous earth-movements have produced conspicuous cleavage and cross-cleavage in the Devonian shales of Watergate Bay, whereby the original bedding is at times entirely lost. Plate iii. is here reproduced, as a particularly beautiful example of cleavage-planes with secondary puckering, and no trace of true stratification.



Puckered slate showing "strain-slip," north-end of Watergate Bay, Newquay, Cornwall.

The Geological Survey of Ireland has issued a memoir on "The Geology of the Country around Limerick," by Mr. G. W. Lamplugh and the staff of the Survey, as constituted at the time of its transfer to the Department of Agriculture and Technical Instruction (Dublin, 1907, pp. vi+120, price 2s.). The drift edition of parts of Sheets 143 and 144, forming a special colour-printed map with Limerick nearly in the centre, is issued simultaneously, price 1s. 6d. The area is largely covered by Boulder-clay, but includes exposures of the interesting volcanic and intrusive rocks that are here associated with the Carboniferous Limestone. The seven photographic plates by Mr. H. J. Seymour illustrate all the important rocks of the district, and include a good example of beds of limestone carried bodily forward in Boulder-clay from the area surveyed by the author of the plate. Though the main object of the memoir was the description of the superficial deposits, a number of new observations on the underlying rocks have been added by Mr. Kilroe. The same writer has dealt with the economic geology, and particularly with the soils and subsoils.

THE COATS OBSERVATORY, PAISLEY.[1]

THIS observatory, the establishment and maintenance of which are entirely due to the munificence and public spirit of the Coats family, is situated about seven miles to the westward of Glasgow. From a meteorological point of view it occupies a very important position, being in the path frequently taken by the storms coming from the Atlantic Ocean. The observatory is now fully equipped with ordinary and self-recording meteorological instruments; there was, however, at first no intention of carrying on meteorological work, but Mr. Thomas Coats before his death, in October, 1883, having provided a standard barometer and thermometer, the committee of management afterwards supplied other instruments, and with these observations were regularly taken morning and evening. The records are preserved by the Paisley Philosophical Institution; readings have been transmitted monthly to the Scottish Meteorological Society, and the results are also separately published by the institution. The observatory was originally established for astronomical purposes, and was placed under the care of the Philosophical Institution. Mr. Thomas Coats generously offered to relieve the society of all expense in the matter, and to provide a suitable building, and he expressed the hope that the establishment would "prove a stimulus to interest the rising generation of the town and neighbourhood in the study of astronomy—a science little understood among us, but which may, under the leading spirits of our Philosophical Institution, become a subject of instruction that will be eagerly sought after." He endowed the institution with the sum of 2000l. in trust, and the observatory was opened to the public on October 1, 1883. We are indebted to the Philosophical Institution for the accompanying illustration of the observatory.

The original design was enlarged by the founder, who supplied a transit instrument, clocks, &c., and after his death his representatives intimated their desire to render the equipment still more complete, and added another

[1] "The Coats Observatory, Paisley; its History and Equipment." By Rev. A. Henderson. Pp. 48. (Paisley: J. and E. Barlake.)

2000*l.* to the endowment fund. The necessary alterations to the buildings were carried out at the expense of Mr. James Coats, who between 1892 and 1898 increased the fund by 6000*l.*, making it 10,000*l.* in all, and also made important additions to the equipment. Milne and Ewing seismographs, magnetometers, and other instruments were also ordered, rendering the observatory one of the most completely furnished in the kingdom. The seismographic observations for the year 1906 show that eighty-two earth movements were recorded.

The following results, taken from the meteorological observations for the twenty-two years 1885–1906, are interesting:—highest reading of barometer 31·002 inches, on January 9, 1896; lowest, 27·584 inches, on December 8, 1886; maximum temperature, 88°·6, on September 1, 1906; lowest, 4°·8, on February 10, 1895 (1°·0 was quoted by the institution on January 17, 1881). The mean annual rainfall is 38·29 inches, the average number of rain-days being 212; the rainfall in 1903 was 69·57 inches, and in 1896 only 24·45 inches. Polar winds prevail, on

The Coats Observatory, Paisley.

an average, on 131 days, and equatorial on 206 days in the year.

The meteorological observations have from the beginning been taken by the curator, Mr. Donald Maclean, formerly assistant to Prof. Grant, at the Glasgow Observatory.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. A. Hill has announced his intention of resigning the mastership of Downing College some time during the long vacation. Dr. Hill succeeded the late Dr. Burkitt some nineteen years ago. He is lecturer in advanced human anatomy, and is the sole representative of medicine and natural science amongst the heads of houses.

The general board of studies will shortly proceed to the appointment of a reader in forestry for a period of five years from October 1, 1907. The annual stipend is 400*l.* Candidates are requested to send in their applications, with such testimonials as they think fit, to the Vice-Chancellor on or before July 15.

The syndicate appointed to obtain plans for the extension of the Cavendish Laboratory has obtained tenders from nine firms. The lowest tender, 7135*l.* (including a provisional sum of 500*l.* for the cost of heating), was that of Mr. W. Sindall, of Cambridge. The syndicate now recommends that the Vice-Chancellor be authorised to accept the tender of Mr. Sindall. The cost of this extension will be largely met by Lord Rayleigh's munificent gift to the University of the Nobel prize.

The syndicate appointed to obtain plans for the extension of the chemical laboratory has laid its scheme before the Senate. It is proposed to fill in the gap which now exists along Pembroke Street between the medical school and the existing chemical laboratory with a three-storied building. This will provide for a large increase to the elementary laboratory, a number of smaller laboratories, and a lecture-room to seat 150 students. The cost is estimated at 13,500*l.*, and in view of the facts that in the last three years the average attendance at the University laboratory has increased from less than 200 students to more than 300 a term, and that Gonville and Caius College proposes to close its laboratory next summer, the building of the extension is urgent. The syndicate learns with regret that Prof. Liveing, who was elected in 1861, proposes to vacate the chair of chemistry some time next year. During the forty-six years he has been professor, the study of chemistry has made great advances in the University. Under his care and control the new chemical laboratory was built in 1887. The success which has attended the school at Cambridge is largely due to his untiring energy and his unselfish devotion to his subject.

The Common Seal of the University has been affixed in the presence of the Vice-Chancellor to:—(1) the certificate of appointment of Prof. Seward to represent the University at the celebration of the 300th anniversary of the death of Ulisse Aldrovandi to be held at Bologna in June; (2) the address to the Royal Swedish Academy of Sciences, Stockholm, in honour of the commemoration of the bicentenary of the birth of Linnæus to be held at Stockholm in May; (3) the certificate of appointment of Mr. F. Darwin to represent the University at the celebration of the bicentenary of the birth of Linnæus to be held at Stockholm in May; and (4) the certificate of appointment of Dr. Harmer, Mr. W. Bateson, and Mr. A. E. Shipley to represent the University at the seventh International Zoological Congress to be held in Boston in August.

Manchester.—Mr. H. Bateman has been elected to the readership in mathematical physics, endowed by Prof. Arthur Schuster to encourage research in mathematical physics, and to which we recently directed attention (Nature, January 24, vol. lxxv., p. 309). Mr. Bateman is a fellow of Trinity College, Cambridge, and was senior wrangler (bracketed), 1903; Smith's prizeman, 1905. He has already published a number of important mathematical contributions. His work in this new post will be followed with interest.

Prof. Ernest Rutherford, F.R.S., is to arrive from Montreal on May 24.

A new departure has been made in the publication of a special prospectus of advanced studies in the faculties of arts and science. A brief account is given of the provision for research in the different departments, as also of the courses of lectures, arranged for the session 1907–8, suitable for post-graduate study. It is hoped in future years to extend the scope of this prospectus so as to give a more extensive record of the resources of the University for advanced study and research.

Mr. C. G. Hewitt has been appointed to the recently founded lectureship in economic zoology.

Oxford.—The following is the text of the speech delivered by Prof. Love in presenting Prof. A. Graham Bell for the degree of D.Sc. *honoris causa* on May 2:—

Adest Alexander Graham Bell, origine quidem Scotus, diu apud Americanos scientiæ promovendæ dux et auctor probatissimus. Qui vir cum primo Physiologiæ Professor esset, dum surditatis causas et naturam diligentissime expendit, instrumenta quædam arte exquisita effinxit quibus surdi audientium more clara voce loqui docerentur: ita miserorum qui hoc incommodo laborant ægritudines aliqua ex parte relevavit. Idem mox longius progressus latiorem apud homines gloriam adeptus est. Hic ille est qui miraculum illud excogitavit, usu cotidiano iam notissimum, ut ipsa loquentis verba et vivam hominis vocem super montes altissimos et flumina latissima per immensos terrarum tractus et sub ipso Oceano transmittere et, ut aiunt, τῆλε φωνεῖν possemus. Virum igitur iure laudamus cum doctrina tum repertis præclarum, qui non solum mortalium commodis naturæ vim inservire coegit sed miseris et mærentibus malorum solamen obtulit.

In a Convocation held in the Sheldonian Theatre on Saturday, May 11, Lord Curzon was admitted and installed as Chancellor of the University. After his installation he conferred the honorary degree of D.C.L. on the Hon. F. R. Moor, Premier of Natal.

An election to the Philip Walker studentship in pathology will be made in October next. The studentship is of the value of 200*l*. a year for three years. Candidates may be of either sex, and need not be members of the University of Oxford. They are asked to send in their applications, with three testimonials, to the Registrar of the University by September 14.

The *British Medical Journal* announces that Prof. August Bier, of Bonn, has accepted a call to the chair of surgery in the University of Berlin, vacant by the death of Prof. Ernst von Bergmann.

The first annual conference of the Association of Teachers in Technical Institutions will be held in Leeds on May 23, 24, and 25. On Friday, May 24, the following papers will be read:—(1) Notes of an educational visit to the United States of America, H. Ade. Clark; (2) the preliminary training of technical students, Barker North; (3) syllabuses and examinations as applied to building subjects, J. Fitzgerald. Excursions, social meetings, and visits to works will form an attractive part of the meeting.

The Royal College of Surgeons in Ireland has sanctioned two post-graduate courses to be held annually in Dublin hospitals during the summer. The first course will extend from June 10 to July 2, and the second from September 23 to October 15. The object of these courses is to render available the whole of the clinical material in Dublin for the post-graduate student, so that he may see as much as possible during the brief time at his disposal. Ten general hospitals are included in the list of institutions at which the student may work, as well as hospitals devoted to special subjects. The tickets for the courses admit to the ordinary clinics of all the hospitals, as well as to the special work of the course. Further information can be obtained from, and all applications should be addressed to, Prof. Fraser, Royal College of Surgeons, Dublin.

Judged in the light of the results of recent examinations of the Punjab University, the study of science does not seem, says the *Civil and Military Gazette*, to be making much headway in the Punjab. Many years ago the Punjab University arranged a faculty of science with the usual matriculation, intermediate, and bachelors degree tests. A few years ago an additional test was established, viz. that for the degree of master. In 1907, whilst 3546 went up for the matriculation examination in the faculty of arts, only fifty-eight appeared in the similar examination in the faculty of science. Thirty-seven went up for the intermediate examination of the science faculty against 674 who appeared in the same examination in the faculty of arts; whilst the number of candidates in the B.A. examination was 341, only thirteen went up for the same examination in the faculty of science. This comparative neglect of scientific studies is much to be regretted, especially in India, where the object of university education is to effect a combination of the highest results of Western culture and science with the learning of the East.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 7.—"Electric Furnace Reactions under High Gaseous Pressures." By R. S. **Hutton** and J. E. **Petavel**.

Two steel chambers of 20 litres and 2 litres capacity respectively provided with valves, windows, and insulated electrode holders have been constructed and employed at working pressures up to 200 atmospheres. Inside these pressure vessels any desired arrangement for arc or resistance heating is mounted.

Apart from the influence of pressure, which was the primary object of the investigation, special attention was paid to the effect of the nature of the gaseous atmosphere upon the reactions.

Some measurements were made of the electrical constants of carbon and metal arcs in different gases at high pressures, and the rate of oxidation of heated metals was also considered. With a charge of 10 kilos. of lime and carbon the preparation of calcium carbide was studied in atmospheres of carbon monoxide, coal gas, and hydrogen under reduced and high pressures. Contrary to expectation, no unfavourable influence of carbon monoxide upon the yield was noticeable, the back reaction being limited to the surface.

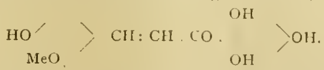
Silica fused under pressure exhibits a marked decrease in vaporisation, but no appreciable increase in fluidity and transparency. The production of carborundum under pressure is much limited, owing to this decreased volatility of silica.

The authors, as a result of a long, detailed, investigation of the reduction of alumina, conclude that this oxide is reducible by carbon at all temperatures above the melting point, but the metal is set free in the form of vapour, and can only be collected if it be protected from reaction with carbon monoxide.

Having overcome the difficulties of maintaining an electric arc in highly compressed air, it is shown that the production of oxides of nitrogen exhibits an increased efficiency attributable to pressure.

Linnean Society, April 18.—Dr. A. Smith Woodward, F.R.S., vice-president, in the chair.—The œcological functions of stolons and cleistogamous flowers: J. C. **Shenstone.** The author pointed out the advantages to the plants by the colony-forming habit, such as its more certain pollination and greater power of holding its own against competitors, instancing as examples *Bellis perennis*, *Thymus Serpyllum*, and *Mercurialis perennis.* Further examples were dwelt upon in the cases of *Urtica dioica*, *Adona Moschatellina*, and the violets, *Viola odorata* and *V. canina*, where both stolons and cleistogamous flowers cooperate in keeping the colonies compact.—The conservation of existing species by constitutional or physiological variation giving greater power of adaptation without perceptible change of structure: A. O. **Walker.** The author referred to a supposed case of two healthy men going to an unhealthy climate: one, proving immune to the local diseases, might conceivably transmit that quality to his children; the other, falling a victim to the climate, would leave no descendants. As instances he brought forward the case of *Crepis taraxacifolia*, long known in Wales as a rarity, which in 1896 onwards became extremely abundant at Colwyn Bay. He considered that this might be accounted for by a different variety, morphologically identical, yet physiologically distinct, having been introduced, which, by its ability to adapt itself to its surroundings, had rapidly extended its area of growth. Another case was of *Cardamine pratensis*, usually stated to grow in moist meadows, which is accurate as regards North Wales, but in Kent its favourite habitat is coppice woods, the second year after cutting the undergrowth. It is frequent on dry banks, on masses of roots of trees or shrubs, probably as xerophilous a station as could be imagined.—An aberrant Coccid: Hugh **Scott.** The species of Coccid, or scale-insect, described was found at the northern border of the Algerian Sahara by Mr. J. J. Lister.—Some results of inoculation of leguminous plants: Prof. W. B. **Bottomley.** In May, 1906, experiments were begun; tares, *Vicia sativa*, were chosen, and inoculated seeds set in sterilised sand, to which the requisite potash and phosphate salts had been added. A second set of pots were prepared with untreated seed, but besides the potash and phosphate, nitrate of soda proportionate to 2 cwt. per acre was added. In the last week of July the results were tested and found to be:—tares, with nitrate of soda, yielded 1·92 per cent. nitrogen; tares, inoculated, yielded 3·07 per cent. nitrogen, showing that the latter contained more than 50 per cent. more nitrogen than those grown with nitrate of soda, the food value being correspondingly increased. Specimens of field crops were obtained from Scotland to check these results, in September, and the three experimental plots proved:—Section A, no nitrogenous manure, 3·41 per cent. nitrogen; Section B, nitrate of soda, 3·75 per cent. nitrogen; Section C, inoculated, 4·04 per cent. nitrogen. Here the differences are less, due to the fact that farm soil invariably contained a certain number of the nitrogenic bacteria, which accounted for these results. Section B showed a yield of 9 tons 8 cwt. per acre, and Section C (inoculated) showed 12 tons 5 cwt. of fodder.

Chemical Society, May 2.—Sir William Ramsay, K.C.B., F.R.S., president, in the chair.—The chemical action of the radium emanation, part i., action on distilled water: Sir W. **Ramsay.** The action of the emanation alone on water decomposes it into explosive gas, mixed with excess of hydrogen; it has been shown that the emanation, when mixed with explosive gas, causes re-combination, and the rate at which the decomposition of water takes place has been measured. The reason of the excess of hydrogen has not yet been elucidated.—Freezing-point curves of the menthyl mandelates: A. **Findlay** and Miss E. M. **Hickmans.** From a study of the freezing-point curves for mixtures of *l*-menthyl *l*-mandelate and *l*-menthyl *d*-mandelate, it is found that *l*-menthyl *r*-mandelate exists as a definite, partially racemic compound having a stable melting point of 83°·7. It was also pointed out that other freezing-point curves indicate the existence of true racemates in the liquid state.—The constitution of homo-eriodictyol. A crystalline substance from eriodictyon leaves: F. B. **Power** and F. **Tutin.** Homo-eriodictyol, $C_{16}H_{14}O_6$, is isomeric with hesperitin, and similar to the latter in many of its properties, contains one methoxyl group, yields a tetra-acetyl derivative, and is hydrolysed by aqueous potassium hydroxide to phloroglucinol and ferulic acid. From these results it is concluded that homo-eriodictyol must possess the following constitution,



Eriodictyol, $C_{15}H_{12}O_6$ (m.p. 267°), a crystalline substance, which was also isolated by the authors from eriodictyon leaves, contains no methoxyl group. Homo-eriodictyol is probably a methyl ether of eriodictyol.—The relation between valency and heats of combustion. Preliminary note: G. **Le Bas.** The heat of combustion of a substance may be regarded as made up of (*a*) an absorption of heat due to the dissociation or decomposition, and (*b*) an evolution of heat due to the combination of the isolated atoms with oxygen. A study of molecular heats of combustion reveals the following law, which appears to be generally valid. The heat of combustion of an organic compound is equal to the heats of combustion of its possible dissociation products. The factor (*a*) is negligibly small as compared with (*b*). The heats of combustion of organic compounds in most cases are found to be the same as those of saturated and unsaturated hydrocarbons and hydrogen, or of mixtures of these. Similarly the factor (*a*) is negligibly small as compared with (*b*) in the case of the saturated and unsaturated hydrocarbons, and therefore their heats of combustion are sensibly those of their isolated atoms, *plus* an excess for the latter, owing to unsaturation. These relations lead to a second law which applies to all the hydrocarbons. The molecular heats of combustion of the hydrocarbons are proportional to their valency numbers.—The velocity of hydrolysis of aliphatic amides by alkali: J. C. **Crocker** and F. H. **Lowe.** The reactions of the aliphatic amides with sodium hydroxide are shown to follow the bimolecular relation

$$K=\frac{1}{\alpha t}\left[\frac{1}{c}-\frac{1}{c^{\circ}}\right],$$

where α is the degree of dissociation of the alkali.—The addition of iodine to acetylenic acids: T. C. **James** and J. J. **Sudborough.**—The chemical changes induced in gases submitted to the action of ultra-violet light: D. L. **Chapman,** S. **Chadwick,** and J. E. **Ramsbottom.** Dry carbon dioxide is decomposed by ultra-violet light. The rate of contraction of a mixture of carbon monoxide and oxygen is practically independent of the degree of desiccation of the gases, due to the fact that, though the presence of moisture causes the rate of formation of carbon dioxide to rise, it results in an equivalent reduction in the yield of ozone.—Studies of the perhalogen salts, part i.: C. K. **Tinkler.**—The interaction of cyanodihydrocarvone, amyl nitrite, and sodium ethoxide: A. **Lapworth** and E. **Wechsler.**—Contributions to the chemistry of oxygen compounds, ii., the compounds of cineol, diphenylsulphoxide, nitroso-derivatives, and the carbamides with acids and salts: R. H. **Pickard** and J. **Kenyon.**

DUBLIN.

Royal Dublin Society, April 23.—Prof. J. A. McClelland in the chair.—Pleochroic halos: Prof. J. **Joly.** The paper is descriptive of more extended observations on the subject. Both in cordierite and biotite the halos attain a like maximum radius, and appear only formed around strongly radio-active enclosures. Their origin appears to be referable to some action of the α rays. In the radial dimension it is found to agree with Rutherford's measurements of the effective range of these rays in matter of similar density.—The quantitative spectra of barium, strontium, calcium, magnesium, potassium, and sodium: Dr. James H. **Pollok** and A. G. G. **Leonard.** The authors showed photographs of the spark spectra of solutions of these elements, using gold electrodes in the manner described in a previous paper, and the progressive disappearance of the lines on continued dilution was noted, the lines surviving with 1 per cent., 0·1 per cent., 0·01 per cent., and 0·001 per cent. of the element being tabulated. The paper is part of a scheme of work designed to facilitate the use of the spectroscope in its application to ordinary analytical work. The residuary or most persistent lines of an element are not necessarily the most intense as ordinarily tabulated, and when only a small quantity of an element is present it is only those residuary lines that show, hence the importance of their determination.

PARIS.

Academy of Sciences, May 6.—M. A. Chauveau in the chair.—Study of the variations in the solar radiation: H. **Deslandres.** After a discussion of the existing state of knowledge in this subject, the author concludes that the continuous study of the distribution of brightness over the surface of the sun should be organised with great care; if it does not furnish the intensity of the variation of the radiation, it shows the existence of this variation, or at least the existence of important disturbances, in a certain and rapid manner.—An extension of the Friedel and Craft reaction: A. **Haller** and A. **Guyot.** A description of the use of aluminium chloride in the condensation of secondary amines and numerous organic substances. Among the reactions studied are indigotin and dimethylaniline, benzil and dimethylaniline, orthodibenzoylbenzene, ethylphenylglyoxylate, benzophenone, isatin, all with the same base, and other condensations with diethylaniline.—The zoological position, the affinities and development of Peneides of the genus Funchalia: E. L. **Bouvier.**—The direct hydrogenation of the fatty isocyanides: Paul **Sabatier** and A. **Mailhe.** In the presence of reduced nickel at a temperature of 160° C. to 180° C., the primary reduction product of the carbamine R.N : C is the amine $R.NH.CH_3$. Some secondary amines are obtained as bye-products.—Study of the relations between the solar activity and the magnetic and electrical variations recorded at Tortosa, Spain: MM. **Cirera** and **Balcelli.** A discussion of the records for the first three months of the present year.—Differential equations of the second and the first degree the general integral of which is with fixed critical points: Bertrand **Gambier.**—Certain congruences of lines: Ch. **Michel.**—An automatic damping arrangement for the rolling of ships: V. **Crémieu.**—Plurivalent atoms: Henri **Pellat.** By admitting the hypothesis that a plurivalent atom consists of a collection of as many monovalent atoms as there are units of valency, numerous facts in electrolysis can be explained.—A speaking condenser: Timoléon **Argyropoulos.**—Wireless telegraphy: L. **Torres.** A discussion and criticism from the point of view of priority of a recent note on the same subject by M. Gabet.—The absolute atomic weight of bromine: Gustavus D. **Hinrichs.** A re-calculation of the analytical determinations of Baxter, from which the value 80·00 is obtained instead of the value 79·953 deduced by Baxter.—The application of the method of limiting densities to the permanent gases at 0° C.; the gas constant for perfect gases: Philippe A. **Guye.** From a critical discussion of the experimental data, the author concludes that the gas constant is not strictly constant, but increases with the critical temperature of the gas, and varies 1/2800 between hydrogen and nitric oxide. This variation is regular, and can be represented by the formula $R=22,410(1+10^{-5}T_c)$.—Inactive dilactic acid: E. **Jungfleisch** and H. **Godchot.**—Decahydronaphthylketone-α and decahydronaphthylamine-α: Henri **Leroux.**—The origin of serpentine and the crystallophyllian series of Aveyron and Gard: Jules **Bergeron.**—The culture of the forage Leguminosæ: J. **Dumont** and Ch. **Dupont.**—Sucrase in musts of apples and ciders: G. **Warcollier.**—The nuclear evolution of the schizonte of *Aggregata Eberthi*: L. **Léger** and O. **Duboscq.**—The origin of the zonal anodian blastoderms: Jan **Tur.**—Researches on the labic activity of the gastric mucus and on the supposed specific labogenic action of milk: Maurice **Dehon.**—The re-establishment of the pulsations of the heart in fibrillation: H. **Kronecker.**—The law of the hæmolytic effect of the Becquerel rays: C. J. **Salomonsen** and G. **Dreyer.**—The experimental reproduction of granular conjunctivitis in the ape, *Macacus sinicus*: C. **Nicolle** and M. **Cuenod.**—The organisation and systematic position of the genus Sezannella: René **Viguier.**

DIARY OF SOCIETIES.

THURSDAY, MAY 16.

ROYAL INSTITUTION, at 3.—Spectroscopic Phenomena in Stars, (2) Motion: H. F. Newall, F.R.S.

MENDELISM.

Mendelism. By R. C. Punnett. Pp. vii+84. (Cambridge: Macmillan and Bowes; London: Macmillan and Co., Ltd., 1907.) Price 2s. net.

A SECOND edition of Mr. Punnett's "Mendelism" has followed the first after an interval of two years. The book gives a very good account of Mendelian work. Issuing as it does from Cambridge, the source of by far the greater part of the Mendelian discoveries of the last six years, it is the most authoritative account of this subject, and as it is eminently readable it is the very book for anyone who wants to know what Mendelism is. It is cheap and of a very convenient size, and we cannot suppress an expression of our admiration for the beautiful purple colour of the cover of the second edition.

At the same time, no good can be done by refusing to face the fact that the truth of the Mendelian doctrine is not universally admitted. No one denies the extraordinary interest of these discoveries. He must be a very callous man who is not fascinated by the way in which the proportions 9:3:4 and 9:7 and the phenomenon of reversion in certain cases have all been brought into line. But we hold that he must be a very rash man who accepts without further question the doctrine of gametic purity. Yet it is just in the sphere of interpretation that Mendelians are so certain. Once in this sphere, we can no longer be guided by facts—if we were dealing with facts we should be in the sphere of discovery—but by "such things as our mind conceives." And one's attitude should be one of continual, unceasing, and active distrust of oneself. The attitude of the Mendelian is different from this. He may reply that he is only triumphant about his discoveries; but we must remember that there is no fixed criterion by which we can say where discovery ends and interpretation begins; and we must be careful not to beg the question by defining discovery as that about which there can be no doubt.

There are those who deny the theory that the germ cells of an extracted recessive are pure in respect of the character of the organism which contains them, and who assert that the characters of the hybrid which produced it are not absent from, but latent in, those germ cells. If this were discovered to be the case, it would be regarded as a demonstration of the falsity of the doctrine of gametic purity by everyone who was not a Mendelian. But we should strongly condemn the proclamation of such a conclusion, because we think it is high time that the spirit which derives satisfaction from the victory of one opinion over another should be swept from science. There is no place for the party system in science; because it tends to make the triumph of truth the main object and truth itself a secondary one. We are not arguing that Mendelian theory is untrue, but that the attitude of anyone daring to say of anything "this is true" should be apologetic rather than victorious.

There is another and a larger point of view from which we may examine the Mendelian position: it is that which refers to the relation between the Mendelian and the material with which he deals. The differences between biometrician and Mendelian have been due partly to the fact that these two sets of workers have dealt with different sets of facts. But we are concerned with the difference between their attitudes to the same classes of facts, and with the paradox that in spite of this difference they both claim to have introduced exact methods into biology. How is it that the two schools which claim to have introduced the exact method into the study of biology are not at peace? What is the relation between the methods of the two schools? One author attempts to express the difference in the statement that the Mendelian deals with units and the biometrician with masses, and illustrates this view by saying that the difference between the relation of the biometrician and that of the Mendelian to the units with which they deal is the same as the difference between the relation of the physicist and that of the Maxwellian demon to the units (the atoms) with which they deal. The physicist and the biometrician deal with them in masses. The demon and the Mendelian deal with them separately. It is striking testimony to the callousness of biologists to general discussion that it has never been pointed out that this comparison, though plausible, is based on a fallacy. To anyone who tries to take a broad view of the matter, the truth or falsity of the statement (repeatedly made by Mendelians) that the biometrician deals with masses while the Mendelian deals with units is the most interesting question presented by this whole subject. For if the Mendelian really does deal with units while the biometrician deals with masses composed of these units, and if the Mendelian sets out with the object of enabling himself to predict what will be the result of a given union, and succeeds, while the biometrician starts on the assumption that a knowledge of the ancestry of a given pair does not enable him to predict the character of its offspring, there is little to be said for the "application of exact statistical methods to the problems of biology."

But is it really true that the Mendelian deals with the units of which the biometrician's masses are composed? We believe not. In order to see what the real state of affairs is we must try to begin at the beginning. The difference between the two schools lies in the difference between their respective attitudes to natural phenomena. The biometrician says, "We look at them as close as we can and we see nothing uniform." The Mendelian, "We look as close as we choose and we see everything uniform." The latter does not pretend that "dwarf" peas are not variable, but treats them as if they were all the same. The former does not pretend they are not all "dwarf," but treats them as if they were all different.

The exactness of the biometrician makes him count the number of hairs per square centimetre on the lower leaf surface of *Lychnis vespertina*; the exactness of the Mendelian enables him to tell at a glance in a row of hybrid stocks which are hoary and which are glabrous. The two forms of exactness correspond to the two ways in which we may try to make certain of hitting the bull's-eye of a target when we shoot at it. We may either improve our marksmanship or enlarge the bull's-eye. The latter is the only method of ensuring uniformity, of enabling oneself to predict the result with certainty. To this the biometrician justly replies, "This is no real uniformity. It is an ideal uniformity substituted for a real variability. Your shots are scattered round the centre of your bull's-eye just as mine are scattered outside mine. I never hit. My bull's-eye is a point. I keep a record of the deviation of every single shot from it. I am faithful." To which the Mendelian replies, "I always hit. I keep no such records. I am successful." We do not hold a brief for either party. A bull's-eye so large that it cannot be missed is as unfair as one so small that it cannot be seen is unpractical. All we wish to insist on is that because Mendelians can predict and biometricians cannot, it does not follow that the units with which the Mendelian deals are the units of which the biometrician's masses are composed. The Mendelian's units *are* the biometrician's masses, except when the latter exceeds his limits and includes within his masses more than one such unit. The Mendelian can no more predict about the units of which the biometrician's masses are composed than the biometrician can, except when the biometrician includes more than one Mendelian unit in his mass.

CERTAIN ASPECTS OF SCIENTIFIC WORK.

Progress of Science in the Century. By Prof. J. Arthur Thomson. Pp. x+536. (London: W. and R. Chambers, Ltd., 1906.) Price 5*s.* net.

IN a book bearing the present title it is surely unfortunate to find that progress in one branch of science, and that certainly not the least important, is wholly ignored. Yet while chemistry, physics, astronomy, geology, physiology, psychology, and even sociology each has a separate chapter devoted to it, not a word is said about the remarkable developments that have taken place in mathematical science during the century. The changes which recent times have witnessed in regard to our conceptions of the notion of space are certainly no less remarkable, and are quite as capable of being outlined in a popular work as the kinetic theory of gases or developments of theories of the ether.

The study of matter and energy is so closely connected with the study of space that a discussion of the former without some reference to the latter must give a reader an incorrect impression of the present state of physical science. But the omission of frequent and explicit mention of the work of the mathematician in certain other directions is also likely to be misleading. Why, the reader may ask, is Lord Kelvin's vortex atom theory recognised—we will not say accepted—by the scientific world while Mr. Horatio Gubbins (to use a fancy name) has been pestering secretaries of societies and editors in vain with his theories of gravitation or the ether, and no scientific man will have anything to say to him? It may be that the reader in question is Mr. Gubbins himself. If he studies the chapters on "The Scientific Mood" and "The Unity of Science," he will find in them every justification for believing that his grand discovery marks a new era in the advancement of science. If, again, he turns to p. 178 and reads the paragraph "Value of these Hypotheses" at the end of the chapter on physics, he will find the sentence:—

"These molecular and ethereal hypotheses are human imaginings—and nothing more; they are constructed in terms of one sense; that of sight; they are attempts to see that which is invisible, to invent a machinery of Nature, since the real mechanism is beyond our ken; but it must be observed that these hypotheses are not *vain* imaginings, for they prove themselves yearly most effective tools of research, and that they are not *random* guesses, for they are constructed in harmony with known facts."

This statement may be true enough, but the *suppressio veri* in the omission of all reference to the rigid framework of mathematical equations and formulæ supporting the hypotheses conveys a dangerous *suggestio falsi* to the unmathematical reader. Mr. Gubbins is perfectly convinced that his own theory, at any rate, is constructed in harmony with known facts, whatever may be said about Lord Kelvin's theories, which he not unfrequently has "*proved convincingly*" are wrong, and he may even take unto himself to say that he has at last discovered a theory which is something more than a mere human imagining. No book of the present kind should be issued which does not strongly emphasise the fact that the true test of every scientific theory is in all cases a quantitative test based on a comparison of the formulæ of the mathematician with the measurements of the experimenter. Otherwise the English reader will be led to believe that the needs of science, which are now being pressed forward, can be adequately met by the erection of laboratories and the endowment of scholarships for passing elementary examinations, while the brain workers who interest themselves in researches carried out in their own studies with ink and paper will find themselves, as time goes on, more and more unable to cope with the accumulation of unsolved problems that is being pressed on them from every quarter.

Descending to matters of detail, we find many important theories conspicuous by their absence. We need only specify the phase rule and the second law of thermodynamics as instances in point. Yet the very possibility of a world existing which is inhabited by living beings, including man, depends essentially on this neglected second law. It seems almost unnecessary, in view of this omission, that the author should apologise in his preface for the absence of any reference to radium on the ground that the book was printed before the discovery had been made.

It cannot be denied that in attempting to trace the scientific progress of a century, even in its barest outlines, in a volume of this size the author undertook an impossible task. It is probable that he would have done better if he had confined his attention to discoveries made in the earlier part of the century, merely sketching their later developments. We do not blame the author for omitting many discoveries of importance, but it is a great pity that he did not realise that the present selection gives a somewhat one-sided view of scientific aims and methods.

Having said so much about a weak point in the book, it would be unfair not to dwell on several useful features. The specialist working in one branch of science is very apt to forget what he ever learnt about other directions of scientific progress. In these days, over-specialisation and over-elaboration are being carried to greater excess every year. Even the subdivision of the Royal Society's Proceedings into two series has completely destroyed their former all-round character. A book like the present, taken up and read in a leisure hour, will recall to the specialist many interesting points in the history of different branches of science of which he would otherwise never think. If there is one class of specialist who is more likely than others to benefit by reading the book, that is the mathematician himself, and next to him, possibly, the physicist. These in particular will be brought into contact with ideas quite different from those with which they are commonly associated, and it may be hoped that the mathematician will learn a lesson, and be less prone to hide his light under a bushel, when he finds how his genius is unappreciated by the writers of popular treatises.

G. H. BRYAN.

ANCIENT AND MODERN LEICESTER.

Glimpses of Ancient Leicester in Six Periods. By Mrs. T. Fielding Johnson. Second edition, with supplementary notes. Pp. xv+439. (Leicester: Clarke and Satchell; London: Simpkin, Marshall and Co., Ltd., 1906.)

THIS book was first published in 1892 as a "History of Leicester from the Earliest Times to the End of the Eighteenth Century." The present edition has been enlarged considerably by a supplement, in which more recent developments have been dealt with. The author belongs to a Leicester family which has taken a leading part in the public life of the town for several generations. Local histories are wont to be rather dull, but in this case, thanks to a lucid and lively style, the writer has succeeded in producing a volume of more than usual attraction for the general reader.

Leicester appears to have been an important Roman settlement, of which the chief remains are a part of the old rampart, now called the "Jewry Wall"; some fine examples of tesselated pavements; and a milestone with an inscription to the Emperor Hadrian, said to be the oldest stone inscription in Britain. During Saxon times the Church of St. Nicholas was built on the site of a Roman temple. This church "still includes in the north wall of its nave portions of the identical walls of the original Saxon church, showing a quantity of material taken from the Jewry Wall and other ruined Roman buildings near the spot." "Under the Norman and Plantagenet kings, Leicester reached its highest point of importance as a mediæval borough," under its greatest earl, Simon de Montfort. Several buildings of this period are in existence; amongst them may be mentioned the Newark Gateway and the Old Town Hall. Memorials of the sixteenth century may still be seen in the Abbey and the Queen Elizabeth Grammar School.

The supplement gives an interesting account of the development of the place from a market town with a population of 17,000 at the end of the eighteenth century into an industrial centre of nearly a quarter of a million people.

In this connection reference should be made to the excellent description of the rise and progress of the present important knitting and hosiery trade. A great impulse was given to the prosperity of the town by the opening of the Leicester and Swannington Railway. This was the second railway in the country, and was built by George Stephenson in 1832. Some of the original rails and other specimens of early railway work are preserved in the town museum.

This useful institution owes its origin to the Literary and Philosophical Society, through which it gained the nucleus of its present valuable collection. The scientific activity of the town has always centred round this society, which was founded in 1835.

The attention of the reader of Mrs. Fielding Johnson's book will be attracted to the names of several of her townsmen who have attained distinction in scientific pursuits, amongst whom may be mentioned Russel Wallace, the naturalist Bates, and another, not so well known, Mr. Ludlam, who assisted Dollond in the production of achromatic lenses for his telescopes.

The history of the educational institutions of the town receives adequate treatment. Secondary education is mainly in the hands of the Wyggeston and Queen Elizabeth Grammar Schools, and Alderman Newton's School, the latter an eighteenth-century foundation. During last century a working men's college and a mechanics' institute were started. The former does useful work still, whilst the latter has developed into a fine technical school.

A special interest attaches to the new edition of this attractive work in view of the forthcoming visit of the British Association to Leicester, and intending visitors would find in it a pleasanter account of their place of meeting than the pages of an ordinary guide-book can afford. The book is admirably illustrated, and is provided with an index.

R. E. T.

A NEW LIFE OF HUXLEY.

Thomas H. Huxley. By J. R. Ainsworth Davis. (English Men of Science Series.) Pp. xi+288. (London: J. M. Dent and Co., 1907.) Price 2s. 6d. net.

MR. DAVIS has produced in small compass an account of the life and work of Huxley that is at once readable and stimulating. It was inevitable that he should draw largely upon Mr. Leonard Huxley's biography of his illustrious father, but the materials have been skilfully employed, and the book is far from being a mere abstract of the larger work. Huxley's energy, industry and fixity of purpose are brought into due prominence; while his intellectual keenness and honesty, his intolerance of pretentious ignorance, his appreciation of everything good in art and literature, his jealousy for the right use of the mother tongue, his admirable social and domestic qualities, all have ample justice done to them in the pages of this modest volume.

The attentive reader will easily discern how it is that among the great names of the Victorian epoch few take a higher place than that of Huxley. Eminent as an original worker in science, whose investigations covered an unusually wide field, he was scarcely less distinguished as a philosopher and as a practical man of affairs. By dint of unwearied industry, of a single-minded love of truth and of a nature at once candid and fearless, he made for himself a reputation in the intellectual life of the last century which will outlive many of those that, for the time being, bulked more largely in the public view.

In controversy, as Mr. Davis often reminds us, Huxley was a strenuous but never ungenerous adversary, though it sometimes seemed hard for him to realise that his opponents might hold their convictions as sincerely as he did his own. The popular notion of Huxley as an intellectual pugilist who found his chief delight in propounding dogmas, the more startling the better, in science and philosophy, is scarcely borne out by the facts of his career. It is true that in his own judgment he was "rather prone to jump at conclusions," and when he felt sure of his ground no man could speak with greater confidence. But questions, even of the first magnitude, as to which the data were not in his opinion sufficient for a solution, were by him left open to the end.

Perhaps the most conspicuous instance of this truly "agnostic" attitude was the position he took up in reference to Darwin's theory of natural selection. Curiously enough, while his acceptance of the fact of evolution was hastened, if not caused, by the publication of the views of Darwin and Wallace, he never committed himself to an unqualified approval of those views. He was converted *by*, but not *to*, the doctrine of natural selection. This, however, did not prevent him from acting as Darwin's champion against attacks dictated by ignorance and prejudice, nor from treating the Darwinian hypothesis as "the most powerful instrument of investigation which has been presented to naturalists since the invention of the natural system of classification, and the commencement of the systematic study of embryology."

It is probable that we here touch upon one of Huxley's limitations. Unrivalled as he was in many departments of biology, it is clear that field natural history did not come to a great extent within his sphere of mental activity. Had this been otherwise, and had his attention been more directed to the study which now goes by the name of bionomics, it seems fair to conjecture that his views as to the validity of Darwin's theory might have undergone some modification.

There are certain slips in Mr. Davis's book which should be remedied in a future edition. We note a few, as follows:—*Ephestia elatella* (*recte* elutella) is not a "small beetle," but a Phycid moth. In the letter given on pp. 204–5, Huxley wrote "inconceivable," where Mr. Davis has "conceivable" with much detriment to the sense of the passage. Finally, Duns Scotus we know, and Scotus Erigena we know, but who is Scotus Erigenus?

F. A. D.

PHYSICAL AND INORGANIC CHEMISTRY.

(1) *Practical Physical Chemistry*. By Dr. Alex. Findlay. Pp. xii+282; illustrated. (London: Longmans, Green and Co., 1906.) Price 4*s*. 6*d*. net.

(2) *Physical Chemistry in the Service of Medicine*. Seven addresses by Dr. Wolfgang Pauli. Translated by Dr. Martin H. Fischer. Pp. ix+156. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1907.) Price 5*s*. 6*d*. net.

(3) *Vorlesungen über anorganische Chemie für Studierende der Medizin*. By Dr. Ernst Cohen and Dr. P. van Romburgh. Pp. viii+431; illustrated. (Leipzig: Wilhelm Engelmann, 1906.) Price 15 marks.

(1) SLOWLY but surely the necessity of systematic laboratory instruction in the methods of physical chemistry is being recognised. One of the causes which may have contributed to the absence of such instruction in many university courses of chemical study has been the lack of a suitable practical textbook. With the appearance of Dr. Findlay's work this regrettable deficiency in laboratory literature can, however, be no longer said to exist. The apparatus required for the measurement of density, viscosity, surface-tension, refractive index, molecular weight, conductivity, transport numbers, electromotive force, velocity of chemical change, solubility, transition temperatures, and thermal changes is described, and instructions for the carrying out of the measurements are given in an easily intelligible form.

The course is modelled on that of the Leipzig school, which for many years occupied a unique position as the Mecca of students of practical physical chemistry. This is doubtless partly due to the author's personal association with this particular school. It may perhaps account for the omission of several important types of experimental exercises. In particular, electrochemical experiments involving the estimation and separation of the metals and the preparation of different classes of compounds afford many valuable applications of physicochemical principles, and the omission of chapters dealing with these phases of the subject is regrettable. Some difficulty may be experienced in interpreting what is meant by the term "maximum apparent error" in the first chapter. With a vocabulary of errors in which relative, absolute, possible, probable, and apparent errors may be spoken of, a careful definition of terms is essential. In the dilatometric determination of transition temperatures (p. 274), Glauber's salt is not nearly so suitable as some other substances for the purposes of a laboratory exercise.

Of the usefulness of the book as a laboratory guide there can, however, be no doubt; it should be in the hands of every serious student of the science.

(2) Dr. Pauli's volume is a collection of seven addresses delivered at various times by the author, and deals with the application of physical chemistry to various branches of medicine—physiology, pharmacology, and pathology—an application rendered possible more particularly by the recent advances made in the study of organic colloids. The problems discussed are of fundamental importance, and even though it be true that "life can perhaps be completely understood only through life itself," yet the volume before us indicates that many great advances may be expected by the proper utilisation of the instruments afforded by physical chemistry. In the separate chapters an account is given of the physical chemistry of cells and tissues, the colloidal state and the reactions in living matter, the relations between ions and their medicinal and therapeutic effects, the changes effected in pathology by recent chemical work, and the significance of the electrical charge of protein. The entire omission of literature references to the large number of investigations by authors whose names are quoted is most unfortunate. The translation is good, although it is not difficult to recognise in it the work of a medical man rather than that of a physical chemist. In medical circles the book should be of general interest.

(3) A distinctive feature of the lectures on inorganic chemistry is the authors' attempt to minimise the number of chemical compounds described, and to illustrate by carefully selected examples the most important general phenomena and the laws which regulate them. In the opinion of one who has had some little experience in the chemical training of medical students this is a distinctly gratifying feature. Whether it is not possible greatly to improve the training of the medical student by demanding a smaller knowledge of isolated facts and a more extended acquaintance with general principles is a question which demands serious consideration. In the twenty-eight lectures, into which the subject-matter is divided, the attention of the reader is continually directed to general relationships in discussing particular facts, and this cannot but have a satisfactory effect on the chemical aspect of the future medical man. For 430 pages of elementary inorganic chemistry fifteen marks is a singularly high price to have to pay, and may be prohibitive to many would-be purchasers.

H. M. D.

OUR BOOK SHELF.

Practical Coal Mining. By Leading Experts in Mining and Engineering. Edited by Prof. W. S. Boulton. Divisional, vol. i. Pp. vii + 160. (London: The Gresham Publishing Company, 1907.) Price 6s. net.

THIS is the first instalment of a work which, when completed in six volumes, is intended to cover the whole ground of modern coal-mining practice. Each of the sections into which the work is divided will be written by a different author, fourteen leading authorities cooperating with the editor in his task. This division of responsibility among many contributors, and the fact that orders are accepted for complete sets only, render it difficult to judge from the first volume what the value of the work as a whole will be.

In the first volume there is undoubtedly a certain want of harmony in treatment of the subject-matter. There are three sections and part of the fourth, dealing respectively with the geology of the Coal-measures, the composition and analysis of coal, trial borings, and shaft sinking. The section on geology, written by the editor, covers sixty-six pages, and contains much useful information. It is questionable, however, whether, in a treatise on practical mining, it is possible to deal usefully with so comprehensive a subject or to give sufficient detail to render the geological manuals superfluous. As an illustration, the information regarding foreign coalfields, which has had to be compressed into a single page, is not nearly so full as that contained in Geikie's "Text-book of Geology."

The editor's literary style, too, is far from faultless. His opening sentence, for example, cannot be regarded as elegant in composition. It reads as follows:—"While some knowledge of geology is necessary for all mining engineers and others connected with coal mining, and especially the ability to construct and interpret geological plans and sections, there are certain branches of the science which bear upon coal mining only very indirectly, and which at present are of theoretical rather than practical importance, and which, therefore, it has been thought advisable to omit in the following pages."

The second section, on the composition of coal, has been written by Mr. C. A. Seyler. It describes the author's new system of classification, or rather of new chemical terms, and does not seem likely to commend itself to practical men, who would probably find such expressions as "sub-para-bituminous-pseudo-anthracitic species" somewhat cumbersome. The third section, on trial borings, which has been written by Mr. H. F. Bulman, is admirable. It contains as much practical information as could possibly have been compressed into thirty pages. The fourth section, on shaft sinking, as far as published, is equally good. Written by Prof. H. Louis in excellent literary style, the information is clearly given, and its value is increased by the introduction of hitherto unpublished details of cost, and by the fact that the illustrations, unlike others in the volume, have in every case an indication of the scale to which they are drawn.

Morale de la Nature. By M. Deshumbert. Pp. 74. (London: D. Nutt, 1907.) Price 1s. net.

THE first part of this essay is devoted chiefly to the thesis that the object of all creation is to produce those forms of life which are the most active, intelligent, and moral possible, that is, life in its most complete form. Good is that which contributes to the increase of life in its high development, and evil is that which has a contrary effect. The latter half of the essay consists of ethical aphorisms which we commend to the notice of the Moral Instruction League.

Spring Harbingers and their Associations. By M. G. B. Pp. 62. (London: Elliot Stock, 1907.)

THE writer of these six short essays on the snow-drop, violet, daffodil, cowslip, daisy, and rose, not only loves flowers, but evidently has made a practice of recording references to her favourites made by the poets she has read—and these are a goodly company.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Structure of the Ether.

THE recent interesting communication of Sir Oliver Lodge to NATURE (March 28) and the *Philosophical Magazine* on the density of the ether recalls an objection to theories of the ether which identify magnetic intensity with resultant ethereal velocity that does not seem to have received the attention it deserves. The objection arises when the distribution of momentum in the system is taken into consideration.

It will be remembered that Sir Oliver Lodge commences by pointing out that the volume occupied by the electrons which constitute a mass of platinum is small compared with the volume of the platinum itself, whence it follows, if the mass of the electrons is that of the ether they carry with them, that the density of the ether must be enormous compared with that of platinum. This conclusion appears to be inevitable if we are to have a hydrodynamical theory of the ether. I do not wish to contest the contention that the density of the ether is enormous.

The second method used by Lodge to evaluate the density of the ether assumes that the magnetic intensity at any point is always proportional to the speed of the ethereal flow. By equating the mechanical and magnetic expressions for the energy of the field, and assuming that the ethereal circulation at the equator of an electron is equal to the velocity of its forward motion, Lodge arrives at the relation

$$e=4\pi a^2\sqrt{\frac{\rho}{4\pi\mu}},$$

where e is the charge and a the radius of an electron, and ρ is the density and μ the magnetic permeability of the ether. This may be combined with the known values $e^2\mu=10^{-40}$ gm. cms. and $a=1\cdot2\times10^{-13}$ cms. to give $\rho=3\cdot83\times10^{10}$ gms. per c.c. This gives for the velocity of ether drift in a magnetic field of intensity equal to 1 electromagnetic unit the value $w=1\cdot44\times10^{-6}$ cms. per sec. These figures enable us to calculate the momentum due to any given magnetic distribution.

A moment's consideration of the simplest possible case, that of a moving charged sphere or an electron, will serve to show that this distribution of ethereal velocity leads to impossible results. We have seen that $\rho=e^2\mu/4\pi a^4$, and by making use of the expression for the magnetic field due to a moving charged sphere of radius a we find that the velocity of ethereal flow w, at a point the coordinates of which are r, θ with respect to the electron and its line of motion, is given by

$$\tfrac{1}{2}\rho w^2=\frac{\mu e^2u^2\sin^2\theta}{8\pi r^4}$$

or

$$w=\frac{a^2}{r^2}u\sin\theta.$$

Hence the momentum per unit volume at a point r, θ from the centre of a sphere of radius a and charge e moving with velocity u is given by

$$\rho w=\frac{e^2\mu u}{4\pi a^2}\,\frac{\sin\theta}{r^2}.$$

Since the momentum is distributed in circles round the line of motion there is no resultant momentum, but if the above expression be integrated it will be seen that there is an infinite quantity of momentum in the field for any finite value of u, and, moreover, there is an infinite moment of momentum about the line of motion. The existence of this momentum would make it impossible to set a charged sphere in motion; the same result would be arrived at by any theory which makes the velocity of the ether proportional to the magnetic force.

Electrodynamic theory has led to an expression for the momentum per unit volume of the ether by ways which are less speculative. This expression is $1/4\pi$ times the product of the electric and magnetic displacements, and it has the merit of making the momentum in the ether equal to the product of the (electric) mass and velocity of the moving charge. If we are to have a hydrodynamical theory of the ether it seems reasonable to make this agree with the fluid momentum. We thus get for the case of the charged sphere

$$\rho w=\frac{\mu e^2u\sin\theta}{4\pi r^4},$$

and from the energy expressions

$$\rho w^2=\frac{\mu e^2u^2\sin^2\theta}{4\pi r^4},$$

whence $w=u\sin\theta$ and $\rho=\mu e^2/4\pi r^4$. This result makes the velocity of flow of the ether independent of the radial distance from the electron, but the amount moved varies inversely as the fourth power of the distance. It has been pointed out by J. J. Thomson that this result can be interpreted hydrodynamically by supposing that the ether is carried along by the tubes of electric force, and that the extent to which the ether is "gripped" by the tubes of force is proportional to the square of their concentration. If we suppose the whole of the ether to be carried along at the equator of the electron, this method would give the same estimate for the density of the ether as that found by Lodge. If only part of the ether were carried along by the tubes of force even at the equator of an electron, the density of the ether would have to be correspondingly increased, so that this method can be regarded as giving the value $\rho=\mu e^2/4\pi a^4=3\cdot85\times10^{10}$ gms. per c.c. as an inferior limit to the density of the ether. The actual value may be much greater than this.

The hypothesis of no ether slip at the equator of the electron leads to what seems to be a difficulty, at present at least. From what has been said it will be seen that it definitely establishes the relation $e=4\pi a^2\sqrt{\rho/4\pi\mu}$, so that the charge on an electron is equal to its superficial area multiplied by a quantity which depends only on the properties of the ether. Thus the size and mass of any electron are determined as soon as its charge is known, and any one of these quantities is determined by any non-identical combination of the others. The experiments of Bragg on the stopping power of different substances for α rays lend support to the suggestion, first put forward by H. A. Wilson, that these are positive electrons. Now the experiments of Rutherford have shown that the value of e/m for the α rays emitted by a large number of radioactive elements is very nearly 5×10^3 e.m.u. per gm. This value of e/m leads, on the hypothesis of no equatorial slip, to the value $e_2=10^{-13}$ e.m.u., or 10^7 times the charge on the negative electron. It would be difficult to make an electron with a charge of this magnitude the foundation of atomic structure. This difficulty occurs with at least equal force on the assumption of magnetic ether flow.

The argument of the last paragraph, so far as it is deserving of weight, tends to show that the ethereal density is greater than the limiting value. The considerations brought forward earlier would appear to show that the ethereal flow, if it exists, is at right angles to, and not along, the lines of magnetic force, and that the effect sought for experimentally by Sir Oliver Lodge is not to be expected. O. W. RICHARDSON.

Princeton, N.J., May 12.

Radium and Geology.

WITH apologies to Prof. Joly (p. 55), I think my estimate of a gradient of 1° F. for 98 feet in the Simplon Tunnel will bear examination. From a contemporary notice in the *Daily Mail* of October 3, 1904, it is clear that the heat in the tunnel was endurable until the hot spring was tapped. The water is stated to have been at 131° F., which agrees *exactly* with 55° C., "the highest temperature" of Prof. Joly. Surely, then, this was the temperature of the spring, and not of the rocks.

I would also remark that Mr. Strutt considered that the amount of radium in the igneous rocks examined by him would, on his theory, account for a gradient as high as 1° in 42·2 feet, a very different thing from the 1° in 70 mentioned by Mr. Fox. O. FISHER.

Graveley, Huntingdon, May 17.

Eye Migration in Flat-fishes and Lamarckianism.

MR. R. H. LOCK, in his recent book on "Variation, Heredity, and Evolution" (reviewed in NATURE of April 27), has, in common with many other writers, adduced the phenomenon of eye transposition in flat-fishes as a cogent argument in favour of the transmission of acquired characters, remarking that "an alternative hypothesis is lacking." I venture to dispute this position, believing it to be decided evidence in support of the potency of natural selection to accumulate small mutations. I quote a part of the passage (p. 35) that my argument may be the better understood:—

"In the adult condition these fishes lie flat on one side; and during their development from the young condition that eye which, if it remained in its original position, would look directly downwards travels round the head until it comes to lie quite upon the upper surface. . . . The very young fish whilst still symmetrical, are known sometimes to fall upon one side, and when in this position to twist the lower eye forcibly upwards. Darwin himself therefore supposed that the origin of the adult structure is to be attributed to the inherited effect of efforts of this kind."

This misinterpretation of the phenomenon seems to me to arise from an inadequate appreciation of the nature of the actual variation, *i.e.* the *capacity to twist the eye*, which is exhibited by the young fish. The young of some other fish are known to exhibit the same muscular control over the orbit ("Origin of Species," p. 292), and we need only to suppose that the forerunner of the modern race of flat-fishes possessed it as a fortuitous variation to the extent of making vision just possible whilst in the recumbent position; and this would seem to be the case, for it is recorded in the "Origin of Species" that a young fish has been observed to "raise and depress the eye through an angular distance of about seventy degrees." In the transmission of the original variation to the offspring it is not the *effect* of the movement which is passed on, but the *structural arrangements which enabled it to initiate the movement*, the amplitude being increased in successive generations by the aid of natural selection.

This contention may be supported by citing a peculiar muscular capacity possessed by myself. I am able to raise and depress the right eyebrow independently of the left, but I have no such control over the other. To test whether this power may not be induced by practice, I have striven to raise the left whilst holding down the right, but find myself quite unable to accomplish it. Herein we see that the capacity to make the movement is of itself a distinct mutation; and assuming that in the case of the flat-fish mobility of the optic aperture was so far possible as to be of advantage to it, natural selection would operate in preserving those of the progeny which were able to retain the eye in the advantageous position with the least possible effort.

I have ventured to tender this explanation to the readers of NATURE because the phenomenon is very generally used as a good illustration of Lamarck's doctrine, and as being "inexplicable on the theory of natural selection."

Bournemouth, May 10. ARTHUR J. HAWKES.

TWO WORKS ON INDIAN ETHNOGRAPHY.[1]

MR. CROOKE'S book appears in a series edited by Mr. N. W. Thomas which, to quote the general preface, "is intended to supply in handy and readable form the needs of those who wish to learn something of the life of the uncivilised races of our Empire." To Mr. Crooke has been entrusted the task of describing the races of northern India, and we may at once state that he has achieved very considerable success. The area covered, extending from Afghanistan to the Chinese frontier, is so great, and its aspects are so complicated, that not even such an authority as this distinguished scholar could venture into details within the limits of the two hundred and fifty odd pages at his disposal; but he has given a broad general view, sketching in with a few accurate and telling strokes the more prominent features of the landscape, so that the whole presents a satisfactory and attractive summary of the racial characteristics of an important section of the British Empire.

After a brief account of the country and of the influence of its environment upon the people, Mr. Crooke describes its three main physical race-types—the Mongoloid, the Dravidian, and the Indo-Aryan. The last-named leads him to the consideration of the castes of the great plains, to the Indian village and its industries, and to the home life, including the occupations of women, together with the games and amusements of the children. Turning to the religion of the people, we have first an account of the birth, marriage, and death rites, and then a general description of the popular religion, magic, and witchcraft. There are more than thirty admirable full-page illustrations, the value of which is somewhat impaired by the binder having placed them at approximately equal distances from each other throughout the book, without consideration of the context to which they refer, and which, in spite of a good index, it is not always easy to find. In other respects, too, the mechanical execution of the work leaves room for improvement. Proper names are not always spelt correctly. The well-known Norwegian philologist appears as Dr. "Steinkonow," and the proof-reader's ideas of the spelling of the name of a writer on Chota Nagpur oscillate between "Bartley-Birt" and "Bradley-Birt," the latter, of course, being the correct form. Worst of all, the numbering of the plates was evidently altered after the text had been printed off, so that not a single reference in the text to the plates is correct.

These are, however, but minor matters, which can easily be set right in the next edition, and for the work as a whole, although we may differ on a few controversial points, we have nothing but praise. Mr. Crooke, while following Mr. Risley in his conclusions as to the race-origins of the Indian people, shows a wise caution in accepting his opinion with regard to details, and, like other scholars, enters a protest against his undue extension of the name "Dravidian" (properly a linguistic term) to the entire mass of the population of northern India which is not Aryan or Mongolian. He himself, on the other hand, seems to have misunderstood the results of the latest philological researches when he states that it has been recently proved that the two great non-Aryan linguistic families of India, the Munda and the Dravidian, are mutually connected. He quotes Dr. Grierson's authority for this; but we are under the impression that, in his latest writings, that scholar has strongly maintained the distinct origin of these two groups of speeches, and the researches of Pater Schmidt, of Vienna, have shown that the Mundas are related, both ethnically and linguistically, to the Mon-Khmer tribes of Further India, and perhaps even to the inhabitants of Polynesia. As for the Dravidian languages, it seems not improbable, although positive proof is yet wanting, that they are connected with those of the aborigines of Australia. The fact that the speakers of Dravidian languages and the speakers of Munda languages have the same physical type has not yet been satisfactorily explained, but Dr. Sten Konow's theory that the common type is really Munda, and has been acquired by the Dravidian-speakers through intermarriage (just as the Indo-Aryan type of the Lower Ganges

[1] "The Native Races of the British Empire. Natives of Northern India." By W. Crooke. Pp. xiv+270. (London: A. Constable and Co., Ltd., 1907.) Price 6*s*. net.

"The Khasis." By Major P. R. T. Gurdon, I.A. With an Introduction by Sir Charles Lyall, K.C.S.I. Pp. xxvii+227. (Published under the Orders of the Government of Eastern Bengal and Assam. London: D. Nutt, 1907.) Price 7*s*. 6*d*. net.

Valley has been similarly altered) is at least worthy of attentive consideration.

In dealing with the general race question, Mr. Crooke adopts the only scientific method (too often neglected) of commencing at the bottom with the so-called aborigines and working upwards through the mixed tribes to the pure Indo-Aryan. His account of the wild hill-tribes, whether Mongoloid or Dravidian, is excellent, and brings together a mass of information that has hitherto been scattered through a number of not always accessible memoirs. When he comes to the Gangetic plains he is on his own ground, and writes at first hand. His unrivalled acquaintance with the people of the United Provinces, their customs, and their religion, makes this the most valuable section of the book. The

FIG. 1.—Raja of Rampur, with attendants, Punjab Hills. From "Natives of Northern India."

thorny question of the origin of caste could not be adequately discussed without trenching on space which might more legitimately be devoted to other purposes, and he contents himself with stating his own opinion, which is a modification of that put forward by Mr. Risley. He considers that castes owe their inception partly to crystallisation of occupation and partly to the persistence of the idea of tribe. He gives the reader a vivid picture of the home-life of the plains villages. It is one with which most Indian officials and missionaries are familiar, but which has seldom been put in print. The existence of an Indian agriculturist is a laborious one, with little to relieve its monotony except a rare pilgrimage or the occasional chance of the greatest luxury of all, a lawsuit. Perhaps Mr. Crooke lays too much stress on his alleged ignorance of any literature. While books are almost unknown to him, he has not only ballad poetry, much of it of real excellence, but is more or less familiar with the works of the great religious writers of his country, such as Kabīr or Tulsī Dās, and has had their best verses ready on his lips since childhood. Here, too, we may point out that while Mr. Crooke's account of Indian village religion is, so far as it goes, masterly, it only illustrates one side of the subject, the worship of local deities. He has failed to take into consideration the results of the great reformation of Hinduism which swept over northern India in the

FIG. 2.—A Panka, Dravidian Weaver, Southern Hills. From "Natives of Northern India.

sixteenth century, and which has, in Rāma, given the village people a personal supreme deity, whom they can and do worship, and who is above all the local gods and godlings. The essence of the reformation was the discovery of the Fatherhood of God, and that fact alone has had immense influence in moulding the general character of the population of the Gangetic Valley.

If we have criticised a few of Mr. Crooke's statements, we freely admit that they deal with points of detail, some of which are objects of controversy. We can strongly recommend his book to the general reader who desires information regarding the native races of northern India. His style is always interesting, and there is not a dull page from beginning to end of the volume.

Major Gurdon's work is the first of a series of monographs on the more important tribes and castes of Assam now being issued by the Government of that province. While Mr. Crooke deals with the broad outlines of the ethnology of the whole of northern India, this work is confined to a single tribe numbering less than two hundred thousand souls. Although they are so few, the Khasis are a race deserving special study. Half a century ago Logan showed their relationship to the distant Mons of Pegu and Khmers of Cambodia, but his researches lay hidden in a local magazine, so that, until Kuhn revived the question in 1883, it was the general impression that the tribe was an isolated survival from prehistoric times, whose language formed a distinct family by itself, and which had no connection with any other known race. The researches of Kuhn, and, later on, of Schmidt, have placed the whole subject on a new and sure footing. We now know that Khasi is a member of an important group of languages including forms of speech, such as Palaung and Wa, closely allied to Mon and Khmer, and also Nicobarese and the Munda tongues of India proper. Moreover, not only are the languages connected, but the speakers all possess the same racial characteristics. This language-group Schmidt has named the "Austro-Asiatic" subfamily, and he maintains that it is related to the "Austro-Nesic" subfamily spoken in Indonesia, Polynesia, and Melanesia—the two together forming, under the name of the "Austric" family, the most widely spread collection of allied speeches upon the face of the earth. A special and minute study, therefore, of the speakers of one of the members of this great family is just now well-timed and of considerable interest, and Major Gurdon, the superintendent of ethnography in Assam, is exceptionally fitted to undertake the task.

For the benefit of those who are not familiar with Indian ethnography, it may be stated that the Khasis are a tribe inhabiting the Khasi and Jaintia Hills in the Indian province of (as it is now called) Eastern Bengal and Assam. They are surrounded on all sides by alien peoples, Tibeto-Burman and Aryan, and are believed to be a survival of a primitive Austro-Asiatic race that once occupied the whole of eastern India until they were conquered and dispossessed in prehistoric times by an invasion of Tibeto-Burmans. The tribal constitution is strongly matriarchal. Inheritance is through the female line, the youngest daughter being the chief heir of her mother; ancestral property can only be owned by women, and the only property which a man can possess is that which is self-acquired. The chief deities are all female. So is the sun, while the moon is represented as a man, and in the grammar and vocabulary the feminine element is much more prominent than the masculine.

Besides chapters discussing introductory and miscellaneous topics, Major Gurdon's work is divided into five sections, dealing respectively with domestic life, laws and customs, religion, folklore, and language. Each subject is treated in great detail, and the book contains much new and valuable matter not hitherto recorded. We may direct special attention to the account of the remarkable memorial stones, menhirs, dolmens, and cromlechs scattered over the country, and also to that of the curious custom of egg-divining (ᾠοσκοπία). The chapter on folklore is also most interesting. It contains a number of stories, both in the original text and in translation. These form part of a larger collection placed at the author's disposal by the Rev. Dr. Roberts, and we are glad to learn that there is a prospect of the entire series being published at some future date. The full-page illustrations of the book are numerous and in their right places, and it is further enriched by an introduction from the accomplished pen of Sir Charles Lyall.

There have been Welsh missionaries among the Khasis for more than sixty years, and to them we owe the fact that the language has been reduced to writing. Under their fostering care the tongue of a once rude and barbarous people has been given an alphabet, a fixed system of spelling (based on Welsh), and a literature. It is now recognised by the Calcutta University as sufficiently cultivated to be offered as a subject for examination by candidates from Khasi-land.

We congratulate the Eastern Bengal and Assam Government on the successful inception of what promises to be a most interesting and useful series of monographs.

ASTRONOMICAL OBSERVATIONS IN PRAGUE, 1900–1904.

THE Astronomical Observatory of Prague, like many other similar institutions which might be mentioned, has its work considerably restricted by the fact that the city in which it is situated has grown. The restricted horizon, the smoke, and the glare of the illuminated air all have tended, year by year, to cut down the amount of useful work such an observatory is capable of doing, and it is quite possible that the time will soon come when it will

Tycbo Brahe's Observatories. A, On the island Hveen (Uranienberg); B, in Wandsbeck; C, in Benatek; D, in Prague (Ferdinandeum); E, in Prague (Curtius's House).

be transferred to a site where its sphere of activity can be extended.

The volume[1] before us contains, therefore, some of the results of observations which can be carried out under such restricted conditions. Of these may be mentioned an excellent series of observations of the culmination of the moon and the crater Mösting A. The determination of the latitude of the observatory was also undertaken. The result obtained, namely, 50° 5′ 16″.02, was in complete agreement with the value obtained by Prof. E. von Oppolzer from observations made in the period 1889 to 1899. Other work here described refers to the observations of Jupiter's satellites, Nova Persei, shooting stars, &c.

The appendix contains, further, a series of useful papers by Prof. Weinek. These, for the most part, deal with some graphical explanations of the theory of the sextant, precession, planet-transits across the sun's disc, cometary orbit determinations, &c.

October 24, 1901, being the 300th anniversary of the death of Tycho Brahe, some very interesting historical notes are given relating to his two years' activity (1599–1601) in Prague. The reader may be reminded that this celebrated Danish astronomer died in Prague, and in the Teynkirche there a handsome gravestone marks his resting-place.

During his lifetime Tycho Brahe had five different observatories, and these were situated (*a*) on the island of Hveen (Uranienberg), (*b*) in Wandsbeck, (*c*) in Benatek, (*d*) in Prague (Ferdinandeum), and (*e*) in Prague (Curtius's House). These are shown in the accompanying illustration, which is taken from one of several of the fine reproductions inserted in this volume.

Others to which reference may be made are a fine coloured reproduction, in colours, of Tycho Brahe from an oil painting in the Prague Observatory; the Belvedere of Ferdinand I. (Ferdinandeum), where he observed; the Teynkirche, where he was buried; his two sextants, and other interesting reproductions of the Prague of to-day.

The volume concludes with a useful summary of the chief lunar maps and photographic moon atlases, commencing with Lohrmann (1824) and finishing with W. Pickering's atlas which was published in 1903.

[1] "Astronomische Beobachtungen an der k.k. Sternwarte zu Prag, in den Jahren 1900–1904." Auf öffentliche Kosten herausgegeben von Prof. Dr. L. Weinek. (Prag: K.U.K. Hofbuchdruckerei A. Haase, 1907.)

THE DISCOVERY OF STONE IMPLEMENTS OF PALÆOLITHIC TYPE IN VEDDAH CAVES.

DRS. F. AND P. SARASIN recently made an expedition to Ceylon for the express purpose of investigating the caves now and in past times inhabited by the Veddahs, to see whether any stone implements could be discovered. Their earlier researches proved the Veddahs to belong to a lower and older type than the other inhabitants of Ceylon, and it is conceded that they must represent the few remnants of the aborigines who were met with by the Sinhalese on their first arrival, and by whom they were called Yakas, according to the tradition preserved in the Mahawansa. Presumably, these autochthones were at that time living in their Stone age; but no record of Veddah stone implements occurs in anthropological literature. From an article in the *Ceylon Observer* of April 22, written by these indefatigable travellers, we find that on this, their fourth, expedition into the Veddah country they were lucky enough to find a cave near the village of Nilgala, which until very recently was inhabited by Veddahs, the soil of which contained in great abundance stone implements of a very rough kind. Further investigations of some other caves, one near Kattragam, the other near Kalodai, led to an identical result. They also succeeded in discovering upon the hilltops of the country of Upper Uva the same rough stone implements in great quantities and still well preserved. Not only the autochthony of the Veddahs can be regarded as a proved fact, but also their former distribution over probably the whole island, including the low country as well as the mountainous districts.

The shape of the chips, knives, lance points, scrapers, and fragments of bone awls enables this stone-industry to be described as analogous to that of the Madelaine period of the Palæolithic age. "Yet," as the cousins Sarasin remark, "this industry is to be denoted as a special *Facies Veddaica*, inasmuch as white quartz (mainly of an ice-like transparency) furnished the principal part of the material." Besides this, they also found a red, yellow, and black variety of quartz (jasper) employed in great profusion, which contrasted strangely with the monotonous grey gneiss of the caves themselves. On the whole, these implements are of small size, suited to small hands, and therefore employed by a small race of men. The stone hammers which were used to strike chips off the cores are of a remarkably small size. The Sarasins conclude their article with these words:—"We, furthermore, may already venture to say that the second main-period of the Stone age, the Neolithic one—viz. that characterised by the polished stone axe—is entirely wanting in the island of Ceylon, the Veddahs having made the step directly from the Older Stone Age into the Modern Age of Iron, which was brought them by the Sinhalese, or perhaps by another people of the Indian continent."

It is believed by some in Ceylon that there are only some hundred Veddahs existing, and Dr. Sarasin informed a *Ceylon Observer* representative that there are but a small number of Veddahs of pure blood to be found, perhaps only about fifty or sixty. These chiefly occur in Nilgala, Bibile, and the Putipola hill in Moligala, where there are only three small communities of the purest blood. Most of them build small, primitive huts, while some live in the open, sometimes in caves, but not always; those who have families build huts. Their own language is lost; being a small tribe surrounded by thousands of Sinhalese they have learnt a simple dialect of Sinhalese. They have no knowledge of their history. There is no chief, but the oldest man is called the speaker; he has, however, no privileges, and is not empowered to issue orders. They no longer know how to make stone implements, and now buy iron from the Sinhalese. Dried flesh and forest fruit are eaten. They have no religious ceremonies, but some believe in ghosts, whom they call *yakas*, though others disbelieve in their existence. Idolatry is not practised, nor do they worship stones or trees, or pray to them; indeed, the majority deny that they know anything about them. The Veddahs are strictly moral, there are no thieves among them, they never take alcohol, and they never tell lies.

A. C. H.

AN ITALIAN MONUMENT TO LINNÆUS AT THE END OF THE EIGHTEENTH CENTURY.

IN these days, when all the world of science unites in celebrating the memory and glory of the great Swedish naturalist, it is interesting to recall from the utter oblivion in which it has remained until now the monument and inscription dedicated to Linné in Naples at the end of the eighteenth century, presumably in 1778, the year of Linné's death.

The monument, which probably consisted only of the marble inscription, was not a public monument, but was raised by the fervour and admiration of Domenico Cirillo, the Neapolitan friend and correspondent of Linné, to whom the latter had dedicated the heathers of the genus Cyrilla, now included in the family of the Cyrillæ.

The Cirillo had been for long a family of doctors, naturalists, and artists. It is said that Domenico Cirillo, who was born in 1739, and graduated in 1759, was the twentieth doctor of medicine belonging to the Cirillo family. At the beginning of the eighteenth century, Nicola Cirillo, who in 1718 became a Fellow of the Royal Society of London, formed in his own private grounds in Naples a botanical garden which continued to be the scientific centre of Neapolitan naturalists until its destruction and the dispersion of the collections and herbarium in the fatal year 1799. In the sack of Cirillo's house were lost the letters written by Isaac Newton to Nicola Cirillo, and the famous herbarium of Ferrante Imperato, preserved since the sixteenth century, before which Martyn Vahl, Linné's friend and disciple, had knelt in admiration when he visited Naples in 1783.

The garden of Cirillo was the rallying point for the flower of Neapolitan thought and science, soon to be decimated and dispersed by royalist persecution during the storms of the Revolution of 1799. Many of the most distinguished men of Naples must have stood round Cirillo when the following inscription was raised in honour of Linnæus:—

CAROLI LINNAEI
Animam sapientissimam
Terris divinitus impertitam
ut
Naturae universae arcana
Declararet patefaceret
Illustraret
Postea
per dephlogisticatam
Aethercam regionem
Obvolitantem
Ne quid respub. Botanicorum
Detrimenti capiat
Vos
Fragrantissimae, soporiferae
Tetrae, spirantes
Ambrosiacae, Aphrodisiacae
Perennis voluptatis ministrae,
Herbae, Arbores, Plantae
Odoribus, Effluviis, aromate
Sistite, involvite, detinete.

The mob destroyed this inscription, together with Cirillo's house and collections, and Cirillo, with many of the noblest thinkers and benefactors of his country, was hanged in the market-place of Naples on October 29, 1799.

The inscription by Domenico Cirillo is one of the first memorials erected in a botanical garden to the memory of Carl Linné. Perhaps it may be raised again in Naples, a memorial not only of Linné's glory and of Cirillo's devotion, but also of that brotherhood of science to which Linné and the societies that bear his name have so much contributed.

ITALO GIGLIOLI.

DR. ALEXANDER BUCHAN, F.R.S.

WITH the death of Dr. Alexander Buchan on Monday, May 13, after a brief illness, a long industrious life and a distinguished scientific career were brought to a close; a genial and striking personality has become a memory.

Born at Kinnesswood, Kinross-shire, in 1829, educated at the Free Church Normal School and the University of Edinburgh, he became a schoolmaster at Banchory, Blackford, and subsequently at Dunkeld. He had, at the same time, an independent taste for field botany and meteorology.

An affection of the throat proved to be an embarrassment in his scholastic work, and in 1860 he was called to Edinburgh to be secretary of the Scottish Meteorological Society. It was a time of remarkable activity; indeed, it was a notable period in the development of the modern science of meteorology. In Paris, Leverrier had traced the progress across Europe of the celebrated Crimean storm. In London, FitzRoy was busy with the daily comparison of reports by electric telegraph from a number of stations in the British Isles. The British Association was maintaining a physical observatory at Kew, in the superintendence of which Balfour Stewart had just succeeded Welsh, a pioneer in meteorological ballooning. In this enterprise Welsh was soon followed by the intrepid Glaisher, under the auspices of a British Association Committee, with the active support of Lord Wrottesley. The Master of Trinity included the design of an anemograph among his achievements. In Scotland, Thomas Stevenson, Milne Home, and Sir Arthur Mitchell, with the support of the great Scottish physicists, formed the nucleus of the energetic society which, under Buchan's management, became one of the most important centres of meteorological investigation, the focus for the collection of observations from all parts of Scotland, and the controlling body for a network of volunteer stations. The work of examination and tabulation, conducted almost wholly by Buchan and his niece, Miss Jessie Hill Buchan, received official recognition as supplying many of the summaries of observations at stations of the second order in Scotland required by the Meteorological Office in London for international purposes, and as preparing the meteorological reports for the Registrar-General for Scotland on lines somewhat similar to, but not identical with, those prepared for the Registrar-General for England and Wales by James Glaisher, first as a member of the staff of the Royal Observatory, and subsequently on his own account.

A few words as to Buchan's scientific work must suffice. With Baxendell, of Manchester, he was largely instrumental in securing the general acceptance of Buys Ballot's principle of the relation of wind to air pressure. He had the faculty of statistical insight, and realised that by the appropriate combination of many observations it was possible to trace the interdependence of phenomena which might be affected separately by a number of independent causes. This insight is illustrated in a remarkable way by his papers with Sir Arthur Mitchell upon the relations of climate and health in London. Such a method of investigation does not always commend itself to the student of physics, who, fortunate in having the conditions under his own control, is accustomed to trace the direct connection between cause and effect in each separate experiment. But the remarkable results of Buchan's work, which still remain to be followed up, enable one to understand the enthusiasm for collecting observations, and more observations, that seem purposeless to some of those who look on.

His "Handy Book of Meteorology," published in 1867, followed by a second edition in 1868, and now long since out of print, though a new edition has always been looked for, and his "Introductory Textbook of Meteorology" (1871) are ample evidence of his general grasp of meteorological work, but his favourite method of meteorological investigation was the map. Beginning from the time when the reduction of the barometer to sea-level for synchronous charts and the identification of closed isobars as cyclonic and anticyclonic areas were novelties, he was the first to trace the course of a "depression" across the Atlantic; and subsequently, by the collection and discussion of data from all parts of the world, to give in a paper before the Royal Society of Edinburgh "the mean pressure of the atmosphere and the prevailing winds over the globe."

This was followed by the monthly charts and tables representing the atmospheric circulation in the volume contributed to the *Challenger* Reports and published in 1889, and the corresponding results for "oceanic circulation" in 1895.

His monthly maps of forty-year averages for the British Isles developed likewise (with the assistance of Dr. A. J. Herbertson) into the compilation of the wonderful atlas of pictorial meteorology published by Bartholomew in 1899. Therein is, indeed, a worthy representation of Buchan's meteorological method.

It was by the method of the map that he proposed to deal with the outstanding results of the Ben Nevis observations, which were collected largely under his own supervision, and have been already the subject of numerous papers. His capacity for dealing in this way with huge masses of figures was amazing. I have often gone with him over the details of daily maps exhibiting the results for Scottish weather at official stations, lighthouses, and private stations to trace some generalisation which had been suggested by his work. His programme was to correlate these daily maps with the observations at the summit and base of the mountain. The methodical care in ordering the entries, and their arrangement as regards colour or design to bring out any salient features, were thoroughly characteristic of his work.

From 1877 until last year, when it was arranged that he should continue the work upon the Ben Nevis observations instead, he was inspector of Scottish stations for the Meteorological Office. Throughout Scotland he succeeded in eliciting from the observers an enthusiasm for accurate work that is truly remarkable. Last year I followed myself the course of his rounds, and was interested to verify the eulogistic phrases about the Scottish stations which used to be characteristic of the reports of the annual visitation.

In 1887, Buchan succeeded Stokes as a member of the Meteorological Council. Sir R. Strachey, Sir W. Wharton, Sir G. H. Darwin, Mr. Galton, Mr. E. J. Stone, and subsequently myself, were his colleagues.

The period of his tenure almost synchronises with that of the final form of the work on Ben Nevis, which was brought into full activity by the endowment by the council of the base observatory at Fort William in 1890. It may also be regarded, not inaptly, as the period during which the interest of meteorological work passed from the geographical extension of observations over the earth's surface to the exploration of the upper air, begun by Welsh, continued by Glaisher, but afterwards allowed to drop. The great enterprise of maintaining a station of the first order at the highest point of the British Isles absorbed practically all the energy of the Scottish society during Buchan's membership of the Meteorological Council. Ultimately it proved to be a greater charge than the society could support, and appeal was made first to the council, who were themselves experiencing the pinch of straitened circumstances, and then to the Government, who after a lengthy inquiry by means of a committee arrived at a misunderstanding; and the closing of the observatories was the result.

Indeed, the course of the negotiations began, as it ended, in a misunderstanding. The financial position of the office was well known; but at the time the National Physical Laboratory was in course of formation, and it was supposed that, being itself in receipt of Parliamentary aid, it would maintain its physical observatory at Kew out of its own resources. The annual sum of 400*l.* voted by the Meteorological Council would thus become free for meteorological enterprise elsewhere. But it was ordered otherwise; the payment to Kew still goes on.

In the course of the appeal some hard things were said of the council in its corporate capacity, but they were not followed by any diminution of mutual respect between its members. The only real difference of opinion was as to the ways and means of enlisting the practical support of Parliament for meteorological work. The motives which actuate the decisions upon such matters are not even now sufficiently clear to obviate legitimate difference of opinion upon the subject.

However one may regret the termination of a great enterprise, it is fair to say that the only possible conditions for its continuance were a sufficient supply of funds. All are agreed that a precarious existence under financial conditions involving semi-starvation of the work of research could not be regarded as an alternative.

Buchan was an honorary LL.D. of Glasgow, and a Fellow of the Royal Societies of London and Edinburgh. He was curator of the library and museum of the latter, and received the Makdougall-Brisbane prize from the society in 1876, and the Gunning prize in 1893. He was the first recipient of the Symons medal of the Royal Meteorological Society of London in 1902. He served for some time on the committee of the Government grant for scientific research. He was president of the Botanical Society of Edinburgh in 1870–1. He was also an honorary member of the Royal Society of Sciences of Upsala, of the Philosophical societies of Manchester, Glasgow, and Emden, and of the meteorological societies of Austria, Germany, Mauritius, Algiers, &c.

In Edinburgh society, and indeed throughout Scotland, he was a well-known figure. His striking appearance, his geniality, his familiar acquaintance with Scottish literature and literary men, and his enthusiastic devotion to his work, easily account for the high degree of respect and affection with which he was regarded in the Scottish capital. He was at his best at the hospitable gatherings of the Royal Society Club, with the management of which he was associated for many years.

He married in 1864 Sarah, daughter of David Ritchie, of Musselburgh, who died also on May 13 seven years ago. He leaves a son, Dr. A. Hill Buchan, with whom he lived, and who was his companion on many journeys.

In thus taking leave of a kindly master and a valued friend, it is not too much to say that the work of Buchan's life has contributed largely to justify the claim of meteorology to be regarded as a separate scientific subject, entitled to separate academic recognition. The physics of the atmosphere has its geographical aspect, but it is not a branch of geography; it has its mathematical aspect, but it is not a branch of mathematics; it has its experimental aspect, but it is not a branch of experimental physics. The constitutional affection of the throat prevented Buchan from using his natural powers of exposition to their full extent, but may we not hope that the University of Edinburgh will see her way to recognise the devotion of her distinguished alumnus by providing the subject of his devotion with a voice among the sciences which she fosters? W. N. SHAW.

NOTES.

We regret to see the announcement that Sir Benjamin Baker, K.C.B., F.R.S., died suddenly on Sunday, May 19, in his sixty-seventh year. We have also to deplore the death of Sir Joseph Fayrer, K.C.S.I., F.R.S., on Tuesday, May 21, at eighty-two years of age.

M. de Lapparent has been elected permanent secretary of the Paris Academy of Sciences in succession to the late M. Berthelot.

The second annual meeting of the American Association of Museums will be held at the Carnegie Institute in Pittsburg on June 4–6.

The *Observer* states that the honorary freedom of the City of London is to be conferred on Lord Lister. The proposal will come formally before the Corporation probably at its first meeting after the Whitsun recess.

The section of geology and geography of the American Association for the Advancement of Science will hold a summer field meeting from July 3 to July 10 in New York State in the region between Lake Champlain and the Adirondacks.

An exhibition of reflex cameras at present on the market, and of photographs illustrating the use of reflex cameras, is to be opened at the house of the *British Journal of Photography* on June 13, and will remain open until July 6.

The will of Mr. C. T. Yerkes, who died at New York on December 29, 1905, has just been made known. The testator bequeathed 20,000*l*. for the upkeep of the observatory at Lake Geneva, Wisconsin, to the University of Chicago, with the condition that the observatory shall always be known as the Yerkes Observatory.

Dr. W. S. Bruce is organising an Arctic expedition, with the special object of completing the exploration of Prince Charles Foreland, Spitsbergen, which he began last summer, in company with the Prince of Monaco, in the *Princess Alice*. The expedition will proceed in the first instance to Tromsoe, in Norway, and from there to Spitsbergen, in a specially chartered steamer.

The German steamship companies Norddeutscher Lloyd and the Hamburg-Amerika Linie will allow a reduction for passage tickets on different lines to members attending the fourteenth International Congress for Hygiene and Demography to be held at Berlin next September. The office of the Hamburg-Amerika Linie in Berlin has undertaken to procure rooms in different hotels for members of the congress. Detailed information concerning the reduction in price for tickets, and means of communication with Berlin, will shortly be published, and is obtainable at the bureau of the congress, Berlin 9 W., Eichhornstr. 9.

On Tuesday next, May 28, Prof. G. H. F. Nuttall will deliver the first of two lectures at the Royal Institution on "Malaria, Sleeping Sickness, Tick Fever, and Allied Diseases," and on Saturday, June 1, Sir William White will begin a course of two lectures on "The Contest between Guns and Armour." The Friday evening discourse on May 31 will be delivered by Mr. A. Henry Savage Landor, on "Recent Journey Across Africa," and on June 7 by Sir James Dewar, on "Studies in High Vacua and Helium at Low Temperatures."

On Friday afternoon, May 17, an earth tremor—possibly due to some shift of strata not wholly unconnected with extensive mining operations—took place in the Rhondda Valley, Glamorgan, and is described by those who felt it as more severe than last year's earthquake. The vibration was very distinctly felt by the miners underground, who estimated its duration at half a minute. Householders also felt the shock, and noticed crockery rattle. The vibration was not noticed anywhere else in South Wales. Similar local shocks have been felt before, notably one in the same spot on October 16, 1896.

In a letter published in the *Times* of May 18, Sir James Blyth suggests the formation of an Imperial Council to continue and elaborate the work which has, with the end of the Colonial Conference, been suspended for a time. Among the subjects calling for investigation by such an Imperial Council, Sir James Blyth includes, with many others, State-aided organisation, where needed, of agricultural activities, such as the improvement of the breeds of cattle and horses, dairy, forestry, seed selection and supply, and the promotion of technical and scientific education, with the endowment of research, in both of which we are greatly behind other nations. This permanent Imperial Council would "act as eyes and ears to the Empire as a whole," and would greatly assist scientific procedure in government.

The Pasteur Institute of South India at Coonoor was opened, the *Pioneer Mail* states, by Sir Arthur Lawley, Governor of Madras, on April 25. The Governor, in the course of a short address, sketched the history of the institute, and said that Lord Ampthill was the originator of the scheme. The consummation of the work was due to the generosity of an American millionaire, Mr. Henry Phipps, who placed one lakh of rupees at the disposal of the Madras Government. The institute will involve annually considerable expense; and the Indian Government has undertaken to bear the chief part of this, but the committee of the institute and the Government look for support to the public and the neighbouring States. His Highness the Nizam of Hyderabad has set an example of generosity by promising, for at least ten years, to give a substantial contribution to the annual expense.

The cold days of May have this year been more than usually pronounced, and for five consecutive days, from May 17 to May 21, the shade temperature in London did not exceed 55°, while on May 19 and 20—Whit Sunday and Monday—the maximum temperature was 51°, or about 15° below the average. The observations of past years commonly show low day temperatures after the middle of the month, although the occurrence is not sufficiently frequent to be exhibited in any marked manner in the mean readings for any considerable number of years. In London and in many parts of England night frosts were frequently registered by the exposed thermometer during the past week, and a very keen north and north-east wind was blowing. The cold snap was more severely felt, following so closely on brighter and warmer weather: the shade temperature in London on May 12 was 28° higher than on May 19 and 20.

With the object of bringing the Smithsonian Institution at Washington into closer touch with the representative national scientific organisations of the United States and to create a new channel for the diffusion of knowledge, the secretary of the institution, Mr. Charles D. Walcott, recently sent an invitation to the National Academy of Sciences and to the American Association for the Advancement of Science to make the Smithsonian Institution their headquarters. The authorities of both the National Academy and the American Association have accepted the offer with thanks, and the step taken will assist greatly to make the Smithsonian Institution a clearing-house of national scientific learning for the United States.

In connection with the second centenary celebration of the birth of Linnæus, the opening article of the April number of *Naturen* is devoted to a sketch of the life and work of the great naturalist, by Mr. J. Holmboe. It is illustrated by reproductions of Hoffman's portrait and C. F. Inlander's medallion.

The practical work of the members of the Australian Ornithologists' Union during the sixth congress, held last November and December in exploiting the bird-life of Mount Wellington, Tasmania, forms the subject of the chief article in the April number of the *Emu*. Among the illustrations to this article is one of a group of Eucalyptus trees showing the manner in which the great black cockatoo strips off the bark in long streamers in order to feed upon the grubs of certain bark-burrowing insects. It is stated that only dead timber is attacked by the cockatoos, which are thus exceedingly useful in keeping in check insects injurious to the forests.

Insects injurious to barley and other grain when in store form the subject of a paper by Mr. W. E. Collinge published in the Journal of the Institute of Brewing, vol. xiii., No. 3. The statement, on the authority of Miss Ormerod, that in the winter of 1884–5 a sum of between 1000*l*. and 2000*l*. was lost on a single cargo of Russian barley by the ravages of *Calandra granaria* gives an idea of the magnitude of the evil, and the list of five-and-twenty injurious species given by the author serves to emphasise the seriousness of the situation. Worse still is the statement that the number of species and of individuals of such pests has notably increased in this country during the last few years. Gauze-covered windows, cleanliness, and fumigation with carbon disulphide are the chief remedies suggested by the author.

In a paper on the so-called renal portal system, published in the April issue of the Proceedings of the Zoological Society of London, Mr. W. Woodland concludes that the structures thus called are misnamed, and that there is really no "portal system" connected with the kidneys. He accordingly proposes to replace the terms "renal portal system" and "renal portal vein" by "renal cardinal meshwork" and "post-renal vein." As the renal cardinal meshwork appears to have no excretory function, the association of kidney and vein is probably functionless, and thus, in a sense, accidental. The meshwork seems, in fact, to be merely "an instance of the extension of a growing organ in the direction of least resistance; in other words, a mechanical product having no direct relation to the physiological needs of the animal."

The *Popular Science Review* for May contains the first connected account of the Jamaica earthquake which has reached us. From this description, by Prof. C. W. Brown, we learn that the earthquake was not remarkable for its violence, as this is not put at higher than 9·5 degrees; of what scale is not stated, but whichever was used, this is far short of that attained by really great earthquakes. The shock, as distinguished from the damage, was not so localised as appeared from telegraphic accounts; there seem to have been independent centres, of lesser violence, on land, and the submarine cable was broken at two places, about four and about twenty miles from Bull Bay, a couple of miles or so of cable being so thickly covered with débris that they had to be abandoned. At several places along the edge of the harbour the bottom has sunk from its old level, the maximum difference being more than six fathoms, but this subsidence was confined to a belt of from a hundred to three hundred yards in breadth, surrounding the harbour and located on the shore or slightly off shore; the middle portion of the harbour and the entrance channel were unchanged.

One of the principal functions of the International Association of Botanists is to provide critical notices of papers and books on botany in their journal, the *Botanisches Centralblatt*. An extension of this review work has given rise to the "Progressus Rei Botanicæ" for the publication of summaries prepared by acknowledged authorities in different branches of botany. The first part, issued in November, 1906, contained articles by Prof. E. Strasburger, on cell-ontogeny; by Dr. D. H. Scott, on Palæozoic botany; and by Dr. C. Flahault, on botanical geography. The second part, lately received, also contains three articles. Dr. L. Laurent reviews the progress of palæobotany with reference to angiosperms, Mr. W. Bateson deals with the subject of genetics, and Dr. F. Czapek writes on the physiology of nutrition. With regard to Dr. Laurent's contribution, he explains that it is concerned with the development of the angiosperms in the Cretaceous and Tertiary periods. Besides recording new observations, the author discusses methods employed and the general trend of results. A noticeable feature of Mr. Bateson's review is the general combination of zoological and botanical facts. Dr. Czapek starts from the date of the publication of the first volume of Pfeffer's "Plant Physiology," and follows that author in his arrangement. Among the subjects receiving special notice are the water-current in plants, methods of absorption, assimilation of carbohydrates and enzymes.

A monthly list of the publications of the U.S. Department of Agriculture is sent to all who apply for it, and is received by us. The activity of the department in obtaining information upon every branch of scientific agriculture and making it available in reports, bulletins, circulars, and other publications, issued at the nominal price of a few cents, is really remarkable. The monthly list now before us is a six-page leaflet containing the titles of many publications of importance, and including as new no fewer than nineteen bulletins, twenty-one circulars, and two farmers' bulletins on flax culture and experiment-station work. Our Board of Agriculture and Fisheries issues many useful leaflets, but its work cannot be compared with that of the United States Department of Agriculture, which is continually obtaining new knowledge. It could not be otherwise under the present conditions; for while a few hundred pounds a year represent the contribution our Board is able to make for agricultural research, the expenditure on investigations under the U.S. Department of Agriculture amounts to more than two hundred thousand pounds annually, exclusive of salaries of permanent officials and expenses of publications. Our politicians profess regard for British agriculture, but they do nothing to provide for the development of the knowledge which is even more necessary in the old country than it is in the new.

Dr. V. Conrad made some interesting experiments on the ionisation of the air at the Säntis Observatory, Switzerland (altitude, 8200 feet), in August, 1905, the results of which are published in the Proceedings of the Vienna Academy for July 12, 1906. The author found that the daily variation in the amount of positive ions exhibited quite a different type from that of the negative ions. The daily range of the amount of positive ionisation showed a principal maximum at 11h. a.m., that of the negative at 3h. a.m. The minima agreed fairly well in time, the positive occurring at 3h. p.m. and the negative at 2h. p.m. A secondary maximum of the positive at 4h. a.m. occurred near the time of the principal negative maximum, while a secondary maximum of the negative, at 11h. a.m., occurred at the time of the principal positive maximum.

In *Meteorologische Zeitschrift* (No. 12, 1906) Dr. A. de Quervain urges several arguments in favour of the real existence of the inversion of temperature at the height of 8–13 kilometres, upon which doubt has been thrown by several persons. M. Teisserenc de Bort instituted a number of ascents at Trappes (near Paris) during the night or early morning, so that the unmanned balloons might reach their greatest heights before sunrise, which seem to show without doubt the real existence of the inversion. Dr. de Quervain points out that in the international ascents made during the daytime at Strassburg, St. Petersburg, and Zürich (as well as other places), every possible care has been taken to eliminate the effect of radiation, and that the results also fully support the reality of the inversion. There is also the fact that a stratum of air is frequently found above the inversion zone, where the temperature again decreases decidedly with increasing altitude.

We have frequently had occasion to refer to the useful work of the Zi-ka-wei Observatory, near Shanghai, in issuing timely notice of the approach of dangerous storms. At the present time it receives telegraphic reports from several of the Chinese stations, and telegrams twice or thrice daily from thirty-two foreign stations, obligingly forwarded with the consent of their respective Governments. Telegraphic storm warnings are sent from Zi-ka-wei to some fifteen of the principal Chinese ports, nearly all of which have semaphores which exhibit storm signals; notices are also transmitted to Vladivostock, Tokio, Formosa, and Indo-China. The Inspector-General of Chinese Customs has, at the urgent request of the director of the observatory, further sanctioned the erection of semaphores at twenty-five selected lighthouses not yet electrically connected, to which, from May, 1907—about the time of the beginning of the typhoon season—captains of ships leaving port are invited to repeat, during the daytime, the warning notices they have seen in the harbours for the benefit of the fishing and other small craft in the offing.

In view of the approaching tercentenary of the discovery of logarithms, Dr. F. H. Loud contributes a note to the semi-annual Bulletin of the Colorado College Observatory in which he proposes several rapidly converging series, and shows how they might be used for the re-calculation of logarithms to a large number of decimal places. A table is given of logarithms of primes below 110 to eighteen places.

Mr. Charles Urban issues a pamphlet recommending the use of the kinematograph for scientific and educational purposes. He has published a large number of rolls demonstrating living objects, such as pond life as seen through the microscope, and it is suggested, among other uses, that the kinematograph may be applied to take records of important surgical operations for future use in class demonstration, and also to exhibit to medical students the details of experiments on living animals without repeating the actual experiments before every fresh batch of students.

Prof. E. Wiedemann is well known for many contributions he has made to the subject of Arabian astronomy. In a recent communication to the Physikalisch-Medizinischen Society of Erlangen he gives the translation of a paper from the Qâsid al Irschad, "Guide to the Aspiring," to which his attention had been directed by Prof Nallino, of Palermo. The original author, who seems to have been indifferently known as al Ansârî or al Sachâwî, was a competent exponent of the astronomy of his day. Astronomy he describes as the science which teaches the nature of separate bodies, their figures and positions, the distances between them, the motions of the planets, and the magnitude of the heavenly bodies. Four fundamental parts are recognised. In the first is investigated what is common to all spheres or orbits, the words seem to have the same significance, to the relations between them, and the proof that they all move, the earth remaining at rest. In the second is demonstrated the character of the motions of the heavenly bodies, how many there are, the divisions of the zodiac, and the phenomena of the eclipses. The third treats of the earth and of the climate in different places, and of the differing lengths of the day and night according to latitude. The fourth part considers the magnitude and the distances of the stars. References are made to classical works in which these subjects can be studied at greater length. Further subdivisions follow, having reference to the calculation of ephemerides, the calendar, the method of observing, the projection of the sphere, and problems connected with the gnomon. Into these it is scarcely necessary to follow either the learned Arabian or his able translator. The paper is interesting, but its scientific value is mainly confined to the elaborate notes with which the author has enriched his translation. These notes are both philological and historical.

Students of the early history of science will find an elaborate and interesting discussion of Petrus Peregrinus de Maricourt's "Epistola de Magnete," by Prof. S. P. Thompson, in vol. ii. of the Proceedings of the British Academy. Petrus Peregrinus, we learn, was a native of Picardy, a friend of Roger Bacon, and a man of very varied knowledge for his time. The "Epistola" is believed to have been written in August, 1269, while its author was assisting in the siege of Lucera, in southern Italy. Peregrinus's chief claim to distinction, in Prof. Thompson's opinion, was his invention of improved forms of the compass. One form, like earlier compasses, was floated in water, but it was the first to possess the equivalent of a "lubber" line and a divided circle. A second form was pivoted, and may be regarded as the precursor of the azimuth compass. An even more curious instrument, which, though illustrated, was presumably never materialised, was to consist of a light pivoted circle, having a number of inwardly directed iron teeth, with a fixed lodestone at its centre. Peregrinus's hope was to secure perpetual motion. There seems here almost an anticipation of one idea at least embodied in the dynamo, but Prof. Thompson is too experienced a writer to enter on this theme with an audience where his remarks would be liable to misconstruction. The discovery of the declination of the compass from true north has been ascribed by some to Peregrinus, but this Prof. Thompson says is a mistake, arising from a spurious addition made to a Leyden MS. of the "Epistola" about the end of the fifteenth century. In Appendices A and B Prof. Thompson enumerates the various MSS. and printed versions of the "Epistola." Of the twenty-eight MSS. enumerated, it is surprising to find that no fewer than twelve are in libraries situated in the United Kingdom, seven being in the

Bodleian and two in Prof. Thompson's own possession. Some of the scientific aspects of Peregrinus's work received a somewhat fuller treatment recently at the hands of Dr. L. A. Bauer (U.S. Coast and Geodetic Survey's "Magnetic Declination Tables and Isogonic Charts," 1902, pp. 16–20), but the present discussion is much more complete on the literary side.

The magazine of photographic art known as the *Practical and Pictorial Photographer*, so ably edited by the Rev. F. C. Lambert, was until quite recently published by Messrs. Hodder and Stoughton. This monthly has now been acquired by Messrs. Robert Atkinson (London), Ltd., and will in future be published at their offices in 10 Essex Street, Strand. From the editorial notes it is gathered that some changes have been contemplated in the new issues, and the March and April numbers point out the direction in which such alterations have been made. The modifications include an attempt to issue the publication on the first of each month; one long or a collection of small articles dealing with one subject in a comprehensive manner in each issue; a change in the inks and paper employed for the illustrations to secure more transparent and luminous shadows in the reproductions; a detachable card which deals with all the constant needs of the dark-room, such as standard developing formulæ for negatives as given in the March number. Another important innovation is the insertion of the text and a page of illustrations in connection with the great National Photographic Record Survey that is being so well taken in hand now all over the country. The reader will therefore gather that the future issues of this excellently illustrated magazine will have an added interest, and the March and April numbers should be seen to fully appreciate the changes made.

The twelfth of a series of Bulletins published by the Engineering Experiment Station of the University of Illinois embodies a detailed report, by Prof. A. N. Talbot, on tests of reinforced concrete T-beams. The tests were made with the object of determining whether the width of the slab is a controlling element in the strength of the beam, and to ascertain the efficacy of vertical reinforcing stirrups in resisting web stresses.

In the Journal of the Franklin Institute (vol. clxiii., No. 4) Mr. Persifor Frazer discusses the application of scientific methods to the study of handwriting, and shows that when the province of this study is recognised as within that of experimental psychology, entirely capable of being conducted like other investigations of the human faculties by exact measurement and numerical statement, the shallow pretenders who have from time immemorial infested it will disappear.

An interesting account of the work of the United States Reclamation Service is given by Mr. C. J. Blanchard in the *National Geographic Magazine*, Washington (vol. xviii., No. 4). The vast expenditure on national irrigation is the outcome of an Act passed in 1902 which provided that the money received from the sales of public lands in fourteen arid States and two Territories should be used as a reclamation fund for the construction of the works necessary to irrigate arid lands in those regions. In the same issue Miss E. R. Scidmore reproduces twenty-five admirable typical illustrations, of great anthropological interest, of women and children of the Far East.

Messrs. A. Gallenkamp and Co., Ltd., have added to their "technical" series of physical apparatus ten useful pieces of apparatus which will greatly assist the practical study of heat. The catalogue describing the instruments shows how satisfactory results may be obtained and used to illustrate principles.

Mr. Edward Stanford announces for early publication a new edition of his "Geological Atlas," which will deal with Great Britain and Ireland in place of Great Britain alone as formerly. The maps and text have been revised, and among the new features is a full list of the figured fossils, with indications of their zoological position and range in time.

Part v. of Mr. Charles Stoneham's elaborate work on "The Birds of the British Islands" has been published by Mr. E. Grant Richards. The work will be completed in twenty parts, and its general character was described in a review of the first part in Nature of October 18, 1906 (vol. lxxiv., p. 607). We shall notice the publication again when the whole of the parts have reached us.

Messrs. W. and A. K. Johnston, Ltd., have placed upon the market a form of their "world-wide sectional pad" which is likely to be of service to surveyors, military men, and others. The side of a small square represents a hundred yards, and intervals of a thousand yards are indicated by slightly darker ruling. The scale of the paper is such that a mile is represented by 1 inch. This form of sectional paper will prove useful to teachers of geography who exercise their pupils in the construction of simple plans. The price of the pad is 1*s*. 6*d*. net.

The new catalogue of microscopical lenses and apparatus issued by Messrs. Voigtländer and Son, whose manufactory is in Brunswick, Germany, is conveniently arranged and beautifully illustrated. Mr. F. G. Phillips, 12 Charterhouse Street, Holborn Circus, E.C., is the sole agent for Great Britain and the colonies. The tabular arrangement adopted in the catalogue makes it easy at once to discover prices, sizes, and other particulars.

Attention is frequently directed in these columns to the valuable preparatory work in observational science which is being accomplished by natural history and similar societies in the secondary schools of the country. An excellent instance of this useful work is provided by the seventy-third annual report of Bootham School (York) Natural History, Literary, and Polytechnic Society. In addition to the encouragement given to field work in natural science, the boys are afforded every facility to study the science of photography, are offered inducements to practise literary expression, and are provided with lectures on scientific subjects. The authorities are to be congratulated on the good year's work described in the report.

A "Guide to the Great Game Animals (Ungulata) in the Department of Zoology, British Museum (Natural History)," has been printed and published by order of the trustees of the museum. The guide has been compiled by Mr. R. Lydekker, F.R.S., and he has devoted the descriptive portion chiefly to the characteristics of the different genera and families. The scientific names employed in the guide are those adopted in the museum, and are, Prof. E. Ray Lankester points out in a preface, "to some extent a compromise between extreme views." The text is illustrated by fifty-three figures, most of which are printed from half-tone blocks. The guide, the price of which is one shilling, will provide the visitor with just the information necessary to enable him to take an intelligent interest in the exhibits.

OUR ASTRONOMICAL COLUMN.

Comet 1907*b*.—From a note published in No. 4175 (p. 366, May 10) of the *Astronomische Nachrichten* we learn that the comet discovered by Mr. Mellish on April 14 had been previously seen by Mr. Grigg, of Thames, New Zealand, on April 9. A set of elements computed by Mr. Merfield from observations made on April 9, 10, and 11 is given.

In the same journal Dr. Ebell continues his ephemeris for this object up to June 19, showing that the comet is now approximately half-way between ι and θ Ursæ Majoris. R.A. = 9h. 2·6m., $\delta = +51° \ 18'$.

The Value of the Solar Parallax.—The discussion of the Greenwich photographs of Eros, the results of which were communicated to the Royal Astronomical Society (*Monthly Notices*, vol. lxvii, No. 6, p. 380) at its April meeting, gave $8''{\cdot}800 \pm 0''{\cdot}0044$ as the value of the solar parallax. This result was obtained from the measurement of 151 plates taken with the Astrographic 13-inch refractor and 103 plates taken with the Thompson 26-inch refractor, between October 14, 1900, and January 15, 1901, and agrees very closely with the value, $8''{\cdot}802 \pm 0''{\cdot}005$, published by Sir David Gill in 1897.

Early and Late Perseids.—In a paper recently communicated to the Royal Astronomical Society Mr. Denning gives a list of the apparent paths of probable and possible Perseids observed by him during the periods July 7 to 22 and August 17 to 25 inclusive, from 1876 to the present time. The observations suggest that true Perseids may be looked for after the first week in July, but not until July 19 does the stream become conspicuous enough to enable a good radiant to be determined. Mr. Denning asks other observers to supply data from which the radiant during the earlier period might be determined with more certainty; at present there is reasonable doubt that the shower commences so early as July 7. Similarly the extension of the date of apparition to August 25 is in question, although Mr. Denning is sure that true Perseids have been observed as late as August 20.

A list of the radiants determined is also given, and the author states that quite possibly the shower extends over a period of fifty nights (*Monthly Notices*, vol. lxvii., April, p. 416).

New Elements of Jupiter's Seventh Satellite.—From twelve observations distributed evenly along the observed arc passed over by Jupiter's seventh satellite during the period January 3, 1905, to September 25, 1906, Dr. F. E. Ross has computed a new set of elements for that satellite. The principal perturbations have been included, and the observations are represented by the elements with an average error of only $0'{\cdot}4$. The inclination of the satellite's orbit, referred to the earth's equator for the epoch January 0·0, 1905 (G.M.T.), is given as $25° \ 18'{\cdot}6$, whilst referred to Jupiter's orbit the inclination is $27° \ 58'{\cdot}3$. The period, according to these elements, is 260·06 days.

Observations secured by Prof. Max Wolf on December 22 and 23, 1906, and by Prof. Perrine on November 23, are not consistent with these elements, the respective residuals in R.A. being $+10'{\cdot}0$ and $-3'{\cdot}3$ (*Astronomische Nachrichten*, No. 4175, p. 359).

The Computation of Cometary Orbits.—In Circular 128 of the Harvard College Observatory, Prof. E. C. Pickering points out what needless duplication occurs in the computation of cometary orbits. For comet 1907*a* three almost identical sets of elements were communicated to the Harvard College Observatory, whilst others, giving similar values, were published elsewhere. To obviate this waste of energy Prof. Pickering suggests that these computations should be carried out on some cooperative system, each computer taking them in turn, and further suggests that the labour thus saved might with advantage be expended on the computation of orbits of minor planets, of which objects so many are now being discovered regularly.

Astrographic Catalogue Work at the Perth Observatory (W.A.).—Although most of the Government Astronomer's report of the work performed at the Perth (W. Australia) Observatory during the year 1905 is devoted to meteorological observation, Mr. Cooke has a few words to say about the regrettable delay in the prosecution of the Astrographic Catalogue work undertaken by the West Australian Government.

The zone apportioned to the observatory was from 32° to 40° south declination, and includes 1375 regions; of these 145 remained to be taken at the date of the report. But the operations of measuring and reducing the plates were not then commenced, and there is a grave possibility that the plates may deteriorate sufficiently to render them useless. The taking of long-exposure plates for photomechanical reproduction was commenced, but was afterwards stopped on account of the expense. Some 10,000 standard stars have to be observed by means of the transit circle, and Mr. Cooke suggests that "this will form the basic work of the Perth Observatory, probably for centuries."

The Total Solar Eclipse of August 30, 1905.—During the total eclipse of August 30, 1905, Prof. Schwarzschild, of the Göttingen Observatory, together with Prof. Runge, made observations with a prismatic camera and a coronagraph at Guelma, in Algeria. Part xxx. of the *Astronomische Mitteilungen der königl. Sternwarte zu Göttingen* contains a complete discussion of the results obtained. The brightness and spectral photometry of the corona are first dealt with at some length, and then the spectra obtained are discussed, the origin, wave-length, intensity, and extension of each arc being given; the region photographed was from λ 4590 to λ 3330, and the identifications include the elements Yt, Zr, La, Ce, Nd, and Yb.

THE ERUPTION OF KRAKATOA AND THE PULSATION OF THE EARTH.

The vibration of the earth may be caused by volcanic eruptions and earthquakes, but it is doubtful if any regular pulsation can be called forth by a sudden impulse such as an earthquake or paroxysmal outbursts of volcanoes. If any rhythmic pulsation ever comes into existence, it is most probably due to some exciting cause of long duration, such as volcanoes of continuous activity giving rise to occasional explosions, thus causing frequent blows to the earth. The eruptions of Krakatoa afford an example of such a method of excitation, and we have reason to believe that there were pulsations with a period of about 67m.

The exact time of several minor explosions before the great outburst at 10 a.m., August 27, 1883, is not well known, but if we assume that the air was simultaneously affected, the record of the gasometer at Batavia gives us valuable information as to the sequence of the numerous explosions beginning on August 26. The regular succession of remarkable excursions in the indications of the gasometer, reproduced in the Royal Society report on Krakatoa eruption, is at once evident from the following table:—

	h. m.		Time interval h. m.	h. m.	m.
August 26 ...	5 20	p.m.	6 49 =	3 24·5 × 2 =	68·2 × 6
,, 27 ...	0 9	a.m.			
	1 55	,,	3 20 =	66·7 × 3	
	2 38	,,			
	3 30	,,			
	4 41	,,			
	4 55	,,	3 27 =	69·0 × 3	
	*5 43	,,			
	*6 57	,,			
	8 25	,,	3 22 =	67·3 × 3	
	9 42	,,			
	**10 15	,,	1 00 =	60	
	*11 15	,,			

The great explosions are marked with asterisks, while the sign is doubled for the principal outburst.

The whole interval = 67·2m. × 16. The mean interval of successive explosions on August 27, if those at 1h. 55m. and 2h. 38m. and at 4h. 41m. and 4h. 55m. are counted as a single phenomenon, is also 67m. The recurrence of several explosions at multiple intervals of 67m. shows that they were not always irregular, but had a rhythmic character. Another remarkable fact is the recurrence of explosions at intervals of about 3h. 20m. Recent investigations in surface seismic waves show that the principal phase of world-shaking earthquakes travels once round the earth in about 3h. 19m., which almost coincides with the recurrence intervals in the several explosions of Krakatoa. Thus the outburst of the volcano after the explosion of 5h. 20m. p.m. happened after the surface wave had made two complete revolutions round the earth. In the absence of the seismograph records at that time, we are quite ignorant of the existence of seismic waves during those explosions, but the magnetograph records at Batavia show distinct evidence of the vibrations of the ground. The repetition of explosions at regular intervals of time, which has such significance in the propagation of seismic waves, does not seem to be a mere chance coincidence. The surface seismic wave requires nearly the same time in traversing the different major arcs of the earth, so that they will meet at the antipodal point almost simultaneously, and in returning will again coalesce at the centre of excitation, in the same manner as the Krakatoa air waves. The disturbance at the origin must therefore re-accumulate at the interval of about 3h. 20m., and tend to call forth a new explosion, if the preceding explosion has already excited the seismic waves. This will probably account for the repeated occurrence at such stated intervals. Without laying too much stress on the effect of the seismic waves, which may have been associated with the spasmodic activity of the volcano, we have another reason to believe that the ground vibrated with the period of about 67m.

In spite of the numerous theories which may be advanced as to the cause of the Krakatoa sea waves, a simple hypothesis of the existence of vibrations with a period of about 67m. both before and after the explosion removes most of the difficulties that will be felt in accounting for the definite periods observed in tide-gauges scattered in different parts of the world. The activity of Krakatoa continuing from May to August 27, 1883, the exciting causes would naturally have been numerous during that interval of time to start sympathetic vibration of the earth. Whether the movement of the ground was confined to the region in the immediate neighbourhood of the volcano or extended round the whole earth could not be easily answered, and whether the period coincided accidentally with the natural mode of vibration of the earth or not is a matter of doubt, but the various data hitherto accumulated as to the rigidity of the earth from various phenomena connected with it tend to show that such supposition is efficacious as a working hypothesis.

The examination of mareograms in different parts of the world shows that the times of arrival of the Krakatoa waves are by no means definite, and the diagrams are sometimes markedly different from each other. In some the waves are blended together with the proper oscillations of the bay in which the instrument was placed, while in others they appear as regular secondary oscillations. In all cases they present long-continued disturbances; the more conspicuous waves are, with the exception of that at Batavia, preceded by minor oscillations, which sometimes merge insensibly into the higher waves, so that it is difficult to decide where the disturbance begins. According to the recent investigations by Messrs. Honda, Terada, and Yoshida, the secondary oscillations in numerous bays on the Pacific coast of Japan can be looked upon as forced oscillations by the waves of the same periods, which already exist in the surrounding ocean. During the Krakatoa eruptions the waves made their way into the surrounding seas and ocean, and the regular succession of waves in bays is to be attributed to the effect of forced vibrations.

The periods of Krakatoa waves recorded on mareograms are:—in Batavia, 122m.; Port Blair, 63m.; Negapatam, 68m.; Madras, 81·2m.; Dublat, 65m.; Beypore, 58m.; Karachi, 69m.; Aden, 67m.; Port Alfred, 64m.; Port Elizabeth, 70m.; Table Bay, 62m.; Port Moltke, 61m.; Colon, 70m. The average period of this wave series, with the exception of Batavia and Madras, is about 66m., which almost coincides with the mean period of explosions from 0h. 9m. to 11h. 15m. on gasometer records. This remarkable coincidence can be corroborated with simple physical experiments in the following manner.

When a pendulum with a magnet attached to it is set in vibration by intermittent current acting underneath, the period is double that of the exciting current, or when the pendulum support vibrates in a vertical path, the frequency is half that of the vertical motion. The well-known experiment of Melde, by which a string is set in sympathetic vibration by a tuning-fork of double frequency, and the crispation produced by the vertical vibration of the support, as observed by Faraday, are examples of forced vibrations with period double that of the exciting force. In the application to the Krakatoa eruption, we notice that the motion of the sea-bed near the place of eruption was nearly vertical; consequently, if the sea vibrates in an analogous manner as a pendulum, the period of the excited wave would be double that of the exciting body. The tide gauge at Batavia shows a big wave of 132m. $(=2\times66\text{m.})$ after the great eruption, and the mean period of the successive fourteen waves is 122m., which is nearly double the mean period of previous explosions. It is quite remarkable that if the rigidity of the earth lies between that of steel and that of glass, the mean fundamental period of spheroidal oscillation is about 67m.

According to Lord Kelvin, the tidal effective rigidity of the earth is about the same as that of steel. I have also lately shown that the prolongation of the Eulerian period to the Chandler period of about 430 days is closely connected with the velocity of seismic waves, and tends to point to the same conclusion as regards the rigidity of the earth. According to Bromwich (Proc. London Math. Soc., xxx., 1899), the periods of fundamental spheroidal vibration of an incompressible elastic solid sphere of the size of the earth are 55m. and 78m., when the rigidity is equal to that of steel and of glass respectively. In the above calculation the effect of gravity is also taken into account, which is to reduce the period by a considerable amount; with the rigidity of steel, the period is 66m. without gravity. The period of 67m. is the mean value when the rigidity lies between that of steel and of glass.

The prevalence of waves of the said period in the tide gauges scattered over the different parts of the earth's surface is a striking coincidence, and may be explained by assuming that the source of the waves was excited by vibrations corresponding to the fundamental mode of oscillation of the elastic gravity waves propagating round the earth. That most of the mareograms show continued disturbance before the appearance of big undulations suggests the probable existence of previous vibrations. Since such vibrations are radial and tangential, the waves appearing in bays at some distance from the exciting source would have mostly the same period as the source, while those observed in the neighbourhood of the eruption, as Batavia, would be double. Some doubts may be expressed as to whether the observed period is not peculiar to these bays, so that whatever may be the period of the exciting source, such undulations should invariably appear. With the exception of Aden and Colon, the proper period of the above-mentioned bays generally differs from that of the Krakatoa wave.

The above considerations favour the view that the vibration of the ground near Krakatoa was extremely slow, and had a period of about 67m. Whether this vibration extended all over the earth, or was confined to the vicinities of the volcano, is a question still to be solved. If the said period is really due to the spheroidal vibration of our planet, we shall have opportunities of determining more exactly the period of vibration when volcanic eruptions of the same character as those of Krakatoa take place, or sometimes even with world-shaking earthquakes. It will be worth examining seismograms, if great earthquakes do not give signs of the existence of vibrations of very long period by enhanced disturbances at regular intervals corresponding to the period of vibration of the earth. Another means of detecting the presence of such vibrations would be to examine the mareograms in bays with the proper period of about 67m. Long-continued observation in such bays will probably reveal the nature of the spheroidal pulsation of the earth, if such really exists.

H. NAGAOKA.

REPORT ON ARCTIC MAGNETIC OBSERVATIONS.

THIS report,[1] which was printed under the auspices of the Videnskabs-Selskabet of Christiania, at the expense of the Nansen Fund for the Advancement of Science, deals with magnetic observations made in the Polar expedition of 1898–1902 under the command of Captain Otto Sverdrup. The observations were taken by Messrs. V. Baumann and G. Isachsen, and reduced by Mr. Steen. A large part of the report is occupied by the reduction of the observations, which were not in reality very extensive. The following abstract of the mean results at the four stations where observations were made comprises the principal facts summarised on p. 81:—

Station	Rice Strait	Havne Fjord	Gaase Fjord	Gaas Fjord
Latitude N.	78° 46′	76° 29′	76° 49′	76° 40′
Longitude W.	74 57	84 4	88 40	88 38
Epoch	1899·2	1900·5	1901·6	1902·5
Declination W.	103° 4′	116° 47′	129° 33′	128° 51′
Inclination N.	86 0	87 1	87 41	87 53
Horizontal Force	0·04031	0·03315	0·02518	0·02353

The observations, as is evidenced by the smallness of the horizontal force, were taken at no very great distance from the magnetic pole, and the instruments, as Mr. Steen explains with regret, were not well adapted for use under such conditions. Captain Sverdrup's original programme, which had to be largely modified, would have taken him further from the magnetic pole, but, even if circumstances had been propitious, a modification in the outfit would seem to have been desirable. However zealous the observers, as Mr. Steen justly remarks, they can hardly be expected to retain their full interest in the work unless the behaviour of the instruments gives them confidence that the results being accumulated are trustworthy; and, it may be added, however competent those reducing the observations, the outcome of their efforts must be accepted with some reserve unless reliance can be placed both in the instruments and the observers. In the present case, economic grounds seem to have been largely accountable for the instrumental deficiencies. After the experience gained during the last few years, those responsible for expeditions to the neighbourhood of the magnetic poles will have small grounds for excuse if they fail to exercise due foresight in the choice of magnetic instruments and the training of magnetic observers in their use.

C. CHREE.

DEVELOPMENT OF LEMUROIDS.

THE development of the tarsier (*Tarsius spectrum*) and the slow loris (*Nycticebus tardigradus*) forms the subject of the seventh fasciculus of Prof. F. Keibel's "Normentafeln zur Entwicklungsgeschichte der Wirbelthiere," now in course of issue by G. Fischer, of Jena. The part before us is the joint work of Prof. A. A. W. Hubrecht and the editor. Although the text is necessarily of an extremely technical nature, the beautiful illustrations of embryos permit the student to see for himself how essentially different are the early phases in the development of these two strange Malay animals, which are included by most zoologists in the order Primates.

Prof. Hubrecht has for several years past devoted special attention to the developmental history of the tarsier, on which he has published papers from 1895 onwards. He has regarded the genus as the most primitive phase of the Primate type, sundered very widely indeed from all other lemuroids, with which it was formerly so closely associated. His unique material has been generously placed at the disposal of his coadjutor for the purpose of illustrating this fasciculus of the "Normal Plates," in connection with such material for the developmental history of the slow-loris as could be obtained—material, unfortunately, much less rich than that available in the case of the tarsier.

While Prof. Keibel, as already indicated, worked out the history of the tarsier, Prof. Hubrecht undertook that of the loris, and has likewise written the general account and the comparison of the two forms.

In the concluding section support is given to Prof. Hubrecht's original suggestion that, in view of the marked and radical divergence of their development, it is illogical to include the loris and the tarsier in the same mammalian order. Before their relative positions can be definitely determined and a thoroughly satisfactory classification of mammals in general formulated, it is necessary that the series of these normal plates of development should be very greatly extended, and our knowledge of the ontogeny of such forms as Manis, Galeopithecus, Hapale, and Chrysochloris and other insectivores very largely augmented. As an instalment to this most desirable end, the fasciculus before us is all that could be desired.

R. L.

MARINE BIOLOGY ON THE WEST COAST.[1]

YEAR by year the report on the Lancashire Sea Fisheries Laboratory increases in bulk, and the fifteenth of the series is again rather thicker than its predecessor. It contains fourteen scientific papers, as against eleven in the previous volume, and in the present case two or three gentlemen other than members of the staff have contributed.

As usual, the volume opens with a general report and review by Prof. Herdman, the honorary director of the scientific work. This is followed by twenty pages by the same author upon sea-fishery research, in which he reviews the present situation and the nature of the work done in the international investigations of the North Sea, and criticises the value of that work from the point of view of the fisheries. Without either agreeing with or dissenting from Prof. Herdman's views, we can say that he has set forth a very clear statement of his case.

Mr. Andrew Scott's report on the sea-fish hatching at Piel again records the liberation of several millions of fry, and again lacks any word as to the results of thus increasing the fish population of the area. In another paper on sea-fish hatching in Norway, however, Captain Dannevig discusses what appear to him to be the results of liberating artificially hatched cod larvæ, but his conclusions are traversed by Mr. K. Dahl, whose paper on the same subject suggests that the increase of cod in the district shows no relation to the liberation of the fry, but is dependent upon variations in the currents of water which are responsible for the distribution of the eggs. Thus the value of "interfering" with the natural reproduction of the food-fishes still remains to be proved.

Mr. Scott also reports, as usual, upon the tow-nettings for the year, and we cannot but admire the amount of trouble taken; at the same time, we are inclined to be sceptical as to whether the value of such work is equal to the labour expended upon it.

The same author contributes a short paper upon the food of young fishes. In this paper also, Mr. Scott illustrates his capacity for taking pains, and there is no doubt that such work will prove valuable, especially when taken in conjunction with work upon the food of mature fishes, such as Mr. R. A. Todd has contributed to the North Sea investigations.

Mr. James Johnstone's paper upon this subject deals only with the plaice and dab, and is upon the same lines as the one he contributed last year upon the same subject. He has now, however, gone more carefully into detail, and shows that, although the dab is less particular than the plaice in its choice of food, both the species depend mainly upon lamellibranch molluscs, especially Solen, and his observations on this point agree well with those of Mr. R. A. Todd on the same species in the North Sea.

The fish-marking experiments were continued during

[1] Report of the Second Norwegian Arctic Expedition in the *Fram*, 1898–1902, No. 6. "Terrestrial Magnetism." By Aksel S. Steen. Pp. 82. (Christiania, 1907.)

[1] No. xv., Report for 1906 on the Lancashire Sea-fisheries Laboratory at the University of Liverpool and the Sea-fish Hatchery at Piel. Pp. 269; illustrated. (Liverpool, 1907.)

1906, and Mr. Johnstone's results agree with his previous ones in so far as they show an off-shore migration in the summer and an along-shore movement in the winter. A number of other movements were observed, just as in the North Sea, where individual fish moved long distances, *e.g.* to the east and south coasts of Ireland, but such movements appear to be irregular according to present knowledge.

The same author also gives a valuable contribution on sewage pollution of shell-fish, and in this connection we regret that Prof. Herdman has not been able to give us a report upon the action of copper in connection with the purification of infected shell-fish, of which a preliminary statement appeared last year.

As usual, there is no lack of charts, tables, and illustrations, and the volume certainly shows very well Prof. Herdman's idea as to the association of scientific research and fishery problems.

FRANK BALFOUR BROWNE.

INCANDESCENT ILLUMINANTS.[1]

A LITTLE more than twenty years ago Auer von Welsbach, who was engaged on researches on the rare earths, invented the modern incandescent mantle. His first mantles were made of zirconia and yttrite earth in the proportion to make a normal zirconate. Shortly afterwards he found that the best material has a basis of thoria. Pure thoria, which requires care in its preparation, gives very little light, but if a small percentage of a coloured and permanent oxide, such as ceria, is added, it gives good illumination.

There has been much discussion about the theory of the incandescent mantle. It has been generally assumed that the temperature of a Bunsen burner is too low for a mantle to give the light it does by simple radiation unless it is much hotter than the flame. Unfortunately, the temperature of the flame is generally taken with a thermocouple, and this gives far too low a reading, as the thermocouple never reaches the real temperature of the flame; but, admitting that the temperature of the flame is high, it is still urged that the light given by the thoria with a small percentage of ceria is so great that there is something more than mere thermal radiation. It is said that the ceria acts as a catalytic agent, and that it oscillates between two states of oxidation. Ceria does act somewhat in the same way as platinum; for instance, if a ceria mantle is put on a lighted burner, the burner turned out, and the gas turned on again, the ceria mantle will glow and finally light the gas. It is odd that this is not brought forward by the advocates of the catalysis theory; but the opponents might urge that zirconia will do the same thing, and the zirconia mantle gives very little light. This does not prove that ceria does not increase the rate of combustion, however.

According to the simple radiation theory, the light depends only on the emissivity, or blackness of the mantle, and its temperature. Its temperature must be lower than that of the flame, as it must be robbing the flame of the heat it radiates. In order to give the flame every chance of supplying the heat, the threads of the mantle have to be made very fine, so that the flame can rush through the meshes, and the hot gas should be in brisk movement through the interstices of the mantle. By using a special draught arrangement, known as the intensive system, about twice the light per cubic foot of gas can be obtained. In order to get the highest temperature the emissivity should be low, that is to say, the mantle should be very white; but then, though it would get to a high temperature, it would give very little light. On increasing the emissivity the light will first increase, but this means a lower temperature, so that as the emissivity is increased from white to black the total radiation increases, but as that means a greater abstraction of heat from the flame, the mantle is cooler, and therefore radiates a larger proportion of the energy as heat and a smaller proportion as light, so the mantle gets redder and gives less light. This is just what happens in practice, whether ceria or any other coloured oxide is used.

It has been urged that, as pure ceria is white, adding it cannot make the mantle blacker; but ceria is white only when cold. A mantle may look quite white cold, and be darker in colour when hot. Rubens has devised an experiment to show this. The mantle is strongly illuminated by an arc and condenser, and its image is thrown on the screen. It looks quite white, of course. On lighting the gas, the mantle, instead of becoming still brighter, at once becomes dull. Again, alumina, which is white, gives little light. Chromium oxide is so dark that it gives only a dull red glow. But on adding a little chromium oxide to the alumina, a dark red light is first given, because the chromium oxide is too dark, but as soon as it combines with the alumina to make a light pink mantle a good light is obtained.

The incandescent mantle is now applied, not only to the ordinary Bunsen burner, but to an inverted form, which lends itself to decoration, and to the petroleum lamp. It is now also applied to air carrying a little hydrocarbon gas, and this application is said to provide an extraordinarily cheap light, which is especially useful for country houses.

One of the drawbacks to gas, compared with electric lighting, is that merely turning on does not light gas. This difficulty has been largely overcome by the use of the bye-pass, but further advances have been made. Welsbach has discovered that an alloy of cerium and iron gives off sparks on being scraped or filed, and a burner has been designed in which the act of turning on the gas scrapes a little wheel of this alloy, causing a spark which lights the gas. This overcomes the drawback of having a little jet always burning. Another invention allows the gas to be lighted from a main tap. Each burner has an attachment which lets the gas straight through to the burner when the pressure is on, but on turning the main supply off, and allowing a little gas to pass at the controlling tap, the attachment to each burner turns off the burner and lights a little pilot jet, which keeps alight until light is wanted again. On turning on the main tap the pilot jets light the various burners and go out themselves. By this means burners can be fully lighted up by turning one tap at the door of the room.

The electric incandescent light is undergoing a great change. Carbon is being replaced by metal wires. It has been found possible to make wires of high enough resistance of tungsten, osmium, tantalum, and a few other metals and compounds. The osmium lamp was the first of these, but there was difficulty in making it of high enough resistance. The tantalum lamp is now in great demand. It is made for 100 volts to 130 volts, and is much more efficient than the carbon lamp. It will not last long on alternating currents, however. The wires of a lamp that have been run for some time on a direct current show a curious notched or crinkled appearance under the microscope; but a wire that has been run on an alternating circuit looks as if the metal had been melted into short cylinders with round ends, and these cylinders had stuck together end to end without their centres being in a line. Sometimes the little cylinders are nearly separated, merely touching at a corner. This action is very extraordinary, and has never been explained. In addition to this, when a lamp breaks down on an alternating circuit, the wire sometimes goes at one point and sometimes it breaks in several places, and tangles itself up in an extraordinary way; at other times it breaks up into numerous little pieces, which will be found lying on the inside of the globe. Some of the other lamps show a change under the action of the current, but it is not so marked as in the case of tantalum.

One of the most interesting of the new lamps is the zircon. It is said to be made of zirconium and tungsten, and lamps of this material have been made for 200 volts, a matter of the greatest importance from a distribution point of view. It is possible that the conductor is really a zirconide of tungsten, and this opens up a new series of compounds. A zircon lamp for 100 volts has really six separate loops of wire mounted in series inside a bulb. A recent improvement is to provide an extremely

[1] Abstract of a Discourse delivered at the Royal Institution on Friday, April 26, by Mr. J. Swinburne, F.R.S.

light spring for each loop, so as to keep it taut. The lamp can then be used in any position.

Tungsten seems to be the favourite metal, as it gives a very high efficiency. It is probable the lamp of the future will have an efficiency of nearly a candle per watt, and this is promised by the use of tungsten. At the same time, it must be admitted that to make a wire with a resistance of 500 ohms small enough to give twenty candles with 20 watts is a triumph of inventive skill.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The board of anthropological studies recommends in a report to the Senate (1) that a diploma in anthropology be established; (2) that an advanced student who has studied some branch of anthropology under the direction of the board, and has presented a thesis, which thesis has been approved for a certificate of research, shall, on the payment of such fees as the Senate may from time to time determine, be entitled to a diploma testifying to his competent knowledge of anthropology; (3) that any member of the University having graduated before the date of the establishment of the diploma, who has presented a thesis on some branch of anthropology, which thesis has been approved by the board, shall, on the payment of such fees as the Senate may from time to time determine, be entitled to a diploma testifying to his competent knowledge of anthropology.

The John Winbolt prize for engineering for 1907 has been awarded to J. E. Sears, St. John's College, for his essay "On the Longitudinal Impact of Metal Rods with Rounded Ends."

The special board for biology and geology has nominated Mr. A. E. Shipley the representative of the University on the council of the Marine Biological Association from the annual meeting of the association in 1907 to the annual meeting in 1908.

Manchester.—The provision for study and research in metallurgy has been recently very materially increased. The equipment for metallography, as also for the heat treatment and mechanical testing of metals, has been brought up to date. Dr. H. C. H. Carpenter, late of the National Physical Laboratory, was elected professor of metallurgy a short time ago, and Mr. C. A. Edwards (Carnegie scholar of the Iron and Steel Institute) has just been appointed demonstrator and research assistant.

Sheffield.—The University council has appointed Mr. Arthur Holden to the post of assistant lecturer and tutor in mathematics. Mr. Holden, who was a scholar of Queens' College, Cambridge, is at present lecturer in mathematics at St. Mark's College, Chelsea. He will enter upon his new duties next session.

The plans for the restoration of the main building of the Merchant Venturers' Technical College, Bristol, have now been approved by the Society of Merchant Venturers; they involve very considerable changes in the arrangements of the original building. From the description of the provision to be made in the new building, it appears that the governors are concentrating the work of their college so as to provide a much more extensive equipment for those departments which train civil, mechanical, electrical, and mining engineers, and prepare for the B.Sc. degrees of the University of London in science and engineering. With this end in view, they will discontinue certain portions of the work formerly undertaken by the college.

Representatives of the University of London to the number of nearly a hundred are this week paying a visit to the University of Paris. The party includes Sir Edward Busk (Vice-Chancellor of the University), Sir Philip Magnus (the Parliamentary representative of the University), Sir Arthur Rücker (the Principal), Dr. Pye-Smith (ex-Vice-Chancellor), members of the Senate, Deans of the several faculties, Mr. P. J. Hartog (Academic Registrar), and other guests. On May 21 the visitors assembled in the grand amphitheatre of the Sorbonne under the presidency of M. Briand, Minister of Public Instruction, who with M. Liard, Vice-Rector of the University of Paris, delivered addresses of welcome, and Sir Edward Busk replied. Prof. Alfred Croiset and Prof. Gardner, Dean of the Faculty of Arts of the University of London, also spoke. Afterwards the English visitors were entertained at lunch by the municipality of Paris, and in the afternoon paid a visit to Versailles. A reception in honour of the visitors was given by the British Ambassador in the evening. On May 22 there was an excursion to Chantilly. To-day is to be devoted to an inspection of the various departments and laboratories of the Paris University; in the afternoon a reception will be given in honour of the visitors at the Elysée by the President of the Republic and Mme. Fallières. In the evening the English visitors will be the guests of the University of Paris at dinner at the Sorbonne, when the French Ministers of Public Worship and of Foreign Affairs are expected to be present. The dinner will be followed by a concert in the great hall, and a conversazione in the reception rooms of the Sorbonne. The party will return to London to-morrow.

The urgent needs of the University of Oxford led to an important meeting being held on May 16 to consider a scheme for raising a fund to meet them. Lord Curzon, Chancellor of the University, presided over a large and distinguished assembly, and in the unavoidable absence of the Lord Chancellor proposed a resolution:—"That a fund be raised, entitled the Oxford University Appeal Fund, to meet the needs of the University as set forth in the letter signed by the Chancellor and Vice-Chancellor, which was published in the newspapers on May 2, 1907." Speaking in support of the resolution, Lord Curzon announced that the fund was being started with promises and gifts amounting to 57,000*l.*, which includes 10,000*l.* from Mr. Brassey, 10,000*l.* from Mr. W. W. Astor, 2500*l.* from Mr. W. F. D. Smith, 2000*l.* from Lord Curzon, and five donations of 1000*l.* Following the Chancellor's eloquent appeal, the Chancellor of the Exchequer seconded the resolution (which was eventually carried unanimously), and took the opportunity to point out several directions in which the work of Oxford University needed development to keep the University abreast of modern needs. The Archbishop of Canterbury moved:—"That a body of trustees of not less than nine, nor more than twelve, be appointed for the administration of the fund, composed of one-third resident and two-thirds non-resident members of the University, and that the hebdomadal council be requested by the Chancellor to nominate the University representatives, and that the Chancellor and Vice-Chancellor be authorised to consult with the leading supporters of the movement as to the appointment of non-resident trustees." Lord Milner seconded the resolution, and it was carried. A further resolution was adopted appointing a committee to consider the best means of raising subscriptions to the fund. Though we are of opinion that the provision of adequate funds for our universities is a State duty, we hope that until that duty is recognised by the Government our men of wealth will see to it that the work at Oxford is not hampered by the want of what is really a modest amount when compared with the greatness of the needs of the University.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 14.—"The Purification and Testing of Selenion." By R. **Threlfall**, F.R.S.

The paper deals with the purification and testing of considerable quantities of selenion with the object of investigating the electrical constants of the element in the pure state. It was found that Ekman's and Petterson's method is suitable and satisfactory as a means of purification of selenion from other known elements, with the possible exceptions of mercury, tellurium, and arsenic. The analytical separation of selenion from tellurium was investigated, and it was found that the most satisfactory method is by fractional sublimation of the dioxides. It is shown that a sharp separation can be made by subliming a mixture of the oxides containing one part of tellurium to ninety-nine parts of selenion at a temperature of 360° C. The sublimate contains certainly less than one-tenth per cent. of tellurium, and probably less than one-fortieth per cent., the extreme limit of analytical discrimination.

A thorough investigation showed that tellurium cannot be detected in presence of selenion in quantity by spectroscopic analysis. Details as to the method of carrying out Ekman's and Petterson's purification are given. The purified product was tested for arsenic with constant reference to check and blank trials, and it was found that arsenic was present to the extent of 0·00038 per cent. Mercury was sought for by the method suggested by Marcel, and also by Dr. Sand with a special electrolytic apparatus, but none was found.

The remaining difficulty in regard to a possible solubility of selenion dioxide in selenion was not entirely overcome, though it is shown that by distillation of a mixture of selenion and selenion dioxide in an inert gas nearly, if not all, the dioxide can be separated, but there does not seem to be any perfectly satisfactory criterion as to the complete absence of dioxide. This uncertainty prevented the subject of the conductivity of really elemental selenion from being undertaken, but the highly purified material obtained was examined by Messrs. Vonwiller and Mason with respect to its specific inductive capacity. The material employed by these observers was returned to the author for re-examination, and it is shown that no material amount of impurity was introduced during the necessary meltings and treatment which it had undergone.

Royal Microscopical Society, April 17.—Mr. G. C. Karop in the chair.—The Podura scale: E. M. **Nelson.** The author traced the efforts of previous observers to interpret the markings on the scales, giving figures—which were drawn to an enlarged size upon the board—to illustrate the various interpretations, including the result of his own observations.—The root bacteria of pulse: Dr. Antonio **Rodella.**

Zoological Society, April 23.—Dr. J. Rose Bradford, F.R.S., vice-president, in the chair.—The ears of the African elephant as a race character: R. **Lydekker.** To illustrate this paper, a large number of photographs and several specimens were exhibited. The author considered that there must be many more local races than those already named by Dr. Matschie, although, with the present material, he hesitated to give separate designations to several of these. He ventured, however, to propose new names for the elephant of the eastern side of Cape Colony; for that of Mashonaland, as typified by a head in the Imperial Institute; for that of the Lake Rudolf district, as represented by a head presented to the British Museum by Mr. H. S. H. Cavendish; and for the Somali elephant, as typified by a head in the collection of S.A.R. le Duc d'Orléans at Wood Norton, this last race being characterised by the very small ears, which, however, were quite different in shape from those of *E. a. knochenhaueri*. The author also directed special attention to a skull from the Albert Nyanza district, for which he had previously suggested the name *E. a. albertensis*. Differing in many points from those of other African elephants, this skull showed a remarkable resemblance to that of the extinct Indian *E. planifrons*, thus suggesting the descent of the African elephant from that species.—Descriptions of three new species and five new subspecies of Siberian birds: S. A. **Buturlin.**—A list of small mammals obtained in the islands of Saghalien and Hokkaido by Mr. M. P. Anderson for the Duke of Bedford's exploration of eastern Asia: Oldfield **Thomas.** Fourteen species were recorded from Saghalien and thirteen from Hokkaido. The faunas of the two islands proved to be very similar to each other, although in some cases subspecific differences between the representative forms in each were perceptible. In one genus only, Micromys, the relationship of Hokkaido seemed to be with the main island of Japan rather than with Saghalien.—A list of the cold-blooded vertebrates of Saghalien: G. A. **Boulenger.**—Notes on hybrid bears: H. **Scherren.** The author referred to cases that had occurred in the society's gardens, the long series bred by Herr Nill in his zoological garden at Stuttgart (now broken up), and a recent case in the garden at Halle-an-der-Saale. Reference was also made to cases said to have occurred at Cologne and Hanover, but for these the evidence was not conclusive.—Some new species of earthworms of the family Eudrilidæ, belonging to the genera Polytoreutus, Neumaniella, and Eminoscolex from Mt. Ruwenzori: F. E. **Beddard.**—South American pseudoscorpions of the family Cheliferidæ in the collections of the British and Copenhagen Museums: C. J. **With.**

Physical Society. April 26.—Prof. J. Perry, F.R.S., president, in the chair.—Electrical conduction produced by heating salts: A. E. **Garrett.** The experiments described are divided into two series. The first, of a preliminary nature, consisted in testing a large number of inorganic compounds up to a temperature of 360° C. Several compounds, chiefly halogen salts, were found to produce easily detected conductivity when heated. In the case of zinc iodide, conductivity could be detected at the ordinary temperatures of the laboratory. The second series was confined to special cases in order to ascertain the causes of the increased conductivity. It was found that in all the cases tried a formula of the form $I = a\theta^{\frac{1}{2}}e^{-\frac{b}{\theta}}$, where I = saturation current, a and b constants, and θ the absolute temperature, represents with fair accuracy the connection between the saturation-current and the absolute temperature.—Solenoids which will move under the action of the earth's magnetic field: W. B. **Croft.** In showing Ampère's experiments, it is not very easy to complete the theory of magnetism by making a solenoid point to the north. Many years ago Ritchie made a solenoid with an iron core, which acted as a motor with the help of a mercury commutator. A copper solenoid without core was shown which had been made to rotate in this manner. The method is unsatisfactory and uncertain, owing to the rigidity assumed by the skin on the surface of mercury in certain conditions. The ampere mercury contacts cause no difficulty when a wire rotates on its own axis, but there are strong hindering forces when the wire is pushed through the mercury, partly from the skin and partly from amalgamation. The best pattern for a solenoid is suggested by the moving coil of an electrodynamometer. Two of such were shown, which were conveniently worked by four dry cells in series. Each of these was hung with very thin metal strip by bifilar suspension, the threads about 5 inches long and 1/10th inch apart. The bifilar control makes the movements manageable; it is convenient to set the coils N. and S., or the axis of the corresponding magnets E. and W., so as to make these swing up to the meridian when a current is sent through the coils.—The influence of pressure upon convection currents, and a criticism of J. Stark's relation between kathode fall of potential and temperature: W. S. **Tucker.** Stark employed as kathode a wire mounted radially in a globe-shaped vessel. The wire was heated electrically, and its resistance, and hence its temperature, determined. He refers to the weaknesses of the method:—(1) the conduction of heat away from the wire by its leads causes the observed mean temperature to be too low; (2) the error made in assuming the kathode dark space temperature to be that of the heated kathode. The author's apparatus was devised to show how seriously these weaknesses affect Stark's results.—A simple apparatus for mechanically illustrating the tangent and sine laws: J. A. **Tomkins.**

Geological Society, May 1.—Sir Archibald Geikie, Sec.R.S., president, in the chair.—The xerophytic character of coal-plants, and a suggested origin of coal-beds: Rev. Prof. George **Henslow.** It is held that the characteristic feature of the great coal-forests was xerophytic, and the vegetation appears to be of an upland type. Illustrations are given from recent and Carboniferous plants to show the characters of leaf, root, and stem which separate these classes of plants. The position of coal-seams is accounted for by the action of earth movements in late Carboniferous times; these threw the forest-bearing surface into shallow waves and troughs, which became gradually accentuated, the latter being gradually filled with sediment, upon which, during intervals of rest, new forest growth took place.—Petrological notes on the igenous rocks lying to the south-east of Dartmoor: H. J. **Lowe.** The rocks described are contained in the Newton Abbot district, the region east of the Dart and south of the Teign. They are most nearly related, both geologically and petrologically, to those of south-west Devon, or the Plymouth district described by Worth.

Society of Chemical Industry, May 6.—Mr. R. J. Friswell in the chair.—An apparatus for the estimation of carbonic acid: H. W. **Rowell.** The sample of carbonate is decomposed by a suitable acid and boiling, and the carbon dioxide collected and weighed in potash bulbs. The apparatus consists of a 70 c.c. flask with a ground-glass stopper carrying a stoppered funnel, for admitting acid and subsequently air, and a bulb water vapour trap. An air washing tube, drying tubes, potash bulbs, and a supporting stand and aspirator complete the apparatus.—The works chemist as engineer: O. **Guttmann.** All chemical works have a large number of engineering problems to solve, and, as a rule, the chemist will have to look after them. The author explained in detail the selection of a site, the disposition of buildings and plant, the erection of buildings to standard sizes, materials, plant, &c., in view of the products to be worked and any special risks attached to them. The installation of a power-house and the many engineering details which are of advantage in the economy and control of the production of power, smoke preventers, automatic stokers and special grates, as well as water softeners and feed-water heaters, were dealt with. The author emphasised strongly that "works operations were not simply laboratory operations writ large." In his opinion it was useless to teach chemical technology with the help of beakers and test-tubes. To train a chemist properly, he ought to go to college better prepared, and have at least four years of study, with more mechanics and physics in the beginning and a proper course of chemical technology in the end. After that it is only necessary that manufacturers should realise that a works chemist is not solely an analyst, but a highly useful practical technologist, who, given a little confidence, will in a short time repay his salary many times over. The paper concluded with the sentence:—"We have heard too much about the many chemists engaged on research in the large colour works of Germany. Highly valuable as they are and important as their discoveries were, the German chemical industry is infinitely more indebted to that far greater number of works chemists, who patiently and thoroughly investigated the manufacturing processes, who had the ability to devise improvements and economies, and who found generous manufacturers and their college-trained sons to give them their confidence. It is on these lines that we must progress."

Paris.

Academy of Sciences, May 13.—M. A. Chauveau in the chair.—A functional equation occurring in the theory of certain equations on derived partials: Émile **Picard.**—Theory of the speaking condenser of M. Argyropoulos: Marcel **Deprez.** Explanation of the theory of the condenser in the secondary coil of transformer of microphone described by M. Argyropoulos on May 6.—The glucose coming from the "potential sugar" (*i.e.* the glucosides) of the blood: R. **Lépine** and M. **Boulud.** Experiments on dogs showing the effect of invertin and fibrin on the quantity of glucose which is set free in defibrinated blood from the glucosides present (compare Lépine and Boulud, *Comptes rendus*, October 8, 1906).—The employment of potassium permanganate to remove sodium thiosulphate (so-called "hyposulphate") in photography: Albert **Granger.** The author points out that the preservation of photographic positives and negatives obtained by means of silver salts depends upon the total elimination of the thiosulphate ("hypo") used for fixing them. Many oxidising agents have been introduced to destroy the last traces of thiosulphate, for example, the perborates and persulphates. These salts are, however, very inconvenient. They are expensive, and they tend tn spoil either positives or negatives if allowed to act beyond a certain time. It is difficult to tell, too, when they have completed the oxidation of the thiosulphate. Potassium permanganate is free from these disadvantages, and the following method of procedure is suggested for ordinary work. The positive or negative, after rinsing two or three times for about a minute with water, is placed in a porcelain or glass dish, and for half-plate size 250 c.c. of dilute permanganate, made by diluting 10 c.c. of a solution containing 1 gram per litre, is added. If the solution turns brownish add more permanganate until a pink tint remains. Then place the print in a 1 per cent. oxalic acid solution to remove any faint brown deposit. Wash with ordinary water until clear. Oxalic acid gives a precipitate with ordinary water, thus giving an indication when washing is completed.—Observations of the new planet ZB made at the Marseilles Observatory: M. **Coggia.**—The expedition to Turkestan for the observation of the solar eclipse of January 14, 1907: Milan **Štefánik.**—Approximate convergence in mathematical analysis: Ernst **Fischer** (compare M. Riesz, *Comptes rendus*, March 18).—A general method for the solution of Dirichlet's problem: S. **Bernstein.**—The representation of equations of the fourth nomographic order with three and four variables: Maurice **d'Ocagne.**—The resistance of air to the movement of bodies: M. **Canovetti.**—The rapidity of detonation of explosives: M. **Dautriche.** This is a continuation of work already published (*cf. Comptes rendus*, vol. cxliii., p. 641).—The alteration of the absorption bands of crystals, and the law of variation of delay of movement of electrons at different temperatures: Jean **Becquerel.** Nernst's theory and the values of the differences of potential at the point of contact of two electrolytes in solution: J. **Guyot.**—The liquefaction of air: Georges **Claude.**—The phosphorescence of calcium compounds containing manganese.—Influence of the constitution and mass of the molecules on the wave-lengths of the radiation emitted: L. **Bruninghaus.**—Action of fluorine on selenium. Preparation of tetrafluoride of selenium: Paul **Lebeau.** Working with metal vessels, so as to prevent any chance of oxyfluorides being obtained, the author prepared tetrafluoride of selenium by direct union, and found it to be a colourless liquid, boiling about 100° C., and forming a white crystalline solid at about −80° C. Brought into contact with water, the compound decomposes with evolution of heat, giving a solution containing selenious and hydrofluoric acids,

$$SeF_4 + 2H_2O = SeO_2 + 4HF.$$

The compound behaves as if saturated, so that the hexafluoride of selenium mentioned by Prideaux (Chem. Soc., vol. lxxxix., p. 316) might require further investigation.—Spontaneous oxidation of cobalt hydrate in alkaline solution: André **Job.**—The silicates of aluminium and calcium: O. **Boudouard.**—The constitution and properties of samples of steel containing boron: Léon **Guillet.**—Condensation of oxalic esters with tertiary aromatic amines: A. **Guyot.**—Some caoutchouc-bearing plants of the south of Madagascar: J. **Constantin** and H. **Poisson.**—Observations on the constitution of the membrane of the Péridiniens: Louis **Mangin.**—The delimitation and relations of the principal species of *Illipées*: Marcel **Dubard.**—The influence of light on the assimilation of the reserve organic matter of plants and bulbs by the plantules in the course of their germination: W. **Lubimenko.**—The function of sieve tubes (botanical): M. **Molliard.**—The comparative effect on the heart of different potassium salts of the same molecular concentration: H. **Busquet** and V. **Pachon.**—The occurrence of iron in animal and vegetable tissues: A. **Mouneyrat.** The author states that he has found iron in all tissues, and that, in fact, iron seems to be a constant constituent of all living cells.—The extraction of the pigments from batrachians: A. **Magnan.**—The adipose tissue replacing the vibratory muscles of the wings after the nuptial flight in queen-ants: Charles **Janet.**—The glacial formations of the Chaux-d'Arlier: Paul **Girardin** and Fritz **Nussbaum.**—The oceanic lithology of ancient seas: J. **Thoulet.**

Cape Town.

South African Philosophical Society, March 27.—Mr. S. S. Hough, F.R.S., in the chair.—A property of symmetric determinants connected with the simultaneous vanishing of the surface and volume of a tetrahedron: T. **Muir.**—The development of the ovary and embryo-sac in *Cassia Tomentosa*: W. T. **Saxton.**—The fertility of snme colonial soils as influenced by the geological conditions: C. F. **Juritz.** Chemical analyses of the soil may be of three different types, according as they show (1) how much plant food exists in a form immediately available for plants; (2) what proportions are present as a reserve stock; or (3) the aggregates of the plant-food constituents in the soil. The third type of analysis may have its value for the geologist, but only the first and second afford the farmer any indications of the land's worth, the former indicating its immediate productiveness and the latter its permanent value. Until recently sufficient samples had not been analysed by a method that could be taken as a trustworthy means of ascertaining the reserve stock of plant food in the colony's soils, nor had the Geological Commission progressed to an extent sufficient to enable it to be used as a working basis. Furthermore, the soils that had been analysed had been selected from definite fiscal divisions without regard to geological conditions. Some 200 soils had, however, been selected from the number hitherto analysed and taken as fairly representative of various geological formations. Of the soils derived from the pre-Cape rocks, those from the Malmesbury slates in the south-western part of the Colony were found to be poor all-round on the average. In the northern portion of the country, where the Campbell Rand series extended over a large area, the soils were rich in lime. The soils derived from the Table Mountain series, which were the lowest rocks of the Cape system and consisted of little else than silica, lacked all the essential mineral ingredients of plant food. Above the Table Mountain series lay the Bokkeveld beds, and these produced soils with satisfactory proportions of plant food. The highest rocks of the Cape system, namely, the Witteberg series, produced soils which may be anticipated to resemble those of the similar Table Mountain series, and the few that had been analysed bore out this view. This was the district in which bone-diseases in cattle prevailed. Of the soils of the Karroo system, those derived from the Burghersdorp beds and Stormberg series were found to be well supplied with potash and phosphates, and contained large proportions of lime. This was also the case with the soils formed from the Uitenhage series, in the Cretaceous system. For hundreds of miles fertile silts were transported by rivers in flood. To the silts thus brought down from the Karroo, the Oudtshoorn division owed its fertility, and the soil of that division was now undergoing transportation to the sea, except where deposited in the Riversdale and Mossel Bay divisions en route.—Some new fossil reptiles from Victoria West: Dr. R. **Broom**. A description is given of three new reptiles found by Mr. T. J. R. Scholtz at Victoria West, in beds which are believed to correspond to the Lystrosaurus beds of Colesberg, Middelberg, and Cradock. Hitherto almost the only fossils known from these beds have been the aquatic Lystrosaurus and fish.—Solifluction: Prof. E. H. L. **Schwarz**. Solifluction is a term coined by Andersson for the flow of saturated soil down mountain sides. Originally used only for regions covered with ice and snow, the object of the present paper is to show that the same action goes on in temperate countries, only to a smaller extent, producing stone courses in the mountainous districts, and a gradual downward creep of soil and subsoil in parts of the country which have less relief. Under the same term must be included the flow of volcanic ashes saturated with water, which are characteristic of the so-called mud-volcanoes in South America, Java, &c.

ALCOHOLISM.

The Psychology of Alcoholism. By George B. Cutten. Pp. xvi+357. (London and Felling-on-Tyne: The Walter Scott Publishing Co., Ltd., 1907.) Price 5s.

The Drink Problem in its Medico-Sociological Aspects. By Fourteen Medical Authorities. Edited by Dr. T. N. Kelynack. Pp. viii+300. (London: Methuen and Co., n.d.) Price 7s. 6d. net.

MR. CUTTEN writes lucidly and well. He has delved deeply in a somewhat dreary field of literature. All men know that alcohol when taken in excess is very injurious, and may be lethal. It has contributed much to the gaiety, but more to the gloom, of nations. In the present work many of the physical and apparently all the mental ill-effects ever alleged by anyone as due to alcoholism are set forth in detail. A large part of the book consists of quotations, some of which (*e.g.* footnotes, pp. 210 and 211) obviously controvert, and were intended by the original writers to controvert, the opinions in favour of which they are quoted. There are some errors. It is stated (p. 1) that

"The use of alcohol is universal. . . . Some form of intoxication has always been found by the investigators of the most primitive people."

Doubtless all peoples who have been in a position to obtain alcohol have abused it, but until recently it has been beyond the reach of various savages, for example, the Esquimaux and Tierra-del-Fuegians.

"Moderate drinking has rarely been carried out successfully, for it almost invariably develops into excess; but to-day there appears to be less and less control, the moderate drinker passing very quickly into the impulsive, violent consumer" (p. 2).

As a fact, all races (*e.g.* Red Indians) when first introduced to drink are "furious drinkers, furious in their drink." But during the lapse of many generations they grow more moderate, as witness the Jews and south Europeans, who were drunken anciently, but to whom alcohol is now "like the taste of sweetness whereof a little more than a little is by much too much." The statement that in England "the women drunkards equal or exceed the men in number" is an exaggeration.

The author gives a very full account of the mental effects of acute and chronic alcoholism, but passes lightly over that vital matter, the psychology of the *potential* drunkard. Why do men drink? Presumably because the act promotes pleasure or surcease of pain or discomfort. Why do some men drink in moderation and others in excess? Formerly it was believed that moderation depended entirely on self-control. But almost any moderate drinker may satisfy himself by introspection that he exercises little restraint. He drinks, as a rule, as much or nearly as much as he desires. At least he has not to struggle against that dire longing that drives the dipsomaniac to destruction as with the force of a tempest. A headache or two, and a little experience of "hot-coppers," suffice to secure his sobriety. A drunkard faces them every day, and ruin, ill-health, and death as well. Men differ, therefore, in their susceptibility to the charm of alcohol. Those who are most tempted tend on the average to drink most, and so to perish. In the course of ages the survival of the fittest results in a race of moderate drinkers, such as the inhabitants of the vine belt in Europe and of the palm-toddy region in Africa. Neither climate, strength of beverages, civilisation, nor race has any influence. Drunken races are found in all zones of the earth; peoples (*e.g.* some savages) who have experience of only very dilute solutions in scanty quantities are very drunken when opportunity serves; some civilised and some savage races are drunken and some are temperate; and all races which now are temperate were anciently drunken. The invariable rule is that every race that commands a sufficient supply of alcohol is temperate (*i.e.* resistant) precisely in proportion to the duration and severity of its past experience of alcohol. The same is true of opium and every lethal disease. Thus, of all peoples that are in the habit of indulging in opium, the natives of India, who have used it longest, are most temperate, and of all peoples exposed to malaria, the natives of tropical Asia, Africa, and America are the most resistant to the disease.

By way of demonstrating that parental drunkenness is a cause of filial degeneration, Mr. Cutten quotes the opinions of various physicians who have proved that it is not uncommon amongst the ancestors of asylum patients. Unfortunately, the extent to which it has prevailed amongst the ancestors of people in the same class of life who are not insane has not been ascertained. No race that has long used and abused drink shows any signs of degeneracy. Thus Italians, south Frenchmen, and Germans are not more degenerate than Tierra-del-Fuegians or Australian Blacks. The protective evolution of races which have been exposed to narcotics or disease is not seriously disputed nowadays. It is difficult to understand, therefore, how races can grow stronger in each generation through the survival of the fittest, and yet, as implied by the authorities quoted by Mr. Cutten, weaker through the inherited effects of parental drunkenness. Obviously, natural selection has no scope if every child is inferior to the parent.

"The Drink Problem," though shorter, is more comprehensive than Mr. Cutten's book, and is altogether a valuable, practical, and readable volume, refreshingly free from fanaticism. Dr. Harry Campbell discusses very interestingly drinking amongst ancient peoples and primitive races, and traces the natural evolution of sobriety. Prof. Sims Woodhead deals with the pathology of alcoholism, and Dr. Claye Shaw with its psychology. Dr. Hyslop discusses alcoholism and mental disease. Other interesting essays are "Alcohol and Public Health," "Alcohol and Life Assurance," and "Alcohol and Pauperism."

Naturally amid much agreement is some conflict of opinion, a fact which has its humorous aspect. Thus, at the close of his essay on "The Criminology of Alcoholism," Dr. Sullivan, who believes that parental alcoholism "has a very high degree of importance . . . in the genesis of those conditions of arrested or perverted development which characterise the moral imbecile and instinctive criminal," refers the reader to the essay on heredity. When, however, we turn to that essay, we find no reference to the alleged effects of parental intemperance on the morals of offspring, but a statement that "we should expect those communities which for the greatest number of consecutive generations have had opportunities for chronic drunkenness—or what comes to the same thing, those possessing the most ancient civilisations—to be the most disposed to temperance."

BERNTHSEN'S ORGANIC CHEMISTRY.

A Text-book of Organic Chemistry. By A. Bernthsen. Edited and revised up to date by Dr. J. J. Sudborough. Pp. xvi+658. (London: Blackie and Son, Ltd., 1906.)

THE new issue of Bernthsen's text-book, which has been edited and revised by Prof. Sudborough, is a great advance on former editions. Although the general arrangement of the contents has been preserved, the amount of additional material has so much extended the scope of the original work that, in its present form, it is practically a new book. Some of the more prominent alterations and additions may be briefly noticed. In the first place, there are frequent references to physical chemistry and its application to problems of organic chemistry which are interesting and suggestive. Secondly, more than 100 additional pages at the end of the book are devoted to topics which have undergone recent development, such as the alkaloids, the terpenes, resins, glucosides, and proteins; there is a section on reagents, a section on stereochemistry, and one on physical constants in relation to structure. Though highly condensed, they are clear and explicit, and are furnished with full and useful references (which, by the way, would be more convenient and less disturbing to the reader at the foot of the page than embodied in the text). Finally, the system of nomenclature has been modernised The term "atomic," applied to alcohols, phenols, &c., has been replaced by "hydric"; "ether," used in connection with organic salts, becomes "ester"; "alcohol radical" is changed to "alkyl," and the word "radical" is properly spelt. The editor seems to have been in doubt about *isomer* and *isomeride*, and *oxy* and *hydroxy*, which are used indiscriminately. The writer entirely sympathises with this uncertainty in the use of certain terms, for the chemist often finds himself awkwardly placed. Not only does he feel obliged to respect the nomenclature adopted by foreign chemists, which is not always happily chosen, but he must conform in some measure to the system laid down by the Chemical Society. The purine derivatives offer a case in point. E. Fischer derives uric acid from purine and calls it a "trioxy" purine, though the usual formula is innocent of hydroxyl groups. The English equivalent, "trihydroxypurine," is consequently misleading. He is therefore confronted with the alternative of either using German nomenclature which is not official or confusing the reader with its English equivalent.

Another example is that of the carbohydrates, to which the term "saccharide" is applied in Germany by analogy with "glucoside." This analogy is lost in the case of the hexose group of sugars, which are not anhydrides in the ordinary sense. The editor in this case has wisely employed the termination "-ose," and divided the group into mono-, di-, tri-, and polysaccharoses. Incidentally, it should be pointed out that the terms monose, biose, triose, &c., which he employs as synonymous with the above are also used to distinguish the sugars by the number of their carbon atoms, with the result that triose is applied equally to raffinose, with eighteen carbon atoms, and glycerose, with three. It is a little unfortunate that the Chemical Society does not tackle these questions of terminology as soon as they arise, and, by a sensible and authoritative revision, remove a real difficulty in the way of writers on organic chemistry. One cannot but think that a generic terminal syllable denoting a particular class of compounds has much to recommend it, and had this been recognised such a word as "proteose" could not have crept into the new *protein* nomenclature.

The defects of the volume before us seem to be few in comparison with its many excellences, and where so much information has been collected and arranged it may appear hypercritical to find any fault.

The following omissions and corrections, however, seem important, and may perhaps be rectified in a future edition. The modern methods used in the manufacture of potassium cyanide, potassium ferrocyanide, and cyanamide are omitted; so are Piloty's synthesis of glycerin, Lawrence's synthesis of citric acid, Bertrand's method for obtaining dihydroxyacetone and other ketonic alcohols, and the citric acid fermentation of glucose. The following errors should also be corrected. The product obtained by Fischer from glycerin by oxidation is mainly dihydroxyacetone, and not glyceric aldehyde (p. 306); in the conversion of pseudouric acid into uric acid, hydrochloric acid, and not oxalic acid, is now used (p. 291); it is not true that all the chlorinated products of benzene up to C_6Cl_6 can be obtained by chlorinating benzene (p. 253), for some of the isomers are not formed in this way; in preparing the esters of the amino acids from the hydrolytic products of protein substances Fischer and Speier's method is not employed, but the alcoholic liquid is saturated with hydrogen chloride (p. 576).

It only remains to add that, in the writer's opinion the new edition of Bernthsen may claim to be one of the best, if not the best, text-books of organic chemistry for advanced students in the English language.

J. B. C.

PRACTICAL PHYSICS.

A Text-book of Practical Physics. By Dr. William Watson, F.R.S. Pp. xvi+626. (London: Longmans, Green and Co., 1906.) Price 9*s.*

SMALL books on practical physics have been very plentiful of recent years since the subject has taken a place in schools, but the number of large and complete treatises in English embracing all branches is still few. Looking back, the present writer can recall to mind as the earliest an English translation of Kohlrausch's "Leitfaden" by Waller and Procter, published in 1873, and the book, in two volumes, by E. C. and W. H. Pickering, on "Physical Measurements," published in 1873 and 1876. The latter was founded on the course of practical physics conducted at the Boston School of Technology by the authors, who have since become two of the foremost astronomers of the United States. After these two books we have to pass to 1884, when Glazebrook and Shaw's "Practical Physics" was published. It was founded on the elementary practical course conducted in the Cavendish Laboratory, Cambridge, and is still in use, and is perhaps the one book on practical physics which has had the widest influence on English laboratory methods. All these books placed the side of accurate measurement before the student, and omitted demonstrations and showy lecture experiments from their contents. They were written for the student's use in the laboratory, and formed a great advance on the descriptive books in which physics and chemistry were mixed, and which constituted the science of the popular lecturer of the early and middle Victorian period.

Later came a treatise by Balfour Stewart and Gee, which contained very detailed descriptions of experiments in properties of matter and in magnetism and electricity. The book came from the Owens College Laboratory at Manchester, and was, we believe, the first in which precise descriptions of magnetic methods appeared. Then from the same laboratory, published in 1901, we received a course of experiments by Schuster and Lees. This book contained only selected exercises from different branches, as the authors considered it sufficient to put before the students a short course of typical experiments.

Now we have before us the latest book on the subject, a complete treatise by Prof. W. Watson, of the Royal College of Science, South Kensington, and it is framed on a plan different from those we have mentioned. Prof. Watson calls it a book of reference for the student when working in the laboratory. It is not intended that any one class shall work through all the experiments, but that the teacher shall select from it according to the requirements of the pupil and the resources of the laboratory. The descriptions and hints apply to almost any form of apparatus suitable for the particular experiment.

As to the contents of the book, the first chapter contains a general discussion of the theory of the treatment of experimental data, the use of logarithmically divided papers, the consequent determination of exponential laws, and the description of calculating machines, including arithmometers and planimeters. It would take too long to go in detail through the entire contents of the book, but to illustrate its scope we may mention that thirty-four chapters are required to cover the whole field of physics. At chapters xxxii. and xxxiii. we are brought to magnetic induction and permeability. The comparisons and absolute measures of the induction coefficients are treated very fully indeed, and in chapter xxxiv. the use of the Dolezalek form of quadrant electrometer and the measure of the saturation current through air in the presence of uranium oxide are described. It will be evident that the author has made the field covered by the book very wide, and has brought into prominence the methods of recent research. We cannot omit to mention the excellent chapters which occur earlier on magnetic measurements and on the constants of terrestrial magnetism, subjects in which the author is a well-known authority.

At the end an appendix, probably one of the most useful parts of the book, contains an account of laboratory arts, glass-blowing, working in quartz, silvering, and other necessary processes. To these descriptions we feel very confident in referring the student, for the great excellence of the Royal College of Science in the branch of laboratory arts is well known. There is also a collection of useful tables.

The book is printed in very clear type, and the diagrams are excellently drawn. The whole setting of the book is of the same high standard as that of Prof. Watson's large work on physics.

Judging from the short experience which we have had of the use of the book in the laboratory, we may conclude by saying that it has proved most acceptable to the students, and we have been able to recommend it to those studying for university degrees. Schoolmasters should have a copy for reference and for their higher work.

S. S.

CLASSIFICATION OF SOUTH AFRICAN STONE IMPLEMENTS.

The Stone Implements of South Africa. By J. P. Johnson. Pp. 53. (London: Longmans, Green and Co., 1907.) Price 7*s.* 6*d.*

THIS is a useful addition to our acquaintance with the Stone age of South Africa. Mr. Johnson has exceptional qualifications for the task he has undertaken, being a trained geologist and surveyor, and a competent observer in the field, whilst his travels have given him the opportunity of examining large sections of South Africa, the collections of implements described having been obtained by himself from localities so widely separated as the valley of the Zambezi, the Transvaal, Prieska, in the north-west of Cape Colony, the Orange River Colony, Algoa Bay, and various intermediary stations.

In this volume, which contains 258 illustrations, Mr. Johnson has confined himself to coordinating the various discoveries of stone implements he has made during the past four years in South Africa, with descriptions of the deposits from whence they were derived; he, however, makes no attempt to review the abundant literature on the same subject already published. The exceptional value of the author's work rests in the fact that he makes little or no direct reference to surface finds or to specimens of man's handiwork which, in the shape of flakes, cores, and implements, are scattered over the surface of South Africa, in extraordinary profusion in some localities; but in every instance in which he describes his "finds" he takes us to the actual deposits from which he extracted the implements, whether it be the high plateau gravels in the neighbourhood of Johannesburg, the river gravels of the Zambezi, Vaal, and Orange rivers, the more recent alluvial deposits of the country, or the middens on the coast of Algoa Bay.

The author divides the stone implements of South Africa into three groups, which he considers well defined, namely, Primitive, Palæolithic, and Advanced; these are, in his opinion, the South African equivalents of Eolithic, Palæolithic, and Neolithic. The artificial character of the implements of the primitive group is, the author admits, still a matter in dispute, but when we come to the Palæolithic group we reach sure ground. If the old level gravels of the Zambezi, below the Victoria Falls, from which undoubted Palæolithic implements have been derived, were deposited prior to the retrocession of the present falls, and there is strong evidence in favour of such being the case, then the presence of man in South Africa is relegated to a past, bewildering in its antiquity. Similar conclusions are arrived at from the presence of Palæolithic implements in the old river gravels of the Vaal and Orange rivers. When we compare the more carefully fashioned implements (which, however, are not represented in Mr. Johnson's illustrations), notably from the Cape Flats, the laterite beds of Natal and Zululand, from rock shelters and the caves and middens of the coastline of Table Bay and Algoa Bay, with the rude weapons of the old river gravels, we unquestionably find a progressive element in their making, though they are not comparable in artistic merit with those found so abundantly in Egypt, for instance. This perhaps may be due to the stone-implement makers of South Africa not having had at their disposal equally suitable material to work on.

Though Mr. Johnson's division of the stone implements of South Africa into three definite groups may be considered by some as perhaps premature in our present state of knowledge, yet it is a step in the right direction, and this volume with its useful illustrations will certainly be welcomed by students of South African prehistoric archæology.

OUR BOOK SHELF.

Pocket-Book of Aëronautics. By Hermann W. L. Moedebeck, in collaboration with O. Chanute and others. Authorised English edition, translated by W. Mansergh Varley. Pp. xiii+496. (London: Whitaker and Co., 1907.) Price 10s. 6d. net.

In this handy little volume we have an excellent comprehensive summary of the whole subject of aëronautics, and the English reading public have to thank Major Moedebeck for producing such a work which has been so capably translated by Mr. Varley.

Although called a pocket-book, the book might really be described as a treatise on the subject, so ably and so well arranged is the mass of material dealt with. In fact, the book takes a very broad view of aëronautics, and leads off with chapters on the physical properties and technology of gases, the physics of the atmosphere, meteorological observations in balloon ascents, and the computation of results. Such a beginning is an indication of the very scientific and complete way in which the author set about bringing the matter pertaining to aëronautics to a focus, and his various collaborators, ten in all, have succeeded notably in their task.

Further, the historical survey of previous attempts to gain the supremacy of the air is by no means omitted, and admirable summaries are included which give the reader a comprehensive and intelligent view of the steps taken in each mode of attempted flight.

To give some idea of the contents and authors who have contributed to the book, it may be mentioned that the subjects referred to above are from the pens of Dr. R. Emden, Lieutenant J. Stauber, and Prof. V. Kremser. The articles on the technique of ballooning, on ballooning, on military ballooning, historical account of artificial flight, and on air-ships, are treated by the author. Prof. W. Köppen deals with kites and parachutes. Dr. Miethe deals with balloon photography, while Prof. W. Kutta gives an account of photographic surveying from balloons. The articles on animal flight by Prof. Karl Müllenhoff, artificial flight by the late Otto Lilienthal and Mr. Octave Chanute, flying machines, motors and air-screws by Major Hermann Hoernes, complete the various sections of the subject. A list of aëronautical societies, numerous appropriate and useful tables, and an index conclude the volume.

In the preface it is stated that the suggestion of translating this work is due to Mr. Alexander, the well-known authority on aëronautics. English speaking aëronauts, therefore, doubly owe to him their gratitude, for the translator's work is not only excellently done, but he has adapted various tables for the use of English readers, and has added an index.

Blackie's Nature-drawing Charts. (London: Blackie and Son, Ltd., n.d.)

This is a series of fifteen sheets bearing coloured drawings of twigs or portions of a plant to show the nature of the flowers or fruit for use in art schools, more especially in schools of design. It is intended that the charts should be used in combination with living specimens, being displayed to serve as a guide in noting essential features and in producing an artistic drawing. Small figures are given of parts suited to conventional treatment, and several examples of conventionalised designs are presented on each chart. These show the adaptation of plantforms for such purposes as brush-work ornamentation and the design of stencils, wall-papers, tapestries, &c.

A book of instructions is supplied to explain which charts or designs are suitable for different standards, and to provide other suggestions as to their utility. The more elementary drawings reproduce the laurel, snowdrop, tulip, and oak; the buttercup, poppy, and wild rose are considered suitable for a higher standard, and the blackberry, narcissus, and marguerite daisy are selected for the most difficult studies. The representations of the plants are botanically satisfactory, except the beech-fruits, that fail in colour and shape. In a few of the adapted designs, while making allowance for conventional treatment, there is unnecessary departure from the natural arrangement. For instance, the opposite insertion of the leaves in the privet is natural and characteristic, and should be maintained; similarly with regard to the pinnate leaves of the rose. It would have been useful to include in the explanatory booklet a short account of such botanical facts as the forms and insertion of leaves, the parts of a flower, their cyclic and acylic arrangements, and similar details. For the most part, however, the designs do maintain and emphasise the natural characteristics, thereby fulfilling the purpose of training students to derive their artistic conceptions direct from nature. The production of the charts is highly creditable, the drawings are bold, and the colour contrasts effective.

Problems in Surveying, Railroad Surveying, and Geodesy, with an Appendix on the Adjustments of the Engineer's Transit and Level. By Howard Chapin Ives and Harold Ezra Hilts. Pp. ix+136. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1906.) Price 6s. 6d. net.

With such a full title-page this book fairly well describes itself. The authors have been engaged in teaching engineering and surveying, and have found this graduated series of simple problems useful for sustaining the interest of their students in their work and for covering the course required by the faculty. The book is addressed to those who are professionally interested in such matters, or who wish to acquire the capacity to carry out certain operations in the field with facility, and with that amount of accuracy which the nature of the work demands. Consequently, there is little reference to theory. We have the ordinary methods of measuring by chain and problems connected with levelling. The compass, theodolite, and sextant come under review, and the mechanical adjustments of these instruments are described, but with no great minuteness. Greater care might have been bestowed on some of the formulæ given; those on p. 36 have apparently been misprinted. The railroad surveying problems are more satisfactory, and seem to be of practical utility.

A chapter on astronomical problems of a most elementary character has been added. In the preparation of this chapter the authors acknowledge the assistance they have received from a third authority. It must strike anyone with surprise that the authors should consider themselves competent to produce a book of this type, and yet feel it necessary to invite or to accept outside aid.

W. E. P.

The Sense of Touch in Mammals and Birds, with Special Reference to the Papillary Ridges. By Dr. Walter Kidd. Pp. viii+176; illustrated. (London: A. and C. Black, 1907.) Price 5s. net.

Having in a companion volume treated of the direction of the hair in animals, Dr. Kidd, in the one now before us, turns his attention to the kindred subject of the structure and function of the papillary ridges on the tactile surface of their hands and feet. Although the subject is by no means new, the author has studied it in a fuller manner than at least most of his predecessors, and has a new theory with regard to the function of the ridges in the Primates, in which alone these structures attain full development. In monkeys, at any rate, it has been generally considered that the main purpose of the rough surface produced by the papillary ridges is to ensure firm hold in grasping. Without denying that this may be a part of their function, Dr. Kidd is, however, of opinion that there are other important uses, which vary in different groups. In man, for instance, the papillary ridges in the hand alone exercise the function of discriminative sensibility, and those in the foot that of maintaining the equilibrium of the body, whereas in the lower Primates both functions are discharged by the ridges of the two pairs of limbs, although sensibility is less marked in the front pair than in the human hand. The most interesting part of the author's conclusion relates, however, to the papillary ridges of lemurs, which are much more complicated than those of apes and man, and are accordingly believed to be subservient to the necessity for special means of preserving the equilibrium in the case of nocturnal creatures.

R. L.

Zur Wirtschafts- und Siedlungs-Geographie von Ober-Burma und den Nördlichen Shan-Staaten. By Dr. H. J. Wehrli. Pp. 130. (Zurich: Lohbauer, n.d.)

Though in completeness and fulness of illustration this popular handbook of the British province of Burma bears, of course, no comparison with Sir J. G. Scott's recent monograph, it contains in a short space all that a merchant or a traveller intending to visit the country needs. The physical geography, climate, ethnology, natural productions, and industries are clearly described in a series of chapters illustrated by four maps and twelve photographic plates. The book is frankly a compilation from the best authorities, of which a full bibliography is appended. The maps, like all German work of the kind, are good, but the political map would be more useful if the boundaries were marked in colours. Except some of the handbooks for emigrants issued by our more important colonial Governments, we have no geographical series in English which corresponds with this. The organisation which has just been started to spread a knowledge of the Empire among British schoolboys might well provide a series of handbooks of this class.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

International Investigation of the Upper Air.

The International Commission for Scientific Aëronautics has for some years past arranged that observations in the upper air by means of kites and balloons should be made on certain pre-arranged days, generally the first Thursday in each month. At the conference held at Milan in October last, M. Teisserenc de Bort suggested that better results would be obtained if a series of observations could be made on several successive days instead of on isolated days as hitherto.

It has accordingly been arranged that while the observations on the first Thursday in each month should be continued, some further days should be arranged for a more extended series of observations. The first of these series is to take place in the fourth week in July, and it is hoped that, besides the ordinary observatories that take part in the monthly ascents, as many meteorologists as possible should assist in order that observations may be obtained from a number of widely extended stations

The three principal days of the series are July 23, 24, and 25, but where possible ascents will also be made on July 22, 26, and 27. All the observatories engaged in upper-air research will take part. In addition, the Prince of Monaco will make observations in a high northern latitude, and a German man-of-war will send up *ballons-sondes* between Iceland and Norway. Another German expedition, under Captain Hildebrandt, will go to the neighbourhood of the Hebrides, while a French man-of-war will be stationed near the Azores. Further south, M. Teisserenc de Bort and Mr. Rotch will send an expedition, in their yacht *Otaria*, to the region of the trade winds and doldrums. It is hoped, also, that the Italian Government will cooperate by sending a man-of-war to some point in the Mediterranean. With the addition of Blue Hill Observatory and other North American stations, there will thus be a net-work of observations over a large region of the northern hemisphere.

In this country Mr. W. H. Dines will send up *ballons-sondes* and pilot balloons at a station on the west coast of Scotland; *ballons-sondes* and pilot balloons will also be sent up at Manchester by Mr. Petavel, and at Ditcham Park, Petersfield. Conditions in this country at the end of July are not likely to be favourable for flying kites, but should there be sufficient wind kites will be flown at Glossop Moor, Pyrton Hill, Ditcham Park, and Brighton.

The Royal Meteorological Society is also making arrangements to cooperate in the investigations, and an allowance (in aid of the expenses) has been made to them from the Government grant for scientific investigations.

It may be possible to obtain the assistance of other observers to send up pilot balloons; by the use of two theodolites and a measured base, the velocity and direction of the wind and the heights of clouds may be determined. By using rubber balloons and filling them to a certain size corresponding to a known rate of ascent, useful observations may be made by a single observer using an ordinary theodolite.

The International Commission has also arranged for a series of observations on September 4, 5, and 6, and on November 6, 7, and 8.

Charles J. P. Cave.

Radium and Geology.

The temperature of 55° C. to which I referred in a former letter is the temperature of the *rock*. I find that Prof. C. Schmidt, of Basel, on his chart of isogeotherms, gives this temperature as attaining 56° C. This is in the dry part of the tunnel, towards the north end.

The difficulty attending the inflow of warm water mainly arose from the *rate* at which heat was thereby brought into the tunnel, necessitating large supplies of cold water to keep down the temperature. Prof. Schardt's paper, to which I have already referred, contains very strong evidence as to the *rôle* of the circulating water. The evidence is far too lengthy to quote here.

Mr. Fisher refers to the Hon. R. J. Strutt's estimates of radium in rocks as capable of accounting for a gradient of 1° F. in 42·4 feet. In point of fact, Mr. Strutt *assumes* this gradient (quoting from Prestwich) as a basis upon which to calculate the thickness of the radium-bearing crust. The gradient in question is, therefore, not derived from Mr. Strutt's observations (nor could it be), but is a gradient taken as a basis of calculation.

That special conditions affect the temperature gradients in mountain ranges appears from the results of observations on the Mont Cenis and the St. Gothard tunnels. Everett's estimate for the former, with correction for convexity of surface, is 1° F. in 79 feet. In the case of the latter there were remarkable variations observed, of which radium will very probably furnish the explanation. The central gradient is 1° F. in 85 feet. At the north end there is a gradient of 1° F. in 38 feet. This brings the general average for the whole tunnel up to 1° F. in 57·8 feet. Dr. Stapff, who conducted the temperature observations in the St. Gothard, subsequently predicted for the Simplon a maximum rock temperature of 47° C., as I have already pointed out.

J. Joly.

Trinity College, Dublin.

AËRIAL LOCOMOTION.

In December of last year Dr. Alexander Graham Bell delivered an address, under the above title, before the Washington Academy of Sciences. This address recently appeared in the March number of the Proceedings of that academy[1] (vol. viii., pp. 407–448), and the interesting nature of the contents is well worth the attention of the readers of this Journal who have not had the opportunity of perusing it.

In the opening paragraphs Dr. Bell refers to the earlier attempts made to travel in the air, and points out how the problem in the last decade or so has gradually been approached from a different point of view. The principle of the gas bag has taken second place, and the heavier-than-air type of machine is now in the forefront.

The researches of Lilienthal are next referred to, followed by those of Chanute, Herring, the Brothers Wright, and Hargrave. The magnificent work accomplished by Langley is here given its proper position. "To Prof. Langley," as Dr. Bell remarks, "is due the chief credit of placing this subject upon a proper basis, and of practically originating what he termed the art of 'Aerodromics.'"

Dr. Bell witnessed the experiments made by

Fig. 1.—Langley's Aërodrome No. 5 in Flight, May 6, 1896.

Langley on May 6, 1896, when a large model of an aërodrome, with a spread of wing of about 14 feet, was driven through the air by a steam engine under the action of its own propellers. With regard to the actual flight he saw, he wrote:—"No one who witnessed the extraordinary spectacle of a steam engine flying with wings in the air, like a great soaring bird, could doubt for one moment the practicability of mechanical flight." Dr. Bell was fortunate enough to secure a photograph of the apparatus while in the air, and this record, which is reproduced in his article, is here given (Fig. 1). In time it will undoubtedly be of exceptional historical interest.

The circumstances connected with the later experiments of Langley are next described, and Dr. Bell's knowledge and great faith in Langley's work allow him to state his unbiased opinion that the full-sized aërodrome, which the newspapers described as a failure, "would have flown had it been safely launched into the air."

It is with regret, however, that we find no mention made of either Hiram Maxim or Pilcher, for the

[1] See also *The National Geographic Magazine*, vol. xviii., No. 1, January.

former spent a great amount of money and time in valuable experiments, while the latter sacrificed his life in advancing the science of gliding.

Perhaps the most interesting portion of Dr. Bell's address is the account of his own initial experiments in the construction of an aërodrome. He has been at work on this subject for many years, and so far back as 1894 Langley visited him and witnessed some of his experiments.

The progress of his experiments is divided by him into three stages, namely, the kite stage, the motor-boat stage, and the free flying-machine rising from the water.

As the first of these is now complete, it is fully described in this address, and indicates that a distinct step in advance has been made. Dr. Bell's kite is quite different from any other form. It is built up of a great number of small structures or cells, all alike in form and size. Each cell has the form of a regular tetrahedron, and, as he says, "possesses in a remarkable degree the properties of strength and lightness." By connecting several of these figures by their corners a very rigid structure is built up, and the whole possesses the same properties of

FIG. 2.—A sixteen-celled kite.

strength and lightness inherent in the individual cells themselves.

The *unit* tetrahedral cell is bounded by four equal triangular faces; if two adjoining faces be covered with some kite material, the result is a "winged cell" resembling a pair of birds' wings with their points raised upwards. By coupling four of these unit cells together at their corners, a four-celled structure is formed having itself the form of a tetrahedron, but with an empty space in the middle octahedral in shape. If now four four-celled structures be connected at their corners, a sixteen-cell structure of tetrahedral form is formed (Fig. 2). Experience has shown that when these structures are flown as kites they exhibit remarkable automatic stability in the air under varying conditions of wind.

Up to the present time, the most stable form of kite is that of the "box" or Hargrave type. Dr. Bell is, however, of the opinion that his compound tetrahedral structure is more stable even than this. To make a comparison, he flew both kinds simultaneously in squally weather. Although the tetrahedral appeared to "shiver" when struck by a sudden squall, the box kite "seemed to be liable to a swaying or tipping motion that would be exceedingly dangerous in a structure of large size forming part of a flying machine."

The good behaviour of the former kite is due, as he suggests, to the porous nature of the structure, the squall passing right through between the covered triangles, and lifting the other side of the kite as well as the side first struck; the blow is thus counterbalanced before the kite has had time to upset.

Although the horizontal aëroplane has always an element of instability about it, it has, nevertheless, greater lifting power than similar surfaces arranged obliquely as in the tetrahedral construction. The structure of winged cells is, however, the reverse,

FIG. 3.—The *Frost King* in the air, flying in a ten-mile breeze, and supporting a man on the flying ropes.

being more stable when in the air, but deficient in lifting power. There seems, however, no difficulty in adding to the number of surfaces in the latter construction in order to secure the desired lifting power, while the condition of stability remains. Further experiments have shown that the blank spaces between the groups of winged cells can be filled up with more cells; in fact, the cells can be massed together "without marked injurious effects." Not only, therefore, is the structural strength improved by this increase of size, but the lifting power, which varies directly as the cube of the dimensions, is increased (Fig. 3).

The result of these kite experiments has been to show that it is possible to build a structure of moderate size, composed simply of these winged cells, that will support a man and an engine in a moderate breeze.

It will be interesting to watch the progress made in the next two stages of Dr. Bell's programme, which literally means the conversion of a kite into a flying machine. These stages consist in mounting his structure on a light catamaran form of boat and propelling it on a water surface by means of aërial propellers until it can be steered upwards into the air. Whether this form of starting is as good or as practical as running it on wheels remains to be seen, but at any rate it seems the safest way to commence with (Fig. 4).

It may be mentioned in conclusion that not only is this printed address accompanied by numerous well-reproduced illustrations and a useful bibliography relating to aërial locomotion, but all details concerning one of the large winged-cell structures and the interesting discussion which followed the reading of the address are inserted.

Among those who took a prominent part in this discussion was Mr. Charles M. Manly, who, as he stated, "had the pleasure and the honour of being associated for some seven years with the lamented Secretary Langley as his assistant in direct charge of the experiments which he conducted at the Smithsonian Institution." In his remarks it is good to read that the work initiated by Langley is not abandoned, but merely temporarily suspended. In fact, it seems quite probable that Langley's machine will again be seen flying through the air, for Mr. Manly proposes to re-equip and launch it again. To use his own words:—

"It is my purpose at the earliest moment that I can possibly spare the time for it, to re-equip the aërodrome with proper supporting surfaces, and, using the same launching apparatus, to give the aërodrome a fair trial, this time over land instead of over the water, when I feel very certain that it will fully demonstrate the correctness of its design and construction and crown Mr. Langley's researches with the success which they so richly deserve, and I trust that the day that this will be achieved is very near at hand. It was the launching apparatus, all will remember, which in both of the experiments caused the accidents that prevented any test of the aërodrome itself. These accidents were not due to defects in the design or fundamental construction of the launching apparatus, for the smaller apparatus of exactly the same design had been used more than thirty times for launching the smaller machines, and without a single failure. Certain minute defects in the releasing mechanism were the sole cause of the trouble."

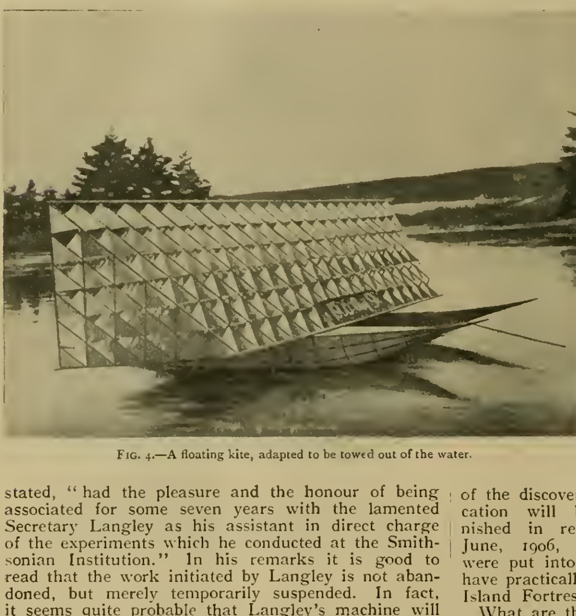

FIG. 4.—A floating kite, adapted to be towed out of the water.

MALTA FEVER.

A LESSON IN PREVENTIVE MEDICINE.

SITUATED in the midst of the Mediterranean, swept by all the winds of heaven, and enjoying brilliant sunshine for several months in the year, the island of Malta should be one of the healthiest of places. Its freedom from swamps or standing water of any kind protects the island from that scourge of warm climates—malaria. For many years past, however, Malta has suffered from the prevalence of a serious local fever, of a most persistent character, which has been the bane of the island, and particularly of the garrison; for a large fraction of the naval and military forces has been constantly incapacitated by this disease. Every year some 650 sailors and soldiers have fallen victims to it, and, as each patient stays on an average 120 days in hospital, this gives a total of about 80,000 days of illness per annum. Moreover, most of these men have to be sent to England to recover their health, and the consequent expense has involved a very considerable loss in money to the Government.

This fever appears to be widely distributed in the world, but is most familiar to us in its incidence around the coasts of the Mediterranean. On the island of Malta it has worked its worst ravages, and hence the name of Malta fever, by which it is best known.

Now, however, all this has been changed by a simple application of the discoveries of science, and widespread gratification will be given by the intelligence, furnished in recently published reports, that since June, 1906, when the new preventive measures were put into practice, Malta fever may be said to have practically disappeared from the garrison of the Island Fortress.

What are these preventive measures, and how has this result been achieved?

The serious ravages of Malta fever made it desirable that a searching investigation should be taken in hand. In 1904 the Royal Society, at the request of the Admiralty, the War Office, and the Colonial Office, undertook to investigate the causes of this fever, and sent out a small commission to Malta for that purpose. This commission, which consisted chiefly of Army and naval medical officers, has been at work for three years, under the supervision of a committee of the Royal Society, and has only lately completed its labours. It is unnecessary to describe the details of the three years' work; it is enough to say that every likely line of research was followed in order to discover how man becomes infected by this disease. So long ago as 1887 an Army medical officer discovered that Malta fever is caused by the entrance into the body of a minute bacterium, which was named the *Micrococcus melitensis*. This microbe was studied from many points of view, but with no success until a discovery was made which cleared up the mystery. This was the remarkable fact that the goats in Malta are susceptible to this disease, and act, as it were, as a reservoir of the virus. In truth, it is probable that Malta fever is primarily a disease of goats, and that man is infected from the goat, not the goat from man. The goat is very much in evidence in Malta, there being some 20,000 of them, which supply practically all the milk used in the island. It was discovered by the commission that half these animals are affected by Malta fever, and that one-tenth are constantly passing the *Micrococcus melitensis* in their milk. Notwithstanding that the goats show no outer signs of the disease, they continue, possibly for years, to secrete milk containing the poison.

It seemed evident, then, that to banish Malta fever from our sailors and soldiers on the station, all that was required was to eliminate goats' milk from their dietary. This step was taken in June, 1906, with the striking result that the cases of fever fell to one-tenth of what had been their normal number. There is, therefore, reasonable hope that this disease will now disappear from the garrison in Malta, and some 80,000 days of illness be blotted out from the yearly records of the Navy and Army.

If these good results are maintained, this investigation will stand out as one of the most notable examples of successful work in the prevention of disease, and will clearly show the economy of spending a few thousands on a thorough scientific investigation.

The research occupied some time, and from first to last employed some twelve men, but the outlay in time and money are as nothing to the result achieved.

INTERNATIONAL ASSOCIATION OF ACADEMIES.

Yesterday morning, May 29, there opened at Vienna the third triennial general assembly of the International Association of Academies, of which the Imperial Academy of Sciences, Vienna, has been the directing academy for the last three years.

Great Britain is represented in this association by the Royal Society of London in the section of natural science, and by the British Academy for Historical and Philological Studies in the section of letters.

The delegates appointed to attend the assembly on behalf of the Royal Society are Sir George Darwin, K.C.B., Sir Norman Lockyer, K.C.B., Lieut.-Colonel Prain, Prof. Schuster, Dr. W. N. Shaw, Prof. C. S. Sherrington, Prof. H. H. Turner, and Dr. A. D. Waller, Prof. Schuster being the delegate charged to deliver the vote of the society; while the British Academy is represented by Prof. Bywater and Prof. Israel Gollancz.

A number of subjects of general scientific importance will be discussed at the meeting, as well as certain questions of internal policy concerning the status of the association, and its mode of working under its statutes.

The Royal Society has put forward two proposals for the consideration of the assembly. One is for the establishment of a uniform lunar nomenclature, and a proposition will be submitted by the council of the association for the appointment of a committee to work out a scheme in furtherance of this object. In this connection the Royal Society propounds suggestions regarding the coordination of lunar nomenclature, which will no doubt form a basis for discussion.

Another proposal of the Royal Society for the cooperation of the International Association in the International Union for Solar Research will probably lead to considerable discussion, not on account of want of sympathy with the movement, but because of questions which have been raised as to the constitutional power of the association to join another organisation.

An important proposal of the Académie des Sciences to create an organisation of meteorological stations at different points on the earth's surface, at the expense of the Governments respectively concerned, will be put forward with the support of the council of the association.

The assembly will also be recommended to approve the resolutions of the committee which met at Frankfurt-am-Main in 1904, proposing changes in the statutes of the International Seismological Association, which have since been adopted. That committee recommends the associated academies to endeavour to induce their Governments to cooperate with the International Seismological Association in dealing with seismic problems of physical interest.

Other matters to be brought before the assembly in the science section are a report of the committee for investigating the anatomy of the brain; reports upon geodetic measurements; a report of the commission appointed in 1904 for the investigation of atmospheric electricity; the consideration of the further working of the committee appointed in 1904 for the magnetic measure of a circle of latitude.

In the section of letters there will be reports presented upon the edition of the works of Leibnitz, initiated by the association; upon the international loan of manuscripts; upon the edition of the Mahabharata; the publication of an Encyclopædia of Islam; the Corpus of Greek records and the Corpus medicorum antiquorum.

THE SMALL PLANETS.[1]

M. Mascart's summary of his own work is as follows:—

Nous avons voulu montrer l'ampleur de la question des petites planètes, qui ne fut jamais encore exposée dans son ensemble, et si nous avons suscité bien plus de points d'interrogation que nous n'en avons levés, nous serons du moins heureux, peut-être, d'appeler l'attention des astronomes sur quelque problèmes assez mystérieux.

Probably an author has seldom given in few words so excellent and accurate a description of his work. M. Mascart has collected on a large scale, and has thus performed a great service to this branch of astronomy. We may turn to his bibliography containing more than a hundred names with a reasonable confidence that nothing of importance has been omitted.

The subject of the small planets appears to bristle with striking statistical peculiarities. To exhibit their nature we note down a few, and may remark that perhaps in no case whatever has a completely satisfactory explanation been given.

(1) If the small planets be arranged in order of mean distance, or of mean motion, there are marked gaps in the series, first noticed by Kirkwood, corresponding to mean motions twice and three times that of Jupiter.

(2) When the inclination to the ecliptic is large, so also, in general, is the eccentricity, and *vice versâ*.

[1] "La Question des petites Planètes." By M. J. Mascart. Pp. 110.

(3) Occasionally there are striking similarities in the elements of two planets, *e.g.*

	a	e	i	☊	ω
(251) Sophie	3·10	0·09	10° 29′	157°	80° 16′
(318) Magdalena	3·19	0·07	10° 33′	163°	80° 5′

The resemblance of the elements in the case quoted is far closer than is reasonably probable, even for a selected pair out of several hundred planets. We, however, are much inclined to doubt whether it is more than an accident. A famous case of coincidence is that between the periods of rotation and revolution of the moon. Here there is a controlling cause tending to produce equality, and the equality is exact. Now in the case of the elements of Sophie and Magdalena, we suppose that there are only three possible hypotheses:—(i.) accidental resemblance; (ii.) a cause tending to produce similarity; (iii.) a common origin with no subsequent connection. We may take as analogies:—(i) two watches that have run down, but happen by accident to show nearly the same time; (ii.) two clocks synchronised with each other; (iii.) two clocks, each constructed with the same object of exhibiting mean time, but entirely independent of each other subsequently. Now, as regards (ii.), we may remark that in the present instance the supposed controlling force has done its work very imperfectly. The objection to (iii.) is that a common origin hypothesis can only be applied in a few isolated cases, of which the above is one, and therefore we ourselves feel inclined to fall back upon (i.), the hypothesis of accidental resemblance, although we fully admit its antecedent improbability.

In the early part of the book an estimate is given of the total mass of the asteroids. It would appear that the entire mass is very far short of a quarter of the mass of the earth, very far short indeed of the mass that would have been expected if a single planet had filled the gap in Bode's law between Mars and Jupiter.

In a few cases approximate linear dimensions are given, founded on measures by Barnard in 1894.

We must congratulate M. Mascart on a very interesting and exhaustive work. We regret, however, the absence of a complete list of all known asteroids with their elements. We should have been glad to have seen such a list in several different forms, with the small planets arranged in order of mean motion, eccentricity, longitude of perihelion, and in the various other ways mentioned in the book. It would have enabled us to follow the arguments from statistics with greater appreciation, and the value of the book as a work of reference would have been much increased. The work admirably fulfils the design of the author.

SIR BENJAMIN BAKER, K.C.B., F.R.S.

SIR BENJAMIN BAKER, whose sudden death in his sixty-seventh year we recorded last week, had a distinguished career as an engineer, and was concerned more or less directly with most of the great engineering schemes of recent years. By his death the profession of civil engineering is deprived of one of its leading members, and the scientific world of a man who combined scientific knowledge with practical training and experience. He was a constant contributor to early volumes of NATURE, and his writings and addresses cover a wide field of applied science.

Sir Benjamin Baker was born in 1840, and for the last thirty years or so was engaged in the design and construction of important engineering works at home and abroad. He carried out numerous investigations relating to the strength of materials and of engineering structures generally, and contributed papers thereon to various scientific societies. He was the author of "A Theoretical Investigation into the Most Advantageous System of Constructing Bridges of Great Span," upon which plan the Forth Bridge and six of the largest bridges in the world have been built.

His name will be remembered chiefly in connection with the Forth Bridge and the great dam across the Nile at Assouan. On the completion, in 1890, of the former engineering feat Sir Benjamin Baker was made K.C.M.G., and when the dam at Assouan was finished in 1902 he was made K.C.B., and received at the same time the first-class of the Order of the Medjidieh from the Khedive. Two years ago plans were submitted to him for the raising of the Assouan dam, and since then he had worked more or less continuously at the subject of stresses on dams. A note by him upon the project appeared in the Earl of Cromer's recent despatch respecting the water supply of Egypt; and in it he stated that a design had been evolved which satisfied all the theoretical and practical conditions, and rendered the storage of nearly two and a half times the present quantity of water in the reservoir a simple problem.

Though his name will always be associated first with the famous works mentioned, Sir Benjamin Baker took a very active part in other great engineering enterprises in many parts of the world. He had much to do with making the Metropolitan Railway, and was associated more recently with the construction of the various tubes for electric traffic under London.

Sir Benjamin Baker was elected a Fellow of the Royal Society in 1890, and in 1895 he became president of the Institution of Civil Engineers. Honorary degrees were conferred upon him by the Universities of Cambridge and Edinburgh, by the Irish Academy, and other learned bodies. He was closely associated with the various engineering societies, and was actively interested in the work of the British Association and the Royal Institution. He was a member of the council of the Institution of Mechanical Engineers, and an honorary member of the American and Canadian Societies of Civil Engineers, and the American Society of Mechanical Engineers. His unexpected death will be deplored wherever pure and applied science are studied, and his personal friends have suffered a loss that cannot easily be realised by those who did not know his broad interests and sympathetic nature.

NOTES.

THE Senate of the State of Pennsylvania has voted 70,000*l.* to the American Philosophical Society to provide a fitting memorial to Benjamin Franklin.

SIR WILLIAM RAMSAY, K.C.B., has received through the Foreign Office the Order of Commendatore della Corona d'Italia from the King of Italy, together with King Edward's permission to wear it.

AT the anniversary meeting of the Linnean Society on May 24, the Linnean medal, awarded by the council to Dr. Melchior Treub, director of the State Botanic Garden at Buitenzorg, Java, was formally handed to Mr. Van Royen, councillor of the Netherlands Legation, who undertook to transmit the medal to Dr. Treub.

MR. ANDREW WATT has been elected meteorological secretary of the Scottish Meteorological Society in succession to the late Dr. Buchan, F.R.S. Mr. Watt has since 1900 been closely associated with Dr. Buchan in the discussion of rainfall and other important meteorological problems.

The Maccabæans, a society of Jewish literary and scientific men, gave a dinner at the Hotel Great Central on May 22, at which some of the leading members of the medical profession were present. Before the dinner a telegram was dispatched to Lord Lister, sending him respectful salutations. Lord Lister replied, returning his warmest thanks to the Maccabæans for their message.

The Transvaal Government Gazette of April 20 announces the appointment of a commission, consisting of the following gentlemen, Dr. Kynaston (Geological Survey Department), Mr. T. N. Leslie (Vereeniging), Mr. J. P. Johnson (Johannesburg), and Prof. R. B. Young (Transvaal University College), "to report to the Government on the Bushmen paintings and stone etchings existing in the Transvaal, and as to what steps should be taken to preserve them from decay and mutilation."

Speaking at the forty-seventh annual dinner of King's College, London, on Monday, May 27, Dr. Headlam, the principal, referred to the loss which the college has sustained by the death of Dr. MacFadyean, and suggested that there should be a public recognition of one who died as a martyr in the cause of science, and for the sake of amelioration of disease and the benefit of the human race. Alluding to the incorporation of the college with the University of London, and to the appeal for funds made in connection therewith, he mentioned that the Goldsmiths' and the Clothworkers' Company have each contributed 5000*l*., and that other promises and donations bring the amount subscribed up to the present time to 15,000*l*.

Reuter's representative at Upsala records that the celebrations at the University of Upsala on the occasion of the 200th anniversary of the birth of Linnæus took place on May 23. The Crown Prince Regent, the Duke and Duchess of Vester-Gotland, and the Dukes of Nericia and Scania, were present. A speech was made by M. Schuck, the Rector of the University, after which the foreign guests read addresses. The speakers were afterwards presented to the Crown Prince. On May 24 the University held a solemn session in the cathedral for the purpose of conferring the doctorate on distinguished Swedes and foreigners on the occasion of the Linnæus celebrations. Among those upon whom honorary degrees were conferred were Mr. Francis Darwin, F.R.S., and Mr. W. Carruthers, F.R.S. The Crown Prince Regent, the Duke of Scania, and the Duke and Duchess of Vester-Gotland attended the ceremony. We hope to give later an account of the celebrations by one of the British delegates now in Upsala.

We learn from the *Lancet* that a movement for the institution of an Italian Association for the Advancement of Science, proposed at Milan last year, has now taken form and development under capable organisers, including Prof. Romiti, of Pisa. The first meeting will be held at Parma in September next, when it is hoped that the sister Powers of Europe, as well as those of the New World, will assist in an auspicious "send-off." Italy has many associations for the advancement of special sciences, but, as Prof. Romiti has put it, she has yet to form an association which shall "represent the synthesis" of them all. Attempts were made in 1839 and 1875 to start such an association on the British model, but they have had no successor. It is hoped and believed that the attempt which has now been renewed will result in the establishment of a permanent institution.

The Aëro Club of the United Kingdom is very active in promoting many aspects of aërial navigation. On Saturday last nine balloons started from the Ranelagh Club, Barnes, in a race for the Harbord Cup, the first balloon leaving at 4 p.m. and the last at 6 p.m. The point to which the balloons were piloted was Goring, in Oxfordshire, and the winner will be the competitor who landed nearest this point. The committee will meet and examine certificates of descents before issuing an official list of placings. On Saturday, June 29, there will be a race for the Hedges Butler Challenge Cup, which will be awarded for the longest voyage in any balloon, airship, or aëroplane on that day. The club offers a silver medal for the best set of photographs taken by a member from a balloon during this year, and a silver and bronze medal for the best set of meteorological observations. Arrangements have also been completed for carrying out a series of important practical experiments in connection with aërial navigation.

The report of the Departmental Committee appointed to inquire into the probable economic effect of an Act of Parliament limiting work in coal mines to eight hours per day has been issued. It is a document that has been prepared with great care, and forms a valuable addition to economic literature. While, on the whole, the committee is of opinion that its immediate effect would be a reduction in total output of about 26,000,000 tons per annum, it is concluded that because the pits would be worked with more energy, the total reduction would be only about one-half this, while the introduction of improved machinery might still further diminish the reduction. The scientific interests of mining were well represented on the committee by Prof. S. H. Cox, of the Royal School of Mines, and by Prof. R. A. S. Redmayne, of Birmingham.

Mr. Walter Wellman, who proposes to make another attempt to reach the North Pole by means of his airship *America*, has left for Norway, on the way to Spitsbergen, where the balloon will be inflated. In the first week of July there will be trials of the airship until it is demonstrated that it is ready for the voyage. The start for the Pole will be made on the first favourable opportunity afterwards, probably between July 20 and August 10, but, if necessary, Mr. Wellman is prepared to start as late as August 20. Mr. Wellman has given Reuter's representative the following particulars of his plans:—The airship has been made 18 feet longer and its lifting power increased by 3000 lb., giving a total lifting force of 19,500 lb. The balloon is 184 feet long and 52 feet in its greatest diameter, its cubic volume being 265,000 cubic feet. With the single exception of Count Zeppelin's airship, this is the largest ever built. The keel or backbone of the airship consists of a steel tank 18 inches in diameter and 115 feet in length, with a capacity for holding 1200 gallons of petrol. At the stern of the vessel is a rudder of some 900 square feet, in the form of a bicycle wheel, which, despite its great size, only weighs 30 lb. A little forward of the centre is placed a very heavy motor, built for endurance and safety, of 70 horse-power, and having a weight of 900 lb. In this new airship the propellers are placed in the centre on either side of the vessel. They consist of two blades of steel, 11 feet in diameter, and capable of 380 revolutions per minute. The living quarters of the airship are in triangular bunk-like spaces within the enclosed steel car. These are capable of accommodating ten or twelve men, twelve dogs, together with the provisions and equipment. The total weight of the steel car and tank is 2200 lb. The motors, screws, and machinery weigh 1350 lb. In the tank will be carried 6800 lb. of petrol, capable of running the motor for 150 hours at a normal speed of 14 knots. The total radius of action is believed to be 2500 miles, or double the distance from the base to the Pole and back again. The balloon will not ascend more than 300 feet to 500 feet, and a guide-rope will trail over the surface of the earth. Instead of employing a steel line a leather tube has been made, 15 inches in diameter and 130 feet long, and weighing about 1400 lb. This is filled with reserve food weighing 1200 lb., and is suspended from the airship by means of a steel rope. The airship will carry 3000 lb. of food, or enough to enable the crew to subsist on its own stores for a period of ten months.

To vol. iii., No. 11, of the zoological series of the Publications of the University of California, Messrs. E. C. Starks and E. L. Morris contribute a descriptive list of fishes taken off the coast of southern California.

We have to acknowledge the receipt of a copy of the first of a series of "guides" to the Peabody Museum of Natural History at Yale University. This deals with the evolution of the horse family, a subject which has been treated in a very satisfactory manner by Dr. R. S. Lull. The "guide" has previously appeared in the form of an article in the *American Journal of Science*.

A very satisfactory result has attended bird protection in a certain district of Norfolk, the black tern (*Hydrochelidon nigra*), which had ceased to breed in that county for a period of something like seventy years, having this season re-established itself in its old nesting haunts. Several nests are recorded, and it is sincerely to be hoped that the species will once more be entitled to a permanent place on the British breeding list.

A paper in the Annals of the Natal Government Museum (vol. i., part ii.), by Messrs. E. Hill and L. G. Haydon, on the characters of the larva in certain mosquitoes of the group Anophelina, is of importance in connection with the endeavour to stamp out malaria. All the fifteen species described are referred to genera other than the typical Anopheles. In a second article in the same issue Dr. R. Broom records, for the first time, the occurrence of remains of anomodont reptiles in the Karoo rocks of Natal. They are referred to the genera Dicynodon, Lystrosaurus, and Scymnosaurus, the representatives of the first and third being regarded as new species.

The evolution of the colour-pattern on the shells ot South African land tortoises, more especially those included in the genus Homopus, forms the subject of a paper by Dr. J. E. Duerden in the Records of the Albany Museum (vol. ii., part i.). Starting with species in which each shield of the shell is of the normal horn-colour, the author finds that the first stage is the development of a dark border, followed later by a dark centre. Next the whole shield becomes dark, excepting light lines radiating from the centre, after which the dark area may break up into spots or flecks. In a second paper the same author describes a giraffe head from British East Africa, provisionally identified with *Giraffa camelopardalis tippelskirchi*.

In a paper on the geographical distribution of closely related species, as exemplified by plants, Mr. R. G. Leavitt, in the April number of the *American Naturalist*, comes to the conclusion "that the study of specific distribution in the vegetable kingdom is not likely to be unfavourable to mutation, regarded as a method, but perhaps not the sole method, of evolution." After putting aside certain cases which may be ascribed, for want of a better name, to "geographical effect," the indications suggest that a good many instances favourable to mutation will be forthcoming, and that those who seek to discredit the mutation theory will find it difficult to procure weapons to support their attack from plant evidence.

We have received from the author, Mr. James Drummond, a copy of a paper on foreign birds acclimatised into New Zealand, published as a Bulletin of the Agricultural Department, and likewise copies of the *Lyttelton Times* of March 23 and 30 containing an account of the bird-sanctuary at Little Barrier Island, near Cape Rodney. As regards the introduction of small birds, which commenced, mainly for sentimental reasons, some sixty years ago, it appears that, on the whole, this has been a mistake, correspondents urging that no more kinds should on any account be admitted. Although sparrows are admitted to have done good in the early days of the colony, when insects were, literally, on the war-path, they are now unmitigated pests, while greenfinches, blackbirds, and even larks (which do enormous damage to young wheat) and thrushes are included in the same category. Little Barrier Island, we are told, comprises 10,000 acres, of which all but about fifty are hilly or mountainous, with abundant timber. It thus appears admirably suited for a bird-sanctuary, and efforts are being made to introduce from the mainland many species not naturally represented on the island.

Four parts have been received of the scientific results of the voyage of the *Belgica* (Expédition Antarctique Belge), now in course of publication at Antwerp, in which Mr. E. Hérouard describes the holothurians, Prof. G. W. Müller the ostracods, and Mr. O. Maas the medusas, while a number of writers deal with the comparatively small collection of insects. Out of nine holothurians obtained, no less than five are new, one being referable to a new generic type. All the Antarctic members of this group belong to the family Elpidiidæ, of which only a single representative (*Elpidia glacialis*) occurs in Arctic seas. The ostracods of the Antarctic plankton include four species of Conchœcia, of which one is new. Jelly-fish (medusas) are but poorly represented, although two out of the small number of species collected by the *Belgica* are regarded as new. As regards insects, the number of species recorded from the neighbourhood of the Antarctic circle is still infinitesimal as compared with those from the opposite pole, the list comprising merely certain colembolids taken near the Canal de Gerlache by the *Belgica* expedition, a podurid and a pediculid collected by the *Southern Cross*, and a dipterid (*Belgica antarctica*) and a larva described in the fasciculus before us. That fasciculus includes, however, descriptions and figures of a considerable number of insects from the lower part of South America and the Falklands, several of which have received new names.

The *Philippine Journal of Science* for March (ii., No. 1) contains a paper on filariasis in the Philippines, by Messrs. P. M. Ashburn and C. F. Craig. They consider that the filaria met with in these islands is a new species (named *F. philippinensis*), owing to its lack of periodicity and certain morphological characters. It develops in *Culex fatigans*. Dr. Musgrave contributes an exhaustive paper on paragonimiasis (infection with the fluke, *Paragonimus westermanii*) in the Philippines. The journal is illustrated with a number of plates.

In the Journal of the Royal Sanitary Institute for May (xxviii., No. 4), Prof. Ronald Ross, F.R.S., discusses some points of interest in connection with tropical sanitation, and Major Horrocks describes some interesting experiments made to determine the conditions under which "specific" bacteria derived from sewage may be present in the air of ventilating pipes, drains, sewers, &c. It would appear that the bursting of bubbles, the separation of dried particles from the walls, and the ejection of minute droplets from flowing sewage, may determine the ejection of specific bacteria from the sewage into the air.

Bulletin No. 4 of the division of pathology and physiology, issued from the experiment station of the Hawaiian Sugar Planters' Association, has been received. It contains the substance of a lecture, delivered by Dr. N. A. Cobb before the association, on some elements of plant pathology relating to disease in the sugar cane.

Mr. D. McAlpine communicates to *Annales Mycologici*, vol. iv., No. 6, an account of the hymenomycete fungus, formerly called *Isaria fuciformis*, as it exists in Australia. Growing on various native grasses and rye-grass, the fungus often forms a conspicuous pest in wet seasons. In general appearance it resembles a Clavaria, but the hymenium or spore-producing layer is borne mainly or entirely on the portion of the fungus attached to the host plant, so that the author refers it to the genus Hypochnus as *Hypochnus fuciformis*.

A short paper by Mr. R. Fitch appears in *Annales Mycologici* (vol. iv., No. 4) describing some experiments on the action of insoluble substances in modifying the effect of deleterious agents upon fungi. It is known that the action of certain toxic solutions on plants varies according to the degree of concentration and that a very weak solution often stimulates growth. Nägeli discovered that the addition of certain solid materials to solutions reduced the toxicity. Similarly it is found by Mr. Fitch that the introduction of sand or glass is equivalent to weakening the proportion of poison in a given solution.

Mr. E. R. Burdon contributes to the *Journal of Economic Biology* (vol. ii., No. 1) an article on the spruce-gall and larch-blight diseases caused by the genus Chermes of the Aphidæ. He points out that, according to investigations made in Germany and Russia, both diseases are induced by the same species, and draws up in a tabular form the sequence of generations. Starting from the gall-foundress generation on the spruce, some of the winged insects of the subsequent generation migrate to the larch, pine, or fir, upon which two generations are developed before there is a migration back to the spruce previous to the sexual generation. The galls are only produced on the spruce and by one of the generations. In order to prevent migration, it is recommended that spruce and larch should not be planted together, but should be separated by a belt of other trees. The author discusses various remedies, among them a paraffin emulsion, with which he washed the trees in winter.

An important addition to the literature on the Phycomycetes will be found in the fifth number of the botanical series of Memoirs of the Department of Agriculture in India, wherein Dr. E. J. Butler furnishes an account of the genus Pythium and some of the Chytridiaceæ. The memoir contains a phylogenetic review and systematic revision of the genus Pythium, for which eighteen species are distinguished, and of these *indigoferae, diacarpum, palmivorum*, and *rostratum* are new. The account of the life-history is based upon the examination of ten species collected in Europe and India. Full details are given of the development and liberation of the zoospores in *Pythium proliferum*. The observations on the Chytridiaceæ made on species of the genera Pleolpidium, Pseudolpidium, Olpidium, Olpidiopsis, and Nowakowskiella enable the author to describe the life-histories of these parasitic fungi.

On September 2, 1906, twenty years had elapsed since the opening of the Sonnblick Observatory, at an altitude of 10,190 feet above sea-level. From Dr. Hann's summary of the results, it appears that the monthly mean barometric pressure is lowest in March and highest in August. The mean yearly minimum temperature is $-22°{\cdot}2$, the mean maximum $49°{\cdot}3$; the absolute extremes were $-35°{\cdot}0$ in January, 1905, and $56°{\cdot}8$ in July of the same year. The relative humidity is the opposite to that which obtains in the plains—the winter is the driest and the spring and summer the dampest; the afternoon is the dampest period of the day. The mean yearly precipitation amounts to 70·71 inches, of which only about 4·77 inches fall as rain, the remainder being chiefly due to snow. The amount is fairly uniformly distributed throughout the year, the mean number of "rain-days" being 212. Fog occurs on 253 days on an average.

The report of the committee appointed by the Governor of Hong Kong to inquire whether earlier warning of the disastrous typhoon of September 18, 1906, could have been given to shipping has resulted in the exoneration of Dr. Doberck and the observatory staff from blame in the matter. The committee was composed of Sir H. S. Berkeley, K.C., Lieut. H. Butterworth, R.N. (King's Harbour Master), A. B. Skottowe (Eastern Extension Telegraph Co.), and Captain A. Sommerville. The evidence taken by the committee, and the documents referred to, are appended to the report. On the afternoon of September 17 the observatory received telegraphic reports from various stations, including Zi-ka-wei (Shanghai), Swatow, and Manila; the barometer readings at those places pointed to the conclusion that there was a gale in Formosa Channel, apparently travelling N.N.W., but in the opinion of the committee these observations did not call for the hoisting of any typhoon signal in Hong Kong on September 17. The evidence as to the appearance and state of the weather on the evening of September 17 and morning of September 18 is conflicting; the Consul for France thought that the appearance of the sky on September 17 indicated a typhoon not far off. But, reviewing the evidence as a whole, the committee found that prior to 7h. 44m. a.m. on September 18 there was no indication of a typhoon approaching Hong Kong, and that by hoisting the signal drum on the morning of September 18 warning was given as soon as was practicably possible.

An address on the "Education of the Professional Chemist," delivered by Prof. C. F. Mabery in his capacity of chairman of Section C of the American Association for the Advancement of Science, is printed in *Science* for May 3. It contains a number of points of educational interest. The methods of teaching chemistry in the elementary schools of the United States are severely criticised; they appear very similar to those which have been attacked in this country during the past fifteen years. "The pupil is taught a text-book rather than chemistry," and has inflicted on him a series of definitions and theoretical principles before he has learned correctly to observe a single fact. In spite of this, the students of technical chemistry appear to be able to overcome at the university such early disadvantages; and we learn that as a result "most manufacturers have a high respect for the advantages afforded by scientific education," and are "ready to receive the young graduate with open cordiality." The lot of the young chemist seems, indeed, to be a particularly happy one in the States in view of the "unprecedented demand for good men." Statistics show that the average salary of the graduates in chemistry of five years' standing from the Case School of Applied Science is about 3000 dollars per annum. At all colleges "there is a far greater demand for graduates than can be supplied." A powerful aid to research has recently arisen in the immense funds devoted by many individuals to this purpose; amongst these the Carnegie foundation for the retirement of teachers is mentioned, "as it relieves the teacher during his earlier years from the anxiety of later need and gives him courage to devote his residual energy in some efforts for the advancement of knowledge."

WE have received a copy (printed for private circulation) of the Friday evening discourse delivered by Prof. A. H. Church at the Royal Institution on April 12 on the "Conservation of Urban Stone-work and Wall-paintings." The most active among the agents tending to destroy the stone-work of buildings of historical interest in large towns is undoubtedly the sulphuric acid produced by the combustion of coal used as fuel. It has been estimated that at least half a million tons of sulphuric acid are formed annually in London in this way. Rain charged with the acid gradually converts the surface of the limestone of public buildings (such, for instance, as St. Paul's Cathedral) into gypsum, the increase of volume accompanying the change being responsible, moreover, for a greater or less degree of disintegration of the more delicate mouldings and tracery. An account is given by Prof. Church of the remedial treatment adopted in such cases, based on the use of a solution of baryta, which has the property of re-cementing together the particles of the decayed stone-work. The baryta acts by forming an insoluble sulphate with the gypsum and liberating lime, which, under the influence of carbonic acid from the air, regenerates the original binding cement of the stone. This treatment is applicable, not only to limestones, but also to sandstones which were originally compacted by a calcareous cement. The success attending its use is well illustrated by the experience obtained in the case of the Chapter House at Westminster. "Before treatment a touch of the finger sufficed to bring away the surface of the carving, afterwards the stone was as sound as that newly quarried and harder." To render the stone subsequently resistant to the action of acids it may be covered with a suitable waterproofing coating of paraffin wax. The conservation of mural paintings or frescoes needs in each special case, according to its character, a different process. A number of typical cases of treatment are described.

AN interesting article on the life and work of Linnæus, by Mr. G. W. Murdoch, appeared in the *Newcastle Daily Journal* of May 23. We congratulate that journal upon being one of the few daily papers to publish a special article upon Linnæus on the 200th anniversary of his birth.

THE *Brazilian Engineering and Mining Review*, which has now reached its fourth annual volume, is a high-class monthly technical journal published in English at Rio de Janeiro. Looking through some back numbers recently sent to us, we notice many articles of permanent value regarding the mineral resources of Brazil, and, continued from number to number, a very important bibliography of the geology and palæontology of Brazil compiled by Prof. John C. Branner.

SEVERAL plates of illustrations of the zoology of the Royal Indian Marine Survey ship *Investigator* have been received from the Indian Museum. The illustrations include Crustacea (Malacostraca and Entomostraca) and Mollusca, and have been prepared under the direction of Dr. A. Alcock, F.R.S., Dr. N. Annandale, and Mr. A. C. MacGilchrist.

A "HANDY Guide to Photographic Requisites," which is a conveniently arranged price list of photographic apparatus, materials, and pure chemicals, has been published by Messrs. Reynolds and Branson, Ltd., of Leeds.

THE much-discussed question of the structure of cyanic acid forms the subject of a communication by F. Carlo Palazzo and E. Carapelle in the *Gazzetta* (vol. xxxvii., ii., p. 184). It is pointed out that, while Nef's experiments have shown that esters of the structure OR.C N derived from normal cyanic acid do not exist, he still adheres illogically to the view that the free acid and its alkali salts are of the normal constitution. The argument that Nef advanced, that the free *iso*-acid, CO : NH, would be unstable in presence of water and undergo change into the normal acid, should, on his own showing, from the great power of addition possessed by the group .C N, be reversed. Cyanic acid when esterified at so low a temperature as $-5°$, by means of diazomethane or diazoethane, gives esters of the *iso*-type CO : NR alone. In view of the fact that the somewhat analogous α-pyridone gives only oxygen esters under similar conditions, and of the probability that isomeric change is excluded at so low a temperature, it is concluded that the free acid and its salts have the iso-structure. The same conclusion was also recently arrived at by Chattaway and Wadmore using a less direct argument.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JUNE:—

June 1. Mars. Apparent Diameter = 17″·6.
9. 1h. Vesta in conjunction with Moon. Vesta 0° 11′ N.
10. 23h. 37m. Mercury in conjunction with ϵ Geminorum (mag. 3·2). Distance between centre of planet and star about 25″.
12. 14h. Mercury in conjunction with Neptune. Mercury 2° 51′ N.
15. 8h. Mercury in conjunction with Jupiter. Mercury 1° 41′ N.
18. 10h. 46m. Minimum of Algol (β Persei).
19. Uranus ½° S. of υ^2 Sagittarii (mag. 5·2).
22. 2h. Sun enters Cancer, Summer commences.
23. Uranus ½° S. of υ^1 Sagittarii (mag. 5·0).
24. 11h. 40m. to 12h. 48m. Moon occults ξ Ophiuchi (mag. 4·5).
26. Mercury at greatest elongation (25° 28′ E).

MAGNITUDES OF MIRA, DECEMBER 14, 1906, TO FEBRUARY 16, 1907.—The results of a number of naked-eye observations of Mira, made at the Radcliffe Observatory during the recent maximum brightness of this star, are published in the Monthly Notices (R.A.S.) for April (vol. lxvii., No. 6, p. 412), together with some notes on the star's colour.

The greatest magnitude, 2·06, during the period of observation was recorded on December 27, when Mr. Robinson found the colour of Mira to be similar to that of α Arietis, *i.e.* yellow. Examined with the Barclay equatorial on January 11, the image of Mira showed red spiculæ around the margin, but the margin was not so broad, nor so deep a red, as that seen by the same observers around Nova Persei in 1901. The image was, however, quite distinct in appearance from those of two other coloured stars, α Ceti and Aldebaran, when the same optical means were employed.

THE INTERNATIONAL EROS CAMPAIGN.—After suffering numerous delays, Circular No. 12 of the International Astrographic Conference of July, 1900, has just been published by the French Academy of Sciences. It contains the results of some thousands of visual and photographic observations of the position of Eros during the favourable opposition of 1900–1 at eleven different observatories. The plates taken at the Upsala Observatory, and part of those taken at Minneapolis, have been reduced at the Paris Observatory, and, in order not to delay the publication of the collected results any longer, the work of the Algiers Observatory is omitted from the present Circular, to be published when ready by the Algiers authorities themselves. A collection of all the important documents relating to the orbit of Eros is included in the present publication.

MARS.—At the coming opposition, which will take place on July 6, the planet's southern hemisphere will be presented, and the apparent diameter will be 22″·8, but, owing to the large southerly declination, the altitude of the planet as seen from Greenwich will be only 10°, therefore the observing conditions will be very poor.

CATALOGUE OF VARIABLE STARS.—The second Harvard catalogue of variable stars, compiled by Miss Cannon, appears as vol. lv., part i., of the Annals of the Astronomical Observatory of Harvard College. It contains all the known particulars of 1957 variable stars, and includes those found in globular clusters, but not those discovered in the Magellanic clouds. The latter number 1791, so that altogether there are now 3748 known variable stars, 2909 of which have been discovered at Harvard.

In addition to the tabulated data for each star, the present catalogue contains a valuable set of notes giving further particulars of numerous individual stars and a brief review of all previous catalogues which have appeared since Argelander published the first, including eighteen variables, in 1844.

ABBREVIATIONS FOR THE NAMES OF STAR CATALOGUES.—No. 4176 (May 14) of the *Astronomische Nachrichten* contains a useful list of abbreviations for star catalogues. The names of the numerous catalogues, to which frequent references are essential, are often lengthy, and different writers use different abbreviations. To obviate the consequent confusion, Dr. A. Auwers has compiled the present list, which includes all the important catalogues from Baily's Flamsteed catalogue (abbreviated to B.Fl.) of 1690 up to the Greenwich second nine-year catalogue ($9y_2$) of 1900.

THE NATAL OBSERVATORY.—The report of the Government astronomer of Natal, for the year 1906, is chiefly devoted to the publication of the meteorological results secured at various stations, as in previous years. Observations of the magnetic elements and the distribution of time signals were carried on as usual, and a number of observations of comet 1905*c* were made with the large equatorial telescope by Mr. Rendell, who, early this year, resigned the position of chief assistant to which he was appointed in March, 1903.

ANNIVERSARY MEETING OF THE LINNEAN SOCIETY.

THE Linnean Society of London, which may be said to have a preeminent position amongst the Linnean societies of the world as the faithful custodian of Linnæus's own library, manuscripts, herbarium, and other collections, along with many personal relics, holds annually its business meeting for the election of officers and the reception of the president's address on May 24, the reputed birthday of Linnæus.

In his presidential address at the meeting on Friday last, Prof. W. A. Herdman dealt with the special circumstances of this year, when the celebration of the 200th birthday of the illustrious Swede has been made the occasion of congratulatory meetings in Sweden and elsewhere throughout the civilised world wherever natural science is cultivated and the debt of the naturalist to Linnæus is gratefully acknowledged.

The Linnean Society has sent to Upsala and Stockholm as its representative on the occasion Mr. William Carruthers, F.R.S., a past-president who has made a special study of the work and the personal history and relics of Linnæus.

Mr. Carruthers, accompanied by the general secretary of the society, is now in Sweden, bearing to the ancient University of Upsala the society's Linnean gold medal, specially struck for the occasion, and conveying both to the University and to the Royal Academy of Sciences at Stockholm congratulatory documents, signed by the president and secretaries, and bearing the seal of the society.

At the conclusion of the section of his address dealing with the Linnean celebrations, the president moved that a telegram in the following terms be sent to the Rector Magnificus of the University of Upsala:—"Linnean Society of London assembled at anniversary meeting congratulates University of Upsala on historic Linnean celebration." The proposal was received with acclamation, and the telegram was dispatched forthwith from the meeting.

In further celebration of the occasion the Linnean Society proposes to hold a social gathering of the fellows and their friends, at the society's rooms in Burlington House, on the evening of June 7, when the society's Linnean relics will be on exhibition, and several short addresses on interesting recent discoveries in natural history will be given by fellows of the society.

THE JUBILEE OF THE SOCIÉTÉ CHIMIQUE DE FRANCE.

A NUMBER of scientific men from all parts of Europe met in Paris on May 16 and the two following days to celebrate the fiftieth anniversary of the Société chimique de France. Founded by a few students for mutual instruction, the society is better known as the Société chimique de Paris, the change in name having taken place a short time ago. British chemists were well represented; Sir W. Ramsay and Dr. H. Brown came on behalf of the Chemical Society; Drs. Markel and Lewkowitsch and Mr. Walter F. Reid for the Society of Chemical Industry. Sir W. Perkin, Prof. Armstrong, and Mr. C. E. Groves were also present.

The proceedings commenced on May 16 in the amphitheatre of the École supérieure de Pharmacie in the Avenue de l'Observatoire. The chair was occupied by M. Bouveault, president of the Société chimique de France, who was supported by M. Reynal, representing the French Government. The president welcomed the guests in a short speech, after which Dr. Graebe, who, with Dr. Liebermann and Dr. von Martius, represented the Deutsche Chemische Gesellschaft, read a somewhat lengthy address in German, and made a short speech in French which was well received. A second German address was presented by Dr. von Martius on behalf of the Verein Deutscher Chemiker, after which Prof. Piutti, of Naples, made a sympathetic speech in Italian which was much applauded. Senator Paternó, also a polished orator, was to have represented Italian chemists, but was detained in Russia on a tariff mission. Sir William Ramsay next read and presented the address of the Chemical Society, saying at the same time a few appropriate words in French. Mr. Walter F. Reid then made a short French speech, and presented the congratulatory address of the Society of Chemical Industry. Other speakers followed representing Russia, Norway, Switzerland, and other countries, after which M. Reynal, representing the French Government, welcomed the foreign delegates and referred to the numerous services rendered to the State by chemists, especially in connection with hygiene, agriculture, and the detection of adulteration and of crime generally.

In the afternoon a special boat conveyed the delegates and many members of the French society to Sèvres, where the porcelain works were visited under the guidance of several chiefs of departments. While not inferior to any other porcelain factory in its perfection of technical handling of the material and artistic treatment of form and colour, Sèvres undoubtedly surpasses all its rivals in the wide range of pigments which it possesses. Many of these are due to the scientific researches of the eminent chemists who have directed the operations of the factory, and research work is still continuously carried on, especially with the rarer elements which modern chemical progress has rendered available. A yellow titanium glaze was much admired, and a new method of decoration produced by the crystallisation of zinc oxalate in combination with various pigments promises to become a valuable adjunct to the decoration of vases and other decorative objects of porcelain. The dazzling white of the Sèvres material is said to be due, not only to the purity of the ingredients used, but also to the kind of wood used as fuel, namely, birch. No doubt there is some reason for this belief, because the heat in the furnaces is so intense that the greater part of the ash of the fuel is volatilised, and, although the ware is carefully packed in saggers and protected as much as possible from the furnace gases, the volatilised ash must to some extent permeate the whole mass. The waste during burning has been reduced of late years by the adoption of an electric pyrometer which enables those in charge of the firing operations to regulate the temperature within a few degrees. An interesting hour was spent in the museum, which contains a unique collection of porcelain from all parts of the world. Of special interest are the specimens of different pigments and glazes, and the ladies of the party regarded with curiosity the artificial rubies and sapphires made by Ebelmen. These were small, and cannot be compared with the beautiful specimens prepared by Hautefeuille which are preserved in the Museum d'Histoire naturelle; but they were the first of their kind, and the precursors of the gems now made in considerable quantities by Moissan's process. It may be remarked that even artificial emeralds are now being produced having the same chemical composition as the natural stones, from which they can only be distinguished by optical tests.

In the evening a banquet was given at the Palais d'Orsay which was attended by the foreign delegates and a number of French scientific men. Among the former were Sir W. Ramsay, Dr. H. Brown, Mr. C. E. Groves, Dr. Lewkowitsch, Dr. Markel, and Mr. W. F. Reid. From Germany came Graebe, Liebermann, and Dr. von Martius; from Italy, Prof. Piutti; from Switzerland, Werner, Guye, and Willstaetter; from Russia, Antonow and Jacovlew. Many distinguished French men of science had assembled to welcome their colleagues from other lands. M. Bouveault, president of the Société chimique de France, presided, ably seconded by M. A. Béhal, secretary of the society, well known for his researches in organic chemistry; M. Lindet, secretary of two international congresses of applied chemistry; MM. Poirrier and Lauth, representatives of the dye-stuffs and pigment industries; Prof. G. Bertrand, discoverer of oxydases; Le Bel, in whose fertile brain the idea of stereochemistry originated; Prof. Cazeneuve, whose researches on the derivatives of camphor are well known; M. Tanret, to whom we owe much of our knowledge of sugars; Le Chatelier, who is still investigating hydraulic cements; M. Haller, member of the institute; M. Armand Gautier, late president of the society; and a number of others no less distinguished.

M. Pichon, Minister of Foreign Affairs, represented the Government, and made an eloquent speech pointing out the advantage to the whole civilised world of such amicable meetings of scientific men of all nations, united in the common wish to promote science and thus advance the well-being of the human race. The British delegates present could not help thinking how unfavourably the action of our own Government contrasted with that of France. The latter had offered decorations of the Legion of Honour to three of the delegates, Sir W. Perkin, Sir W. Ramsay, and Mr. W. F. Reid, but the British Government raised objections, and at the time of the jubilee celebration these had not been withdrawn. The current explanation was that some mediæval rule exists that foreign orders are only to be received by British subjects connected with the Army or Navy. But the Legion of Honour is not a military order, and was specially founded for men of such eminence as Sir W. Ramsay and Sir W. Perkin, and Mr. W. F. Reid, who originated the modern industry of smokeless powder, may certainly claim to be placed on as high a level as Mr. Thomas Atkins, who uses it. It is high time that our Government paid more attention, if not to the claims of scientific men, at any rate to those of international courtesy. Their action in this matter has not given satisfaction in the French capital, and contrasts very unfavourably with that of Germany, which accepted gratefully what was, of course, intended as a graceful international compliment.

On Friday, May 17, proceedings commenced at the early hour of 8.30 a.m. with an exhibition of products and apparatus of the members of the Société chimique de France. Among many important exhibits, two especially aroused the interest of the visitors. Abbé J. B. Senderens showed a number of products obtained by a new method of catalysis. Amorphous phosphorus prepared at a low temperature is placed in a tube and heated to about 300° C. in a current of hydrogen gas. The vapour of the substance to be decomposed is then passed through, with the result that water is formed and condenses in the receiver with the product of the reaction. M. G. Bertrand exhibited about forty samples of products obtained by the action of a bacterium which he has isolated from sorbose. These contained a number of substances of extreme interest to the chemist, including several artificial sugars. At 10 o'clock a general meeting took place, at which M. Armand Gautier, a former president of the society, read an account of the work done by members of the society since its formation. Few societies can show such a record of discoveries of the first magnitude.

A distribution of prizes to the successful students of the École supérieure de Pharmacie then took place. At 1 p.m. a special train started for Chantilly, where the priceless art treasures presented to the nation by the Duc d'Aumale were inspected. In the evening a meeting of the Société chimique de France was held, at which country members only were entitled to read papers. Some communications of importance were read, and will be published in the Bulletin.

On Saturday a reception was held in the Hotel de Ville by the municipality. The president of the municipal council, Dr. Lefèvre, is himself a biological chemist, and made some humorous allusions to the important part played by chemists in modern municipal work. The beautiful paintings with which the building is decorated were shown and explained to the visitors, who also witnessed some of the preparations that were being made for the reception of the delegates of the University of London in the ensuing week.

During the evening a theatrical soirée was given at the Palais d'Orsay, which terminated the proceedings officially. There were, however, numerous private offers of hospitality extending into the following week, and the British delegates were loth to part from their hospitable colleagues of the Société chimique de France.

STUDIES FROM A NORTHERN UNIVERSITY.

THE two contributions to science referred to below[1] form part of the publications issued by the University of Aberdeen when the quatercentenary of its foundation was celebrated in September of last year. When men move northwards to occupy chairs in the most outlying university of the kingdom, it has been said that the isolation and absence of external incentives are apt to cause a premature cooling of their zeal for science. However that may be, these two volumes contain convincing evidence that in recent years Aberdeen University has been

1 "Studies in Pathology." Written by Alumni to celebrate the Quatercentenary of the University of Aberdeen and the Quatercentenary of the Chair of Pathology therein. Edited by William Bulloch, M.D. Pp. xxx+412. (Aberdeen, 1906.) Price 15s.

"Proceedings of the Anatomical and Anthropological Society of the University of Aberdeen, 1904–1906." Pp. viii+241; illustrated. (Aberdeen University Press, 1906.)

able to produce graduates who are both willing and able to widen the bounds of real knowledge.

The volume containing the studies in pathology is of such merit that the history of its origin deserves a brief mention. In reality, its preparation was commenced five-and-twenty years ago, when Sir Erasmus Wilson wisely presented the University with sufficient funds to establish a chair of pathology—the second created in this country. By a happy inspiration Prof. D. J. Hamilton was asked to occupy it. Out of the raw material provided by the surrounding country Hamilton has raised the school of pathologists which has produced the volume under review, and very fittingly dedicated it to him. The studies are seventeen in number, and illustrate the diverse directions in which pathology has branched in recent years. To the old pathology—the morbid anatomy of Rokitansky and Virchow—only three of the studies belong, those of Dr. A. Keith, on the malformations of the heart; Dr. A. Low, on epignathus; and Dr. G. Duncan, on exophthalmic goitre. Experimental pathology, a recent development, is represented by Prof. A. Cushny's excellent paper on paroxysmal irregularity of the heart, and by Dr. J. J. R. Macleod's study of the condition that follows a direct diversion of the portal blood into the systemic circulation.

All the other studies, with the exception of that by Prof. St. Clair Symmers on bilharziosis, are concerned with bacteriology—a subject which has expanded into its present gigantic proportions since Prof. Hamilton went to Aberdeen in 1882. Five of the researches deal with a matter of the very utmost importance—that of immunity. To this group belong the papers by Dr. G. Dean, on plague immunity; Dr. Wm. Bulloch, on *Bacillus pyocyaneus*; Dr. G. G. Macdonald, on pneumococcal infection; Dr. R. D. Keith, on the relationship between hæmolysis and phagocytosis of red blood corpuscles; Dr. J. G. G. Ledingham and Dr. Wm. Bulloch, on the relation of leucocytosis to the opsonic content of the blood serum. The question of infection of the body from the alimentary canal is discussed by Prof. Hamilton in connection with his investigations of the disease in sheep known as "louping-ill." The bacteria found with this disease are described by Drs. J. M. Adam and B. R. G. Russell. Dr. Wm. Hunter has employed the data he collected as bacteriologist in Hong Kong to demonstrate that there is a very direct relationship between the epidemics of plague amongst rats and men. The administrative means which may be employed for the prevention of human tuberculosis are discussed by Dr. W. L. Mackenzie; the results of experiments on the efficacy of certain disinfectants are given by Dr. A. R. Laing. The manner in which these studies have been edited and arranged reflects the greatest credit on Dr. Wm. Bulloch.

To the quatercentenary publications the Anatomical and Anthropological Society of the University contributed a special volume of its Proceedings. Prof. R. W. Reid, the president of the society, has organised a fully-equipped department of anthropology in the University, with the result that graduates bring back most valuable information regarding the people of the countries or colonies in which they have stayed, and contribute their observations to their old society. In this volume appear five papers which deal with native races. Mr. George Moir writes on the natives of the Malay Archipelago; Mr. F. S. Maxwell contributes notes on Hausaland; Mr. D. Horn deals with the people of the New Hebrides; Captain A. W. C. Young, with the Tibet mission force to Lhassa; and Dr. R. H. Spittal describes skulls of New Guinea. Important papers on ancient or prehistoric subjects are contributed by Dr. Alex. Low, by Mr. A. Macdonald, and by Dr. J. S. Milne. Dr. A. Keith writes on the results of an anthropological investigation of the external ear, and Dr. R. J. Gladstone on the variations in shape and size of the skull. The paper on the development of the lower jaw in man, by Dr. Alex. Low, deserves especial commendation, both for the importance of its facts and for the very exact and complete manner in which he has recorded his observations. There is also an excellent paper by Miss A. V. Baxter on 1500 finger-prints which are recorded in the archives of the anthropological laboratory of the University.

THE FLOWERING PLANTS OF THE MESOZOIC AGE, IN THE LIGHT OF RECENT DISCOVERIES.[1]

THE subject which I have chosen for my address relates to plants of Mesozoic or Secondary age, ranging from the Trias, through the Jurassic, to the Cretaceous, the great period which bridges the gulf between the antique vegetation of Palæozoic days and the essentially modern type of flora which characterises the Tertiary formations.

We have abundant evidence of the existence of seed-plants in very early days, in fact, practically as far back in the Palæozoic as our records of terrestrial plants extend. On this occasion, however, I am going to speak of flowering plants, by which I do not mean the same thing as seed-plants, though the two terms have often been used as synonymous. One of the results of recent discoveries in Palæozoic botany has been to show that the seed-bearing and flower-bearing characters by no means coincide, for the fern-like seed-plants of Palæozoic age were in no sense of the words flowering plants. The evidence shows that their seeds, like the fructification of ordinary ferns, were borne on leaves differing but little from the vegetative fronds, and not aggregated on any special axis as are the parts of a flower. The nearest and, indeed, the only analogy to be found among recent seed-plants is in the female plant of Cycas, to which we shall return presently. The Mesozoic plants, however, with which we are now concerned were not only seed-plants, but they bore their reproductive organs in a form which everyone would naturally describe as a flower. They were flowering plants in the full sense of the term, however different in other respects from the flowering plants of the present day.

The Mesozoic floras from the Upper Trias to the Lower Cretaceous maintain, on the whole, a very uniform character, widely different from that of the preceding Palæozoic vegetation. True ferns were abundant, more so, no doubt, than in the earlier period; true conifers, often much resembling recent genera, were a dominant group; the family now represented by the maidenhair tree (Ginkgo) was prevalent, but the most striking feature of the vegetation was the abundance, in all parts of the world, of plants belonging to the class of the cycads, now so limited a group.

We will concentrate our attention on the cycad-like plants, or Cycadophyta, to adopt the broader class-name, appropriately suggested by Prof. Nathorst. The living Cycadaceæ are, it will be remembered, quite a small family, embracing only nine genera, and, according to a recent estimate, about 100 species, inhabiting the tropical or subtropical regions of both the old and new worlds, but nowhere forming a dominant feature in the vegetation. Throughout the Mesozoic period, however, at least until the Upper Cretaceous is reached, plants with the habit and foliage of cycads are extraordinarily abundant in all regions from which secondary fossils have been obtained; they are as characteristic of Mesozoic vegetation as the dicotyledons of our recent flora.

The most important point in questions of affinity is the fructification. Throughout the recent cycads this is of a simple type; in all the genera the staminate fructification is a cone, consisting of an axis densely beset with scales or sporophylls, each sporophyll bearing on its lower surface a number—often a very large number—of pollen-sacs, grouped, like the sporangia of a fern, in small sori. In eight out of the nine genera the female fructification is also strobiloid, each sporophyll bearing two marginal ovules. In Cycas itself, however, so far as the female plant is concerned, we find a much more primitive arrangement; no cone at all is differentiated, but the carpels are borne directly on the main stem of the plant, in rosettes alternating with those of the vegetative leaves. The carpels themselves are lobed and extremely leaf-like, bearing as many as six ovules in many cases, though in one species the number is reduced to two. Thus in Cycas the seeds are borne on organs still obviously leaves, and

[1] Abridged from the presidential address delivered by Dr. D. H. Scott, F.R.S., before the Royal Microscopical Society on January 16, and published in the Journal of the Society for April.

nothing of the nature of a flower is differentiated. No other living seed-plant is so primitive as this, but the cycads as a whole are undoubtedly the most primitive family of present-day Spermophyta, as is most strikingly shown in their cryptogamic mode of fertilisation by means of spermatozoids, which they share with Ginkgo alone among seed-plants.

When we go back to the Mesozoic age we might, on what one may call the elementary view of evolution, expect to find the Cycadophytes, which were so abundant at that period, still simpler and still nearer the cryptogamic condition than the members of the class which have come down to our own day. But this is by no means the case; there were, no doubt, a certain number of cycads in Mesozoic times which were about on the same level of organisation as their living representatives, but the great majority, so far as the available evidence shows, attained a much higher organisation, at least in their reproductive arrangements, far surpassing any of the gymnosperms now known to us. This is one of the many facts in palæontology which show that evolution is by no means the obvious progression from the simple to the complex which many people have imagined. Just as the lycopods and the horsetails of the Coal-measures were not simpler, but far more complex than their successors, so the Cycadophyta of Mesozoic age were, on the whole, on a much higher level than the surviving family Cycadaceæ, which now represents them. The history of the vegetable kingdom, so far as its records are known, is the history of the ascendancy of a succession of dominant families, each of which attained at some definite period its maximum, both in extent and organisation, and then sank into comparative obscurity, or died out altogether, giving place to some other race, which, under changing conditions, was better able to assume the leading *rôle*. The cycadophytes of the Mesozoic were, in their day (and it was a long one), a dominant group, almost as much so as the dicotyledons are now, and they equipped themselves with a correspondingly high organisation, even rivalling the angiospermous flowering plants (perhaps cadets of the same stock), which ultimately displaced them.

Among the Mesozoic Cycadophyta there were some, as already mentioned, which seem to have been essentially similar to our recent cycads. I do not, however, propose to dwell on this line of descent, but will now pass on to those Mesozoic Cycadophyta which attained a higher level of organisation, giving them a better title to the name of "flowering plants" than any of their predecessors or contemporaries.

The genus Bennettites was founded by Carruthers in 1868[1] for certain cycadean stems, of Oolitic and Lower Cretaceous age, with fruits borne on secondary axes, not protruding beyond the bases of the petioles. The species on which, for many years, our knowledge of the group was principally based is *Bennettites Gibsonianus*, of which a magnificently preserved specimen was discovered, just fifty years ago, in the Lower Greensand of Luccombe Chine, in the Isle of Wight. Some years later a second specimen was found in the same locality, but no others have as yet come to light. In *B. Gibsonianus* and other species the external appearance of the stem was similar to that of many recent cycads, its surface being completely invested by an armour of persistent leaf-bases. Anatomically, there is also a marked agreement, the chief distinction consisting in the simpler course, in the case of the fossil, of the vascular strands which pass out from the stem into the leaves. A striking feature is the presence, in great numbers, on the leaf-bases and bracts, of flat, scaly hairs, of the same nature as the ramenta characteristic of ferns. Even in external appearance, however, a Bennettitean stem, if in the fruiting condition, differs conspicuously from that of any recent cycad in the presence of a number of short, lateral branches, like large buds, wedged in between the leaf-bases, and arising in their axils (see Fig. 1, from an American species). These bodies are the fructifications, the characteristic feature of the Bennettiteæ. In structure, as well as in position, they differ totally from any form of fructification met with in recent cycads or other gymnosperms.

The peduncle bears many spirally arranged bracts, which completely enclose the fructification. The end of this peduncle expands into a convex receptacle, on which organs of two kinds are borne, the one fertile, the other sterile. The fertile appendages consist each of a long, slender pedicel, terminating in a single orthotropous seed, with the micropyle directed outwards. The seed-bearing pedicels are present in large numbers; the sterile appendages, or interseminal scales, are still more numerous. They form a dense packing between the seed-pedicels, and somewhat overtop the seeds themselves, expanding at their apices to form an almost continuous envelope, leaving only small perforations, into which the micropylar ends of the seeds are fitted. They form collectively a kind of pericarp, differing, however, from that of an angiospermous fruit in the presence of openings for the micropyles of the seeds. The whole complex fruit is enclosed in the mantle of overlapping bracts. In *Bennettites Gibsonianus* the fruits discovered are practically ripe, for each seed contains a large dicotyledonous embryo, with somewhat fleshy cotyledons. The embryo almost fills the seed, which was thus nearly, if not quite, exalbuminous—an unprecedented condition in

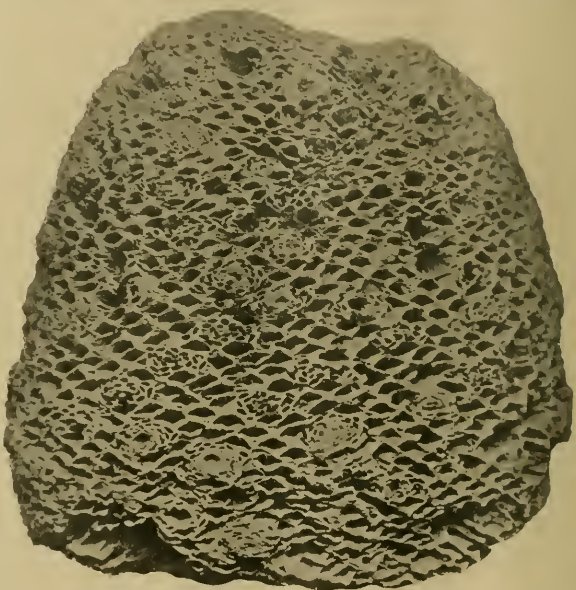

FIG. 1.—*Cycadeoidea marylandica.* The earliest described American fossil Cycad. From an original daguerreotype. Nearly thirty young fruits are marked in the present view by the groups of bract scars interpolated between the old leaf-bases. About one-fourth natural size. From Wieland's "American Fossil Cycads."

[1] "On Fossil Cycadean Stems from the Secondary Rocks of Britain." Trans. Linn. Soc. London, xxvi.

a gymnosperm. This plant, and a few of its immediate allies, afford the only instances, so far known, of the preservation of the embryo in a fossil seed.[1]

In the whole arrangement of the floral organs, the presence of a pericarp, and the character of the seed, the fructification differs entirely from anything known in gymnosperms, and the inclusion of Bennettites in Saporta's class "pro-angiosperms" appeared justified on grounds of analogy if not of affinity.

So far, however, nothing whatever was known of the staminate organs of these plants, and no one suspected that the fructifications already known were other than unisexual. The complete elucidation of the subject was reserved for the American palæontologists, who possess a wealth of material for the investigation of Mesozoic Cycadophyta far exceeding anything that Europe can show. No less than sixty species of silicified cycadean trunks have now been described from the Mesozoic of America, ranging from the Upper Triassic to the Lower Cretaceous.

The specimens are often extremely numerous; thus the twenty-nine species from the Black Hills of South Dakota are represented by nearly 1000 more or less complete trunks. In fact, the Cycadophyta of the American Mesozoic are as important to the botanist as the gigantic saurians (with which they are often associated) are to the zoologist.

FIG. 2.—*Cycadeoidea ingens.* Restoration of an expanded bisexual flower in longitudinal section, showing the central ovuliferous cone, the compound stamens bearing numerous synangia, and the surrounding bracts, hairy with ramenta. About half natural size. From Wieland's "American Fossil Cycads."

Fig. 1 represents the first American fossil cycad ever discovered; it was found about 1860 in Maryland, between Baltimore and Washington, by the geologist, Philip Tyson, and well illustrates the external features of the group. A third of a century elapsed before any further discoveries were made, so the present magnificent material has been accumulated within quite a short period. The systematic arrangement of the specimens has been principally the work of Prof. Lester Ward, while the morphological investigation has fallen to the share of Dr. Wieland, of Yale University, to whom the discoveries we have now to consider are due. In referring to Dr. Wieland's work, I shall follow him in using the name Cycadeoidea, but it must be understood that this is synonymous, so far as we can tell, with Bennettites.

In external features, as well as in anatomical structure, the American species so far investigated agree wonderfully closely with the European species of Bennettites, but it must be remembered that the vast extent of the material will necessitate many years of arduous research before its investigation can be completed. During the eight years or so that Dr. Wieland has been at work, a marvellous amount has been accomplished. His results are embodied in a magnificent volume issued last August by the Carnegie Institution of Washington.[1]

[1] Solms-Laubach, "On the Fructification of *Bennettites Gibsonianus*." English translation in Ann. of Bot., v. 1891.

The male organs of the Bennettiteæ were first found in 1899, in the species *Cycadeoidea ingens.*[2] Two years later the important fact was established that the organs of both sexes occurred in the same fructification, the whole thus constituting a "hermaphrodite," or bisexual flower.[3] Twenty-five trunks bearing bisexual flowers have now been investigated, belonging to seven American species. The conditions in *Cycadeoidea dacotensis*, one of the cases most fully investigated, are as follows. The whole fructification has a length of about 12 cm., and protrudes beyond the leaf-bases of the trunk. About half the length is occupied by the peduncle, the upper part of which bears 100 or more spirally arranged bracts, enclosing the essential organs. The centre is occupied by the ovuliferous cone, about 4 cm. in height, corresponding to the receptacle, with its seeds and other appendages, as found in *Bennettites Gibsonianus*. In *C. dacotensis*, however, the stage of development is far earlier, immature ovules taking the place of the ripe seeds of the more advanced European specimens. We have to do, then, in this case with an organ in the stage of a *flower*, as distinguished from the *fruit* previously described. The ovuliferous cone, or gynæcium, is completely surrounded by the hypogynous staminate disc, as Dr. Wieland calls it, springing from the rim of the receptacle at the base of the cone (see diagram, Fig. 2). The stamens are numerous (eighteen to twenty in *C. dacotensis*), and arranged in a whorl; their stalks are united to form a continuous sheath, which extends to about the level of the top of the gynæcium. Here they become free from each other; each stamen is a compound, pinnate sporophyll, about 10 cm. long altogether, and is folded inwards towards the gynæcium, the deflexed tip reaching down nearly to its base. The alternate pinnæ, of which there are about twenty pairs, are likewise bent inwards. The pinnæ, with the exception of those at the apex and base of the frond, which are sterile, bear the pollen-sacs in two rows, ten in each row on the longest pinnæ. Thus the stamens are highly complex organs, resembling the fertile fronds of a fern rather than the stamens to which we are accustomed in our modern flowering plants. The complexity, however, does not end here, for each pollen-sac is itself a compound structure containing two rows of loculi, ten or more in each row. It thus constitutes a *synangium*, comparable to that of the marattiaceous ferns, and especially the genus Marattia. The similarity to the fructification of such a species as *Marattia Kaulfussii* is, in fact, surprisingly close.

It appears that all the specimens actually investigated were in the bud condition, the stamens being still infolded, as described above. Presumably the stamens eventually opened out, and the diagrams introduced in Figs. 2 and 3 show them in the expanded condition. The ground-plan of the open flower, shown in Fig. 3, is based on *Cycadeoidea ingens*, a species in which the number of stamens is smaller than in *C. dacotensis*.

The leading features in the organisation of the Bennettitean flower may be briefly recapitulated as follows:—The centre is occupied by the gynæcium, seated on the convex receptacle, and consisting of numerous long-

[1] "American Fossil Cycads." By G. R. Wieland (1906).

stalked ovules, imbedded among the interseminal scales. Surrounding this central body is the hypogynous whorl of stamens, fused below to form a tube, and expanding above into the pinnate sporophylls, bearing very numerous compound pollen-sacs or synangia, filled with pollen. The whole is surrounded by an envelope of spirally arranged bracts springing from the upper part of the peduncle. The general arrangement of parts is manifestly just the same as in a typical angiospermous flower, with a central pistil, hypogynous stamens, and a perianth. The resemblance is further emphasised by the fact, long known, that the interseminal scales are confluent at their outer ends to form a kind of pericarp or ovary-wall. When to these general features we add the practically exalbuminous character of the seed, with its highly organised dicotyledonous embryo, the indications of affinity with the higher flowering plants become extremely significant. The comparison was drawn by Dr. Wieland in 1901, immediately on his discovery of the hermaphrodite flower. The angiosperm which he specially selected for comparison was the tulip-tree, Liriodendron. The elongated strobiloid fruit, with many carpels spirally arranged in the receptacle, no doubt suggests similarity, and, on general grounds, we should naturally look for analogies among the less specialised polypetalous dicotyledons, such as Magnoliaceæ, in some of which the leaves of the perianth are spirally arranged. Analogies may also be found in our familiar Ranunculaceæ, such as Anemone, or, still better, the globe-flower (Trollius), with its numerous sepals, or, again, in the water-lilies (Nymphæaceæ). In certain respects, indeed, the Bennettitean flower was in advance of these more primitive dicotyledons, as seen in the arrangement of the stamens, which have abandoned the spiral phyllotaxis of the other organs to range themselves in a definite whorl, while at the same time their stalks are fused into a tube, thus becoming "monadelphous," as in the mallows of our own flora.

The flower, with its great stamens, 10 cm. long in some species, must have been a striking object when it opened (Figs. 2 and 3). As, of course, we can know nothing of the coloration of the perianth and other parts, we cannot tell how brilliant its appearance may have been; the bright tints of the carpels and ovules in some recent cycads, such as species of Cycas and Encephalartos, suggest the probability that the attractions of colour were not wanting to the more elaborate flowers of the older Cycadophyta; the possibility of a relation to the insect life of the period cannot be ignored. It is not my intention to push further the comparison of the Bennettitean fructifications with the angiospermous flower; the deeply interesting questions which must suggest themselves to the mind of every botanist, as to how far these manifest analogies are likely to indicate an immediate affinity, will be fully discussed elsewhere by others. Enough has been said to show that the remarkable organs discovered by Dr. Wieland fully merit the name of "flower," in the same sense in which we apply it, in everyday language, to the flowers of our gardens and fields.

As stress has been laid so far on the points of agreement with the flower of the angiosperms, some reference must now be made to characters which indicate relations in other directions. The structure of the gynæcium renders it probable, if not certain, that the Bennettiteæ were still gymnosperms as regards their mode of pollination, for the openings between the scales of the pericarp leave the micropyles of the seeds exposed. One must therefore suppose that the pollen was received by the ovule directly, without the intervention of a stigma, so that functional angiospermy had not yet been attained. This is, no doubt, a primitive condition, but it by no means excludes an affinity with angiosperms. Just as in Lagenostoma, the seed of the pteridosperm Lyginodendron, the beak of the nucellus was still the receptive organ for the pollen, in spite of the presence of an integument,[1] so, in the Bennettitean flower, the micropyle of the seed was still the receptive organ in spite of the presence of a pericarp. The integument in the one case and the pericarp in the other might be termed a "prophetic organ" in the only sense in which such organs exist, *i.e.* an organ which has not yet assumed all the functions to which it is destined.

The stamens, while by their arrangement and position they suggest those of a typical angiosperm, carry us back by their structure and form to the sporophylls of a fern (see Figs. 2 and 3), so that the characters of the flower as a whole may almost be said to bridge the gulf between cryptogams and the higher flowering plants. The fern-like characters, however, have probably come to the Bennettiteæ, not directly from true ferns, but through the

FIG. 3.—*Cycadeoidea ingens.* Plan of bisexual flower consisting of a central ovuliferous cone, a hypogynous whorl of compound stamens, united at the base, and a series of spirally inserted enveloping bracts, all shown diagrammatically on about the same scale as Fig. 2, and as if pressed out flat. From Wieland's "American Fossil Cycads."

intermediate group of the Palæozoic pteridosperms. The fact that the pollen-grains are borne in compound pollen-sacs, or synangia, like those of the Marattiaceæ among ferns, is one of great significance.[2] It is impossible to emphasise too strongly the extraordinary combination of characters which the Bennettitean flower presents, uniting in itself features characteristic of the angiosperms, the gymnosperms, and the ferns, and suggesting that the passage from the Filicineæ to the higher flowering plants may have been (comparatively speaking) a short cut. The complexity of this earliest known type of a true flower indicates the probability, as Dr. Wieland points out,[3] that

[1] See Oliver and Scott, "On the Structure of the Palæozoic Seed *Lagenostoma Lomaxi*," Phil. Trans. Roy. Soc., Series B., 197 (1904), p. 231.

[2] The general question of the relation of the early seed-plants to ferns is discussed in my article, "On the Present Position of Palæozoic Botany," Progressus Rei Botanicæ, Heft 1. 1906.

[3] "American Fossil Cycads," p. 143.

the evolution of the angiospermous flower was a process of reduction. There is thus no longer any presumption that the simplest forms among the flowers of angiosperms are likely to be the most primitive. The tendency of the older morphologists to regard such flowers as reductions from a more perfect type appears fully justified by the discovery of the elaboration of floral structure attained by the Mesozoic Cycadophyta before the advent of the angiosperms themselves.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The special board for biology and geology has approved a grant of 150*l.* from the Balfour fund made by the Balfour managers to W. E. Agar, of King's College, in furtherance of his proposed expedition to the Paraguayan Chaco.

The board of agricultural studies reports that the fund for providing the department of agriculture with a permanent building of its own has received substantial additions during the year, the conditional contribution of 5000*l.* by the Drapers' Company having been secured. The fund now amounts to 13,030*l.* 10*s.*

Manchester.—Mr. F. T. Swanwick, Richardson lecturer in mathematics, has been appointed Fielden lecturer in mathematics in place of Mr. R. F. Gwyther, who is now devoting his whole time to the joint matriculation board of the northern universities. Mr. J. E. Littlewood (Cambridge) has been appointed Richardson lecturer in mathematics; he was bracketed senior wrangler in 1905, and was placed in the first division of the first class of part ii. of the mathematical tripos in 1906. Mr. H. M. Priestley (Cambridge) has been appointed assistant lecturer in mathematics; he was fifth wrangler in 1905, and was placed in the second division of the first class of part ii. of the mathematical tripos in 1906.

Plans have been prepared for new engineering laboratories, and building will shortly be commenced on a site on the north side of Coupland Street, near the present physical laboratories. For some time past need has been felt for this extension, and the new buildings will afford ample space for the whole work of the engineering department to be carried out under one roof. In addition to the main laboratory of 75 feet by 166 feet, lecture rooms, a large drawing room, and a boiler house are to be erected.

Sir Arthur Rücker, F.R.S., principal of the University of London, will distribute the prizes to the successful students at Guy's Hospital on Thursday, July 4.

Sir John Kennaway, Bart., M.P., will preside at the commemoration day proceedings of Livingstone College, Leyton, E., on Wednesday, June 5. Livingstone College exists for the purpose of solving one of the greatest problems connected with missionary effort, viz. the preservation of the health of missionaries and others in tropical climates.

It is stated in *Engineering* of May 24 that the Technikum at Ilmenau, in Thuringia, is one of the few technical schools that are conducted in direct connection with commercial works. The director is also head of a firm of engineering and electrical works, and the students are, at all times, when not occupied by their regular lectures and laboratory practice, admitted into the works, in which advanced pupils can receive further training. The combination seems to answer.

In the *Engineering Magazine* (vol. xxxiii., No. 2) Mr. H. Cole Estep discusses the attitude of technical students towards the engineering-apprenticeship courses which are offered by the leading manufacturers of the United States. He finds the attitude unsympathetic. The present low flat-rate system of wages is discouraging rather than encouraging to the average college student. The objections are also raised that the courses are too long, that there is no reward at the end, and that the invention clause existing in many apprenticeship contracts is unfair.

A course of instruction in natural history has been arranged at the Horticultural College, Swanley, for students who, having passed through the ordinary training in gardening, wish for additional training in natural-history subjects, in order to qualify as teachers of gardening and nature-study. Other students will be admitted to the course provided they can show they are able to take full advantage of the instruction. Students will be given an insight into field work in natural history based on laboratory instruction; the work will be practical, and students will be shown how to prepare their own material and to construct their own apparatus. The course will last a year, of which the first two terms will be devoted to general work in botany, zoology, and geology, and the third term to special subjects. Fuller particulars may be obtained from the principal at the college, Swanley, Kent.

In his presidential address to the Royal Geographical Society on Monday, May 27, Sir George Goldie again directed attention to the omission of geography in examinations for the Foreign Office and other branches of the Civil Service. For a good many years the Foreign Office stood in an exceptional position amongst the Civil Services of the Crown by including geography amongst the subjects for the entrance examinations of candidates and making a pass in this subject compulsory. After next month, however, geography will cease to be a subject which candidates for the Foreign Office may select even voluntarily. So many sons of the well-to-do classes of this country compete in examinations controlled by the Civil Service Commissioners that the standing in the whole educational sphere of any subject depends to some extent upon whether it is or is not a means of gaining marks in the civil and military examinations, and it may be asserted that if geography is included as one of the subjects of examination, it will very shortly take its place in Great Britain, as it has long since done in the United States, Germany, and other countries, as one of the fundamental and indispensable elements in the education of childhood and youth. That this has not been the case up to now is probably due to the unintelligent and unmethodical manner in which the subject was taught until a few years ago, with the result that the majority of those who are to-day in a position to speak with authority retain an entirely incorrect impression of its scope and objects. It is to the University of Oxford, supported, Sir George Goldie added, by the Universities of Cambridge, London, Edinburgh, and other great centres of education, that geographers must look for a satisfactory solution of this important question; for, so far as can be gathered from the correspondence on the subject which appeared some months ago, the Civil Service Commissioners are willing to consider the admission of geography as one of the voluntary subjects for examinations, provided the great universities will give a lead. In taking such a step, both the universities and the commissioners would have behind them the pressure of public opinion, owing to the sudden awakening both of interest in the Empire as a whole and of recognition of our widespread ignorance of its geographical conditions.

SOCIETIES AND ACADEMIES.

London.

Royal Society, January 31.—"On the Thermo-chemistry of Flame Spectra at High Temperatures." By Prof. W. N. **Hartley**, F.R.S.

(1) The oxides of calcium, strontium, and barium are not dissociated by heat alone, because they show no spectrum in a carbon monoxide flame; (2) they are reduced by the combined action of heat and hydrogen in the oxy-hydrogen flame and by the action of cyanogen in the cyanogen flame; (3) the flame coloration is due to the metal, because not only is the flame spectrum from lime essentially the same as that of the metal calcium, but also the heats of formation of CaO, SrO, and BaO have very nearly the same value, and that where calcium oxide can be reduced the other oxides could, on that account, undergo a similar reduction. Whether the compound of strontium or barium in the flame be a sulphide or an oxide, the same spectrum is emitted, but there is some

uncertainty as to whether the barium sulphide is not converted into oxide by water-vapour in the flame.

The explanation given by Lenard, of the flame coloration by the alkali salts, appears to be inapplicable to the coloration of the carbon monoxide flame by the haloid salts of the alkaline earth metals.

February 21.—"Longitudinal Symmetry in Phanerogamia." By Percy **Groom.** Communicated by Dr. D. H. Scott, F.R.S.

The paper describes a graphic method of recording the longitudinal distances apart of plant members, and gives results obtained by the method, which is as follows:—

On squared paper the successive internodes (or other segments) are recorded as successive ordinates, and the resultant curve is termed the internode curve (or other curve).

In a typical herb the internode curve of the main axis is a regular ascending-descending one, while those of the successive branches commencing at the base of the herb more or less completely and gradually change from this complete curve to a purely descending one. These internode curves are shown to be inherent, though liable to modification by external conditions.

In alternate-leaved Chenopodiaceæ the internode curve invariably shows a periodic zigzag form, and, by connecting the alternate ordinates, can be analysed into two "subcurves" which are frequently not synchronous in period. Both these subcurves of the main axis are of the ascending-descending type, while those of the successive branches traced from below more or less change into the purely descending form. Of the two subcurves, one is the "internode subcurve" and the other is the "displacement subcurve." Evidence is given in favour of the view that the original phyllotaxis of the Chenopodiaceæ was opposite, that the internode subcurve represents a modification of the original internode curve, and that the displacement subcurve represents a series of intercalated segments registering the distances up which single leaves have been displaced from the original opposite arrangement.

This view is confirmed by the fact that a similar displacement curve is formed by recording the heights of the successive branches above their subtending leaves in certain Boraginaceæ. It is shown, too, that the Boraginaceæ are probably opposite leaved in design, and that in *Solanum Dulcamara* the familiar leaf displacements high up the stem are foreshadowed by others lower down.

One point of significance in connection with these assumed hereditary displacements is that they follow the rule formulated by de Vries in reference to the dimensions and distribution of monstrosities.

The paper also discusses smaller or more fluctuating displacements of leaves; double-leaves; the correlation of alternate rather than successive internodes and nodes where phyllotaxis is cyclic; and the theory of stem structure.

Finally, the applicability of the method to other morphological problems is tested by observations on sympodes, with a positive result in the case of *Ampelopsis hederacea.*

March 14.—"Capillary Electrometer Records of the Electrical Changes during the Natural Beat of the Frog's Heart." By Prof. Francis **Gotch,** F.R.S.

The chief points brought forward in this communication are the following:—(1) The electrical changes during the natural rhythmic activity of the frog's heart, when kept *in situ* and supplied with blood, resemble in all essentials those observed by Waller, Starling, Bayliss, Einthoven, &c., in the mammalian heart, but do not correspond with those observed by Engelmann, Burdon-Sanderson, &c., in the excised frog's heart artificially excited. (2) The more prolonged character of the activity of the frog's heart, and the ease with which the locality of any change can be determined, render it clear that the special feature of the natural beat is the occurrence of two chief electrical changes of similar sign. (3) This is explicable as due to the first or base change being more prolonged and of greater magnitude than the apex change. (4) The increased duration and magnitude of the base change is mainly caused by the circumstance that, although the base change occurs first, the whole of the base is not involved, the portion around the spring of the aorta remaining quiescent until the activity has occurred at the apex; this aortic portion then becoming active produces the terminal effect. (5) Each contraction wave thus starting at the auriculo-ventricular junction is propagated to the apex, and returns from the apex to the part of the base around the start of the aorta; from this it spreads to the aortic bulb; at 15° C. the propagation rate is about 130 mm. in one second, *i.e.* 6/100″ after the first base change, an apex change is perceptible, and 6/100″ after the apex, a second aortic base change. (6) The return wave is brought into prominence when the heart is distended with blood, or has been so distended, and is associated with the persistence of the early tubular condition which prevails in the heart of the tadpole. (7) The return wave reveals itself in the records as a double reversal of the electromotive condition of the whole base contact; this is at first galvanometrically negative (base activity), then suddenly positive (apex activity), and then, again, suddenly negative (second aortic part of base activity). It is confirmed by records made under a variety of conditions, comprising local alterations of temperature, local injury, and altered position of electrometer contacts. All the records were those of the displacements of the capillary meniscus, photographed upon moving sensitised plates.

Entomological Society, May 1.—Mr. C. O. Waterhouse, president, in the chair.—*Exhibits.*—Coleoptera from Iceland: Mr. O. E. **Janson** exhibited a small collection of Coleoptera made by him in Iceland in July, 1906, comprising thirty-nine species, of which some were previously unrecorded as inhabiting that island. He also directed attention to the affinity between the beetle fauna of Iceland and of Scotland, only one of those taken, *Colymbetes groenlandicus*, Aubé, not occurring in both countries.—Larvæ of *Otiorrhynchus sulcatus*: Mr. J. A. **Clark** brought for exhibition living larvæ of *Otiorrhynchus sulcatus* feeding on the roots of ferns.—Coleoptera from the south of France: Commander J. J. **Walker** showed living specimens of *Oxythyrea stictica*, L., *Epicometis hirtella*, L., and *Anthaxia parallela*, taken by Dr. T. A. Chapman at St. Maxime, Var, S. France.—Mimetic relation of *Leuceronia argia*, ♀: Dr. F. A. **Dixey** exhibited specimens of seven different forms of the variable female of *Leuceronia argia*, Fabr., showing that each form stood in mimetic relation with a separate model. The models belonged to the genera Belenois, Phrissura, Pinacopteryx, and Mylothris, and the association was probably in every instance synaposematic.—Mimicry in Coleoptera: the **President** exhibited some Coleoptera collected in Pahang by Mr. H. C. Robinson, and recently received at the Natural History Museum.—Living luminous Coleoptera: Dr. G. B. **Longstaff** exhibited living specimens of the Elaterid *Pyrophorus noctilucus*, Linn., brought from Trinidad by Dr. F. L. J. M. de Verteuil, R.N.—*Quedius riparius* and *Trypodendron quercus*: Mr. H. St. J. **Donisthorpe** exhibited on behalf of Prof. T. Hudson Beare and himself specimens of *Quedius riparius*, Kell., and *Trypodendron quercus*, Eich., taken by them at Porlock, Somersetshire, on April 16 and 17. Also *Hydrovatus clypealis*, Shp., taken by them on April 14 at Worle, near Weston-super-Mare.—Dipteron associated with ants: Mr. **Donisthorpe** also showed the larva and pupa of a Dipteron of the genus Microdon, taken in a nest of *Formica fusca* at Porlock last month.—*Hemimerus talpoides*, Walk.: Mr. R. **Shelford** exhibited a specimen of the curious parasitic orthopterous insect *Hemimerus talpoides*, Walk., from Portuguese Guinea.—*Paper.*—A case of homœotic variation in a cockroach: R. **Shelford.**

Linnean Society, May 2.—Prof. W. A. Herdman, F.R.S., president, in the chair.—The respiratory mechanism in certain elasmobranchs: A. D. **Darbishire.** The author exhibited living examples of the dog-fish, ray, and angel-fish, and explained that the primary object of the investigation was to determine the question whether water went in, or was expelled, from the spiracle of the dog-fish. The method employed to elucidate this point consisted in liberating from a pipette some powdered carmine suspended in sea-water in the immediate vicinity of the spiracle. The cloud of carmine was seen to be vigorously drawn in at each inspiring phase. A remarkable difference was discovered to exist between the respiratory mechanism in the dog-fish and the ray on the one hand, and the angel-fish, *Rhina squatina*, on the other, for whilst in the case of the former two fish the gill-covers are purely passive agents in determining the respiratory current, in the case of Rhina the undulation of the gill-covers seemed to be solely responsible for the flow of water into the spiracle and mouth.—The common elements of the fauna and flora of Abyssinia and West Africa: Prof. E. B. **Poulton.** The author based his remarks on his observations of a group of African butterflies. The paper was illustrated by a series of lantern-slides and a large orographical map.—The fauna of the Sudanese Red Sea: Prof. W. A. **Herdman.** Four papers of a proposed series on this subject were laid before the society; they consisted of (1) an introduction, by the president; (2) a narrative of Mr. Cyril Crossland's explorations; (3) Mr. Crossland's account of the formation of certain shore-cliffs in Egypt; and (4) of the Red Sea coral reefs; with (5) Mr. E. R. Sykes's enumeration of the Polyplacophora collected.—Pseudo-scorpions: C. J. **With.** The specimens described all belong to the British Museum. They comprise in the Australasian group, under the family Cheliferidæ, Hagen, four new species of the genus Chelifer, Geoffroy. In the Asiatic group three species of the same genus are re-described, one of them, which Pocock in 1900 referred to *C. javanus*, Thorell, being now named as a distinct species, *C. pococki*. A single species of Chelifer from Africa is the subject of comment, but notice is taken of the large additions to our knowledge of the Chelifer fauna in that continent recently made by Ellingsen. Under the family Garypidæ, Hansen, a new species of Garypus, Koch, is described from the island of Grenada; a new species of Olpium, Koch, from St. Vincent; and another from Stewart Island, New Zealand. Further, a species from Funafuti, which Pocock in 1898 referred to *Olpium longiventer*, Keyserling, is here transferred to the genus Garypinus, Daday, as an independent species, *G. oceanicus*; and another species, from Kauai in the Sandwich Archipelago, assigned by Eugène Simon in 1900 to *Olpium longiventer*, now becomes *Garypinus mirabilis*, n.sp. An appendix reviews the species *Chiridium ferum*, Simon, fam. Cheliferidæ, and *Ideoroncus cambridgei*, Koch, fam. Obisiidæ, chiefly with regard to peculiarities in the structure of the antennæ. The paper is accompanied by numerous illustrations, and contains many notes on distribution.

Zoological Society, May 7.—Mr. G. A. Boulenger, F.R.S., vice-president, in the chair.—Original drawings of *Spirochaeta anodontae* from the crystalline style and intestine of *Anodonta cygnea*: H. B. **Fantham.** This was the first record of the occurrence of this parasite in the British pond-mussel, though Keysselitz recorded probably the same organism from *Anodonta mutabilis* about a year ago, without giving its dimensions. The organism was found to be about 40 μ long and about 0·7 μ broad, with pointed ends and an undulating membrane. Its motion was most rapid, but seemed to be both spiral and vibratory.—The Cephalopoda of Zanzibar and East Africa collected by Mr. Cyril Crossland in 1901–2: Dr. W. E. **Hoyle.** The collection was not extensive either in point of individuals or species, and a large proportion were young individuals to which it was impossible to affix definite names in the present state of our knowledge. Five were identical with forms contained in a collection recently made by Prof. Herdman near Ceylon, whilst others occurred also in the Red Sea, thus showing a marked similarity in the cephalopod fauna of the whole of this region. Advantage had been taken by the presence of several specimens of *Sepioteuthis loliginiformis* to give a full description of that species. Some octopod embryos showed epidermal structures very similar to, if not identical with, those described by Chun as constituting a bristle coat in young octopods, and an account of these, as full as the material allowed, was given.—The mammals collected by Mr. M. P. Anderson during the Duke of Bedford's exploration of eastern Asia: O. **Thomas.** The present paper (the fifth of the series) gave an account of a collection from central Korea, just north and south of Seoul, the capital. Seventy-three specimens were dealt with, belonging to thirteen species, of which several were new, additional to those already discovered by Mr. Anderson during a previous visit to the southern part of the peninsula.—Some new buildings in Continental zoological gardens, based upon recent visits to those of Stellingen, Hamburg, Berlin, Dresden, Breslau, Vienna, Budapest, Frankfort-am-Main, Amsterdam, Düsseldorf, Rotterdam, and Antwerp: A. **Trevor-Battye.**

Physical Society, May 10.—Prof. J. Perry, F.R.S., president, in the chair.—Stereoscopy with long base-line illustrated on the screen: Dr. T. C. **Porter.** The use of a long base-line for telestereoscopy occurred to M. Selb, of Brussels, and in 1903 he obtained stereoscopic mountain photographs. The applications of the method for military, geographical, and meteorological purposes, although obvious, do not seem to have been used before, and the author discusses the possibilities of these applications.

PARIS.

Academy of Sciences, May 21.—M. A. Chauveau in the chair.—New determination of the metre in terms of lengths of luminous waves: R. **Benoit,** Ch. **Fabry,** and A. **Perot.** The length of the standard metre in terms of wave-lengths of the red ray of the spectrum of cadmium at 760 mm. pressure and 15° C. on the hydrogen scale was found as a mean of four series of experiments to be equal to 1,553,164·13 λ, whence $\lambda = 0{\cdot}64384696\ \mu$. These four series were selected from seven series which together gave a mean of 1 metre $= 1{,}553{,}163{\cdot}99\ \lambda$ and $\lambda = 0{\cdot}64384702\ \mu$, but three of these seven series are to be omitted in calculating the absolute value. The authors point out, however, that the mean of the seven series agree in a remarkable manner with the value obtained at the International Bureau of Weights and Measures by Michelson, the originator of the idea, and M. Benoit in 1894, namely (after due correction), $\lambda = 0{\cdot}64384700\ \mu$. From the authors' results it is easy to see that if all standard metres were destroyed, a determination to within one ten-millionth of the actual value could easily be made.—The reduction of diketones by hydrogen in presence of reduced nickel: Paul **Sabatier** and A. **Mailhe.** Typical α-, β-, and γ-ketones were studied. Diacetyl, $CH_3.CO.CO.CH_3$, gives

$$CH_3.CH(OH).CO.CH_3 \text{ and } CH_3.CH(OH).CH(OH).CH_3$$

on reduction. Three-fourths or more of the acetyl-acetone tested split up according to the equation

$$CH_3.CO.CH_2.CO.CH_3 + H_2 = CH_3.CHO + CH_3.CO.CH_3,$$

while acetonyl-acetone, $CH_3.CO.CH_2.CH_2.CO.CH_3$, gave chiefly oxyhexane 2·5, $CH_3.\underbrace{CH.CH_2.CH_2.CH}_{O}.CH_3$. The authors are to continue similar work with the quinones.—Observations of the sun made at the Observatory of Lyons during the first quarter of 1907: J. **Guillaume.** Tables are given of the distribution of spots and faculæ as regards latitude.—The variation of double integrals: M. **Hadamard.**—Continuous, infinite, and simple groups of transformations (mathematical analysis): E. **Cartan.**—The surfaces produced by a circular helix: M. **Barré.**—The absolute sensibility of the ear: Henri **Abraham.** The sensibility of the ear was determined in absolute value by producing in it variations of pressure of known amplitude. The variations of pressure were produced in a cylinder of known volume by the vibrations of the membrane of a telephone, which formed one of the bases of the cylindrical cavity. The other base of the cylinder was also closed, except in the centre, where an opening connected with a bell-shaped orifice, which could be applied against the ear, was arranged. The results obtained seem to show that the limit of the sensations of the normal ear corresponds to variations of pressure having a magnitude of four ten-millionths of a millimetre of mercury. The author points out that his results agree approximately with those of Max Wien, who measured variations of pressure in Helmholtz resonators, but that they do not agree—being much smaller—with the values of different authors, who have used methods analogous to that indicated some time ago by Lord Rayleigh.—The ultimate lines of metals in dissociation spectra: A. **de Gramont.** A summary of the lines which may be regarded as specially characteristic for a number of common metals is given, and it is indicated that the lines termed ultimate by the author are the same in the condenser-spark, in the ordinary spark discharge without condenser, in the electric arc, and in very hot flames.—Application of Trouton's law to the determination of molecular rise of boiling point of solutions: D. E. **Tsakalotos.**—Explosive mixtures of air and ether: J. **Meunier.** The lower limit of inflammability is about 58 to 60 milligrams of ether per litre of air, and the upper limit is about 200 milligrams. From 100 to 175 milligrams per litre it is more or less explosive.—The removal of water from alcohol by the catalytic action of red phosphorus and the phosphates: J. B. **Senderens.**—The action of magnesium amalgam on the aldehydes: André **Kling** and Paul **Roy.** Certain compounds such as polymerised formaldehyde (trioxymethylene) and chloral do not react, but others, *e.g.* acetic and benzoic aldehydes, react readily.—The double compounds of aluminium sulphide with the protosulphides of chromium, nickel, cobalt, and magnesium: Marcel **Houdard.** Al_2S_3MnS, Al_2S_3FeS, and Al_2S_3CrS were isolated and analysed. They are considered to be similar to spinels in crystalline form and structure.—The dissociation of silicates of lithium: Edgard **Derome.**—Study of the calcium salt of paraoxybenzoic acid: Œchsner **de Coninck.**—The products formed by the condensation of ethyl oxalate with dimethylaniline in presence of aluminium chloride: A. **Guyot.**—Synthesis of ketones of the hexahydroaromatic series: G. **Darzens** (*cf. Comptes rendus*, vol. cxlii., p. 714).—Metallic thiosulphocarbamates: preparation of sulphocarbimides of the fatty series: Marcel **Delépine.**—The respiration of the vegetative aërial organs of vascular plants: G. **Nicolas.** The author summarises his results as follows:—(1) the different aërial organs of vascular plants have each their own intensity and special respiratory quotient; (2) the stalk and the petiole have generally intensities and respiratory quotients similar to each other; (3) of all aërial organs, those which are essentially charged with the assimilatory function are those which have the greatest respiratory intensity and the lowest respiratory quotient.—Properties of the pigments of batrachians: A. **Magnan.** The properties, including solubility, of green, yellow, brownish-yellow, red, and black pigments are described.—The reaction of the tissue of the iris to light: A. **Nepveu.** The iris is irritable to light in cephalopods, fish, and birds, but not in mammals.

PREHISTORIC ITALY.

Introduction à l'Histoire romaine. By Basile Modestov. Translated from the Russian by Michel Delines. Pp. viii+473. (Paris: Félix Alcan, 1907.) Price 15 francs.

PROF. MODESTOV'S work, which appeared originally in Russian, with an analysis in French, in the years 1902 and 1904, is a learned if somewhat conjectural attempt to reconstruct by the aid of archæological evidence the history of prehistoric Italy, with the view of elucidating the antecedents of Rome. In his own words (p. 341):—"abordant l'histoire de Rome, il se donne la tâche de discerner toutes les influences qui ont entouré la ville de Romulus dans la première phase de son existence." Basing himself on the work of Italian archæologists, which for the most part lies buried in the pages of periodicals, he begins with the Palæolithic age, and ends with the arrival of the Etruscans, which he dates somewhere about 1000 B.C. His learning is incontestable. It ranges from Rome to Berlin, and from St. Petersburg to London; it includes at once the work of Prof. Conway on Italic dialects and the researches of Mr. Arthur Evans and Mr. J. L. Myres on prehistoric Greece. Every scholar must be grateful for this laborious and exhaustive synthesis of the knowledge accumulated, during the last forty or fifty years, with regard to the history of primitive Italy.

Yet the critic may be pardoned if, in some respects, he ventures to criticise Prof. Modestov's work. For one thing, the author seems to exaggerate unduly the value of archæological research and archæological results. Etruscan pot-sherds and the débris of *terramari* are valuable in their way, but our sense of their value must not allow us to pooh-pooh, as Prof. Modestov too readily does, the work of a great constructive historian like Mommsen. The spade of the archæologist is, after all, a meaner tool than the pen of the historian, and the failing of the Pharisee is one to which the archæologist is so readily liable that it behoves him to be on his guard. It must be admitted, however, that the polemics of Prof. Modestov are directed against brother archæologists still more vehemently than against Mommsen. He wastes not a few pages, and exhausts not a little the patience of the reader, by continual diatribes and disproofs, which may cause a flutter in the dovecots of Italian archæology, but end by annoying the uninitiated scholar. There is something of a barbarous zest in such a sentence as:—

> "Only the reasoning of M. Helbig, which M. Marthe has elected to follow, can vie, in its inconsistency and lack of scientific profundity, with that of its imitator."

And this suggests, what the reviewer has again and again noticed, that the author lets us too much into the workshop, and shows us too much rude workmanship and too little finished work. These argumentations represent the scaffolding of a book, which ought to be taken down when the building is finished, instead of remaining to spoil the view. Prof. Modestov has been so much interested in his matter that he has forgotten its form. He repeats himself, for instance, again and again, and one comes to notice, as a running refrain, the information (some four times repeated) that Pliny narrates the capture of 300 towns from the Umbrians by the Etrurians (though, by the way, at the fourth time of mentioning, p. 448, the captors are the Proto-Pelasgians).

The author is somewhat too prone to *risqué* conclusions, which he is not averse to supporting by dubious arguments. Though he is ready, upon occasion, to controvert Sergi, he accepts without reluctance the most hazardous of his conclusions, and believes in a "Mediterranean race" originating from Northern Africa. This is, he thinks, the earliest Italian race, and its representatives are the so-called Ligurians and Sicels, who came into Italy by way of the Straits of Gibraltar, and formed the basis of Italian population during the Stone age. To attain this conclusion, Prof. Modestov follows Sergi in exalting the evidence of skulls far above the testimony of language; to support it he is willing to accept the most dubious of linguistic evidence, and to connect the language of the Basques with that of the Berbers, or, indeed, with that of the hieroglyphics of Egypt. Is it for this, one asks, that Mommsen and Ihne are rejected in scorn? But the conclusions of Prof. Modestov on which he would himself wish most stress to be laid are not those which relate to the Stone age or to the Mediterranean race, but those which are concerned with the age of Bronze and the age of Iron (the *civiltá Villanovana*); and with the races by which these ages were introduced; while still more important, perhaps, in the eyes of the author is the part of his book in which he attempts to solve the problem of the origin of the Etruscans (pp. 341–468).

We may conclude by a brief indication of the conclusions which the author reaches on these important points. The age of Bronze came in two ways. Partly it came by way of commerce, from Cyprus—more especially in southern Italy; partly it came through immigration of an Aryan stock from the valley of the Danube. The first entry of this Aryan stock is represented by the *terramari* of the lower valley of the Po, as is proved more particularly by the Aryan custom of incineration (instead of burial), which can be shown to have been practised in the *terramari*. The first Aryan stock left the lower valley of the Po owing to the pressure of a second Aryan immigration, and, forced gradually southward, it settled in Latium, and became the parent of the *populus Romanus*. The second Aryan immigration is that of the Umbro-Sabellians, who came about 1000 B.C., and introduced the age of Iron, the so-called civilisation of Villanova, which they had derived from the Greeks by way of the Adriatic. The first Aryan stock, which had settled in Latium, borrowed from these new-comers something of their civilisation (their use of iron, their methods of decorating in bronze, and their rudimentary writing), while it also absorbed certain elements from the primitive Neolithic civilisation of the original "Ligurians" of the Tiber valley. Finally (*tantae molis erat Romanam condere gentem*), there came the Etruscans, at about the same date as the Umbro-Sabellians. The Etruscans, according to Prof. Modestov, who accepts, and fortifies by archæological evidence, the testimony of Herodotus, were a people from Asia Minor, who came by sea to Tuscany, bringing, *inter alia*, Eastern methods of divination which they had borrowed through the Hittites from Chaldæa. To corroborate this view, Prof. Modestov alleges the conclusions of a Danish scholar, who seeks to connect the mysterious Etruscan language with the dialects of the southern Caucasus. Here Prof. Modestov seems somewhat inconsistent, for while he compares the archæological relics of the Etruscans with those of south-western Asia Minor, he compares their language with the dialects of the north-east.

We should be ungrateful if we did not mention the many illustrations, for the most part original, with which the author has ornamented his book and sought to aid his readers. The Etruscan illustrations are particularly interesting.

ERNEST BARKER.

THE FUNCTIONS OF THE BRAIN AND SPINAL CORD.

The Integrative Action of the Nervous System. By Dr. C. S. Sherrington, F.R.S. Pp. xvi+411. (London: Archibald Constable and Co., Ltd., 1906.) Price 16*s*. net.

THE unravelling of the arrangement and complications of the nervous system has always been of great interest, not only to physiologists, but also to mankind in general. The specially human attributes which distinguish our species from the rest of the Mammalia have at least an intimate connection with the superior development of the central nervous system, and we have therefore a peculiar interest in tracing the methods by which this complexity is of advantage to the individual.

The central idea of the book under review is the action of the nervous system in connecting the various cells composing the body into one individual, as distinguished from a mere collection of separate items. While there are other agencies that work to this end, mechanical as well as chemical, still the nervous system is preeminently effective in this respect from the delicacy and speed with which the intercommunication is effected. The unit reaction, to which all the complex phenomena of nervous activity are referable, is recognised to be the "simple reflex action."

The recognition of this definite unit, in place of the vague generalities too often quoted, marks the first important step in the study of the subject.

Prof. Sherrington then goes on to show that the anatomical basis underlying this simple reflex consists of three parts:—(1) the *receptor*, the sensitive organ which receives the impression; (2) the *conductor*; (3) the *effector*, the organ which effects the reflex act.

The various details of the apparatus are then considered. By an arrangement of this kind the threshold is lowered for one kind of stimulus and heightened for others, so that the reflex becomes selective. The phenomena called out by these stimuli are then considered, namely, the irreversibility of the direction of the impulse, the long latent period, and the rhythm of the action. By the method of "successive degeneration" it is possible to examine the conductor apparatus, and the conclusion is arrived at that the simple reflex arc is at least *disynaptic*, that is, composed of three separate neurones as a minimum, that the "effector" part of the arc is a "final common path" for all the reflexes using the particular end organ attached to it, and that somewhere in the "conductor" (the part of the arc connecting receptor and effector) there is some mechanism which gives a refractory phase. The importance of this is seen when such a phenomenon as the scratch reflex is examined, as this consists of a rhythmic series of movements the rate of which is governed by the purpose for which the reflex acts, and not by the rapidity of the successive stimuli. Further, as such a reflex is a coordinated action, there must be rhythmic *inhibition* of a series of muscles as well as rhythmic *contraction* of the opposing set, and by a series of well-devised experiments and careful consideration of the results the author again makes an important advance. This becomes more evident when the next chapter of the story is considered, namely, the compounding of reflexes, and the method by which one reflex becomes prepotent over another which would use antagonistic muscles.

The limited space at a reviewer's disposal will not permit the further description of Prof. Sherrington's account of the functions of the cerebral cortex and the very ingenious experiments on sensual fusion, but it will be found that the later chapters of the book possess the same wealth of information and lucid reasoning as the earlier. The only criticism that might be gently urged is that occasionally the language in which the reasoning is conveyed becomes nearly as complicated and abstruse as the subject-matter of the discourse. Sometimes, however, this recondite phrasing hides gems of humour as well as knowledge, as in the sentence on p. 317:—

> "Into that sequestered nook the organism by appropriate reactions gathers morsels of environmental material whence by chemical action and by absorption it draws nutriment,"

which by careful examination of the context appears to mean "Tommy ate a piece of cake!!!"

But, jesting apart, we have in this book the most valuable contribution to the comprehension of the functions of the nervous system that has appeared up to the present time, not only from the records of the experiments quoted, but also from the logical and orderly way in which the due inferences from the experiments are put forward, and the volume stands out as a landmark in our knowledge of the subject.

PHYSIOLOGICAL CHEMISTRY.

Practical Physiological Chemistry; Junior Course; Senior Course. By R. H. Aders Plimmer. Pp. 55 and 83. Privately printed. n.d.

"THIS book has been compiled as a handbook for practical work in Physiological Chemistry at University College. Much use has been made of the books by Milroy, Cole, Halliburton, Hofmeister and others, from which some pages have been adapted almost in their entirety."

The foregoing quotation from the preface shows that the work makes no attempt at originality. It is mainly a compilation from various sources of what a teacher considers most suitable in his own classes. Every teacher has his own ideas as to what a student in physiological chemistry should perform for himself; if any other teacher were to adopt Dr. Aders Plimmer's book as a guide in his practical classes, one anticipates that he would modify the arrangement, adding here, omitting there, and in still other places transposing parts from the junior to the senior course, and *vice versâ*. The line between a junior and senior class is always difficult to draw, and every teacher has his own ideas as to what should be placed on either side of the line.

The book, from another point of view, is, however, different from all others hitherto published, for it includes the pure organic chemistry necessary for the understanding of the chemical problems of the physiologist and medical man. One of the difficulties of medical education to-day is the ever-increasing scope of the preliminary sciences, and the deciding as to how much of each is to be crowded within the few years of the curriculum. Science grows, but the years devoted to its study still have only 365 days each. The question is becoming an acute one as to which parts of each science the pruning knife must be applied. In the University of London, chemistry always has been, and still is, specially insistent on its claims; it has, moreover, been successful in obtaining an additional six months in the time devoted to it over and above the year that physics and biology are satisfied with. It is for this reason that so many teachers are anxious to see chemistry as a preliminary science cut down to the single year's work which suffices for the other subjects. Unfortunately, in many instances lecturers on chemistry, not having themselves had a medical training, know but little of what the students of medicine really need, and teach the subject as though their pupils hoped to be expert chemists. Such teachers point out the importance of chemistry as a groundwork of much that follows later in the course, but lose sight of the fact that a student has not done with chemistry when he passes his preliminary examination in science; he has later on in his studies to consider chemistry in its applications to both physiology and pathology.

In these circumstances it is not to be wondered at that the teachers of other subjects which have a more direct bearing on the study of medicine are urging that if the work of the pure chemist is limited to the one year, which they regard as ample for the learning of the groundwork, the superstructure will later on have to include more physiological chemistry diluted to a suitable degree with those parts of organic chemistry which are absolutely necessary for its comprehension. As an earnest of what can be done with this object in view, Dr. Plimmer's book should meet with a hearty welcome.

W. D. H.

CEMENT AND CONCRETE.

(1) *Portland Cement: its Composition, Raw Materials, Manufacture, Testing, and Analysis.* By Richard K. Meade. Pp. viii+385. (Easton, Pa.: The Chemical Publishing Co., 1906.) Price 14*s*. 6*d*. net.

(2) *Reinforced Concrete.* By C. F. Marsh and W. Dunn. Third edition, revised and enlarged. Pp. vii+654. (London: Archibald Constable and Co., Ltd., 1906.) Price 31*s*. 6*d*. net.

(1) THE author is chemist to the Dexter Portland Cement Co., and the analytical methods described have all been used to some extent in his laboratory. The treatise is a second edition of a small manual, published some four years ago, on the chemical and physical examination of Portland cement. In preparing this new edition, a considerable amount of fresh matter dealing with the manufacture of Portland cement has been added. The first two chapters, which form an introduction to the book, are devoted to the history of the development of the Portland cement industry in America; the growth in the total consumption, and the growth in the consumption per head of population, have both increased in a remarkable degree during the last sixteen years—in 1890 the total production in the United States was 335,000 barrels, and by 1904 this had increased to more than 26½ million barrels; but even in that year the consumption was in excess of the domestic production, and more than two million barrels had to be imported.

In the next section of the book, chapters iii. to viii., a comprehensive and complete account is given of the processes of manufacture; the raw materials are described in detail, and much information is given as to the localities in the States in which they are found, and one of the chapters is devoted entirely to the subject of quarrying and excavating the raw materials. In dealing with kilns and the burning of the raw materials, modern rotary kilns are described; this chapter will be found a very valuable one for reference purposes; the thermochemistry of the calcining is discussed in a very exhaustive manner. In connection with the description of the process of grinding, Mr. Meade not only explains the construction and working of the various ball and tube mills, which are now generally employed, but he gives plans and sections of the complete equipment of a modern Portland cement plant on the wet process plan and also on the dry process plan, with notes as to the cost of plant and manufacture.

The next section treats of the analytical methods which are, or should be, employed in determining the quality both of the raw materials and of the finished product. This portion of the book will be very useful to chemists engaged in Portland cement factories, and to every analyst who may have to deal with the problem of determining whether or not a given sample of cement is up to the standard of some particular specification. The different methods employed are explained with great clearness, and the apparatus necessary is shown in well-drawn illustrations; so explicit are the instructions that an engineer who has had a fair training in the elements of chemical analysis could, should necessity arise, make many of these determinations for himself after procuring the necessary apparatus.

The last section of the book is devoted to the physical testing of Portland cement, and this section will be invaluable for reference purposes to the civil engineer and to other users of Portland cement. The author describes in turn all the ordinary physical tests, and his comments upon the various tests and their value in enabling a conclusion to be drawn as to the quality of any given sample are of much practical value.

(2) The first edition of this work appeared in the autumn of 1904, and since that date there has been such great progress in the employment, and in our knowledge, of reinforced concrete that a new edition was rendered imperatively necessary; much new matter has been added in addition to a general revision of all the portions of the book dealing with calculations. Reinforced concrete is still not used in this country to anything like the extent to which it has been employed both in America and on the continent of Europe, but much of the opposition to its use is now steadily declining.

The first three parts of the book are devoted to a general description, with excellent illustrations, of the various systems which have been employed up to the present date, and give a brief account of the materials, including both concrete and the reinforcing metal. Great stress is laid on the absolute necessity of employing only the best material in connection with the concrete, and of ensuring that the materials shall be of uniform quality and the concrete well and carefully made.

Part iv. deals with the practical construction of reinforced concrete for various purposes, and the construction of the necessary moulds for beams, floors, arched ribs, chimney shafts, pipes, sewers, and reservoirs. The next two sections are devoted to a very full and complete account of the experimental researches, and the data deduced therefrom, which form the basis of all calculations necessary in designing reinforced concrete; the authors are to be congratulated on the admirable way in which they have brought together, in a most convenient form for reference, information scattered through a very large number of publications, and on the complete way in which they have brought up to date all the data obtained in experimental investigations. The chapter devoted to calculations necessary in design work has been almost entirely re-written and very considerably simplified, with great advantage to the designer who may desire to consult this work, the method of treatment adopted for the case of singly reinforced rectangular and T-beams being entirely new.

The last section of the book, as in the earlier editions, is devoted to a descriptive account of various buildings and structures which have been erected up to the present time in reinforced concrete; this chapter contains a series of most admirably reproduced photographs of many large buildings and handsome arched bridges built entirely on this system.

The regulations which have been laid down by the Prussian Government for the employment of reinforced concrete in buildings are printed *in extenso* in appendix ii., and another appendix contains the report of the experiments carried out by the United States Geological Survey Department on the permeability of reinforced concrete pipes.

The present edition is a great improvement on previous issues, and every engineer and architect who utilises reinforced concrete on anything like a large scale in his constructional work will find this book an indispensable addition to his reference library.

T. H. B.

BOOKS ON ELEMENTARY BOTANY.

(1) *Principles of Botany.* By J. M. Bergen and B. M. Davis. Pp. ix+555. (Boston, U.S.A., and London: Ginn and Co., n.d.) Price 6s. 6d.

(2) *Introduction to Plant Ecology for the Use of Teachers and Students.* By Rev. G. Henslow. Pp. x+130. (London: E. Stanford, 1907.) Price 2s. 6d.

(3) *An Introduction to Practical Botany.* By E. H. Davies. Pp. x+127. (London: J. M. Dent and Co., 1906.) Price 2s.

(4) *The School Garden. A Handbook of Practical Horticulture for Schools.* By J. E. Hennesey. Pp. 155. (London: Blackie and Son, Ltd., 1906.) Price 1s.

(5) *Flowers Shown to the Children.* By J. E. Kelman and C. E. Smith. Pp. xii+154. (London and Edinburgh: T. C. and E. Jack, n.d.) Price 2s. 6d. net.

(1) IN the "Principles of Botany" the authors have introduced an innovation that offers definite advantages, and promises to be as suitable for practical work as for lecturing. The book is apportioned into three sections; the first comprises the morphology and physiology of the seed-plant taken in combination; classification and comparative morphology of cryptogams and phanerogams are treated in the second portion; and ecology, with a short reference to economic botany, forms the final section. As a result, only those morphological facts are noted in the first section that are required to explain the construction of the plant as a living entity, and much detail is appropriately transferred to ecology. Whilst most favourably impressed with the book in its entirety, the taxonomic portion, that more particularly demands judicious selection and

compilation, has been ably presented by Dr. Davis. He keeps the evolutionary sequence constantly before the student, and directs special attention to the significance of alternation of generations, heterospory, and the evolution of the sporophyte. Under ecology, chapters are devoted to recent work on the origin of species and plant breeding.

The book can be confidently recommended to students and teachers, and the latter will find the arrangement well worthy of consideration.

(2) Having devoted special attention to the ecological aspect of botany, Prof. G. Henslow has prepared an introduction to the subject. The earlier pages contain a discussion of methods of teaching botany, and in subsequent chapters the nature of plant associations, modifying factors, and plant surveying are considered. The information is mainly suggestive, and will therefore be found too diffuse for the ordinary student. On the value of ecology as an educational study the author advances arguments with which one is in accord, but with regard to certain criticisms on anatomy and physiology it can only be inferred that he has not had the opportunity of observing what an excellent training is provided by a judicious laboratory course.

(3) The main object of the course planned by Mr. E. H. Davies is to enable the learner to obtain his information by his own observation, so that the lessons, except in so far as they give instructions, consist of a series of questions. The assistance required to furnish the answers is contained in a glossary at the end of the book. The detail is well thought out, and if the exercises selected are a trifle too elementary, more difficult ones can be easily substituted. The author very rightly insists on the necessity of making outline drawings of all objects examined.

(4) The advantages of a school garden where children may acquire practical knowledge are sufficiently obvious, and in country schools there should be no difficulty in securing the necessary ground. For teachers who have not the requisite horticultural experience, Mr. Hennesey provides in "The School Garden" just the information required for directing their operations. The laying out of the garden, trenching, propagation, and the cultivation of fruit trees, vegetables, and flowers are rationally and practically expounded; to these are appended suggested courses of work and general hints as to ways and means.

The book provides a concise manual of elementary horticultural instruction that may be profitably consulted, not only by teachers, but generally by those who grow their own fruit and vegetables.

(5) A coloured picture-book of flowers arranged for children, so that they can distinguish them and find out their names, describes the nature of the last book under notice. Arranged according to colour, the illustrations furnish the means of determination. The type and general form of the book are pleasing, and the short descriptions, referring mainly to the flower, are expressed in simple language.

OUR BOOK SHELF.

Ballooning as a Sport. By Major B. Baden-Powell. Pp. xx+135. (Edinburgh and London: William Blackwood and Sons, 1907.) Price 3s. 6d. net.

Flying Machines: Past, Present, and Future. By Alfred W. Marshall and Henry Greenly. Pp. 128. (London: Percival Marshall and Co., n.d.) Price 1s. net.

MAJOR BADEN-POWELL himself, in a chatty introduction, describes his book as a *réchauffé* of a few magazine articles mostly written some years ago. The essays deal with the past of ballooning pure and simple, but their bright conversational style will commend them to a wide circle of readers.

The second little volume provides a popular account of flying-machines, dirigible balloons, and aëroplanes. Mathematical formulæ and calculations for designs have not been included, though the authors say they intend their information to "assist the reader with serious intention of making an attempt to produce a flying-machine, or air-ship." The book is fully illustrated, and should prove of interest to the general reader.

Principes de Géologie stratigraphique, avec Développements sur le Tertiaire parisien. By G. Courty. Pp. xiv+78. (Paris: A. Hermann, 1907.)

THOSE who look on Lyell's "Principles of Geology" with a filial regard, and those who keep by them Dr. Marr's scientific introduction to stratigraphy, will be disappointed with the title of this little book, which deals with elements rather than with what we know in this country as principles. Prof. Stanislas Meunier contributes a preface, in which he dwells on the constantly changing character of the earth's crust; and the author also holds that his work contributes towards the realisation by the reader of this "vitalité tellurique." But we are given little else than a summary of what is to be found in an ordinary text-book, and no attempt is made at generalisation. For a French work this is remarkably void of inspiration.

Outlines of Practical Sanitation. By Dr. H. B. Bashore. Pp. vi+208. (New York: J. Wiley and Sons; London: Chapman and Hall, 1906.) Price 5s. 6d. net.

THE scientific principles of public health and personal hygiene are explained in a simple and attractive style in this volume. Though the author refers particularly to conditions in rural and urban districts of the United States, his descriptions are concerned in the main with considerations of causes affecting health in general, both of the community and the individual. Familiarity with the principles described ought to be regarded as an essential qualification of every member of a sanitary committee of a public body. The book should be found useful as a means of imparting sound ideas of the laws of healthy living to teachers and citizens.

Essay on the Creative Imagination. By Th. Ribot Translated from the French by Albert H. N. Baron. Pp. xix+370. (Chicago: The Open Court Publishing Co.; London: Kegan Paul, Trench, Trübner and Co., Ltd., 1906.)

THE translator, enumerating some of his reasons for translating M. Ribot's essay, summarises the results at which it arrives by stating the author has shown clearly that "imagination is a function of mind common to all men in some degree," and that it is as highly developed in "practical inventors as in the most bizarre of romantic idealists." The chapter on the scientific imagination will appeal especially to the student of science.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature *No notice is taken of anonymous communications.*]

The Origin of Radium.

In a previous letter to Nature (January 17) I gave an account of some experiments which I had made upon the growth of radium in preparations of actinium. The results obtained were in substantial agreement with the earlier observations of Boltwood in this Journal (November 15, 1906), but it was pointed out that there was no definite evidence that actinium itself was the true parent of radium. The experimental results could be equally well explained by supposing that the parent substance of radium was ordinarily separated from radio-active ores with the actinium, but had no direct radio-active connection with the latter.

Observations have been continued upon the growth of radium in the actinium solution prepared in the manner indicated in my first letter. The rate of growth was found to be uniform over a period of 120 days, and to agree closely with the rate of growth observed in the solid preparation of actinium which had been set aside for a period of two and a half years. Another sample of actinium was then taken and successively precipitated with ammonium sulphide in order to remove the radium from the solution. In this way a solution of actinium was obtained initially almost entirely free from radium. By examination of the α-ray activity, it was found that the actinium after this chemical treatment contained an excess of radio-actinium. This was shown by the rise of the activity to twice its initial value in about twenty days, and then a gradual decay to a steady value. Special care was taken to measure accurately the rate of growth of radium in the solution at short intervals in order to see whether it depended in any way upon the variation of the activity. No such connection was observed, for the radium was produced at a constant rate over the whole period of examination, viz. 111 days.

For equal quantities of actinium, the rate of growth of radium observed in this solution was 1·5 times greater than the normal. This indicated that only a portion of the actinium had been precipitated, while the radium-producing substance had been precipitated with the actinium in excess of the normal amount. This conclusion was confirmed by an examination of the filtrates, which were found to contain more than half the actinium. After suitable chemical treatment, a small precipitate of actinium was again obtained which was about one hundred times as active, weight for weight, as the original preparation. This actinium precipitate was dissolved in hydrochloric acid, and observations of the amount of radium in it were made at regular intervals. *No appreciable growth of radium was observed over a period of eighty days.* If there were any growth at all, it was certainly less than one two-hundredth part of that normally to be expected. In order to make certain that the absence of apparent growth of radium in this solution could not be ascribed to the precipitation of the radium in some non-emanating form, the solution was again chemically treated. The actinium was precipitated with ammonia and re-dissolved in hydrochloric acid. Again no growth was observed over the period of examination, viz. twenty days. The solution in its present state contains a just measurable quantity of radium, viz. about 2×10^{-12} gram.

From these observations I think we may safely conclude that, in the ordinary commercial preparations of actinium, there exists a new substance which is slowly transformed into radium. This immediate parent of radium is chemically quite distinct from actinium and radium and their known products, and is capable of complete separation from them.

It is not possible at present to decide definitely whether this parent substance is a final product of the transformation of actinium or not. It is not improbable that it may prove to be the long-looked-for intermediate product of slow transformation between uranium X and radium, but with no direct radio-active connection with actinium. If this be the case, the position of actinium in the radio-active series still remains unsettled.

It is intended to continue observations on the growth of radium in the solutions described above. Experiments are also in progress to isolate this new substance in order to examine its chemical and radio-active properties.

Manchester, May 30. E. Rutherford.

The Structure of the Ether.

I welcome the interesting and helpful letter from Dr. O. W. Richardson, of Princeton, in Nature of May 23, in which he adduces arguments against an ether flow along magnetic lines of force, and in favour of a flow in the direction of the Poynting vector EH. The result comes out much the same, but it is probably a better way of regarding the matter. Prof. Hicks also has given a simple geometrical proof that a magnetic field cannot consist solely of ether flow; and I am referring to this in a note, already printed, in the *Phil. Mag.* for June.

We shall doubtless hear in due course from the mathematical physicists to whom the first idea of a magnetic ether flow is due, whether they are satisfied with the modification of their original conception now introduced. Meanwhile, I doubt if integration of momentum, without regard to direction, can be sound. Oliver Lodge.

Birmingham, May 28.

Root Action and Bacteria.

The remarkable and all but fatal effect of growing grass over the roots of freshly planted apple trees has been studied at the Woburn Experimental Fruit Farm since 1894, and formed the subject-matter of the third report of that station (1903). No satisfactory explanation of the action was obtained. Experiment showed that it could not be attributed to the abstraction of food or moisture from the soil by the grass, nor to the influence of the grass on the soil temperature or on the gaseous contents of the soil, and subsequent experiments have excluded the formation of acid or alkali from the possible causes. The conclusion drawn was that the action was probably that of a poison produced either directly by the grass or indirectly through the agency of bacteria. Since the publication of this report, further work has been done on the subject, and the view that bacterial agency is concerned has become much strengthened. The action is not confined to any particular grasses, nor to apple trees, but different grasses and different kinds of trees act and suffer, respectively, to different extents. The difference in the results, however, produced by different soils are much more conspicuous, especially in cases where trees are not grassed over until a few years after they have been planted. Though the deleterious action of grass may generally be noticed throughout the country, many notable exceptions have been met with, and these cannot be explained by any of the patent characteristics of the soils in question. Various pot experiments have been made which emphasise these observations. Trees grown in earth in pots are affected by grass in just the same way as they generally are in the field, the grass reducing the growth and vigour of the tree by at least 50 per cent.; but if the trees are grown in sand instead of earth (suitable nourishment being supplied), the grass has very little effect on them, reducing their vigour by about 5 per cent. to 10 per cent. only.

Following up this and other observations, twenty-six similar trees were planted in pots last February under various conditions; seventeen of them were in soil or sand which had not been heated, and nine of them in soil which had been sterilised, or partially sterilised, by heating to about 200° C. and to 82° C. respectively, the water lost in the process being made good. Of the seventeen in unsterilised material, all started into growth uniformly at the same time, whereas of the nine in sterilised soil two started about two days later, six did not start until at least fourteen days later, and one has not started yet.

The heating of the earth, especially to the low temperature of 82°, cannot have appreciably affected its chemical composition, and, indeed, the starting of a tree into growth is independent of nourishment supplied to it, as is shown by the behaviour of trees in sand; the only alteration produced in the soil by the heating must have been an alteration in the living organisms present in it. That bacteria are connected with root action has, of course, been established in certain special cases, but in these the connection consists of the bacteria being the means of augmenting the food supply of the plant; the present case is altogether different, for it appears as if the mere functioning of the roots was dependent on bacterial action. Such a conclusion would be one of far-reaching significance. Of course, the facts require much more examination and confirmation, but, even in their present state, they are sufficiently evident to warrant notification.

That two out of the nine trees in sterilised soil showed very little retardation in activity is not surprising, as there were many opportunities for the re-inoculation of the soil, the pots containing the trees having been exposed in the open since February 4, and no attempt having been made to sterilise the trees themselves before planting, though the roots were washed free from soil. The two exceptional trees were in earth which had been heated to the higher temperature; they were two out of six planted under these conditions. It may also be mentioned that heating to the lower temperature does not destroy all soil bacteria, indeed, it may increase the total bacterial contents; it is probably, therefore, a question of killing some particular bacteria which are connected with root activity.

SPENCER PICKERING.

The Astronomical and Archæological Value of the Welsh Gorsedd.

FROM the very interesting communication of the Rev. John Griffith (May 2, p. 9) it would at first sight appear that the modern "Druids" had indeed preserved a tradition of the May year as well as of the solstitial year in connection with the circles set up by them for the performance of their ceremonies. I should be glad to think that this was the case, but I find considerable difficulty in connecting the modern circles with the ancient ones; there is no ancient circle which shows any sign of ever having possessed such an array of outlying stones as appears in the plan given by Mr. Griffith, and the outlying stones that remain do not always conform to it either; nor is there any ancient circle, except those in which a sepulchral cist forms the central point, and Stonehenge, which has a flat stone in the centre. The late "Myfyr Morganwg, Archdruid of Wales," set up a circle round the rocking stone at Pontypridd in the middle of the last century, but in place of the eight outlying stones figured by Mr. Griffith it has curved avenues forming the head and tail ends of a serpent, so it does not appear that modern "Druidic" authorities are agreed upon this important subject. "Myfyr Morganwg" also published a book in Welsh, the principal illustration to which represents a Druid standing on a flat stone (sometimes it is a three-legged dolmen), surrounded by a circle of twelve others, on which converge three rays of light coming from the north-east, east, and south-east, and forming, no doubt, the original model of the "broad arrow" and of the "Y cross," but without any outlying stones, though three smaller stones are represented in those lines inside the circle; three stones which may represent these, or may, with others there, be intended for an inner circle, also exist in his Pontypridd circle. The central stone for sitting or standing on seems to be a *sine quâ non* with the modern "Druids," but it is not found in ancient circles. There are upright stones in the middle of the circles at Callernish, Boscawen-un, the Stripple Stones, and the Marshpool or Hoar-stone circle (Shropshire), and there was one in the middle of the southern inner circles at Avebury, where also the middle of the northern inner circles was occupied by a "cove," or open shrine of three stones, as again was the case at Arborlow, but at none of these places, except perhaps in the Shropshire circle, could any man stand or sit on these stones, though he might stand in front of them. In the other great British circles (Stonehenge, which occupies a place by itself amongst them, excepted) there is nothing in the centre nor any appearance of there ever having been anything, although there is reason to believe that whatever was done in them was done at or about the centre.

I am therefore inclined to think that the type of circle represented by Mr. Griffith, and probably much of the ritual connected with it, were evolved during the process of "re-codifying or otherwise dealing with the bardic traditions," which, as he says, took place between the twelfth and nineteenth centuries, when, as he also says, a "voluminous body of traditions grew up," and that whatever old ideas may be preserved amongst those traditions have got there rather in an accidental sort of way than by continuous use or direct descent. The traditions, however, though of no real authority in matters of detail, are not without value as indications of an opinion of very great antiquity as to the use of the ancient circles.

The number nineteen occurs at Stonehenge, Dawns Maen, Boscawen-un, the Cosdon circle (Dartmoor), and in the proportionate measurements of Stanton Drew. It probably refers to the cycle of nineteen years in which the sun and moon were thought to return to the same relative place in the heavens, and which was known in the fourth century B.C., if not, indeed, much earlier, in the island described by Hecatæus, usually identified with Great Britain.

A. L. LEWIS.

35 Beddington Gardens, Wallington, Surrey.

I AM glad that a brief summary of the evidence for the antiquity of the Welsh Gorsedd has interested Mr. A. L. Lewis.

(1) The name "Druids" for the Welsh bards should be dropped. It is retained at the Gorsedd as the name of one of the three classes of members. There is very little authority for calling the presiding bard archdruid. The proper name is Priv-vardd, Chief Bard. Let "Druids" and "Druidism" remain as general terms for the use of the "pre-historian." The Welsh bards insist on a grander name, *Gorsedd Beirdd Ynys Prydain*, the high court of the bards of the Isle of Britain.

(2) As to the May year, it has not become obsolete in Wales. There is practically no other in our ancient literature. Its omission from the conventional Gorsedd instructions, while it is everywhere present in the bardic traditions with that exception, is, I think, due to monastic influence. The Church year became solstitial. The bards fraternised with the monks, and Gorsedds were held in chapter-houses and churches. One result was that the bards adopted the festival year as fixed by the Church, so that the favourite time for a Gorsedd was neither solstitial nor agricultural, but such a time as Whitsuntide. This, the only serious meddling with the traditions that I can find, was done, say, about the twelfth century, when the Cistercian monks of Margam, Glam., where the Gorsedd traditions were chiefly preserved, found a new use for the Gorsedd, as a model for the round or polygonal chapter-house.

(3) It is not likely that a stone circle can be found exactly like a Welsh Gorsedd. In the earliest traditions, like those of the oldest Mabinogion, we seem to find the temple observatory in actual use, say, by the Druids; but, speaking generally, in the Gorsedd traditions themselves it is only a matter of minor importance, preserved as well as such a comparatively useless thing could be for the sake of some sacred associations. Modern bards do not understand the plans they have preserved. When a new Gorsedd is set up, no account is taken of the height of the horizon in the direction of the sunrise stones, a matter of much importance to the builders of the megalithic monuments. The bards have religiously preserved the general plan. At some point of time, when it was deemed necessary to preserve such a thing after it had ceased to be of practical use, the bards did better than copying any individual monument, which, as a rule, gives only one decisive sight-line to sunrise or sunset. They set up a complete almanac in stone. The perfect plan I have directed attention to (NATURE, May 2) presents sight-lines to the quarter days of both the solstitial and May years. As the individual monument is usually oriented to some one festival day, uniformity in detail is not to be looked for. The Gorsedd presents in one plan the combined sunrise sight-lines of all the circles in fair preservation that have been astronomically surveyed.

(4) The form of the central stone is immaterial in discussing the plan. At a temple observatory, what was chiefly necessary was to mark the exact centre of the circle. Where no "cove" was erected, an upright stone would suit well. Where neither was present, the priest-astronomer would simply stand on the spot to make his observations. The present fashion of placing a large boulder on the flat in the centre of the Gorsedd seems reminiscent of both the "cove" and the later kist.

(5) "Myfyr Morganwg" is only to be followed so far as he can produce some earlier authority. He tried to mix the contents of the "Asiatic Researches" with those of Welsh tradition. I have before me a plan of the Pontypridd circle, published in the second quarter of the last century, in which the three station stones, or sunrise stones, form alignments to the equinox, May, and November.

(6) The bards were not allowed to sit in a Gorsedd; they were to stand uncovered, head and feet.

(7) I did not mean that the process of "re-codifying or otherwise dealing with the bardic traditions" was in operation only from the twelfth to the nineteenth century. It seems very likely that there was a larger body of Gorsedd traditions known in the twelfth century than we find at any subsequent period. Again, I applied the epithet "voluminous" to the whole stock of printed and manuscript materials on the subject still extant. They have "grown," not to any large extent by addition or accretion, but by the multiplication of versions or recensions of what was recited at the Gorsedd meetings, as was the fixed rule. There is much work to be done by way of collating these recensions. I have an impression that the recital of the Gorsedd traditions proper would not have occupied a longer time than an old-time sermon. The only considerable additions concern the rules of poetry. There is no evidence, except the indirect evidence respecting the solstitial year, that the conventional instructions about the Gorsedd circle itself have been subjected to any revision. This is distinctly stated to be a matter of minor importance—the circle with its ceremonies. The following words, translated from a Welsh extract from an old book at Raglan Castle, before that place was destroyed by Cromwell's forces, shows the attitude of the bards towards the subject here under discussion:—

"Now follows an account of things that appertain to institutional ceremonies, and that accord with the reason and inherence observable in the reminiscence and customs of the bards of the Island of Britain; but which, nevertheless, are not considered as indispensably requisite parts of the system; because every truth and knowledge—every recollection and intention—as well as every art and science, may be acquired without them:—still they corroborate and illustrate reminiscences and primary regulations; for which reason, it is deemed laudable to perpetuate them in memory and usage; especially as they comprise the ancient forms transmitted, by the retentive memory of Gorsedd" ("Iolo MSS.," p. 445).

Then the scribe begins the list of non-essentials as follows:—"It is an institutional usage to form a conventional circle of stones, on the summit of some conspicuous ground," and he gives complete details. This is not the tone of a scribe who was conscious of any weakness in the traditional account.

I take no serious exception to anything that Mr. Lewis says. He has himself furnished very valuable data for this inquiry. But a better theory than an "accidental sort of way" must be found to explain highly finished and polished statements which, like pebbles in glacial drift, speak of the remotest origin.

JOHN GRIFFITH.

Llangynwyd, Glam.

MARINE ZOOLOGY AT THE CAPE.[1]

THE third volume of reports on the Cape marine fauna contains ten papers published between 1904 and 1905. Of these memoirs, two, dealing with eighteen new species of fish and the development of South African fishes, are by Dr. Gilchrist, to whose enterprise and ability these sustained and extended investigations of the resources of the Cape seas are largely due. In this work he has been ably seconded by European colleagues. Prof. McIntosh contributes two papers on the polychæt annelids; Prof. Hickson a second report on the Alcyonaria; Prof. Jeffrey Bell three contributions, dealing respectively with the echinoid, asteroid, and ophiuroid echinoderms; Mr. Stanley Gardiner publishes a careful study of the turbinolid corals; and Prof. Cleve submits a first instalment of a study of the South African marine plankton.

Dr. Gilchrist's second contribution to a knowledge of the life-histories of the Cape fish contains several matters of interest, although he has only succeeded in referring nine of the eighteen stages or eggs he describes to known species. The development of the saury-pike (*Scombresox saurus*) is worth noticing for two reasons. In the first place, the young fish before hatching keeps up a rapid and almost constant movement of one pectoral fin, and when hatched, keeping its tail well submerged, it skims the surface with its mouth as if in search of food. The second peculiarity of the saury, if well founded, is of greater interest, and consists in the presence of blue pigment arranged in chromatophores, massively developed on the dorsal surface and sparsely below. The presence of an indubitable blue pigment concentrated in cellular elements is probably a new fact in animal coloration, and one that suggests how wide a field of investigation is afforded by the phenomena of pigmentation in fish. Another noteworthy feature of this article is the account of cannibalism prevalent among the unborn young of *Cataetyx messieri*. It appears that this deep-sea fish is viviparous. In the one case described, the right ovary consisted of a mass of undeveloped bright red eggs with a single larva coiled up in a dense mucous substance, whilst the left ovary contained seven larvæ also strongly flexed and embedded in mucus. When these were detached it

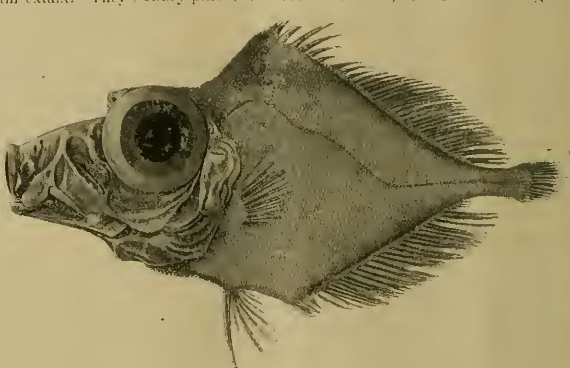

FIG. 1.—*Cyttosoma Boops*, ng. et sp. From "Marine Investigations in South Africa."

[1] Cape of Good Hope, Department of Agriculture. "Marine Investigations in South Africa." Vol. iii. Pp. 269+45 plates. (Cape Town: The *Cape Times*, Ltd., 1905.)

was found that in one case the larva had swallowed a smaller one, and that the others had partially digested their younger fellows. Further details of this habit are promised.

The papers on Polychæts are of interest, chiefly as affording further confirmation of the prevalence of European forms, and even of their parasites, in South African waters. The luminous Chætopterus, for example, that occurs on the Devonshire coast and among the Channel Islands, is found between tide-marks in False Bay and Simon's Bay at the Cape. Many of our commonest littoral annelids are found under similar conditions on the shores of these bays. Fifteen out of the thirty-eight species here described are British, and the majority of the remainder are closely allied replacing forms. Where the agreement is so close it is rather curious to note that no mention is made of the presence of the common lugworm or of its allies.

Prof. Hickson's paper on the Alcyonaria is a continuation of his previous work on this branch of the Cape fauna. It contains, amongst other matter, descriptions of a new family, two new genera, and four new species. The new family, Malacogorgiidæ, is remarkable as comprising Gorgonians, or sea-fans, without any calcareous structures. Of more general interest is the combination of local and of widely diffused corals that occur in the Cape waters. At least six peculiar Cape species, belonging to four genera, are now known, one of which, *Alcyonium purpureum*, is impregnated by a soluble purple pigment which deserves fuller investigation. On the other hand, the affinities of the members of the group in this region with Atlantic, Indian, and even Antarctic Alcyonaria are clearly indicated. We may expect a further investigation of these difficult problems of distribution from the distinguished author of this work.

FIG. 2.—*Platophrys dimorphus*, n. sp. Upper figure, male; lower, female. From "Marine Investigations in South Africa."

The remaining papers can only be briefly summarised. Mr. Stanley Gardiner's work on corals is of that high standard to which his previous papers have accustomed us. It is based on a large series of comparisons, and is executed in the most careful and thoughtful manner, both as regards the skeletal and malacological characters. Prof. Jeffrey Bell reports the discovery of the echinid Palæolampas in a living state.

The plankton investigations by Cleve is a most useful summary of the distribution of the Copepoda found in South African seas, and also gives the percentage of this fauna that extends northwards, the result showing that in Mediterranean waters the percentage reaches more than 70, thus supporting the view enunciated by Cleve that the waters of the north temperate Atlantic "originate not from the Gulf Stream, but from the Benguela current, which is supposed to pass as an under-current below the waters of the Tropical Atlantic." Finally, a word of praise must be added for the forty-five excellent plates that adorn this work.

REFORM IN RURAL EDUCATION.

THE Gloucester conference on rural education in 1904 directed public attention to the need for adapting rural education to rural requirements. Several county education authorities have since instituted inquiries into the subject, chambers of agriculture have passed resolutions, and now the County Councils Association, through its Rural Education Sub-committee, has published a "Memorandum as to certain subjects suitable for the upper standards of elementary schools, and for evening schools in rural districts." This memorandum is worthy of careful examination. The case for reform may first be briefly stated.

It is a disturbing thought that during the past half-century scientific method has largely disappeared from rural elementary education. The child, whose education chiefly consisted in learning from what he saw and did in the field, sheepfold and farmstead, grew into a man who, though his range of view was limited, possessed a remarkable store of accurate first-hand knowledge upon those things which concerned his work in life. With the introduction of a system of compulsory schooling, in which knowledge was principally gained from the lips of the teacher, the scientific method of basing knowledge on individual experience largely disappeared. Now faculties, while easily developed in children, as easily become atrophied through disuse, and, under the present system, it is too often the case that lads as they leave school have neither the power of intelligent observation which is essential to success in rural industry, nor have they acquired an interest in country things. In the absence of such interests, the amusements of a town prove an irresistible attraction, and this, it is believed, has been one of the factors in bringing about rural depopulation and the scarcity of skilled men on the farms, while at the same time we meet in every London street with able-bodied out-of-works.

In the memorandum of the County Councils Association, nothing is said about less schooling, but the guiding principle in all the subjects of the curriculum is to be to *let surroundings teach*, and thus to put back scientific method into rural education. Geography and history are to be based on the physical features of, or the events associated with, the neighbourhood. In arithmetic, out-of-door measurement of land, crops, stacks, and cisterns is to be introduced. School-gardening is to be regarded not merely as instruction in the operations of gardening, but as a study of the growth of crops in relation to the soil.

Thus, although no teaching of agriculture is to be introduced, partly perhaps because the teachers are not qualified to teach it, partly because it would be waste of time to those boys who do not afterwards follow agricultural pursuits, still knowledge of surroundings is being acquired, habits of intelligent observation are being cultivated, and every subject of the school curriculum is acquiring a reality which no oral teaching could ever give it, and which must render the education a better training for life, whatever the after careers of the lads may be.

But while agriculture is not taught, it is noticeable that in the study of surroundings such subjects are suggested as will yield knowledge that is useful to the farmer or farm-hand. For example, the boys are to collect the field and garden weeds, and study their root systems and time of seeding with the view of learning the reasons for their abundance and the best means of dealing with them. From the point of view of cultivating intelligent observation, such an exercise is as good as one that has no utilitarian bearing, and it has this additional value, that the boys learn to apply their knowledge to the practical purposes of rural life.

This idea of *purpose* is kept prominently in view in all the subjects named in the memorandum. Manual work naturally takes an important place, for it is as necessary to cultivate the habit of manual work in childhood as it is the habit of intelligent observation, and its neglect has been another factor in the preference shown by lads after leaving school for non-rural employment, and therefore in rural depopulation. But, again, the manual work is to have purpose. The woodwork is to be directed to making useful things, the gardening to growing useful vegetables, and thus the boys' hearts, as well as their heads and hands, become impressed into their education.

One omission is noticeable—that the teaching of science finds no place in the suggestions. But to acquire a scientific habit of mind, the study of a science is certainly not necessary, nor even perhaps desirable, for children of twelve and thirteen. It is nature-study rather than the study of a natural science that is advocated, for while the correlation of a number of facts or phenomena of the same kind is likely to weary children, the coordination of one fact or phenomenon with others of a different order stimulates their interest and widens their outlook, and permits more readily of application to the purposes of daily life.

The memorandum is followed by a series of "suggestions for the encouragement of rural education." These include the establishment of junior naturalist societies and boys' agricultural clubs, nature-study exhibitions, and school museums of local natural history, together with a suggestion that facilities should be provided for the training of teachers in rural subjects.

LANDSCAPE PROTECTION IN GERMANY.

An abstract of a lecture delivered on October 1, 1906, at Munich, at the annual meeting of the "Heimatschutz" League, by Prof. H. Conwentz, was recently published in pamphlet form. It deals with what has been done in Germany, and more especially in Bavaria, for the preservation of the forests, of bird and plant life, and of the beauty of the landscape in general.

Even so far back as 1803 a private property near the town of Bamberg, in Bavaria, was bought up by the State, and turned into a people's park. At one time the banks of the Danube were gradually becoming disfigured by large quantities of stone being taken away; it was then determined that the stone for public buildings should be obtained from those quarries which did not interfere with the landscape.

In 1841 an order was issued which dealt more especially with the trees. By it it was made almost impossible to remove or alter the existing avenues in the streets; further, oaks, elms, and beeches were specially to be looked after, and also any trees connected with history or legends. By the Bavarian forest-law of 1852, private as well as public forests came under State superintendence.

About 1902 an order was circulated that for the welfare and the increase of birds, hedges and bushes should be planted, or existing ones looked after. Moreover, uncommon birds were to be particularly safeguarded and spared, as complaints had been forthcoming that their number was decreasing.

Similarly, orders were issued for the preservation of certain local plants which were threatened with extinction in the neighbourhood of Garmisch.

In several cases, telephone wires have been laid underground, and in Saxony a certain proposed mountain-railway was not built in order not to spoil the view.

More recently, we find that in Prussia similar regulations have come into existence. There in 1903 a law was passed forbidding the disfigurement of provincial neighbourhoods by advertisements. The author directs attention to the fact that other countries might profit by obtaining such a law. How beneficial such a one would be to this country!

Further, we find that Saxony, Baden, Hesse, and Weimar have all adopted, in one respect or another, the same precautions.

Before concluding, the author points out how London has led the way in the matter of commons and of retaining woods in its more distant environs, referring more especially to Epping Forest.

SIR JOSEPH FAYRER, BART., K.C.S.I., F.R.S.

On Tuesday, May 21, Sir Joseph Fayrer died. He was born on December 6, 1824, and he died full of years and full of honours, for he was honorary physician (military) and physician extraordinary to the King, honorary physician to her late Majesty Queen Victoria, M.D. and LL.D. of various universities, and fellow of many learned societies. Yet all his honours were richly deserved, and he bore them with the most unassuming modesty. Many men are acquainted with parts of his work, but very few know the whole. When Huxley died, a wail of grief went up from the scientific world, but many people are unaware that but for Fayrer the course of Huxley's life might have been completely different, and a great part of his scientific work might never have been done. They were fellow students together, Huxley being senior by a year, though Fayrer was actually older by a few months. When Huxley had finished his medical studies he was, as he himself says in the autobiographical sketch prefixed to his essays, wondering what he should do to meet the imperative necessity of earning his own bread, when Fayrer suggested that he should enter the naval medical service. He did so, and after a few months at Haslar he went on his famous voyage on the *Rattlesnake*, and thus began his scientific career. The attraction which drew Fayrer and Huxley together and led to their close friendship was the great likeness between them in many respects. It has been said that in every human face a resemblance may be traced to some animal, and this was markedly so both in Huxley and Fayrer. Especially in his later years Huxley's face and head suggested that of a lion, while Fayrer's large, open forehead and calm expression reminded me of an elephant, and one could hardly look at him without thinking how rightly the Hindoos have chosen an elephant's head for their god of wisdom. Both men were alike in the stern uprightness of their characters, in the extent of their knowledge and the wideness of their interests, in the clearness of their views, the correctness of their decisions, their absolute fearlessness, their prompt and energetic action, their firm determination to carry out what they thought right, in their tenacity of purpose, in a certain impatience of opposition, and in their great success in overcoming it. Associated with these qualities which compelled admiration were an extraordinary kindness and tenderness of heart which gained the affection of all who knew them.

It is not so easy to draw a comparison between their intellectual powers, because their spheres of activity were so very different. Huxley's life was passed in the pursuit and teaching of science and philosophy; Fayrer's scientific work was done in the short intervals of time that he could snatch from the pressure of other occupations. While Huxley was on board the *Rattlesnake*, Fayrer was engaged in amputating limbs and treating gunshot wounds in the insurrection at Palermo, and narrowly escaped death at the siege of Rome by the French. Between such occupations, however, he managed to learn sufficient Italian to pass the examinations and obtain the degree of M.D. in the University of Rome, perhaps the only doctor not a Roman Catholic who ever did so.

Before his friend Huxley had come back from his voyage, Fayrer went out to India, and again saw active service in the Burmese war. During this war he distinguished himself so highly that the Governor-General appointed him residency surgeon at Lucknow, the best appointment at his disposal, as a reward for his services.

In order to carry on his work he had to learn Hindostani and Persian, and in addition to all his medical work he had to conduct a great deal of the correspondence between the British Government and the King of Oude. When the Indian Mutiny broke out, Fayrer's house in Lucknow was one of the most exposed to the enemy's attack, and he himself took an active part in the defence of the town as well as attending to all the medical and surgical work which disease from insanitary conditions, unsuitable food and the wounds by shot and shell caused amongst the besieged.

Broken in health, Fayrer returned to England after the Mutiny, but instead of remaining idle he went to Edinburgh, worked at the university, passed his examinations, and received the degree of M.D. He then returned to India, where he became professor of surgery in Calcutta.

In 1870 he went with the Duke of Edinburgh on his travels in India, and in 1875 accompanied the King, who was then Prince of Wales, to India. He was a keen sportsman, and was fond of zoology, and in 1867, when president of the Asiatic Society of Bengal, he proposed to found a Zoological Gardens in Calcutta, a proposition which, after some years, was carried into effect. He also proposed an ethnological investigation of the races of India, but this was never fully carried out.

Much of his time was taken up by pathological investigation and sanitary work, but the research in which he took the greatest interest was his zoological work on the snakes of India and his physiological investigation into the action of their venom. It was during this investigation that he first tried the effect of various antidotes, one of which, permanganate of potash, is now beginning to be used in such a way as to preserve life in cases of snake bite which would otherwise have been fatal. The difficulties under which his scientific work was carried out are shown by the fact that he had often to leave an experiment of this kind in order to attend to his hospital work, and that while there amputating a limb or performing some other operation his mind would be disturbed by anxiety regarding the condition of his private patients, who were anxiously waiting for him. But for Fayrer's extensive knowledge and firm dedecision in difficult circumstances, the Prince of Wales, with whom he was travelling, might possibly have been induced by the earnest entreaties of various personages to visit infected places, with the probable result that cholera might have spread over large districts of India, and that our King might never have returned from his visit to that part of his Empire. Not only do scientific men owe a great debt to Fayrer for his own contributions to science and for the bias he gave to Huxley's life, but also for the care which he took of our King's life and the benefits which its preservation has conferred upon the Empire.

At Fayrer's funeral one of the wreaths bore the gracious inscription,

"For Auld Lang Syne from Edward VII."

Lauder Brunton.

SIR DIETRICH BRANDIS, K.C.I.E., F.R.S.

By the death of Sir Dietrich Brandis, which occurred at Bonn on May 28, a man of world-wide renown has been removed. Brandis was born on April 1, 1824, at Bonn, being the son of Dr. Christian Brandis, professor of philosophy in Bonn University. As a boy he followed his father to Greece, where he spent several years. On his return to Germany he was educated at the Universities of Copenhagen, Göttingen, and Bonn. He became, in 1849, lecturer (*Privat-docent*) on botany at Bonn. In 1854 he married a daughter of Dr. Marshman, of Bengal. This happened to be the turning-point in his career.

After the occupation of the province of Pegu in Burma, Lord Dalhousie was looking for a man to take charge of the important teak forests of that province, when his attention was directed to Brandis by the latter's brother-in-law, General Sir Henry Havelock. Lord Dalhousie wrote to Brandis that if he would come to India he would be appointed superintendent of the Pegu teak forests. The offer was accepted, and Brandis landed at Calcutta in 1856. He explained his views to Lord Dalhousie, who, in taking leave of him, said, "Dr. Brandis, if you carry out the scheme which you have explained to me, you will confer a great benefit upon this country." Brandis never saw Lord Dalhousie again, but his parting words remained with him throughout his service. Brandis set to work to save the Burma teak forests, in which endeavour he had the full support of Major (afterwards Sir Arthur) Phayre. After a long-continued struggle the forests were placed under systematic management, and they, with the forests of Upper Burma, are now the chief supply of teak timber to the world.

In 1862, Brandis was called to Simla, at the suggestion, it is believed, of Dr. Cleghorn, one of the principal pioneers of forest conservancy in India, to advise the Government of India on forest matters in other provinces, and in 1864 he was appointed the first Inspector-General of Forests to the Government of India. He then set to work to introduce systematic forest management throughout India. A regular department was established and a forest law passed. Brandis travelled from one end of the Bengal Presidency to the other, advising and organising the department. He also visited Bombay twice, and spent two years (1881–3) in Madras. The department thus created has grown until it has now an area of 239,000 square miles, equal to twice the area of Great Britain and Ireland, under its management.

When Brandis first started operations he had to do with what staff he could lay his hands on; but he determined to obtain one fit to deal with the requirements of the case. In 1866, while on sick leave in England, he obtained the sanction of the late Lord Salisbury, then Secretary of State for India, to train young Englishmen in Continental forest schools, and under this scheme a number of highly qualified foresters have been sent to India. The training at Continental forest schools was subsequently supplanted by that at Coopers Hill College, and now at the University of Oxford.

But Brandis went a step further. In 1878 he started a forest school at Dehra Dun for the training of natives of India, which has now been raised to the rank of "The Imperial Indian Forest College," and sends annually from forty to fifty trained executive officers into the service.

By these means a trained staff of 200 Englishmen have been obtained, who control the operations of the forest department, assisted by about 11,000 native officials of various grades. The results are most gratifying. The supply of timber, firewood, grass, and other produce for the teeming millions of India has been placed on a satisfactory footing, while the net revenue from the forests has risen from 40,000*l.* in 1864 to 660,000*l.* in 1904, although produce valued at a similar sum is given free to the people of the country.

During his career in India Brandis wrote an endless number of reports, and in 1874 he brought out the "Forest Flora of North-west and Central India," a work which was so highly thought of by Sir Joseph Hooker and others that he was made a Fellow of the Royal Society in 1875. It may not be generally known that Brandis was the first who compiled a rainfall map of India; it has been improved since, but as regards the main points it holds good to this day.

Brandis retired from the Indian service in 1883, at the age of fifty-nine years; but he continued to devote himself to the advancement of forest conservancy in India, by articles and letters of advice to his friends in India. From 1888 to 1896 he superintended the practical instruction in Germany of the Coopers Hill forest students.

The last eight years of his life he devoted to the writing of a general Indian forest flora, which he published in 1906 under the title of "Indian Trees," a monumental work, which is likely to be the standing book of reference on the subject for another generation. Scarcely had he completed this when he fell ill, and he never rose from his sick bed. He was made a C.I.E. in 1876, and a K.C.I.E. in 1887.

It should not be omitted to mention that Brandis had a great share in the development of forest conservancy in the United States. He guided the studies of quite a number of young Americans, who have since established a great department in the United States. His influence in this respect has been so great that President Roosevelt presented him with his picture and the following dedication:—"To Sir Dietrich Brandis in high appreciation of his services to forestry in the United States, from Theodore Roosevelt."

Apart from India and the United States, Brandis's action has been felt in almost all parts of the British Empire, including these islands. He has left his mark upon every continent of the earth; at any rate, his name will go to posterity as the father of systematic forest management in the British Empire.

W. SCHLICH.

NOTES.

WE regret to learn that Dr. Maxwell T. Masters, F.R.S., whose writings on botanical and horticultural subjects are familiar to many readers of NATURE, died on May 30 at seventy-four years of age.

THE annual conversazione of the Institution of Electrical Engineers will be held at the Natural History Museum, Cromwell Road, on Tuesday evening, June 18.

DR. W. S. BRUCE and the remainder of his staff, who are starting on an expedition to the Arctic, have left Edinburgh for Spitsbergen. The expedition will finally be relieved and brought back to Europe by the Prince of Monaco on board his yacht the *Princess Alice*.

PROF. PAUL EHRLICH will deliver the second and third of his series of Harben lectures of the Royal Institute of Public Health on Friday, June 7, and Tuesday, June 11. The subject of the lectures is "Experimental Researches on Specific Therapeutics," and they will be delivered at the Royal Medico-Chirurgical Society, 20 Hanover Square, at 5 p.m. on each day.

GILBERT WHITE'S autograph manuscript of his "Natural History and Antiquities of Selborne," in the form of letters to Thomas Pennant and Daines Barrington, and arranged in a folio volume, will be sold by Messrs. Sotheby on July 1. The MS. remained in the possession of the author's descendants until 1895, when it was sold at Sotheby's and acquired by the present owner, Mr. Stuart M. Samuel, M.P.

THE council of the Society of Arts, with the approval of His Royal Highness the Prince of Wales, its president, has awarded the Albert medal of the society for the current year to the Earl of Cromer "In recognition of his pre-eminent public services in Egypt, where he has imparted security to the relations of this country with the East, has established justice, restored order and prosperity, and, by the initiation of great works, has opened up new fields for enterprise."

AT a meeting of the Corporation of the City of London on May 30, the Lord Mayor presiding, it was decided unanimously to present the freedom of the City to Lord Lister and the Earl of Cromer. Mr. Alderman Alliston, in moving that the honorary freedom of the City be presented to Lord Lister in a gold box, in recognition of his eminence as a surgeon and the invaluable services he has rendered to humanity by the discovery of the antiseptic system, remarked that more than one hundred years have elapsed since the Court bestowed the freedom of the City on a member of the medical or surgical profession. The last was that given to Edward Jenner, the discoverer of vaccination, in 1803. Since then the Corporation has welcomed Royal personages, great warriors, eminent statesmen, and others, but the still small voice of the personal ills that flesh is heir to—their amelioration and remedy—have, Mr. Alliston pointed out, somewhat escaped the City's notice. The deficiency is now to be rectified, and the City Lands Committee has been empowered to make the necessary arrangements for the presentation of the freedom to Lord Lister at an early date.

ON August 15, weather permitting, the international laboratory for Alpine investigations, at the Col d'Olen, on Monte Rosa, will be formally opened. In two articles contributed by the late Sir Michael Foster to NATURE (vol. lxv., p. 568, and vol. lxxi., p. 443), he described the laboratory established on the Gnifetti peak of Monte Rosa, at an altitude of 4560 metres, and referred to the valuable researches at high altitudes carried on in connection with it. The supplementary laboratory shortly to be opened is at an altitude of 3000 metres, and will therefore permit work to be carried on for longer periods and under less difficult conditions than at the higher Gnifetti laboratory. The new building provides accommodation for work in botany, bacteriology, zoology, physiology, terrestrial physics, and meteorology, including material and instruments usually required for investigations at high altitudes. Eighteen investigators can find places in the laboratory, and two of these places are for British men of science. Prof. A. Mosso, Turin, to whose zeal and activity the laboratories largely owe their existence, will give further particulars concerning the conditions under which places in them can be secured by investigators desiring to study physiological and other problems in the High Alps.

PLANS have been perfected recently, we learn from *Science*, for a detailed and systematic investigation of the Atlantic and Gulf Coastal Plain stratigraphy and palæontology. Several State surveys, including those of North Carolina, Georgia, Alabama, and Mississippi, will act in cooperation with the United States Geological Survey. The aim of the work is to determine the extent of the subdivisions recognised in New Jersey and Maryland on the north and Alabama on the south, to determine their relations to one another, and in general to establish satisfactory correlations throughout the district between the Potomac and the Mississippi River. Economic studies, especially on the phosphates, will also be made. The supervision of the work rests with a board of geologists, consisting of the State geologists in the Coastal Plain districts and the chief geologist and chief hydrographer of the national survey, Dr. W. B. Clark being chairman. The field work is in charge of Mr. M. L. Fuller, who will put seven parties into the field during the summer. It is hoped to complete the investigation in Virginia, North Carolina, South Carolina, and Florida within a year, while the work in the remaining States will be finished in 1908 and 1909.

THE closing sitting of the International Association of Academies was held on June 2. An article upon this third general assembly appeared in last week's NATURE (p. 105); and the Vienna correspondent of the *Times* gives, in Tuesday's issue, a short account of the proceedings, from which the following report of progress has been derived:—The next meeting will be held in Rome three years hence, and the management of the association during the interval will devolve upon the Accademia dei Lincei. The association has agreed to the issue of a complete and authentic edition of the works of Leibnitz, both the mathematical and the philosophical departments of the association recognising its desirability. Notable progress was reported in the preparation of the great Encyclopædia of Islam, of which Prof. de Goeje, of Leyden, laid before the meeting the first section in three languages—English, French, and German. The ideas of forming a Corpus of Greek documents and a Corpus Medicorum Antiquorum are taking practical shape. The Belgian Government has announced its intention of subsidising the scheme for an international bibliography of historical and philosophical subjects, and it is hoped that support will also be forthcoming from England and America. The proposal that the association should choose an international auxiliary language, such as Esperanto, for use in the communications between members was negatived by twelve votes to eight. The members of the association are gratified by the reception accorded to each of them personally by the Emperor Francis Joseph, and express warm gratitude for the hospitality extended to them by the Vienna Academy and by the Austrian authorities.

THE accounts which have been published in the Press, through Reuter's Agency, of the expedition of Dr. A. F. R. Wollaston to the Ruwenzori region give a terrible picture of the ravages of sleeping sickness. In the Manyuema country the sights are described as being fearful, with people dead and dying on the roadside, as it is the custom of those people to turn out stricken natives to die. A similar custom prevails in Uganda, and is inspired by the belief, firmly held by the natives, that persons affected with sleeping sickness are infectious to others living with them. Scientific investigations into the mode of transmission have so far demonstrated, however, only one means of conveying the infection, namely, by the intermediary of tsetse-flies (*Glossina palpalis*, also *G. fusca*, *fide* Koch). But since the fly has only been shown to transmit the disease by the direct method, that is to say, by taking up into its proboscis from sick persons the parasites which cause the disease, and inoculating them directly into healthy subjects, it seems at least within the bounds of possibility that other biting parasites, such as fleas or lice, might be able to do the same thing. Moreover, in a paper read before the Royal Society last November, Prof. E. A. Minchin suggested the possible occurrence of a mode of infection which he has termed *contaminative*, to contrast it with the ordinary *inoculative* method (see NATURE, December 27, 1906, vol. lxxv., p. 214). These suggestions, if confirmed, would account for the native theory of infection. On the other hand, no patient has ever yet been found to be infectious when removed to a healthy region from one where sleeping sickness is rife. It is evident, however, that the etiology of sleeping sickness is a subject which has not been exhausted, since there are several possibilities which require definite proof or disproof.

THE first part of vol. xxix. of Notes from the Leyden Museum is entirely devoted to descriptive zoology, and therefore mainly interesting to specialists. Reference may, however, be made to the description, by Dr. Jentink, of a new bat of the genus Taphozous from Batavia, which, in the possession of a wing-pouch and a gular sac, approximates to the rare *T. longimanus* of India.

IN the course of an editorial note in reference to the photograph of the skull of a hippopotamus which forms the frontispiece to the April number of the (*Haslemere*) *Museum Gazette*, it is stated that "the hippopotamus has its nearest British alliance in the pig, but unlike the latter, it has four toes." We are led to wonder how many digits the editor considers a pig to possess. We are also surprised to learn (p. 564) that Proechidna takes the place in New Guinea of Echidna in Australia, seeing that zoologists recognise a local race of the latter from Port Moresby. As to the list of mammalian names on p. 569, perhaps the less said the better.

THE structure and physiology of the male generative organs of the dibranchiates forms the first part of a critical study of cephalopod molluscs in general, by Mr. W. Marchand, of Leipzig, now in course of issue in the *Zeitschrift fur wissenschaftliche Zoologie*, this instalment appearing in vol. lxxxvi., part iii. As the result of his investigations, the author concludes that modern pelagic dibranchiates, in which the sexes are distinct, are the descendants of non-pelagic hermaphrodite forms, with longer bodies and "shells." The question as to whether these hypothetical ancestral types are represented by the belemnites is discussed towards the close of the paper.

JUDGING from the annual report for 1905–6, affairs have not been working quite smoothly at the Indian Museum. A proposal has been made that the museum should be divided into several sections (including one devoted to art), and that the whole establishment should be presided over by a director, who should not be a zoologist. Exception is taken to this proposal by the superintendent of the natural history section, who also expresses himself somewhat strongly with regard to the uses to which some of the galleries under his charge have recently been put. "I feel it my duty," he writes, "to record that this section has of late been seriously embarrassed and discouraged by a series of sudden evictions from its galleries and by constant schemes of Museum reorganisation in which its well-established claims, and the interests of zoology in general, have not received sufficient consideration." The zoological collections, with the exception of the insects (which suffer from the climate), are in the main in satisfactory condition, and have largely increased during the period under review.

THE annual return of experiments performed under the Vivisection Act has just been issued. In all, 46,073 experiments were performed by 279 licensees, of which 43,287 were of the nature of simple inoculations, hypodermic injections, &c. Nearly 6000 experiments were performed for Government departments, county councils, municipal corporations, and other public health authorities; 2144 experiments were performed for the Royal Commission on Tuberculosis, 8659 for the Imperial Cancer Research Fund, 4732 for the preparation and testing of therapeutic sera and vaccines, and 1079 for the testing and standardising of drugs. Irregularities occurred in the case of four licensees, the result of inadvertence or misunderstanding. The inspectors report that they have made the usual visits of inspection of registered places, and found the animals suitably lodged and well cared for, and the licensees attentive to the requirements of the Act.

A NUMBER of excellent illustrations of Maoris and others at the New Zealand International Exhibition are given in the *Weekly Press* (Christchurch, N.Z.) for December 12, 1906. One series shows the "Canoe dance," in which an elaborate story is told in pantomime by means of the *poi*, a small ball of *raupo*, at the end of a string of flax. Another series deals with the Fijian fire-walkers, whose performances were discussed in NATURE some years ago, and were the subject of a paper in the Proceedings of the Victorian Branch of the Royal Geographical Society of Australasia in 1892. There is also an excellent full-page plate of a Fijian dancing party.

THE Journal of the Anthropological Institute, vol. xxxvi., part ii., contains Prof. Petrie's Huxley lecture, illustrated by twenty-eight maps, mainly of Central Europe, with an appendix on the interpretation of curves. Mr. Torday continues his excellent series of papers on the tribes of the Congo, and, in collaboration with Mr. Joyce, deals with the Bahuana. Dr. C. S. Myers publishes two parts of his anthropometric survey of modern Egypt, treating of the Mohammedans and comparing them with the Copts and the "mixed" group. Mr. G. U. Yule attacks the validity of Dr. Karl Pearson's statistical methods in cases where ill-defined qualities, such as shades of colour, are in question. MM. Frič and Radin deal with the Bororo of central Brazil; a great part of their paper is devoted to ornaments, weapons, and music. Other papers in this part are by Miss Layard on the Ipswich Palæolithic site, and by Mr. Parkinson on the Ibos; Major Sykes publishes a second vocabulary of the Gipsies of Persia, giving words from three districts for comparison with Prof. de Goeje's Armenian and Egyptian lists. The number contains twenty plates, which, as usual, are of a high standard, both as regards interest and workmanship.

THOSE mysterious prehistoric excavations—the dene-holes—are found in great numbers in the neighbourhood of Bexley, some five miles from Woolwich, and in smaller numbers near Grays, in Essex, and numerous other localities in east, south-east, south, and south-west of England. Some recent explorations have unearthed a few more interesting evidences of their antiquity, and thrown a little more light on the problem of their origin. In sinking a shaft at Gravesend lately, the workmen discovered the nether cavity of a dene-hole, which had been almost entirely filled in by subsidences. The shaft was quite filled up, but the bee-hive chamber at the bottom is now being cleared of rubbish, and in the sand and earth a number of partially worked axe-heads of flint have been found, together with the bones and skull of an animal, probably a wolf, which are now being identified. The walls are covered with pick-marks, which seem to have been made with an instrument of either wood or bone, possibly a pick made of an antler.

IN the *Biologisches Centralblatt* (May 1) Prof. Haberlandt returns to his theory that the leaves of certain plants are enabled to perceive the stimulus of light because their epidermal cells are domed and function as lenses, whence he calls them "ocelli," since they resemble a primitive eye. He has somewhat modified his previous explanation, as follows:—If the light falls obliquely on the leaf, the rays act as a "tropic" or directive stimulus on the plasma-lining of the cell, causing the leaf to turn until it lies at right angles to the incident rays. In support of his theory, Prof. Haberlandt demonstrated that the cells can be prevented from functioning as lenses if the leaves are immersed in water, because the convexity is nullified by the water having a refractive index almost equal to that of the cell sap; to meet the arguments of critics he now shows that a continuous film of water on the surface is sufficient to prevent the leaf from turning.

AN article on the hybridisation of wild plants was contributed by Prof. D. T. MacDougal to the *Botanical Gazette* (January). The principal subject of examination was the oak tree, *Quercus heterophylla*, characterised by the veining and indentation of its leaves, that has generally been accepted as a hybrid. The author adduces evidence from the cultivation of seedlings in favour of regarding the species as a hybrid between *Quercus Phellos* and *Quercus rubra*. The article is, however, more important on account of the general remarks as to the methods of tracing supposed hybrids. Occasionally a hybrid may be synthetised from its supposed parents; sometimes evidence may be obtained from anatomical examination of the hybrid and parents, or, as in the present case, from cultures of the seedlings. These methods are, however, fraught with pitfalls that are better understood since the elaboration of the Mendelian principles.

IN connection with the silting up of Karachi harbour, Mr. G. K. Betham advances the opinion, in the *Indian Forester* (March), that much advantage might be derived from calling in the services of the forestry department.

The source of the enormous deposits of sand is traced partly to the sediment brought down by the Indus and partly to the drift from the littoral of Mirpur Sakro lying to the south-east of Karachi. While the control of the waters of the Indus is primarily the work of the irrigation department, it is urged that it would be possible to reduce materially the sediment if the banks and certain deposits, "kachas" in the upper waters were protected by planting with such grasses as *Typha elephantina*, *Eragrostis cynosuroides*, and *Eleusine aegyptiaca*. The problem of checking the sand drift from Mirpur Sakro is essentially one for the forester, and Mr. Betham maintains that, despite the want of water, it would be possible to develop plantations of Casuarina, tamarisks, and Agave.

DR. N. M. STEVENS, in Publication No. 36 of the Carnegie Institute of Washington, has given an interesting account of his investigations on the so-called heterochromosomes in a number of insects, especially the beetles. These chromosomes commonly form a pair differing in size from the rest of these nuclear bodies. One of the pair is smaller than the other, and this may go so far as to culminate in its entire suppression. The special point of interest attaching to these heterochromosomes lies in their different behaviour in the male and female animal respectively. The female always possesses an *equal* pair, and in those forms in which the small one has entirely disappeared from the cells of the male its surviving counterpart is still preserved in the female. A comparison of the eggs and sperms brings out the remarkable fact that half the eggs contain, and half quite lack, the large chromosome, whilst similarly the sperms, four of which are produced from each mother cell, divide the big and little ones between them when both are present, or they lack them altogether when they are absent from the somatic cells of the species. Thus it comes about that on fertilisation, on the average, half the offspring possesses, and half are destitute of, the large chromosome. Stevens correlates these remarkable nuclear characters with the differentiation of sex, but exercises a judicious restraint in forcing his conclusions. The paper contains full details, and should be consulted by those interested in these matters.

AT the annual meeting of the American Antiquarian Society on October 24, 1906, Dr. A. Lawrence Rotch read a paper entitled "Did Benjamin Franklin Fly his Electrical Kite before he Invented the Lightning Rod?" It is generally supposed that the kite experiment led to the invention of the rod, but Dr. Rotch's researches seem to show that the experiment was probably performed later than has been supposed (June, 1752), and that before then certain buildings in Philadelphia were provided with "points," probably as lightning conductors, and, further, that prior to Franklin's first account of the kite experiment he had drawn up precise directions for the erection of lightning rods. These directions were printed in "Poor Richard's (Improved) Almanac" for 1753, which was advertised in the *Pennsylvania Gazette* of October 19, 1752, as being then in the press. It is admitted that Franklin suggested the possibility of the lightning rod as early as 1750, but the directions referred to by Dr. Rotch and reprinted in his paper show that it was probably invented about a year earlier than has been supposed.

THE twenty-ninth report of the work of the Deutsche Seewarte, Hamburg, for the year 1906, shows that, in common with other national meteorological organisations, the scope of its operations is constantly increasing, with the result that some important investigations necessarily fall into arrear, *e.g.* the publication of the valuable "Daily Synoptic Weather Charts for the North Atlantic Ocean," undertaken in conjunction with the Danish Meteorological Office, which had commenced its twentieth year at the time of the issue of the Hamburg report for 1906. With regard to the necessary collection of trustworthy observations at sea, we observe that the Deutsche Seewarte received in 1906 some 1592 logs of different kinds from Imperial and mercantile vessels, containing 3627 months' observations. The observers are encouraged by the award of medals and diplomas, as well as by liberal presentation of publications. The department dealing with agricultural meteorology has greatly enlarged the area of its work, and issues special weather forecasts and charts in connection with that service. The important investigation of the upper air by means of kites and balloons is continued whenever practicable; 206 kite ascents were made in the year.

IN the *Geological Magazine* for April, Mr. G. J. Williams discusses the geological age of the Parys Mountain, Anglesey, and records a number of fossils recently discovered in shale beds opened up by the boring of a tunnel in the Mona Mine.

PROF. CHARLOTTE A. SCOTT contributes to the *Annals of Mathematics*, viii., 3, an interesting note showing how the regular polygons of five, seven, or nine sides can be constructed by determining four of their vertices as the points of intersection of a circle and a rectangular hyperbola.

IN the *Journal de Physique* for May, M. Ch. Maurain discusses the influence of torsion on magnetisation, and refers to the methods adopted in order to separate the effects of torsion from those of hysteresis. This paper may with advantage be taken in conjunction with one by K. Honda and T. Terada on the change of elastic constants of ferromagnetics, published in the Journal of the College of Science (Tokyo), vol. xxi., art. 4.

AN interesting paper on the genesis of mathematics is contributed by M. Jules Sageret to the *Revue scientifique* (vii., 19). The author gives a detailed account of Rouse Ball's observations on the Rhind papyrus, and refers to Tannery's conclusions regarding the work of the geometrical schools of Thales and Pythagoras. He considers that mathematics originated out of an empiricism which might have attained a high stage of development before any science came into existence, and that the fertile germ came from certain metaphysical ideas of imagination (shall we say intuition?) in the early ages of human thought. The genesis of mathematics differed from that of other sciences owing to the important part played in the latter by experience and observation. We can only wish that papers on the lines of M. Sageret's appeared more frequently in popular journals in Britain. They would do much to remove that unpopularity of mathematical study which arises from a too exclusive consideration of the mere examination ideal.

IN the *Psychological Bulletin* (iv., 4), Mr. David Coyle contributes a note on the inversion of the image in vision, and points out that the eye-movement theory of upright vision does not necessitate the inversion of the retinal images. In other words, an organism fitted with an eye capable of giving an upright image would execute the same eye-movements in turning its eye towards any definite object. In connection with this simple result, it might be interesting to direct attention also to the ease with which a microscopist can pick out diatoms under a non-erecting microscope, where the eye-movements are opposite in direction to the movements of the hand, showing how readily even the eye-movement sense of direction can be reversed by habit.

An interesting contribution to the study of the so-called "addition-compounds" is contained in a paper by L. Mascarelli and U. Ascoli in the *Gazzetta* (vol. xxxvii., I, 125). Many aromatic nitro-compounds combine with mercuric chloride or bromide to form "salts" analogous to those obtained from the corresponding iodoxy derivatives. Most of the substances formed in this way are, however, comparatively unstable, undergoing dissociation into their constituents in presence of the ordinary solvents; none of them has a true melting point. Their formation, however, is clearly demonstrated by the manner in which the melting point of the nitro-compounds varies as the mercuric haloid is added. The salts formed with mercuric chloride are more easily obtained than those derived from mercuric bromide, whilst mercuric iodide fails to give additive compounds at all.

MESSRS. A. GALLENKAMP AND Co. have sent us a copy of their catalogue of bacteriological and hygienic apparatus. It forms a volume of 260 pages, is profusely illustrated, and every piece of apparatus likely to be of use in laboratories of bacteriology and hygiene seems to be included.

MR. EDWARD STANFORD has published a second edition of his Geological Atlas of Great Britain and Ireland, based on Reynolds's Geological Atlas, which was reviewed in NATURE on February 2, 1905 (vol. lxxi., p. 315). The new edition is, like its predecessor, preceded by descriptions of the geological structure of Great Britain and its counties and of the features observable along the principal lines of railway. Mr. H. B. Woodward, F.R.S., the editor of the atlas, has added to the new edition, however, a sketch of the geological features of Ireland, its counties, and main lines of railway, and this subject is illustrated by geological maps of the country. A full list has been appended of the figured fossils, with indications of their zoological position and range in time.

MR. ROBERT SUTTON has published a third edition of Mr. T. Charters White's handbook for beginners on "The Microscope and How to Use it." Mr. Maurice Amsler has contributed to the new edition a chapter on staining bacteria, and the author has added a chapter on the marine aquarium as a field for microscopical research. The price of the new issue is 3*s*. net.

A CLASSIFIED list of publications of the Smithsonian Institution available for distribution as an aid to research or study has just been published by the institution. The list contains the titles of about one thousand papers, memoirs, and reports upon scientific subjects, grouped, so far as possible, according to the system of the International Catalogue of Scientific Literature, and arranged in each group alphabetically according to names of authors. Many of the papers can be obtained upon application by investigators interested in the subjects with which they deal, and others can be purchased at a nominal price from the Smithsonian Institution, Washington, D.C., U.S.A.

ANOTHER new edition—the fifth—of Mr. R. Kearton's "Wild Life at Home" has been published by Messrs. Cassell and Co., Ltd. The increasing popularity of what Mr. Kearton aptly calls "this new and bloodless form of sport" is a hopeful sign, as likely to lead to an increase of knowledge of the natural surroundings of living animals and their characteristics in the wild state. Mr. Cherry Kearton's photographs are both remarkable and artistic, and some of them provide abundant evidence that the peaceful sportsman need not lack the excitement which comes from danger to life and limb. The hints given how to study and photograph wild life should prove invaluable to naturalists beginning work in this direction.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—A telegram from Kiel announces the discovery of a thirteenth-magnitude comet by Prof. Giacobini, at Nice, on June 1.

The comet's position at 10h. 54·7m. (Nice M.T.) was

R.A. = 10h. 14m. 19·7s., dec. = +24° 4′ 41″,

very near to ζ Leonis.

The daily movement is given as +1° 10′ in R.A. and −36′ in declination.

SEARCH-EPHEMERIS FOR COMET 1900 III. (GIACOBINI).—A continuation of Herr Scharbe's ephemerides for comet 1900 III., during the apparition of 1907, is given in No. 4177 (p. 11, May 18) of the *Astronomische Nachrichten*.

These ephemerides give the positions, for every eighth day, from May 24 to July 27, for ten different values of the comet's daily movement, the normal argument being that perihelion will be passed on June 8.

COMET 1905 IV.—A further instalment of the ephemeris for comet 1905 IV. is given by Prof. Weiss in No. 4177 (p. 12, May 18) of the *Astronomische Nachrichten*.

This comet has been under observation for nearly 2½ years, and is now so faint (mag. = 14·0 approx.) that it will only be observed with the largest instruments. The present ephemeris gives the position of the comet at 12h. (M.T. Berlin) for 1907·0, and extends from June 1 to August 12.

DISCOVERY OF A SECOND ASTEROID NEAR JUPITER.—An investigation of the orbit of the minor planet 1907 XM, which was discovered by Dr. Kopff at Heidelberg on February 10, has been carried out by Dr. E. Strömgren, and has led to the interesting result that this asteroid is similar to (588) [1906 T.G.] in that its abnormally great aphelion distance lies in the immediate neighbourhood of Jupiter's orbit. The elements, derived from observations made on February 10, March 11 and 21, and April 12 and 16, are as follows:—

Epoch 1907 *February* 10·0 (*M.T. Berlin*).

$$\begin{array}{ll} M = 335^\circ\ 47'\ 12''\cdot3 & \phi = 2^\circ\ 8'\ 23''\cdot6 \\ \left.\begin{array}{l} \varpi = 183\ 51\ 51\cdot9 \\ \Omega = 341\ 58\ 21\cdot9 \\ i = 18\ 7\ 16\cdot9 \end{array}\right\} 1907\cdot0 & \begin{array}{l} \mu = 292''\ 584 \\ \log a = 0\cdot722504 \end{array} \end{array}$$

From the above it is seen that the length of the semi-major axis of this planet's orbit is roughly 5·28 astronomical units, that of Jupiter being 5·20.

This discovery of a second asteroid near Jupiter raises the question as to whether we are just discovering a hitherto unknown group of minor planets which for ages has been retained by the major planet in the neighbourhood of his orbit, or are dealing with the harbingers of an extension of the system of minor planets. The importance of answering this question is a further justification for vigorously prosecuting the apparently endless business of asteroid discovery (*Astronomische Nachrichten*, No. 4177, p. 13, May 18).

THE ECLIPSE OF JANUARY 14, 1907.—The official report of M. Milan Stefánik's expedition to Ura-Tjnbe (Russian Turkestan) to observe the total eclipse of the sun which took place on January 14 is published in the *Comptes rendus* for May 13. His intended observations—like those of MM. Belopolsky, Hansky, and Wittram, who occupied the same station—were prevented by a snowstorm, which commenced on the eve of the eclipse and continued without interruption until the evening of January 15. The crescent sun was glimpsed but once, at twelve minutes before third contact. At the time of totality the darkness was not profound, the earth and sky being of a purplish-blue tint. The passage of the moon's shadow on the lower layer of cloud was plainly visible.

PROGRESS IN REGIONAL GEOLOGY.

AMONG recent publications in the *Verhandlungen der k.k. geologischen Reichsanstalt* for 1906, it is fair to note that Prof. Hörnes and Dr. Franz Heritsch have replied to Vice-director Vacek's onslaught, the tone of which we regretted in a previous article. The stratigraphy of the picturesque basin of Graz thus receives further explanation (p. 305). Herr Gejza v. Bukowski (*ibid.*, pp. 337, 369, and 397) reports his work in the far south of Dalmatia. Among other points, he notes that the Eocene Flysch changes its lithological character according to that of the rocks on which it lies. Dr. E. Römer's discussion of what he styles "fossil dunes" (*ibid.*, 1907, p. 48) has a wide interest for students of the great European lowlands. The author urges that the post-Glacial valleys, which are cut in the deposits left on the withdrawal of the ice, have exercised a controlling action on the formation and origin of the dunes. Evidences of formerly prevailing east winds, and, later, of our present westerly winds, are clear to him, as to previous observers; but he connects the direction of the dunes with that of the river-valleys, into which the winds blew at right angles to the valley-sides. His studies in Galicia, round the head-waters of the Vistula and the Bug, assure him that the typical barchan, the dune with concave front and outstretched wings, is a phenomenon of deserts, and is constantly in a state of change. The European dune, now often surrounded with peat and itself grown over, is a stable product connected with a climate of steppes, not deserts. Dr. Römer (p. 53) observes how Neolithic settlements were established in the shelter of the dunes, indicating a wetter climate, following on that of the east winds and the steppes. Then a return of the steppe-climate led to the formation of sandbanks over the hearths and dwelling-places; and, finally, our present moister climate has restored the boglands and promoted the growth of trees. Anyone who has seen the winds in Poland laying bare the roots on the outskirts of a clump of pines will realise how easily the present balance may be disturbed, and how a slight meteorological change may allow the dunes again to grow.

In a paper on the Gosau beds of the lower valley of the Enns (*ibid.*, 1907, p. 55), Herr G. Geyer incidentally refers to the occurrence of red pisolitic bauxite in the base of the Cretaceous strata, at the unconformable junction with Triassic dolomite below. Two analyses are given, both with 25 per cent. of ferric oxide and about 50 per cent. of alumina.

The *Tenth Annual Report of the Geological Commission* (for 1905, published in 1906) reaches us from the Cape of Good Hope. Through Prof. Schwarz's appointment to a chair at Grahamstown, the staff of the survey has been reduced to two; but the director, Mr. A. W. Rogers, feels that the grant for travelling is not large enough for the requirements of three officers in the field. A pleasant reference is made to the geological tour of members of the British Association, which Mr. Rogers organised with such conspicuous energy and tact. The director contributes an account of a survey of parts of Uitenhage and Alexandria, with preliminary lists of fossils from the Cretaceous strata. Prof. Schwarz describes the coastal plateau south of the Outeniqua and Long Kloof Mountains, the latter rising to some 5000 feet, and the plateau or large shelf lying at 700 feet, bounded by a bold cliff towards the sea. Prof. Schwarz (p. 82) now regards this shelf as a continental ledge cut by the sea, and subsequently elevated. Mr. du Toit gives, in a paper on the Indwe coal area, a striking plan and section of a dolerite sheet undulating among horizontal beds of sandstone over about 2000 square miles of country. The part played by these intrusive basic rocks in the structure of hill-masses in South Africa is well seen in his other sections. Mr. Rogers revises some of Stow's conclusions in a paper on Hay and Prieska, north of the Orange River. Mineralogists will appreciate his description of crocidolite and its alteration-products (pp. 157–161). An ancient glacial conglomerate is well displayed at the top of the Griqua Town series in this area, while the Permian Dwyka boulder-beds are also represented in places. As an example of the work which a pioneer survey has to undertake, it may be mentioned that the structure of 4000 square miles of country, in parts impassable through drought, had to be realised in some three months.

More familiar ground is dealt with by Prof. Schwarz (p. 261) in the Ceres and Worcester area, which is known to most dwellers in Cape Town on account of the fine rock-scenery of the coast-ranges along the railway. We wish that the Hex River Valley (pp. 277–9) and some of the adjacent splendid examples of folded strata could have been illustrated by photographs, instead of by the rough sketches employed throughout this paper and the others in the report. Certainly, sunlight and opportunity are not lacking for geological photography in South Africa, and Mr. Rogers's well-known "Geology of Cape Colony" shows how the structure of so bare and open a country lends itself to the intervention of the camera. The report, with its envelope of maps, is a record of unflagging energy; and we have since received sheets 4 (1906) and 2 and 45 (1907) of the colour-printed geological map of the Colony of the Cape of Good Hope, on the scale of 3·8 miles to the inch. The topography is, of course, broadly set down, without representation of the surface-relief; but descriptions of the type of country are written across each distinctive area on sheet 45, and probably this practice will be continued. Sheet 4 includes the Great Berg River from Wellington to its alluvial area in St. Helena Bay, and the Breede River and Hex River on the east side of the watershed, where they cross the strike of the coast ranges in ravines of sandstone that remind one oddly of the limestone *cluses* among the Juras. The synclinal infolds of the Devonian strata are well indicated in the south-east of the map.

In the *Records of the Geological Survey of India*, vol. xxxiv., part iii. (1906), it is pleasant to note a paper by Mr. R. D. Oldham on explosion craters in the Lower Chindwin district, Burma (p. 137). These crater-pits are often occupied by lakes, since they have been excavated by explosive action to a lower level than that of the permanent saturation of the country. They show no sign of heat or of normal eruptions of ash, although they occur in a region of volcanic action. In accepting Mr. Oldham's explanation, we are reminded of the hydrothermal theory of the South African diamond-pipes, and of the trifling amount of contact-alteration on their margins.

In the same part (p. 172), Mr. Vredenburg discusses the "Tertiary system" in Sind, with references to his previous paper on the Foraminifera as zonal guides in this group of strata. In the field, he finds that the group, previously regarded as a continuous one, "includes five totally independent series," the unconformities between them being fortunately clear in Baluchistan. The basal series is thrown back to the Senonian, the supposed passage-beds into the Eocene disappear, and there are evidences of disturbance at the top of the Eocene and in Middle Miocene and Pliocene times. In Sind, layers of laterite, formed on low-lying continental surfaces (p. 179), represent the stratigraphical breaks. The amended classification leads to a re-examination of the Echinoidea described by Duncan and Sladen in 1882–6, and Mr. Vredenburg is able to separate faunas formerly, and somewhat naturally, confused. The stratigraphical breaks become all the more emphasised by this revision of the genera and species. The paper has thus a considerable additional interest for students of fossil Echinodermata.

Going further east, Herr Georg Boehm adds considerably to his previous exploration of Jurassic strata from Celebes to New Guinea ("Neues aus dem Indo-Australischen Archipel," *Neues Jahrbuch für Min.*, &c., Beilageband xxii., 1906, p. 385). In Buru, contemporaneous volcanic ashes are found containing ammonites and belemnites (p. 399). The occurrence of European species in the Far East is regarded as surprising, but is paralleled, as the author points out, by facts in animal distribution at the present day. *Argonauta argo* and *Octopus vulgaris* are cited as examples.

The *Geological Survey of New Zealand* forwards to us Bulletin No. 2, a quarto on the "Geology of the Alexandra Sheet, Central Otago Division," by Prof. James Park, of the University of Otago. The region is a mountainous one in the South Island, and is of importance in the production of gold. The possibility of the alluvial gold having been derived from folia of quartz in the old mica-schists, a view quoted (p. 33) with hesitation from Mr. A. McKay, reminds us of the problems of the Klondike. The uptilted lacustrine gravels, on which the Pleistocene moraines rest unconformably, are regarded provisionally as Pliocene, but raise an interesting stratigraphical question. The photographic illustrations, one of which we reproduce, are admirable, and may be commended to the notice of the authorities who hold the public purse at Cape Town. The petrographic section, where the rocks are described from the point of view of the laboratory, includes analyses of several of the schists, and photographs of rock-slices on the unnecessarily liberal scale adopted in the first bulletin of this survey.

The *Summary Report of the Geological Survey Department of Canada* for 1906, which bears two dates on its title-page, 1906 and 1907, informs us that the survey has decided to send its maps and reports "free to any *bona fide* applicant in Canada." This surpasses even the generosity of the United States Survey, which still, we believe, places a price upon its maps. The colour-printed sheets of part of Nova Scotia, surveyed by Mr. Hugh Fletcher, and sent us with the report, are as large as those for which we charge eighteenpence in England. Of course the topography shows far less detail, but the scale is, like ours, one inch to one mile, and the sheets have the price of 10 cents printed on them. We gather, however, on the other hand, that the sums paid in Canada to the junior members of the staff are not at all adequate, considering the competition with mining companies, which draw away the best geologists. The same difficulty has been met in India (Circular of the Department of Commerce and Industry, September 7, 1906) by a courageous increase in the salaries of the official geologists. The Canadian Survey spreads its operations over an enormous field, the areas examined being largely determined by the economic requirements of the year. The routes of projected railways naturally receive attention. This is Mr. A. P. Low's first annual report.

The Manuherikia River, New Zealand, forming a gorge along fault rifts in the schist series.

We fancy that Mr. G. R. Mansfield's paper on the Roxbury conglomerate near Boston (*Bull. Mus. Comp. Zoology at Harvard*, vol. xlix., 1906, pp. 91–272) would not have been a third as long had it not been presented as a thesis for a degree. Pages 105–151 contain a disquisition on conglomerates in general, according to the custom of American geologists when introducing a special subject in a literary form. The conclusions on p. 259 make us wonder whether the Roxbury conglomerate was worth describing at all; but this is probably because our sense of irritation, in this busy world, inclines to make us unfair to an obviously accurate observer.

G. A. J. C.

THE FEDERAL CONFERENCE ON EDUCATION.

IT is often made evident that the Government in this country leaves very important matters to be initiated and even carried on by private enterprise. Those who do not already know, will hardly be surprised to learn that the Federal Conference on Education, which was opened by Lord Crewe on May 24 in Caxton Hall, was organised by an independent society, the League of the Empire, and the League may well be proud, for it is understood that the next conference, which will be held in 1911, will be convened by the Government.

The business of the conference was divided as follows:—There were first of all the meetings of the representatives of colonial and Indian education departments and their committees. These took place behind closed doors, and were attended by the officials of the English, Welsh, Scotch, and Irish Boards. This official conference discussed a number of important matters, and we give some of the results of their deliberations. For instance, they decided that at present, owing to the way in which certificates are awarded and various local conditions, it is impossible to arrive at any complete recognition of the teachers' certificates issued by different educational bodies in different parts of the Empire. The desirability was recognised of teachers and inspectors acquiring experience in other parts of His Majesty's dominions than their own, and the conference thought that financial and administrative arrangements should be made to enable this to take place.

While it was not deemed desirable to attempt uniformity as to curricula and text-books, it was urged that the different education departments should define year by year with precision the terms used in their publications. Other important conclusions expressed were that a conference of representatives chosen by the Governments should be held every four years, and that the Imperial Government should summon the first. Furthermore, the present conference was unanimously agreed as to the importance of a central bureau of educational information.

The next series of meetings to be considered are those of the full conference, consisting of the representatives already mentioned and delegates from universities and associations. On Monday, May 27, Lord Reay presided, and higher technological education was considered, and various speakers, including Prof. Hopkinson (of Cambridge), Dr. Headlam (Principal of King's College, London), Dr. Bodington (Vice-Chancellor of the University of Leeds), and Dr. G. R. Parkin (University of New Brunswick), urged that technical training should go on side by side with the study of classics, poetry, and philosophy. Afterwards the following resolution, proposed by Dr. Clay, was unanimously agreed to:—

"That it is desirable that the Colonial Office and the Board of Education should cooperate in issuing officially, particulars as to the courses of study, fees, expenses of living, &c., at colonial universities, technical colleges and agricultural colleges, together with statements of the advantages attaching to their degrees and diplomas, and that information should be circulated in the colonies as to similar advantages and facilities which exist in this country."

On the following day, Mr. Inch (Superintendent of Education, New Brunswick) took the chair, and Mr. C. W. Bailey (Liverpool University) supported the idea that freedom should be given to each individual school, while Dr. H. J. Spencer (Headmasters' Association) pointed out with regard to the suggestion that each school should shape its own curriculum according to the needs of its pupils that there were several types of a good general education, any one of which might be chosen.

On Wednesday, May 29, under the presidency of the Vice-Chancellor of Cambridge University, two topics were discussed; first, the advisability of various educational bodies recognising each other's certificates of admission was generally agreed upon, and afterwards the question of cooperation between the old boys' associations throughout the Empire was discussed. Dr. Gow (Headmaster of Westminster) spoke of the difficulties of organising permanent associations of old boys of English public schools who go to the colonies, while Mr. L. A. Adamson (Victoria Secondary Schools' Association) made the following suggestions:—(1) that it is desirable to form a union of the great boys' schools of the Empire; (2) that this will best be done through their "old boys'" associations; (3) that the League of the Empire be asked to act as the organising centre.

At the open meeting on May 27, Sir Philip Magnus presided, and Sir Horace Plunkett gave an address on agricultural education in which he traced the work that had been going on in Ireland, and said that the problem of rural life was to be solved mainly by education, general and technical. During the discussion, Lord Monteagle pointed out that the farmer should be taught to appreciate technical instruction by practical demonstrations, and that the interest of the children should be awakened by nature-study.

Lord Elgin took the chair at a similar meeting on May 28, when the connection between elementary and secondary schools was discussed. The chairman pointed out that it was now the boast of Scotland that the path was open from the parish school to the university, and he thought that Scotland had done a great deal to bring about what is required. Several representatives from the colonies described in some detail the state of affairs in their own countries.

Meetings were arranged by the three standing sections of the League and other sections which were constituted for the occasion. The following is a list of sections with their chairmen:—History, Prof. Bury; nature-study, Sir John Cockburn, K.C.M.G.; museums, Lieut.-Colonel Plunkett; universities, Sir Arthur Rücker; technical, Sir Philip Magnus, M.P.; teaching of English, Prof. Saintsbury; training of teachers, Canon G. C. Bell.

Such a large number of papers were read in the various sections that it is impossible to summarise or even enumerate them here. In the technical education section many important aspects of the subject were dealt with in a series of special papers, which included the questions of training and research, both in this country and in the colonies.

The museums' section was chiefly occupied in passing the following useful resolutions:—

(1) "That the formation of school collections illustrative of science or art is a valuable aid to education" (proposed by Dr. R. F. Scharff).

(2) "That when school collections are made to illustrate natural history or other branches of knowledge, arrangements for the exchange of such collections between various parts of the Empire will assist the objects for which the League is instituted" (proposed by Dr. Chalmers Mitchell).

(3) "That teachers and others should discourage the making of such collections as might tend to the extermination of rare plants or animals, and should assist in preserving such objects by fostering a knowledge and love of nature" (proposed by Sir Harry Johnston, G.C.M.G.).

(4) "That this conference recognises the value of arrangements for the circulation of museum objects, as organised at the Victoria and Albert Museum, South Kensington, and at the Dublin Museum of Science and Art, at Sheffield Museum, and elsewhere, and warmly advocates an extension and development of the system" (proposed by Prof. Kidd).

(5) "That this conference recommends the organisation of a permanent collection of objects specially interesting and useful to those engaged in educational work, in connection with one of the great museums in London. That such a collection should include typical school museums and the outlines of a local educational museum" (proposed by Mr. John Maclaughlan).

In the nature-study section the following resolutions were carried:—

(1) "As nature-study gives that wide knowledge of the world and its products which is required throughout life, it should be inculcated at all stages of sound general education, and this section recommends its earnest encouragement in the home, in the school, and in the outside world. Furthermore, this section trusts that the education authorities of the Empire will endeavour to extend and encourage knowledge self-gained from original observations, as a vitalising factor in the progress to full intellectual efficiency" (proposed by Mr. T. R. Ablett).

(2) "That the supply of teachers acquainted with true methods of nature-study being the greatest present requirement, special efforts be made to provide facilities for the proper preparation for the work, of students and teachers in training" (proposed by Miss Rees George).

The museum section arranged exhibits consisting of a large series of travelling cases from Dublin Museum, and one of the cases illustrating the structure of birds now being arranged in the Lawson Memorial Wing of Eton College Museum.

In connection with the nature-study section were a number of exhibits illustrating the main phases of nature-study in this country, including the work of the Royal Drawing Society. The hon. secretary of the section on May 27 gave a lantern lecture entitled "Illustrations of Nature-study."

A large series of photographs was sent by the Government of New Zealand illustrating its educational work, and a very large number of publishers and makers of apparatus exhibited in the trade section.

Mr. S. H. Butcher, M.P., acted as chairman of the official conference, and Mrs. Ord Marshall as honorary secretary.

THE BIOLOGY OF THE COLORADO BEETLE AND ITS ALLIES.[1]

DR. TOWER, who is already well known as the author of a careful monograph on the development of colour in insects, has set forth in this bulky volume the results of his prolonged researches into the life-histories and interrelations of a group of plant-feeding beetles, one species of which is celebrated as a dreaded potato pest. The work certainly bears ample witness to the patience and ingenuity of this observer, who is one of that ever-increasing school of zoologists holding the view that further light can be thrown on the mysterious problem of evolution mainly by observation of and experiments on the living animal.

The first chapter treats of the geographical distribution of the genus Leptinotarsa; southern Mexico is regarded as the centre of origin of the group, whence it has spread southwards to the Isthmus of Panama and northwards to the United States. Much interesting information and speculation on the dispersal of the Colorado beetle *L. decemlineata* is supplied. Spanish caravans and wandering herds of bison are regarded as the agencies whereby the hooked and spined seed-pods of *Solanum rostratum*, the characteristic food-plant of Leptinotarsa, were transported from Mexico to Texas, Arizona, and the eastern slope of the Rocky Mountains; the insects followed in the track of their food-plant, and became established in these areas. The westward advance of civilisation in the middle of the nineteenth century brought with it the cultivated potato, which proved a most acceptable food to the beetles; all obstacles to the eastward extension of this destructive insect were now removed; in 1872 it had reached the Atlantic sea-board, and in less than fifty years it was generally distributed over the United States and southern Canada.

In chapter ii. the variation of colour patterns and structural characters is examined both qualitatively and quantitatively. The nature of the material not lending itself to minutely accurate measurements, the author has evolved a highly complicated series of formulæ which express succinctly forms of coloration on different parts of the body; these formulæ are "seriated into classes," and the percentage of individuals possessing given colour-formulæ

[1] "An Investigation of Evolution in Chrysomelid Beetles of the Genus Leptinotarsa." By William Lawrence Tower. Pp. x+320; illustrated. (Washington, D.C.: Carnegie Institution of Washington, 1906.)

is recorded. The author proves to his own satisfaction "that the highly complicated methods of biometry are no more reliable in their results as far as this material is concerned than other methods far less cumbersome and slavish." The nature of coloration and its ontogeny in the adult beetles and in the larvæ is discussed in chapter iii., and Dr. Tower adheres to his former view that colour originates from definite centres, and all patterns are merely extensions of these centres; all species start in life with an identical arrangement of colour-producing centres, which become modified, suppressed, or accentuated in different stages and in different species. Strong evidence against atavistic influences on the colour-development is adduced in the case of three species. Large numbers of specimens in all stages of growth were subjected to the most various conditions of temperature and humidity, and the conclusion is reached that like results are produced by diverse stimuli, *e.g.* any factor, such as heat, above or below the normal has the effect up to a certain point of producing increased pigmentation, beyond that point, of retarding it. The author believes that stimuli applied before the germ-cells begin to develop produce somatic variations only, which are not heritable; on the other hand, if the beetles were subjected to abnormal conditions when their germ-cells were sensitive to such stimuli, heritable variations resulted, and he attributes the inheritance of characters produced in the experiments of Weismann, Standfuss, and others to the fact that the stimuli acted on sensitive germ-cells, not on the soma. The subject is open to considerable argument, and doubtful critics may be referred to pp. 212–5 of Dr. Tower's monograph for a complete exposition of his views. Of high interest are the observations on the protective value of the gaudy coloration of these beetles. All the species have on the elytra and round the edge of the thorax, rows of glands whence exudes an oily and distasteful fluid; young fowls turned loose in a potato field, where *L. decemlineata* was common, eagerly attacked the insects at first, but soon learnt to avoid them, and subsequently could not be induced to eat them even when offered in company with edible insects. Specimens with the yellow stripes of the elytra covered with blackened shellac were given to experienced fowls, and then were readily seized, but as soon as their distasteful properties were realised they were dropped.

Limitations of space forbid a discussion of the experiments on selective and pedigree breeding, but they are of much interest and of great importance; the experiments extended over several years, but were brought to an abrupt conclusion through the carelessness of some workmen; Dr. Tower has with indomitable perseverance recommenced them, and his final conclusions will be awaited with eagerness. In the last chapter Dr. Tower confesses the faith that is in him; he will have none of the "Weismannian id-biophore-determinant hypothesis." He puts his finger on the weak spot in the theory of de Vries, and asks how mutants fare under natural conditions; his experience with Leptinotarsa shows him that they are rigorously exterminated. Variations he regards as epigenetic, not predetermined, evolution is continuous and direct, and new species have arisen in magrating races by direct response to the conditions of existence, natural selection acting as the conservator of the race by limiting the variations to a narrow range of possibilities. R. S.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. T. B. Wood, university reader in agricultural chemistry, has been appointed Drapers' professor of agriculture in the University. Mr. Wood has been secretary of the Board of Agriculture since the foundation of the board, and the marked success of the agricultural department at Cambridge is in no small sense due to his energy and initiative. The professorship was vacated owing to Prof. Middleton being appointed assistant secretary to the Board of Agriculture and Fisheries. Mr. Wood is the author of many scientific and practical papers on agriculture, and he is co-editor of the *Journal of Agricultural Studies*.

Keith Lucas has been appointed an additional demonstrator in physiology; and F. A. Potts has been appointed assistant to the superintendent of the museum of zoology.

Demonstrations in practical physics will be given during the long vacation, commencing on Monday, July 8. The chemical laboratory of the University will be open for the use of students during the months of July and August. Notice is also given that during the month of July, Mr. Fearnsides will deliver a course of elementary lectures on "The Study of Rocks."

An examination for one "Surveyors' Institution Scholarship" will be held on July 24–27. The scholarship will be tenable for three years, and of the value of 80*l.* per annum. Candidates will be examined in (*a*) elementary chemistry and physics; (*b*) more advanced chemistry, physics, botany, and geology.

OXFORD.—In the Convocation to be held on June 26, it will be proposed to confer the honorary degree of D.Sc. upon the following men of science, nominated by the Chancellor on the occasion of the Encænia following his installation:—Sir Norman Lockyer, K.C.B., F.R.S.; Sir Richard D. Powell, president of the Royal College of Physicians; Sir William Ramsay, K.C.B., F.R.S.; Sir William H. Perkin, F.R.S.; Prof. W. Watson Cheyne, C.B., F.R.S.; and Dr. Ludwig Mond, F.R.S.

THE report read at the annual meeting of the City and Guilds of London Institute on May 28 referred to the negotiations which have taken place with the Board of Education with the view of the Central Technical College of the institute being included in the scheme for the establishment of the Imperial College of Science and Technology at South Kensington. The draft provisions dealing with the purpose and scope of the new institution, and the manner in which the Central Technical College will be associated with the scheme, have been approved by the executive committee.

As was explained in an article in NATURE of May 16 (p. 56), the new Imperial College of Science and Technology is shortly to be incorporated in accordance with a charter which is to be considered immediately by a committee of the Privy Council. The suggested charter provides for the continuance of the Royal School of Mines and of the diploma of Associate of the Royal School of Mines, and the Central Technical College is to retain its individuality and to continue to exercise its privilege of awarding its diplomas of associate and fellow. A question was asked in the House of Commons on May 30 whether, under the proposed charter, it is intended also to retain the title and associateship of the Royal College of Science. The President of the Board of Education replied that the new governing body when established will consider the question and decide whether it is expedient to continue the name Royal College of Science and its diploma, and to secure to present associates of the college their existing privileges.

THE Imperial Department of Agriculture for the West Indies has established agricultural schools at St. Vincent, Dominica, and St. Lucia, and the result has been to provide a good practical training in agricultural science to a selected number of boys. Instruction is given in the theory and practice of agriculture and in agricultural botany and chemistry, in addition to the subjects of an ordinary education. Each boy receives daily training in raising the crops under cultivation and in the care of live-stock. At each school a portion of the land is divided into experiment plots for testing varieties of different plants, the introduction of new plants of economic importance, and methods of controlling insect pests and fungoid diseases by insecticides and fungicides. Besides these facilities, the *Agricultural News* of Barbados reports that rabbit breeding is taken up, and pure-bred Belgian hares have been introduced in order to improve the local stock. Poultry raising also receives attention, and now, by the use of incubators, a good supply of well-bred chickens is available for disposal throughout the different islands. The pupils become acquainted with all the details of work in the field before the theoretical knowledge of science necessary for keeping abreast with agricultural progress is learned. It has been found that the blending of practical xperience with theoretical knowledge is the most desirable nethod of producing young men qualified to take up esponsible positions.

The first annual conference of the Association of Teachers n Technical Institutions was held at the University of Leeds on May 22 and 23. The president, Mr. V. A. Mundella, of the Northern Polytechnic Institute, London, occupied the chair, and about one hundred delegates were present. Mr. Graham, secretary for higher education in Leeds, said that one of the great difficulties from an educational point of view, especially where it is wished o give students an all-round view of their particular calling, is that of the technical teacher teaching a bread-and-butter subject. If teachers could be convinced that it is absolutely necessary that the pupils should understand the scientific principles underlying that subject and get an all-round view of their particular trade, and not one particular little picture of it, a very great service would be done to technical education. In his presidential address, Mr. Mundella directed attention to the great leakage represented by the passing outside the pale of educational effort of children beyond the age of twelve, and he urged that up to the age of seventeen secondary education, widely diversified to meet local conditions, the standing of pupils, and the wishes of parents, should be made compulsory. There would thus be a perfectly natural development of the child. Scholarships, he said, not meet the requirements, and grammar schools and lic schools have no effect on the problem of second y education, which is the provision of suitable schools for the 600,000 children who leave the present element ry schools. The examination system for scholarships is fundamentally wrong, besides being very expensive. It works out for the whole country at about 20*l.* per scholar on the average, a sum almost twice as great as would maintain the child in a provided secondary school belonging to the local authority. Mr. H. A. Clark, head of the engineering department of the Northern Polytechnic Institute, read a paper entitled "Notes of an Educational Visit to the United States." He referred to the brotherly feeling between English and American men of science, and described his journey through the States and the various institutions visited. Mr. Barker North, chairman of the West Yorkshire branch of the association, read a paper on the preliminary training of technical students. He condemned the preliminary training of students entering technical colleges as very inefficient, this being in the main due to the desire of educational committees to secure large classes, paying inadequate attention to the training of the students, and unmindful of the fact that it was better to produce six highly-trained men than six dozen inefficiently trained. A paper by Mr. J. Fitzgerald, of the South-Western Polytechnic Institute, and Mr. E. L. Bates, of the London County Council School of Building, Brixton, on syllabus and examinations as applied to building subjects, was read by Mr. Bates. At the outset Mr. Bates referred to the impossibility of one individual becoming proficient in more than one craft. He also dealt with the best course of technical instruction for the craftsman and the general foreman. Several discussions of an instructive kind followed the reading of papers.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 14.—"On the Specific Inductive Capacity of a Sample of Highly Purified Selenion." By O. U. **Vonwiller** and W. H. **Mason**. Communicated by Prof. Threlfall, F.R.S.

The paper contains an account of the application of methods of measurement described by Pollock and Vonwiller (*Phil. Mag.*, June, 1902) to the determination of the specific inductive capacity of selenion. Two methods were employed, one an absolute electrometer method employing forces of a frequency of about fifty per second, and the other a resonance method employing electric oscillations of a frequency of 24 millions per second, which is believed to be more accurate than any high-frequency method hitherto employed. The selenion was cast into the form of a plate, 15 cm. diameter and 1 cm. thick, this plate being cast in such a manner as to ensure its being in the vitreous condition, after which it was ground with carborundum powder until the surfaces were flat and parallel. After each set of measurements the plate was broken up into small pieces, and the density of these pieces compared with that of the plate as a whole.

The following results were obtained :—

Density at 13°·8 C., 4·29.

Specific inductive capacity—by electrometer method, 6·13 at 16° C.; by oscillation method, 6·14 at 23°·6 C.

Specific resistance in the dark, approximate—between $2\cdot2\times10^{16}$ ohms at 20° C. and $6\cdot5\times10^{15}$ ohms at 25° C.

Resistance measurements were made in the dark, and it was noticed that the specific resistance fell considerably in the light as in the case of the conducting variety of selenion.

It was found that a thin reddish film forms on the surface of the selenion, though it is only exposed to air, and the comparatively high conductivity of this film gave considerable trouble before it was discovered.

February 28.—"The Enzymes associated with the Cyanogenetic Glucoside Phaseolunatin in Flax, Cassava, and the Lima Bean." By Prof. W. R. **Dunstan**, F.R.S., Drs. T. A. **Henry** and S. J. M. **Auld**.

The authors show there is reason to believe that these three plants, flax, cassava, and the lima bean, contain a mixture of the two glucosidolytic enzymes, emulsin and maltase.

The same authors had previously proved that the production of prussic acid from the lima bean, cassava roots, and the seeds or embryo plants of flax is due to the decomposition of the cyanogenetic glucoside, phaseolunatin (α-dextrose ether of acetone cyanohydrin), contained in each of these plants, by an enzyme which resolves this substance into acetone, dextrose, and prussic acid (Proc. Roy. Soc., 1902, lxxii., 285; 1906, lxxviii., 145; and *Ann. Chim. Phys.*, 1907 [viii.], 10, 118).

Since the mixture of enzymes obtained in the usual manner from any one of these three plants decomposes phaseolunatin and amygdalin, the characteristic glucoside of bitter almonds, whilst the enzyme which occurs with amygdalin in the almond decomposes amygdalin, but not phaseolunatin, it seemed clear that flax, cassava, and the lima bean must contain either a mixture of emulsin, with some other enzyme capable of hydrolysing phaseolunatin, or a new enzyme having the property of decomposing both glucosides.

Fischer's generalisation that the glucosidolytic enzymes so far systematically examined are divisible into two classes, the one capable of decomposing the α-alkyl ethers of the hexoses and the other the stereoisomeric β-alkyl ethers of these sugars, has rendered it possible to classify an unknown glucosidolytic enzyme by ascertaining whether it is active towards the α-alkyl ethers of the hexoses or towards the stereoisomeric ethers, and E. F. Armstrong has extended Fischer's work in this direction by showing that when the α-alkyl ethers of the hexoses are hydrolysed by enzymes of the maltase type the sugars immediately liberated are the α-forms, and that similarly the stereoisomeric β-ethers on hydrolysis by appropriate enzymes furnish the β-forms of the hexoses.

These methods have been applied to the investigation of the mixture of enzymes contained in these three plants and to the determination of the nature of the dextrose residue in phaseolunatin.

It was found that the mixture of enzymes has the property of hydrolysing amygdalin and salicin, which are both known to be β-glucosides, and similarly it decomposes α-methyl glucoside and maltase, which both have the α-structure.

Further, phaseolunatin is decomposed by yeast maltase and by the mixture of enzymes occurring with it in the three plants already named, yielding, in the first instance, the α-form of dextrose, so that it must be regarded as an α-dextrose ether of acetonecyanohydrin. Accepting Fischer's generalisation, it seems clear from these data that flax, cassava, and the lima bean contain at least two glucosidolytic enzymes, the one of the emulsin or β-type, the other of the maltase or α-type, and that it is the latter to which the decomposition of phaseolunatin is due, since this glucoside is derived from α-dextrose.

April 18.—"The Fermentation of Glucosides by Bacteria of the Typhoid-coli Group and the Acquisition of New Fermenting Powers by *Bacillus dysenteriae* and other Micro-organisms." Preliminary communication. By F. W. **Twort.** Communicated by Dr. Leonard Hill, F.R.S.

(1) A large number of glucosides may be fermented by many members of the typhoid-coli group of bacteria. The fermentations vary with the micro-organism tested, and the variations are as marked inside each subgroup of bacteria as between adjacent subgroups.

(2) The sugar-fermenting powers of an organism may be artificially changed by growing the said organism for a succession of generations in media containing a sugar which at the commencement of the experiment it was unable to ferment.

By this means a pathogenic organism may be altered until it gives fermentative reactions characteristic of a non-pathogenic member of its group. It is possible, indeed, that pathogenic organisms in the typhoid-coli group may so alter their characters that they become unrecognisable when growing for some time outside the body in soil, water, &c. If this is so, it might partly account for the difficulty experienced in isolating *B. typhosus* from these situations.

It also seems possible that a non-pathogenic organism may lose its fermenting powers and become pathogenic should it find a suitable medium such as the alimentary canal, and regain its old characters when outside the body. This is, however, only a suggestion, which at present is in no way proved.

In view of the results obtained with the typhoid-coli group of organisms, it seems quite possible that other organisms may show similar changes, and that the fermentation tests worked out by Mervyn Gordon for the Streptococci may also be inconstant, if the same means of experimentation are employed.

May 2.—"On the Variation of the Pressure developed during the Explosion of Cordite in Closed Vessels." By Prof. C. H. **Lees**, F.R.S., and J. E. **Petavel.**

(1) As most of the modern explosives used in ballistics follow the law of combustion by parallel surfaces, it appears from the results described that their properties may be defined by four constants, which may be determined without difficulty by direct experiment.

(2) The constants b and c (of formula 1) fix the maximum pressure which will be attained under any given charging density. The constants a_0 and a (of formulæ 4 and 9) measure the rate of combustion and determine the time which elapses between the ignition of the charge and the development of the maximum pressure.

(3) When the explosive is made up in a cylindrical form, the time occupied by an explosion for the same gravimetric density is proportional to the diameter of the cylinder.

(4) The rate of increase of the pressure is most rapid when about two-thirds of the maximum pressure has been attained.

(5) The maximum rate of rise of pressure per second is equal approximately to $1{\cdot}54a$ into the square of the maximum pressure in atmospheres divided by the diameter of the cordite in centimetres.

(6) When the explosion is fired under a high gravimetric density, the "effective" time of combustion may for practical purposes be taken as equal to the time required if the combustion proceeded always at its maximum rate.

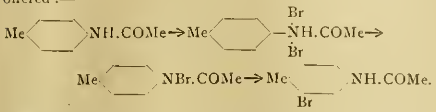
For cordite Mark I. this time is given by $T=36\,D/P$ if the diameter D is measured in centimetres and the maximum pressure P in atmospheres, or $T=0{\cdot}6\,D/P$ if the units are inches and tons per square inch.

Throughout the above investigation the cooling effect of the walls of the containing vessel during the combustion was taken as small enough to be neglected.

Challenger Society, May 3.—Mr. L. W. Byrne in the chair.—Mr. **Byrne** exhibited and made remarks upon rare deep-water fish of the N.E. Atlantic obtained from various sources.—Dr. **Fowler** exhibited a new horizontal closing tow-net which he had designed for use at different depths down to about 100 fathoms, pointing out that recent work had shown the necessity for a more precise knowledge of the depth at which an organism was captured in the upper zones than was furnished by the ordinary method of open tow-nets of the common surface pattern.—Dr. **Fowler** also exhibited a new "constant resistance" net, designed to avoid damage to delicate organisms collected for morphological or embryological study; it was so arranged that the area of the mouth automatically diminishes in proportion as the resistance (pace) increases.

Royal Meteorological Society, May 15.—Dr. H. R. Mill, president, in the chair.—The standard rain gauge, with notes on other forms: Dr. **Mill.** When the late Mr. Symons founded the British Rainfall Organisation forty-seven years ago, such observations as were being carried on were made with rain gauges of the most varied patterns, set up at any height from the ground that suggested itself to the observer, and read irregularly at almost any hour of the day or night. Since that time there has been a steady approximation to uniformity, and now the greater number of rain gauges in use are of a few definite patterns, set, for the most part, at nearly the same height above the ground. Dr. Mill strongly recommends the Snowdon pattern rain gauge, which is 5 inches in diameter, has a vertical rim to the funnel of 4 inches, and has an inner can and also a bottle. He does not recommend rain gauges with shallow funnels, nor the Howard and Glaisher patterns.—Account of a captive balloon being struck by lightning at Farnborough during a thunderstorm on April 11: Colonel J. E. **Capper.** The lightning flash appeared to travel along the wire until it reached the wagon; then a sudden bright light appeared and ran right up the wire into the clouds in which the balloon was hidden. The wire was fused, being burnt entirely away where it first touched the iron pulleys which guide the wire when running out. One side of the balloon and net was burnt, probably owing to the hydrogen catching fire, but the other side was uninjured.—A remarkable excavation made by lightning in peat earth on August 2 or 3, 1906, in a moorland district of Northumberland: Prof. A. **Herschel.**—Apparatus for measuring fog densities: J. W. **Lovibond.**

Chemical Society, May 16.—Prof. R. Meldola, F.R.S., past-president, in the chair.—The relation between the crystalline form and the chemical constitution of simple inorganic substances: W. **Barlow** and W. J. **Pope.** Close packed, homogeneous assemblages made up of two or more kinds of spheres of nearly the same size must approximate in marshalling to holohedral cubic symmetry or holohedral hexagonal symmetry with the axial ratio $a:c=1:0{\cdot}8165$. All the known crystalline forms exhibited by the elements can be interpreted in the light of the above geometrical principles, which also explain how binary compounds composed of two elements of the same valency crystallise in the cubic system and how silver iodide crystallises in the hexagonal system. The axial ratios of CsI_3 and RbI_3 are also in accordance with the geometrical principles stated above.—Experimental investigation into the process of dyeing: J. **Hübner.** It is shown that the absorption of dyes by cotton and wool is similar in many points to the absorption of these colours by inorganic materials such as graphite and charcoal, and hence it is deduced that dyeing is a purely physical phenomenon.—Esterification constants of substituted-acrylic acids, part ii.: J. J. **Sudborough** and E. R. **Thomas.** The results illustrate the retarding effect which a double bond in the $\alpha\beta$ position has on the velocity of esterification.—The addition of bromine to the α- and β-chloro- and bromo-cinnamic acids and their methyl esters: J. J. **Sudborough** and G. **Williams.**—The addition of bromine to unsaturated compounds, part i.: J. J. **Sudborough** and J. **Thomas.**—Separation of cadmium from zinc as sulphide in the presence of trichloroacetic acid: J. J. **Fox.** For the complete separation of cadmium and zinc by this means two precipitations are desirable, but this is unnecessary when the proportions of cadmium and zinc are about equal, or when cadmium is present in excess.—The mechanism of bromination of acylamino-compounds. Preliminary notice: J. B. **Cohen** and W. E. **Cross.** In the ordinary process of brominating acylamino-compounds in acetic acid solution, the crystalline product, which is first formed, yields, on pouring it into water, the nuclear brominated compound. This intermediate compound has been isolated in the case of aceto-*p*-toluidide. The following provisional explanation of the action is offered :—



—Mixed semi-ortho-oxalic compounds: G. D. **Lander.** The amide chlorides of methyl and ethyl oxanilates are stable below 100°. On decomposition by heat they pass, by loss of hydrogen chloride, into the imide chlorides, which are further resolved into alkyl chloride, carbon monoxide, and phenylcyanate.—Some derivatives of γ-pyranol allied to certain derivatives of brazilein and hæmatein. Preliminary communication: W. H. **Perkin,** jun., and R. **Robinson.** *o*-Hydroxybenzaldehyde and its derivatives condense with certain acetophenone or hydrindone derivatives to form derivatives of γ-pyranol. Thus β-resorcylaldehyde and acetophenone condense readily in presence of hydrogen chloride to give 7-hydroxy-2-phenyl-1 : 4-benzopyranol hydrochloride. With 1-hydrindone, 7-hydroxy-2 : 3-indeno-1 : 4-benzopyranol hydrochloride is formed. β-Resorcylaldehyde and 5 : 6-dimethoxy-1-hydrindone are condensed by hydrogen chloride in methyl-alcoholic solution to give 7-hydroxy-5 : 6-dimethoxy-2 : 3-indeno-1 : 4-benzopyranol hydrochloride. The substances thus produced may also be obtained by the action of alcoholic hydrochloric acid on the *o*-hydroxybenzylidene-1-hydrindones, and, conversely, the latter are again produced from the pyranols by the action of alcoholic potash.—Arsenic di-oxide: J. T. **Hewitt** and T. F. **Winmill.** The authors have examined Bamberger and Philipp's arsenic di-iodide, and find that it has the formula As_2I_4. Pyridine decomposes it immediately, liberating arsenic.—The formation and reactions of imino-compounds, part iv., the formation of 1 : 4-naphthylenediamine from ethyl γ-imino-α-cyano-γ-phenylbutyrate: J. F. **Thorpe.**—Mercury derivatives of pseudo-acids containing the group .CO.NH.: S. J. M. **Auld.** Unlike cyanuric acid, which forms two isomeric mercuric salts, all the pseudo-acids containing the group .CO.NH. examined have given only one derivative, in all cases an N-salt containing the group .CO.Nhg.—The influence of substitution in the nucleus on the rate of oxidation of the side-chain, iii., oxidation of the nitro- and chloronitro-derivatives of toluene: J. B. **Cohen** and H. J. **Hodsman.** —The reducibility of magnesia by carbon. Preliminary note: R. E. **Slade.** The two methods, which furnished a positive result, confirm the experiments of Lebeau, but whereas this author considers that the reduction only occurs at or above the boiling point of magnesia when the vapours come in contact, the present research seems to show that the reaction can take place at temperatures below the melting point of this oxide.—The reaction between organo-magnesium halides and nitro-compounds. Preliminary note: R. H. **Pickard** and J. **Kenyon.** Aromatic nitro-compounds react very vigorously with an organo-magnesium halide in ethereal solution.—A method for the determination of the equilibrium in aqueous solutions of amines, pseudo-acids and bases and lactones: T. S. **Moore.**—The "true" "ionisation constants" and the "hydration constants" of piperidine, ammonia, and triethylamine: T. S. **Moore.**

Institution of Mining and Metallurgy, May 16.—Prof. William Gowland, president, in the chair.—Siberian mines and mining conditions: A. L. **Simon.** A description of the mines and mining conditions more particularly in the province of Tomsk, the Ural and Orenburg districts, and the Kirghese Steppe. Beginning with a brief historical note, the paper dealt with climate, travelling conditions, the Russian system of weights and measures, mining laws and administration, the methods adopted in applying for claims, prospecting, opening out and working iron, copper and gold mines in Siberia, with details of costs and labour conditions.—Notes on a modern stamp mill: Gilmour E. **Brown.** A series of notes on various details of two stamp mills, compiled from personal experience and observation, containing figures relative to wear, cost of renewal, and the general efficiency of different component parts of the installation.—The use of zinc in assaying copper matte, &c.: Donald M. **Levy.** A description of results obtained by the employment of zinc for separating copper from the solution when assaying mattes, the copper and iron contents of which were both to be determined. The method described involves the use of only one reagent for the two operations. Figures were given of a series of comparative experiments showing the success of the method in practice. —A method of leaching gold ore tailings: R. S. **Botsford.** A brief note showing how, by slow and careful upward leaching, and continuous drawing off from below with the addition of fresh solution above the ore, a material saving was effected in the time occupied by the leaching process.

PARIS.

Academy of Sciences, May 27.—M. Henri Becquerel in the chair.—The suspended collimator of M. Schwarzschild: G. **Lippmann.** The arrangement described by the author in a recent number of the *Comptes rendus* was anticipated by M. Schwartzschild in 1904.—The flora and the relative levels of the coal borings of Meurthe-et-Moselle: R. **Zeiller.** More than 10,000 specimens of fossil imprints of plants have been obtained from these trial borings. These represent 145 species, some of which are new, and of which a detailed account is given.—The positions of the datum stars concerning the planet Eros deduced from the Toulouse negatives: B. **Baillaud.** An examination of the causes of the differences between the results of the reduction already published and those obtained from the same plates by Mr. Hinks.—The absence of polarisation of the prominences: P. **Salet.** Light from the edges of the sun and of the prominences is not polarised, and hence there is a contradiction between the theories of Schmidt and Julius and Fresnel's theory of polarisation.—Applications of a theorem of approximate convergence: Ernst **Fischer.**—The viscosity of fluids: Marcel **Brillouin.** A tentative formula for the viscosity of fluids is given and applied to the case of carbon dioxide, the viscosity of which has been studied experimentally both in the liquid and gaseous states.—A new property of gases issuing from flames: Maurice **de Broglie.** The gases from flames contain centres electrically neuter, possessing the properties of taking a charge under the influence of the radium radiation or Röntgen rays, and of being arrested by an ordinary cotton-wool filter and destroyed by heat. Gases containing these centres, after washing in dilute saline solutions, acquire a higher ionisation.—The sensibility of the electrostatic telephone: Henri **Abraham.**—Measurements of wave-lengths in the iron spectrum for the establishment of a system of spectroscopic standards: H. **Buisson** and Ch. **Fabry.** A completion of results already published by measurements in the ultra-violet.—Some double sulphites of hypovanadic acid: Gustave **Gain.** The alkaline bases possess the property of combining easily with hypovanadic acid in presence of sulphurous acid, giving well-defined double sulphites. Details are given of the compounds obtained with potassium, ammonium, rubidium, cæsium, thallium, sodium, and lithium.—Lead selenide: H. **Pélabon.** A study of the fusibility curves of mixtures of selenium and lead.—The methyl ethers of allyl and propargyl carbinols: M. **Lespieau.** A study of the action of allyl bromide and monochlormethyl ether on magnesium. The resulting mixture of di-allyl and the ether

$$CH_2{=}CH{-}CH_2{-}CH_2.O.CH_3$$

could not be separated by fractional distillation, but the separation was easily effected after converting into the bromine addition products.—A new crystallised principle from kola: M. **Goris.** Hitherto only two definite compounds, caffeine and theobromine, have been isolated from kola; the author describes a method of treatment by means of which a third substance can be obtained, kolatine, a phenolic substance of the formula $C_8H_{10}O_4$.—The ferment of the fig (*Ficus carica*): A. **Briot.** The coagulation of fresh milk by extract of fig is retarded or prevented by the existence in the milk of an antiferment. Heat destroys this antiferment, and hence boiled milk is more easily coagulated than fresh milk by this ferment.—The measurement of the mechanical work furnished by oxen of the Aubrac breed: M. **Ringelmann.**—The frontal gibbosity in fishes of the genus Ptychochromis: Jacques **Pellegrin.**—The duration of the larval life of Eucyphotes: H. **Coutière.**—The results furnished by the complete realisation of the physiological conditions which should be satisfied by the respiratory apparatus to permit man staying and working without danger in irrespirable atmospheres: J. **Tissot.** The conditions necessary are laid down in the following order, from the points of view of mechanics, chemistry, security, and efficiency.—The work developed during phonation: M. **Marage.** The work is measured by VH, where V is the volume of air which escapes from the lungs in a given time, and H its pressure. The author was able to make measurements of these magnitudes in two subjects, one with an artificial larynx, the other with normal vocal cords and with a tracheal cannula. For public speaking, the study of breathing is of the first importance; more energy is expended in speaking in a low pitch than a high one.—Researches on the action of waters containing sulphur compounds in the mercurial treatment: A. **Desmoulières** and A. **Chatin.** It is now well known that syphilitic patients under mercurial treatment who are taking sulphurous waters can tolerate doses of mercury compounds four or five times as great as those permissible without the use of such waters. This tolerance has been usually attributed to the precipitation of the mercury as sulphide, an insoluble form, but according to the authors' researches this is not the case. The effect is produced by increasing the solvent power of the blood serum with respect to the mercury albuminates.—Contribution to the study of the oscillations of the coast line in the Bay of Callao: P. **Berthon.**—The volcanoes of the Logudoro and Campo d'Ozieri, Sardinia: G. **Deprat.**—The dômes of the Coal-measures in French Lorraine: J. **Bergeron.**—The exploration of the free atmosphere above the Arctic regions: M. **Hergesell.**—A new theory of anthelia, paranthelia, and the white halos of Bouguer and Helvetius: Louis **Besson.**

DIARY OF SOCIETIES.

THURSDAY, JUNE 6.

ROYAL SOCIETY, at 4.30.—On the Two Modes of Condensation of Water Vapour on Glass Surfaces, and their Analogy with James Thomson's Curve of Transition from Gas to Liquid: Prof. F. T. Trouton, F.R.S.—The Mechanical Effects of Canal Rays: A. A. Campbell Swinton.—On the Velocity of Rotation of the Electric Discharge in Gases at Low Pressures in a Radial Magnetic Field: Prof. H. A. Wilson, F.R.S., and G. H. Martyn.—The Osmotic Pressure of Compressible Solutions of any Degree of Concentration: A. W. Porter.—The Distribution of Blue and Violet Light in the Corona on August 30, 1905, as derived from Photographs taken at Kalaa-es-Senam, Tunis: Prof. L. Becker.

ROYAL INSTITUTION, at 3.—Chemical Progress—Works of Berthelot, Mendeléff, and Moissan: Sir James Dewar, F.R.S.

LINNEAN SOCIETY, at 8.—Contributions to our Knowledge of the New Zealand Holothurians: Prof. A. Dendy and E. Hindle.—Observations on Australasian Polyclads: Prof. W. A. Haswell.—Report on the Marine Fishes collected by Mr. J. Stanley Gardiner in the Indian Ocean: C. Tate Regan.—The Lithothamnia of the *Sealark* Expedition: M. Foslie. Notes sur les Ixodidæ recueillis dans les iles de l'Océan Indien, par M. J. Stanley Gardiner: Prof. L. G. Neumann.—*Exhibitions: Orobanche Ritro* and some New Varieties of Plants from the Channel Islands: G. Claridge Druce.

CHEMICAL SOCIETY, at 8.30.—The Relation between Absorption Spectra and Chemical Constitution, Part vii., Pyridine and some of its Derivatives: F. Baker and E. C. C. Baly.—The Interaction of Methylene Chloride and the Sodium Derivative of Ethyl Malonate: F. Tutin.—Molecular Weight of β-Naphthol in Solution in Solid Naphthalene: E. P. Perman and J. H. Davies.—Synthesis of Hexatriene Derivatives, Preliminary Notice: I. Smedley.—The Constitution of the Diazo-Compounds: J. C. Cain.—*p*-Cresol Sulphoxide and Sulphide: S. Smiles and T. P. Hilditch.—*p*-Dioxyphenylsulphoxide: S. Smiles and A. W. Bain.—Coloured Azo-derivatives of 1:3-Diphenylbarbituric Acid. Dynamic Isomerism among the Hydrazones of 1:3-Diphenylalloxan: M. A. Whiteley.—Dibromoaminoazobenzene: J. T. Hewitt and N. Walker.

RÖNTGEN SOCIETY, at 8.15.—Some Recent Investigations in Connection with Crookes' Tubes: A. A. Campbell Swinton.

FRIDAY, JUNE 7.

ROYAL INSTITUTION, at 9.—Studies in High Vacua and Helium at Low Temperatures: Sir James Dewar, F.R.S.

GEOLOGISTS' ASSOCIATION, at 8.—The Chalk of Surrey, Part ii., The Western Area: G. W. Young.

MALACOLOGICAL SOCIETY, at 8.—Description of a New Species of Clathurella, probably from Ceylon: H. B. Preston.—Nudibranchs from New Zealand and the Falkland Islands: Sir Charles Eliot.—Note on the Name "Bourcieria": E. R. Sykes.—Description of Two New Species of Australian Helicoids, and Note on the Presence of a Double Wall in some Species of the Diaphora Group of Ennea: H. C. Fulton.

SATURDAY, JUNE 8.

ROYAL INSTITUTION, at 3.—The Contest between Guns and Armour: Sir William H. White, K.C.B., F.R.S.

MONDAY, JUNE 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.45.—Oceanic Circulation: Dr. Otto Pettersson.

TUESDAY, JUNE 11.

MINERALOGICAL SOCIETY, at 8.—Hamlinite from the Binnenthal: H. L. Bowman.—Note on Faceted Beads of Zinc: T. V. Barker.—On Chlormanganokalite: Dr. H. J. Johnston-Lavis and L. J. Spencer.

THURSDAY, JUNE 13.

Sandberg.—The New Rand Gold-field, Orange River Colony: A. R. Sawyer.—Cast-iron Tubbing: What is the Rational Formula? H. W. G. Halbaum.

CONTENTS.

THURSDAY, JUNE 13, 1907.

MEDICAL TREATMENT BY HEALTH RESORTS.

Climatotherapy and Balneotherapy: the Climates and Mineral Water Health Resorts (Spas) of Europe and North Africa. By Sir Hermann Weber and Dr. E. Parkes Weber. Being a third edition of The Mineral Waters and Health Resorts of Europe, much enlarged in respect to Medical Climatology. Pp. 833. (London: Smith, Elder and Co., 1907.) Price 15*s.* 6*d.* net.

As the causation and character of chronic ailments are better understood, more and more reliance is placed upon baths and climates for their treatment. The health resorts combine many conditions favourable to health, and, in fact, represent more or less a return to nature, a reaction which becomes necessary in proportion to the increase of civilisation. The work of Sir Hermann and Dr. Parkes Weber upon these topics is well known in America and Europe, and is conveniently presented in the present volume, which has been much enlarged in the section of climatotherapy. It now affords the most complete account of the therapeutics of climate, waters, and baths that has yet been published in our language.

The real difficulty in the use of these natural agencies has been ignorance. Indeed, so vast an amount of detailed information of localities, which is apt to get out of date, must be combined with special experience and power of selection, that not even every physician is likely to be an expert in these subjects. In cases of difficulty, and where individual characters have to be primarily considered, the expert must, of course, have the last word, but for everyday purposes this book presents a clear account of general principles and a mine of useful information, and will form a work of reference helpful alike to the practitioner and the public.

Change of climate is but one of the objects of going abroad. The influence of environment at the health resort, and of travel *per se*, both upon bodily and mental functions, are rightly emphasised in this work. They are, indeed, often a more essential element of treatment than either climates or baths. As regards climate, it will now be generally admitted that there are comparatively few disorders for which the climates of Great Britain are not as well adapted as any other. If a necessary exception be made for some forms of consumption and of chronic joint disease and defective circulation, and for failing vitality of old age—for all of which a less humid and more sunny winter climate is sometimes advisable—our health seekers might well, as respects climate, remain within our own shores. The present authors, after a survey of many climates, give little countenance to the common complaint of the "changeable weather" of these islands, but rather affirm that "frequent moderate changes of weather are favourable to health and vigour." Although we may be limited, as the meteorologists inform us, to less than one-third of our possible sunshine, whilst Italy with a more translucent air enjoys more than one-half; although the microbes and spores in the atmosphere of our towns may reach to many hundreds or thousands in the cubic metre, whilst they are absent from the alpine, arctic, and ocean airs, yet notwithstanding our people have developed, thanks partly to the climate, a power of resistance to disease which gives them, on the whole, a standard of health and energy probably unsurpassed in the world.

We note the useful distinctions drawn between the various marine climates. The *warmer* group for winter use include the equable and humid climates like those of Madeira, the West Indies and Ajaccio, and also relatively dry climates like those of the western Riviera. Again, the *colder* seaside resorts of northern Europe and the Baltic are valuable bracing stations in summer. In dealing with the effects of climates of high altitude, an interesting fact, to which Sir H. Weber has already directed attention, is again stated, namely, that an elevation of 500 feet to 800 feet in Great Britain is equivalent or more than equivalent to 2000 feet or 3000 feet in southern Europe. The statement is well within the truth, and many instances could be adduced in confirmation, for example, the highlands of the north-east of Scotland. The quality of the air in that region appears to resemble that of the Alps without the rarefaction, and it is a remarkable fact that some of the disorders, such as degenerative vascular changes, dilatation of the heart, and nervous prostration, which are unfavourably affected by an alpine climate, are markedly benefited in our own more northern but less elevated and equally bracing climates. The effect of latitude upon conditions of disease might well receive more detailed treatment in a future edition.

The recent additions to our knowledge of soil and subsoil as factors in climate are here well summarised, but our appreciation of the effect of local variations is still very imperfect. Here, as elsewhere, there exists a body of valuable but empirical observation, which needs to be collated and systematised. For example, the influence both of soil and subsoil upon rheumatism is of acknowledged importance.

The second half of this volume is devoted to balneotherapy. This is a branch of medical science and practice in which, thanks to the conscientious work of modern spa physicians, a very salutary change has been effected of late years. Like other branches of treatment, it was once vitiated by charlatanism, and later obscured by irrational tradition and routine. Balneotherapy has been founded anew upon exact observation, and the present treatise is a striking testimony to the fact. We are here furnished with a good *résumé* of the effects of the different classes of mineral waters, of which some of the most active are but weakly mineralised. Not many years ago it was often denied by competent authority that ingredients in such dilution could have any therapeutic effect, and the curative results experienced were ascribed to the imagination. It is now recognised that dosage is not to be measured by bulk. How far we have travelled from the older doctrine may be appreciated on reading such statements as the following:—"in very dilute solutions the salt molecules are supposed to be held in solution almost entirely in a state of dissociation, as *ions*" (p. 319); and "It must be confessed, however, that minute quantities . . . apparently too insignificant to deserve mention, may ultimately turn out to have a real importance" (p. 327).

The selection and employment of baths in chronic disorders belong mainly to the spa physician. The present volume contains much suggestive material, but there is still room for a good practical treatise on the use of baths by a practising balneologist. The need for an "after-cure" in all serious cases is here very properly insisted upon. It may be safely affirmed that the failure of health-resort treatment is due in most cases either to the neglect of the "after-cure" or else to the common error of indulgence in a too prolonged course of baths, or in baths at too high a temperature. The valuable place of *sub-thermal* baths, given at temperatures below blood heat, has never been sufficiently emphasised as a mode of treatment at all the spas.

The discussion of the indications for climatic and spa treatment in the closing chapters should be of service to all those who have to do with the selection of a health resort.

THE CORAL PORITES.

Catalogue of the Madreporarian Corals in the British Museum (Natural History). Vol. vi., The Family Poritidæ, ii., The Genus Porites, Part ii. By H. M. Bernard. Pp. vi+173. (London: Printed by Order of the Trustees of the British Museum, 1906.) Price 20s.

WITH the publication of the second volume of the Poritidæ it may be said that Mr. Bernard's system of cataloguing the corals in the British Museum has been given a fair trial. A great deal of skilled labour has been devoted to this work, and a great deal of money has been spent upon it. It is therefore right that the merits of the system itself should be re-considered in the light of the results obtained.

That the catalogue is of some value no one would be disposed to deny. We have now, not only a record of the existence of a number of specimens of corals in the British Museum, but a careful, detailed account of their form of growth and skeletal characters. For those whose business it is to catalogue or study certain genera of corals, it is now possible to ascertain, without making a special journey to London for the purpose, that their specimens are similar to others in the possession of the British Museum. Students of coral structure have, moreover, the advantage of considering the general remarks on the variation in the mode of growth, of the arrangement of the septa, pali, &c., made by an authority who has had a very large number of specimens to examine.

But Mr. Bernard has abandoned the time-honoured plan of arranging his specimens in groups of species and has adopted the system of ticketing each specimen with the name of the locality in which it was found and a meaningless number. Thus the specimen in the Paris Museum, which has for nearly a hundred years been known as the type of *Porites clavaria*, Lamarck, is recorded in the British Museum catalogue as *Porites americana incertae sedis secunda*.

It is true that the attempt to apply the Linnean system to the Madreporaria and other orders of Cœlenterata is beset with many very great difficulties. Everyone who has worked at the systematic zoology of these animals has met these difficulties, and has probably realised that in the present state of knowledge his solution of them is crude and unsatisfactory. But we are still in the early period of the history of coral morphology, and until our knowledge of the anatomy of the coral polyps, of their tentacles, of their mesenteries, of their mesenteric filaments, and of other features of their anatomy is considerably extended, we are not in a position to conclude that the Linnean system is not applicable to them. The advantage of using the Linnean system, however, even in the present state of knowledge, is that it enables the naturalist who has made a special study of a genus to express his opinion, by the arrangement of the specimens into specific groups, of the relations he believes they bear to one another. His opinion may not be sound, it may even prove to be misleading, but the stimulus it gives him to careful and accurate observation is the very soul of his work, and alone gives life to systematic zoology.

In Mr. Bernard's catalogues we find simply a bald statement of facts. There are descriptions and figures of specimens, there are tables and lists, but there is not one word concerning the thoughts or opinions of the man who has devoted so considerable a part of a lifetime to the collection of these facts. It is like a quantity surveyor's estimate of bricks and stones without an architect's plan of the building they are to construct. We do not get in this system what we might expect to get, the benefit of the author's long experience, and, on the other hand, for those who would follow him in the systematic zoology of corals his volumes offer nothing but discouragement.

The time has come when a new line of research should be undertaken, namely, a systematic study of the soft parts of a large number of specimens of some one genus such as Porites, and a comparison made of the relation of the anatomy of the zooids to the different forms of skeletal growth. In this investigation some of Mr. Bernard's tables may prove useful, but the naturalist will have to go through a great deal of the work again in order to make the record valuable for systematic purposes. Such a study may achieve a great deal in clearing up the difficulty of distinguishing between characters that are intrinsic and transmitted by heredity to successive generations and characters that are due to the immediate influence of the environment. It may indicate to us the characters that are of value and those that are not of value for purposes of classification. In the meantime, it would be a serious mistake if those in charge of collections of corals were contented to adopt the *non possumus* attitude of Mr. Bernard and make no serious attempt to arrange their specimens in systematic groups.

One of the most important observations recorded in this volume is that there seems to be a fairly constant difference between the Atlantic and Indo-Pacific specimens of Porites. This difference lies simply in "the fact that the trabecular, horizontal and synapticular elements which compose the skeleton are thicker and coarser in the Atlantic and West Indian forms than they are in those of the Indo-Pacific." This difference is one which may prove to be of great importance in the re-arrangement of the species that will be made in the future, and although there are some exceptions (p. 19) that may require special investigation, it will be of interest to inquire how far a difference in the anatomical character of the polyps coincides with this difference in a skeletal character.

Mr. Bernard devotes one chapter of his introduction to what he terms "metameric" growth in Porites. This principle of growth is well known to workers in the various groups of corals, but it is not one to which zoologists have hitherto applied the expression "metamerism." The metameric segmentation of a living animal body such as we see, for example, in the developing larva of a Polygordius is one thing, a linear series of gemmations in which the last of the series alone survives is another. To confound the two by using the same word for them will certainly not assist in the elucidation of the problems of coral growth. The phenomena of "overgrowth" in corals, as this process may more conveniently be called, are not fully understood, and may be due to several natural and circumstantial causes, but none of them seems to be due to any process that is at all comparable with the metameric segmentation of a worm or of an arthropod.

Although it has been necessary to express freely an opinion as to the value of the method employed in this volume, we may express our admiration of the careful descriptive account of each specimen in the catalogue and of the excellence of the plates.

S. J. H.

REALISTIC SCHOOL MATHEMATICS.

A School Course of Mathematics. By David Mair. Pp. viii+379. (Oxford: The Clarendon Press, 1907.) Price 3*s*. 6*d*.

FOR some years past the Civil Service Commissioners have systematically set themselves the task of framing their examination questions so as to make them of practical interest instead of merely being a test of a candidate's capability in abstract mathematics.

Mr. Mair, in the present book, has given a most useful and interesting collection of such of these examples as he considers should be within the range and powers of boys while still at school. These questions are given in sets at the end of the various chapters, which are devoted to the discussion of a few typical questions. These typical questions are discussed with variations and from different points of view, the discussion being thrown into the form of questions by the teacher, and answers supposed to be given by the pupil.

It is somewhat difficult to realise how these discussions are intended to be made use of unless they are meant only as typical, to be taken merely as suggestions, and not to be followed in detail; it would certainly not do for the class to have the book open during the discussion, and it would take too long for the class to write down the questions to which they are asked to give an answer, and yet in many cases the questions are somewhat difficult to answer unless the pupils can have them in writing. Moreover, in some cases the work involved in the discussion before the pupil has satisfactorily arrived at the generalisation which the teacher is striving to bring him to is so lengthy that it could not be completed in a single sitting, and consequently the continuity of thought required would be seriously interrupted. This difficulty seems not to have been contemplated by the author.

Moreover, he does not seem to have sufficiently realised that the young pupils for whom he is catering in the earlier chapters are incapable of the sustained thought and the considerable efforts of memory and chains of reasoning which he requires, and, most serious defect of all, even if the pupils are brought to perceive and retain the mathematical truths thus presented to them, these truths are so detached from each other and are so various in kind that they do not form in any sense a *mathematical course*.

In spite of this, however, the book will be of very great use. Thus, in some schools it is already being used with the upper army classes for the sake of the excellent examples with which it is crowded, the question and answer part being for the most part ignored with these classes, and, with regard to the text, if the teacher can find time to go carefully through the book, he will find a great deal of help given him as to the best way of bringing home some mathematical facts to boys in a more realistic and vivid manner than he might otherwise be able to do. For example, the author has a special way of his own for introducing boys to logarithms. This method is very carefully worked out, and is particularly worthy of study. Possibly each teacher will elaborate some modification of his own which he prefers, but he certainly should very carefully consider the author's method, which is most ingenious and well worked out so far as he goes, though there is a gap at the end which he has jumped. The author's treatment of questions in solid geometry also is good, giving them a reality and vividness which will make this part most valuable as an introduction or as a companion to the theorems of the eleventh book of Euclid or its modern equivalent.

The impression left on the reviewer's mind is that the book in no way supersedes the regular class books on the various subjects, but that it may be a most valuable adjunct to them in two ways, first, by suggesting methods of presentment of new mathematical ideas by means of concrete illustrations which will bring them home more vividly and interestingly to the pupil, the method of question and answer being often used to make the pupil think for himself—though, indeed, this is generally done now by good teachers as occasion serves—and, secondly, by the teacher taking the class from time to time through a selected set of the examples when they have assimilated the underlying book-work.

There is one thing which the author has touched on, though apparently only in an example (No. 7, p. 293), which one would have liked to see brought into much greater prominence, viz. the graphic solution of a quadratic equation $x^2-bx+ac=0$ by drawing lines $OA=a$, $BC=c$, perpendicular to a line $OB=b$, and drawing a circle on AC as diameter, cutting OB in P, Q: the roots being OP and OQ. This method gives the clue to the geometrical solution of many problems some of which would otherwise be difficult; for example, the construction of a triangle of given area when two sides are given in position, and a point in the plane through which the third side is to pass; also the construction of a right-angled triangle from the data given in the book on p. 261; also the division of a line in extreme and mean ratio; and, indeed, any problem the solution of which depends on a quadratic. It is a most valuable link between algebra and geometry. Another method which is applicable to the case of $x^2 \pm bx = a^2$, and is perhaps better than the first for this particular case (though really only a modification of the above general method), is given on p. 264. The book is, in fact, bristling with ideas and suggestions, and we wish it the great success it undoubtedly deserves. A. L.

EGYPTIAN ANTIQUITIES.

Egyptian Antiquities in the Pier Collection. Part i. By G. C. Pier. Pp. 27+xxi plates. (Chicago: University of Chicago Press, 1906.) Price 17s.

MR. GARRETT CHATFIELD PIER, of New York, is an amateur of Egyptian antiquities, and has begun to publish a catalogue of his collection, of which the first part has reached us. The book is produced by the Academical Press of the University of Chicago, which, at the instigation of its Egyptological specialist, Prof. Breasted, is beginning to take an important part in Egyptian archæological work.

We find various traces of Prof. Breasted in Mr. Pier's book. The learned professor's "particular wanities" in the way of transliteration of Egyptian names, such as "Ikhnaton" for Akhenaten, or "Harmhab" for Haremheb, either stamp Mr. Pier as a faithful follower of Prof. Breasted or show that the professor revised Mr. Pier's Egyptology. Mr. Pier's use of the Berlinish algebraic transliteration (*e.g.* "s;-r‘ Nb-m;‘-t-r‘-nb-t;wj" for what might just as well be written *sa-ra Neb-maat-Ra neb-taui,* p. 5) points the same way. But Mr. Pier should be careful, if he uses this highly learned transliteration, to use it consistently, and not write sometimes "Nub-khprw-r‘" (p. 19), sometimes "‘,’-ḫprw-r‘" (p. 22), sometimes "Mn-ḫpr‘," sometimes "Men-khepr-r‘" (p. 21), or "Ishrw" (p. 6) for "Jšrw," or "Thy" (p. 13) for "Tjj," in such a sentence as "Śtn-ḥmt-wr-mrj-f-Thy (surely, surely, Tjj! ‘nḫ-ty," which also exhibits confusion between the orthodox Teutonic "j" and the slightly heretical English "y." Thy is the queen whose tomb has just been discovered at Thebes; if the German transliteration is used for her name at all, it must appear as "Tjj," but in reality there is no need whatever to use pedantically, in a guide to a collection of objects of purely anthropological interest, a transliteration of ancient Egyptian which is utilised only by a few German or germanised philologists for purely philological purposes.

Mr. Pier's collection does not, so far as published, appear to contain anything of extreme interest, compared, that is, with such important private collections as those of Mr. Hilton Price or Mr. Macgregor. He seems to be chiefly interested in objects of the prehistoric period and scarabs of the XVIIIth Dynasty, of which he possesses some fine specimens. Of later scarabs he does not appear to own many, which may account for the inaccurate statement on p. 15:—"with the Twenty-sixth Dynasty richer materials are used for scarab seals and plaques, such as carnelian, amethyst, serpentine, &c., *rarely, if ever, inscribed.*" We italicise the erroneous statement, which may well seem odd to those who know how constantly the little stone scaraboid plaques of the Saïte period were inscribed with all manner of sentences, wishing a good new year, invoking Khonsu as a protection, and so forth. But probably Mr. Pier has not yet devoted much attention to these later objects. He is thinking of the fact that the XIIth Dynasty amethyst and other stone scarabs were but rarely inscribed: this is so.

Mr. Pier draws his scarabs extremely well, much better than his flint implements, of which he publishes some scratchy pen-and-ink representations [Plates v.–ix.: Plate ix. (of a slate) is especially bad]. The mirror on Plate x. is also very badly drawn, and the two dishes on Plate xi. are not much better. Mr. Pier would be well advised to reproduce these things by means of photography in future, and to confine his artistic efforts to scarabs and hieroglyphs, which he knows how to draw.

His coloured plates of ceramics are very successful, though not so successful as Mr. Henry Wallis's in his "Egyptian Ceramic Art." Mr. Pier's blues, yellows, and violets do not so perfectly reproduce their originals, and Mr. Wallis's do. But it would be indeed difficult to rival Mr. Wallis's drawings or Mr. Carter's in the publication of the "Tomb of Thoutmosis IV."

So far as the literary part of the book is concerned, quite apart from the usual aberrations of American spelling, Mr. Pier has one or two specialities of his own. One is "faun-colored" (for "fawn-coloured"), which occurs two or three times, and so cannot be a misprint. Presumably Mr. Pier has forgotten what a "fawn" is, or what colour it is, and is thinking of a Greek faun. True, if we are to believe the sculptors, the fauns and hamadryads did live naked in the open air most of the time, so were probably slightly tanned. And what does Mr. Pier mean by "hackling" (p. 10)? Was a "hackling implement" the sort of flint you threw at a prehistoric election candidate: to "heckle" him? Or does Mr. Pier mean simply "hacking"? One talks of a dog "putting up his hackles." We pass on, unconvinced. On p. 11 we read a description of a vase as "handled for suspension or portage." By *portage* Mr. Pier probably means "carrying": his word is an odd one, and sounds as if it were of Canadian origin; we have not met with it in this particular sense before, and we do not like it at all.

Real misprints are rare. We notice "Chelleen" for "Chelléen" (p. 6), and one or two others of no importance.

The disadvantages of the book are such as the author can easily remedy in the succeeding parts, and we hope that he will continue his plan to its end. Such catalogues of private collections are extremely valuable to the student, and those collectors who publish them are to be congratulated on the scientific spirit that impels them to make their antiquities known. H. H.

OUR BOOK SHELF.

Heat Shadows. By Walter Jamieson. Pp. viii+30. (London: Blackie and Son, Ltd., 1907.) Price 6*d*. net.

THIS pamphlet describes some new experiments in conduction and radiation of heat. The author has prepared a series of grades of paper sensitised to heat by impregnating them with a "sympathetic ink" which turns green on heating (*i.e.* on drying). The tint attained in any experiment may be considered as depending roughly upon the amount of heat absorbed; thus the paper acts as a calorimeter rather than as a thermometer. This law would be true if the absorbed heat were all transformed into the latent heat of steam; since, however, the paper sensibly warms (and, therefore, radiates), the law is not so exact; though even so there is a time-temperature compensation. The double iodides sometimes employed for the purpose are thermoscopes rather than calorimeters, for their transition points are somewhat too high, and when reached the transformation is rapid and automatic; that is, it is independent of the heat supply.

Specimens of the sensitive paper were received along with the pamphlet, and we have been able to test it. We think that it will prove very useful for demonstrating the phenomena of conductivity and radiation in schools where thermopiles are out of the question. Too much stress must not be laid, of course, upon quantitative experiments. The first experiment is to fasten a strip of the paper, sensitive side up, upon a board with a thick copper wire between. If the wire is heated at one end the green tint spreads out more widely near the heated end. We do not think that the teacher is justified in *measuring* the width of the coloured band and in thus trying to find the law of the decrease of temperature; he should be content with the inference of "more or less." Most of the experiments are excellent. We think those on radiation are the best.

As a bright surface Mr. Jamieson employs a test tube coated with a metallic paint. This forms a very good coating, but the inquiring child (and teacher) may wonder whether the varnish with which it is applied has anything to say to the result.

This metallic coating is also employed by the author for coating electrical condensers, proof planes, &c., and is very readily applied both to the inside and outside of any jar

Handbook of American Indians North of Mexico. Edited by Frederick Webb Hodge. Pp. ix+972. In two parts. Part i. (Washington: Government Printing Office, 1907.)

THIS volume is Bulletin 30 of the Bureau of American Ethnology in connection with the Smithsonian Institution. The handbook contains a descriptive list of the stocks, confederacies, tribes, tribal divisions, and settlements north of Mexico, accompanied with the various names by which these have been known, together with brief biographies of Indians of note, sketches of their history, archæology, manners, arts, customs, and institutions, and the aboriginal words incorporated into the English language. All the tribes north of Mexico are dealt with, including the Eskimo and those tribes south of the boundary more or less affiliated with those in the United States. Under the tribal descriptions a short account of the ethnic relations of the tribe, its location at various periods, and statistics of population are included. There are many illustrations. Though confessedly incomplete, the handbook represents a vast amount of research by an army of observers, and students of ethnography will look forward to the publication of the second part with keen anticipation.

A German Science Reader, with Notes and Vocabulary. By Dr. W. H. Wait. Pp. vii+321. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1907.) Price 4*s*. 6*d*.

THE greater part (180 pages) of this book consists of selections from standard German works on the chief departments of science. The extracts describe some fundamental facts and principles of chemistry, physics, geology, mineralogy, astronomy, and anatomy; and they have been selected from the point of view of interest as well as that of instruction. Helpful notes are given on each division of the book, and also lists of words commonly mispronounced and of words and phrases with special or idiomatic meanings. A vocabulary at the end of the book gives the English rendering of words used in the German text. Any student of science having a slight acquaintance with German grammar will find in the book all the assistance required to enable him to read the extracts with interest and profit. As an introduction to German scientific literature, the volume will be found of real service both by teachers and students.

Les Bases de la Philosophie naturaliste. By André Cresson. Pp. iv+179. (Paris: Félix Alcan, 1907.) Price 2.50 francs.

THE title of this little volume serves to define its purpose. The author provides a short and impartial explanation, likely to be understood by a reader of average intelligence, of the fundamental principles upon which modern philosophy rests. The scope of the book will be clear from the titles of the six chapters into which it is divided: the first deals with the old anthropocentric view of things, and this is followed by chapters on science and the inorganic world, science and life, science and mind, science and society, and conclusions.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE *No notice is taken of anonymous communications.]*

The Origin of Radium.

I cannot let Prof. Rutherford's letter in Nature of June 6 pass without directing attention to one striking consequence, in which I personally am interested. During 1904 and 1905 I published (Nature, May 12, 1904, January 26, 1905, and *Phil. Mag.*, June, 1905, p. 768) the result of an experiment which went to show that a kilogram of uranyl nitrate, purified initially from radium by precipitating barium as sulphate in its solution, and kept 550 days, generated a quantity of radium which, although only one-thousandth part of what is theoretically to be expected on the view that a direct change of uranium X into radium takes place, was still one hundred times the amount initially present. Boltwood (*Am. Journ. Sci.*, September, 1905, xx., 239), working with one hundred grams of uranyl nitrate purified from radium initially by repeated crystallisations from water, was unable to observe any detectable increase after a period of 390 days, and concluded that "the results obtained by Mr. Soddy are without significance," and averred that my results were due to the introduction of radium salts during the tests.

Now such a criticism and such an imputation on the part of one investigator dealing with the work of another surely ought only to have been made if it was the only possible explanation of the discrepancy. As it was, to me at least, it was not even the most obvious explanation. Boltwood did not give consideration to the all-important influence of the method of purification of the uranium from radium on the results obtained. My result, that the rate of production of radium from uranium was only one-thousandth of the theoretical, brought into being the present theory of the existence of several hypothetical intermediate transition forms between uranium and radium. It is obvious that, according as the method of purification employed does not or does remove these transition forms as well as the radium, so one will or will not expect to observe an initial production of radium in a solution of uranium. Now the method of precipitating barium as sulphate in a uranium solution is designed to *remove only* the radium, whereas the method of repeated crystallisation from water adopted by Boltwood is well calculated to *purify* the uranium, that is, to free it from all other accompanying substances. Hence there is no necessary discrepancy between the results of the two experiments. This view has been put forward by Rutherford ("Radio-active Transformations," p. 159).

I would not now have raised this matter had not history apparently repeated itself, and Prof. Rutherford's most recent results (Nature, June 6, p. 126) enabled me, without making any special claim to infallibility, to exhibit clearly the real nature of Boltwood's criticism. In the *American Journal of Science* for December, 1906, p. 537 (Nature, January 3), Boltwood published a "Note on the production of Radium from Actinium" in which evidence was given that actinium is the parent of radium. This was quickly followed (Nature, January 17, p. 270) by some confirmatory evidence of a similar character by Rutherford, who, however, pointed out that there was no proof that actinium was itself the true parent of radium, although this parent was undoubtedly present in the actinium solutions employed. Now Rutherford shows in last week's issue that actinium *purified from radium in a different manner* yields no appreciable growth of radium. Is Boltwood's previous positive result then "without significance"? Surely not. But if Boltwood's result on the production of radium from actinium can be explained, as, of course, it can be explained, without charging him with introducing radium into his solution, so in the same way can mine with uranium. Indeed, whereas the intermediate product, which is the parent of radium, is a *necessary* companion of *any* uranium preparation which has not recently been subjected to a purification process capable of removing it, it has yet to be shown that the association of this parent with actinium is genetic and not purely fortuitous.

I hope this exposure of an old criticism, made without due consideration of the complexity of the problem, will clear the way for the publication of some further results. In the two years that have elapsed since the publication of my last paper I have had the advantage of the cooperation of Mr. T. D. Mackenzie in the steady and continuous prosecution of the work under the most favourable conditions. We have from the commencement, which dates prior to Boltwood's first communication on the subject, had as the basis of the work the all-important influence of the method of purification adopted, and we have used throughout a new method of purification, which, though not without difficulty and danger in its application to the purification of large quantities of uranium salts, was deliberately chosen as affording a reasonable guarantee that it would separate the uranium from all other substances present. Mr. Mackenzie has purified with the utmost care three separate kilograms of uranyl nitrate by this method, and I may anticipate our results to the extent of saying that, so far, they entirely confirm and extend the results obtained by Boltwood in which re-crystallisation was the method of purification employed. The first preparation, containing after purification about 500 grams of uranyl nitrate, has been kept for 600 days, and has not shown the slightest detectable increase in the amount of radium initially present. Now that these three purified preparations have been set up in a form to allow of continuous and extended observation, our attention is being directed to the residues from the three kilograms, which should contain the parent of radium, if my earlier positive result was correct. After all, it would be a little surprising if this parent of radium was entirely absent from commercial salts of uranium, for although Boltwood and Rutherford have found it in preparations of actinium, it must not be forgotten that the only source of actinium is that from which commercial uranium salts are prepared.

Frederick Soddy.

The University, Glasgow, June 8.

The Structure of the Æther.

In the current number of the *Philosophical Magazine* I have given in some detail certain objections to identifying the magnetic vector with translational æthereal motion, and to a large extent these are on all fours with Prof. Hicks's objection, which is cited by Sir Oliver Lodge in the same number, and of which I had lost sight. Very briefly, thus: if bodily æther flow were (within a constant factor) identical with magnetic induction, or were even an essential feature thereof, our judgment as to whether or not a given region was pervaded by magnetic induction would depend on the arbitrary origin of coordinate axes relatively to which we chose to measure velocities, motion of bodies through the æther being physically indistinguishable from an equal and opposite motion of the æther with those bodies at rest.

Much the same difficulty (concerning the essential relativity of motion) seems to me to arise when resultant æthereal momentum is taken to correspond to the vector product of the electric and magnetic vectors; in this case, moreover, further difficulties are encountered. Consideration of a progressive train of electromagnetic waves shows that, with this æthereal-flow interpretation of the Poynting vector, we should have a resultant æthereal motion made up of a steady flow in the direction of wave propagation, together with to-and-fro motions parallel to that direction and kinematically exactly simulating the motion of a gas which is transmitting waves of sound. This clearly implies *compressibility of the aether*, not merely as a minute residual phenomenon, but as a fundamental relation of electromagnetism.

And what would happen in the case of such a body as the sun, which consistently radiates more energy than it receives by radiation? There would be a flow of æther outward in all directions, maintained throughout immense periods of time. This difficulty seems almost insuperable.

There appears to me to be much evidence in favour of the view that the resultant velocity of the æther (referred to suitable axes) is everywhere zero—at least so far as electromagnetic phenomena are concerned.

Though I find myself in agreement with Prof. Richardson's conclusion that magnetic intensity is not to be identified with speed of æthereal flow, as explained in his letter to NATURE of May 23, I venture to dissent from his arguments. These proceed from the contention that, on the contested assumption, certain integrals would become infinite. Now, in the first place, it appears to me from mere inspection that both these integrals (which I have not actually evaluated) are in reality finite; in the second place, neither integral expresses a magnitude which bears directly on the point at issue, one of them being justly criticised by Sir Oliver Lodge in NATURE of June 6 as apparently devoid of mathematical meaning. The question proposed is as to the momentum due to an electric charge upon a moving sphere, and in this connection the really significant magnitude is the kinetic energy, expressed in terms of the translational velocity. Differentiating this expression with respect to the velocity, we have at once the momentum, the result obtained being independent of any physical theory as to the ultimate nature of the energy in a magnetic field. C. V. BURTON.

Cambridge, June 8.

Decomposition of Radium Bromide.

YESTERDAY, on opening a glass tube containing 1 milligram of radium bromide which had been hermetically sealed for almost exactly twelve months, there was a very strong odour of bromine which hung about the tube for about ten minutes. The amount of the bromide decomposed in this period would be about $5{\cdot}4\times10^{-7}$ grams according to Rutherford; the amount of bromine corresponding to this would be about 2×10^{-7} grams. Perhaps some chemist could say definitely whether this amount of bromine would be detectable by its odour. The volume of the tube was about 4 cubic centimetres.

ALFRED W. PORTER.

University College, London, June 8.

The Mass of the α Particle.

APPARENTLY the following simple and obvious method of calculating the mass of the α particle has been overlooked.

According to Rutherford, the number of α particles emitted per second by a gram of pure radium is $2{\cdot}5\times10^{11}$. Of these particles, one-quarter comes from each of the four elements Ra, RaEm, RaA, RaC. The particles from these four elements are emitted with velocities $0{\cdot}82\ V_0$, $0{\cdot}87\ V_0$, $0{\cdot}90\ V_0$, $1{\cdot}00\ V_0$ respectively, where V_0 is $2{\cdot}6\times10^9$ cm./sec.; they all cease to produce ionisation when their velocity is $0{\cdot}43\ V_0$. Hence the loss of kinetic energy of all the α particles emitted from one gram of radium in passing over their ionising ranges is

$$\frac{2{\cdot}5\times10^{11}}{4}\times\tfrac{1}{2}m\times\{(0{\cdot}82)^2+(0{\cdot}87)^2+(0{\cdot}90)^2+1^2-4\times(0{\cdot}43)^2\}(2{\cdot}6\times10^9)^2=m\times5{\cdot}3\times10^{29},$$

where m is the mass of an α particle.

At the same time, it is known that one gram of radium gives out 105 gram-calories per hour (mean value), or $1{\cdot}22\times10^6$ ergs per second. If we may identify this quantity of heat energy with the kinetic energy lost by the α particles in ionisation we have

$$m\times5{\cdot}3\times10^{29}=1{\cdot}22\times10^6$$

or

$$m=2{\cdot}3\times10^{-24}.$$

The ratio e/m for the α particle is $1{\cdot}56\times10^{14}$ electrostatic units. The two most probable theories of the nature of the α particle are (1) that it consists of an atom of helium carrying a charge 2ϵ, where ϵ is the electronic charge $3{\cdot}4\times10^{-10}$, and (2) that it is a molecule of hydrogen carrying a charge ϵ. On the hypothesis (1) the mass of the particle is $4{\cdot}26\times10^{-24}$; on the hypothesis (2) it is $2{\cdot}13\times10^{-24}$. The calculation given indicates that (2) is correct, and explains the failure of Greinacher and Kernbaum to obtain helium from the α rays of polonium (*Phys. Zeit.*, 1907, p. 339).

If it be assumed that the whole of the kinetic energy of the α particles, and not only that part of it which is spent in ionisation, appears as heat energy, the value for m is found to be

$$1{\cdot}78\times10^{-24}.$$

I have thought it best to give the maximum estimate of that quantity which can be attained by this method.

NORMAN R. CAMPBELL.

Trinity College, Cambridge, June 3.

The "Renal-portal System" and Kidney Secretion.

I RECENTLY published a short paper (Proc. Zool. Soc., 1906) on the significance of the so-called "renal-portal system" found in most of the lower Vertebrata. In this paper I advanced strong reasons for supposing that the "renal-portal system," or, as I prefer to call it, renal cardinal meshwork, is non-excretory in nature. I showed that, both developmentally and structurally, there was every reason to doubt whether the renal cardinal meshwork takes any part in the formation of the plexus of blood-vessels which surrounds the urinary tubules (although, of course, these are connected with each other), and that therefore the blood apparently supplied to the kidney by the "renal-portal" (post-renal) vein is in all probability not utilised in the production of the kidney secretion. This conclusion, opposed to that held by most physiologists and morphologists, I supported by citing the physiological experiments of Nussbaum (*Pfluger's Archiv*, xvi., xvii., 1878; *Anat. Anzeig.*, i., 1886) and Beddard (*Jour. Physiol.*, xxviii., 1902), which afforded valuable confirmation. These experiments, as is well known, proved that after the arterial supply of the frog's kidney had been eliminated all secretion immediately stopped, notwithstanding the facts that the "renal-portal" circulation was still in full swing and that powerful diuretics were employed. The sole objection to regarding these experiments as conclusive was that, in consequence of the kidney being deprived of oxygenated blood, the tubular epithelium had degenerated, and was therefore not in a condition to secrete. While recognising this objection, yet for the other reasons which I had already advanced I ventured to maintain that, even if the blood in the post-renal vein could be artificially oxygenated, no secretion would occur.

Unfortunately, I was not aware of more recent physiological work on this subject when I made this last suggestion. Since then, however, Prof. Halliburton has kindly directed my attention to the papers of Bainbridge and Beddard (*Biochemical Journal*, i., 1906) and Cullis (*Jour. Physiol.*, xxxiv., 1906), in which the reverse result has been obtained; that is to say, according to these later experiments, a secretion can be obtained from the "renal-portal" circulation provided that the tubule epithelium is maintained in a healthy condition by means of a sufficient supply of oxygen, and that powerful diuretics like urea and phloridzin are employed. This result at first sight appears to be contradictory of my previous conclusion and confirmatory of the generally accepted "portal" theory of the renal cardinal meshwork, but it is the object of these remarks to show that such is, after all, not necessarily the case.

In the first place, these recent experiments have clearly shown that the "renal-portal" circulation will not yield the slightest secretion in the absence of powerful diuretics; in other words, the result obtained by Bainbridge, Beddard, and Cullis is at best an abnormal one. Under more normal conditions, *i.e.* in the absence of diuretics, with a healthy tubule epithelium and with the "renal-portal system" alone working, no secretion whatever occurs.

Secondly, the very fact that when the venous blood contained in the renal cardinal meshwork alone "supplies" the kidney, the tubule epithelium degenerates, proves that in the normal living animal this blood is not in contact with the tubules, *i.e.* does not take part in the formation of the blood-plexus surrounding the tubules, since, as the experiments prove, these latter require the oxygenated blood derived from the renal arteries in order to live and much more to secrete.

Thirdly, it must be remembered that in the experiments of Bainbridge, Beddard, and Cullis, the elimination of the arterial circulation of the kidney does away with the blood current which normally flows *away from* the region of the tubules, and, this being the case, the venous blood of the renal cardinal meshwork, encountering no resistance, is enabled to penetrate to the tubule plexus, carrying with it the injected diuretics which cause the secretion observed. There is no reason why the secretion should not occur under these abnormal conditions. The tubule epithelium is well supplied with oxygen, the veins are gorged with impure blood, and in experiments in which at all large secretions were obtained the pressure was artificially raised by forced injection or otherwise.

It is easy, then, to account for the secretion obtained by the investigators named, and at the same time to believe that the venous blood takes no share in the formation of the kidney secretion under normal conditions.

It has always surprised me, speaking as an outsider, that physiologists have so readily assumed that they possess in the frog and other animals with "portal" kidneys so many convenient anatomical contrivances in which the glomeruli and the renal tubules are supplied by separate vessels. It is true that the renal cardinal meshwork is continuous with the blood plexus surrounding the tubules, but surely it is very unsafe to assume from this one fact that the venous blood is used by the tubules for secretory purposes. Another equally patent fact, that the similar tubules of mammals employ arterial blood, should suffice to cast doubt on the assumption. And when we recall to mind the statements of Hyrtl (*Wiener Akad. SB.*, xlvii., 1863) and Vialleton (*C. R. Hebdom. Séances Soc. Biol. Paris*, liv., 1902), among others, that in those "portal" kidneys in which the vascularisation has been histologically examined, viz. those of the frog and certain sharks, the renal cardinal meshwork is structurally distinguishable from the tubule plexus (the former consisting essentially of large channels putting the post-renal vein into communication with the post-caval, and the latter consisting of capillaries which open into the channels), there is still more reason for supposing that the flow of blood is from the tubule plexus into the renal cardinal meshwork, and not in the contrary direction. The numerous experiments which have been based on the aforesaid assumption have, I should imagine, given rise to incorrect ideas as to the normal functions of the urinary tubules.

If I needed any additional physiological evidence in support of my contention that the post-renal vein has nothing to do with the vascular plexus of the urinary tubule, *i.e.* does not supply the kidney for excretory purposes, I find it to hand in the recently issued British Association Report for 1906, York. In a report on "The 'Metabolic Balance Sheet' of the Individual Tissues," p. 427, it is shown to be exceedingly probable, by the relative amounts of oxygen used up by the kidney tissue of a frog and a mammal respectively, that the "renal-portal" vein of the frog bears a very different relation to the kidney tubules as compared with that of the renal vein of mammals—which is the conclusion I am maintaining. It is further stated that "when the same kidney is perfused at different times through the aorta and through the renal-portal system, there is a greater consumption of oxygen in the former case than in the latter (double to treble in four experiments)." If we assume what is generally held to be a well-established fact, viz. that the kidney-tubule epithelium plays quite as important a part in kidney secretion as the glomerular epithelium, then it is difficult to understand, on the portal theory of the kidney, why the quantity of oxygen absorbed by the kidney tubule is totally out of proportion to the work done by it. Obviously the only rational conclusion to draw is that in the above experiment the oxygen perfused through the "renal-portal" vein did not come into contact with the tubule.

To sum up, I think I may say that I have clearly shown that the recent work of Bainbridge, Beddard, and Cullis does not disprove my original contention that the renal cardinal meshwork is, under natural conditions, non-excretory, that, in short, the so-called "renal-portal" vein does not supply the renal tubules, as physiologists commonly assume, and that, in consequence, experiments based on this assumption are liable to give rise to misleading ideas.

W. Woodland.

Mendelism and Biometry.

In the striking and suggestive review of Mr. Punnett's work on "Mendelism," in Nature of May 23, the reviewer cites, without naming the author, a view expressed by Mr. A. D. Darbishire (*Manchester Memoirs*, 1906) to the effect that "the Mendelian deals with units and the biometrician with masses," and states that this idea, "though plausible, is based on a fallacy," for "the Mendelian's units *are* the biometrician's masses, except when the latter exceeds his limits and includes within his masses more than one such unit."

I have no doubt that Mr. Darbishire read the review with as much enjoyment as myself, but it seems to me that his statement of the case is dismissed with scarcely sufficient consideration. The reviewer's points, if I understand aright, are two:—(1) that Mendel's laws (by which he seems to mean, not merely the law of segregation, but the laws of observed proportions) are really mass-laws and not laws of the individual; (2) that the biometrician's masses are the masses to which Mendel's laws apply. But surely (1) Mendel's laws are based on definite conceptions as to the germ-cells of the *individual*—and that is the important point—and are true of the *individual* to a degree of approximation which is the higher the greater the number of offspring (quite a high degree in such a case as Mr. Lock's maize). Further, (2) if the "Mendelian's units" were the "biometrician's masses," there should be inheritance of individual variations, within each of two races A and *a*, for any character to which Mendel's laws applied on crossing those races; for inheritance of individual variations is what the biometrician has observed for nearly all characters in his masses.

I indicated the importance of an investigation on this point some time ago (*New Phytologist*, i., 234)—for it is almost a fundamental question whether a single determinant, such as may be assumed to exist for a unit Mendelian character, is or is not capable of variation from individual to individual—but I am not aware that any such investigation has been made. The reviewer's assumption may, therefore, be true, but it is unproven, and theories at present in the field (Pearson, *Phil. Trans.*, 1904; Yule, *Conference on Genetics*, 1906) are based on the opposite assumption, viz. that heritable individual variations are due to the character concerned being determined by *n* allelomorphic couplets, and not by one. If this be true, the "biometrician's masses" are precisely masses to which Mendel's laws, in their simplest form, do *not* apply.

The question referred to above, whether a unit Mendelian character exhibits heritable individual variations or no, seems to be one that urgently calls for experimental investigation.

G. Udny Yule.

Mr. Yule is probably right. The question is this: Is the inheritance which the biometrician always finds within the limits of his masses due to the fact that he is dealing with a large number of Mendelian units, or that he is measuring the intensity of heredity *within* such a unit?

If the former, Mr. Yule is right in saying that I criticised the view expressed by Mr. Darbishire unjustly. If the latter, the mass of the biometrician *is* the unit of the Mendelian. But before we can give an answer to this question we must know, as Mr. Yule points out, whether there is inheritance of fluctuating variations within the limits of a single Mendelian character such as "tall," in peas. If we may argue from stature in man to stature in peas, we should compare the character tall (or normal) in peas to tall (or normal) in man, and dwarf in peas to dwarf in man. We know that there is inheritance within the character tall in man, and, if this analogy is legitimate, we should expect to find it so in peas. If it were, the answer to the question whether the view expressed by Mr. Darbishire were right or not would depend on whether we still called the character tall the unit or extended the conception of unit to the smallest heritable variation within the category tall.

The Reviewer.

SOME INSTANCES OF UNSCIENTIFIC ADMINISTRATION.

In recent letters to Nature and the *Times*, I had occasion to criticise the lack of science displayed by the Indian authorities during their conduct of the operations against plague in the great outbreak of 1896. The Editor of Nature, who has so frequently and ably urged the claims of science on the public, now asks me to give any more instances of the same nature which I may have observed.

Probably few any longer accept the teaching of Hume, that the object of government is no other than "the distribution of justice." The function of an ideal civilised government might be described as the performance of all acts for the good of the public which individual members of the public are by themselves unable to perform—that is, the organisation of public welfare. The individual can certainly add much by intelligence and virtue to his own welfare; but these qualities do not suffice to protect him altogether against those evils which can be combated only by concerted action, such as the depredations of disease and of external and internal human enemies; and where he is powerless, the Government, and only the Government, can help him. Now such concerted action is likely to be successful only when it is based on sufficient knowledge; and a scientific administration differs from an unscientific one just in this particular, that it seeks the necessary knowledge, while the other acts blindly. In nothing is this more manifestly the case than in connection with that departmen of public administration which is charged with the protection of the public against disease—a department second to none in importance, because it concerns not only our sentiments and our pockets, but our health and our lives. Before such protection can be obtained, two things are absolutely necessary—first, an exact knowledge of how diseases are caused and how best they may be checked, and, secondly, an efficient organisation to act upon that knowledge when it is obtained. I will now try to examine how far, within the range of my own subject and experiences, this ideal of a scientific administration has been reached.

My experiences commenced in the Indian Medical Service in 1881. The Indian governmental machine is a bureaucracy placed mostly in the hands of soldiers and Indian civilians, who are selected from the British middle-classes by competitive examinations in branches of knowledge among which (be it noted) science, except mathematics, does not hold a very prominent position. The medical establishment, to the care of which the health of about three hundred millions of people is mostly entrusted, is divided into a civil and a military branch with corresponding duties, and contains, I think, more than a thousand qualified medical men, chiefly British, belonging to the I.M.S. and R.A.M.C., with a large subordinate staff of apothecaries, hospital assistants, and so on. The heads of this organisation are medical men, but they do not generally, I think, have seats on the supreme executive councils.

When I entered the I.M.S. it had a great reputation, which it still possesses, and, together with the Army Medical Department, had done fine work. Both these services were on the whole very well organised; but I could not help noticing several anomalies. Many of the Indian diseases are, of course, different from those met with at home. Our knowledge of them was then chiefly in the clinical stage, and very insufficient, both for treatment and prevention; and what we possessed was due, not to any organised official inquiries, but to the efforts of individuals. I remember being struck even then with the absence of organised research. It is true that pathological laboratories existed in the universities (under men burdened with other duties); that Government had specially appointed two commissioners, Lewis and Cunningham, to study this subject; that temporary inquiries had been made on leprosy and on certain local outbreaks; and that there was a good Indian medical journal; but these were obviously insufficient to enlighten us on the multitude of strange and mysterious diseases we were called upon to deal with. Why did not Government carry on much more extensive researches? The time-worn answer always was, because they could not afford it. But, surely, if they could afford such a large and expensive medical establishment, they should also be able to afford those researches which were essential to making that establishment effective. Of what use was the one without the other? An inefficient machine is the most expensive of all. Did they think that we medical men should know all about these diseases by intuition? But no!—content with having appointed a legion of "doctors" to fight disease, they never seemed to consider that it was necessary for those doctors to know how to do it.

But this invariable cry of "no funds" was palpably untrue. Many of the administrative and judicial offices in India were being paid above their market value, and were of little public importance compared with medical research. Huge sums, which would pay for such research for years, were being spent on engineering works of only local value. Even within the medical budget, money was being wasted on certain sinecures and useless administrative posts. Indeed, logically it would have been wise in the Government to sacrifice almost anything in the department in order to obtain the necessary information about disease, for the simple reason that without such information the work of the department was largely useless—the old castor-oil treatment and conservancy-cart sanitation had their limits! But what struck me most was the fact that Government failed to make use of literally hundreds of potential investigators whom it could have set to work for almost nothing. The medical services in India must be always kept on something approaching a war footing—that is to say, with a staff in excess of peace requirements. In other words, there must always be a large number of medical men, generally juniors, who in times of peace have little to do and are employed doing it in the military hospitals. I was one of these for about twelve out of my eighteen years' service, and therefore know the facts about which I write. For most of this time my official duties occupied me for less than, say, two hours a day, and I knew scores of my colleagues who were equally busy—we amused ourselves for the rest of the time. Now why did not, and why does not, the Government make use of all these men for investigation? Young, ardent, vigorous, intelligent, "spoiling" for work they were, and are, of the stuff that is now doing most of the scientific work of the country—precisely the same as those who have been labouring in my department in this university—who have even sacrificed their lives for Athena Hygieia. They had, and have, leisure and opportunities unparalleled. A microscope, a few test-tubes, a word from the chief, a little approbation, some evidence that scientific work leads, if successful, to preferment, and the authorities could have had almost for nothing scores of enthusiastic and, I will expressly add, capable workers for the great cause of medical science. But the pigeon-holed report and the official snub awaited us, and we returned disappointed to our idleness.

It is advisable to emphasise this point, because it illustrates the brainless character of much of the administration. In 1884 (I think) I asked my chief if he would like me to investigate fevers during my abundant leisure; he replied that my duty was not to investigate, but to cure—as if we could do the second without the first! Many men have told me that they have received similar replies, and two brothers of mine quite rightly left the naval medical service because of this attitude in the authorities. A man who discourages enthusiastic juniors from doing gratuitous work in addition to their duties must be a fool of a very advanced type, and it is surprising that such men should ever be able to find their way into administrative posts. In addition to the actual discouragement of voluntary research (which I will discuss further presently), the organisation made no adequate provision to ensure scientific efficiency in the staff. There were no examinations for promotion. Leave and opportunities for study could scarcely be obtained, and even now there are difficulties—see, for instance, *British Medical Journal*, May 11, 1907, p. 1156. That first essential, recent scientific literature, was most difficult of access, and the authorities still seem to have made no adequate attempt to improve matters in this respect. Microscopes and bacteriological apparatus were generally wanting, although they are absolutely necessary in tropical clinical practice for the detection of numerous parasites, and this fault has not even yet been entirely removed, to judge by the report of the Army Medical Department for 1905, p. 224. The heads of the department frequently showed ignorance of recent scientific advances, as was apparent from their antiquated statistical methods and regulations for dealing with epidemics and their general lack of ideas; and, lastly, the annual "Records of Service" of officers, upon which their preferment was supposed to be based, was a hopelessly stupid form which made no attempt to distinguish their real scientific and professional ability—so that, as everyone remarked, appointments, like kissing, went by favour!

About the year 1880 occurred that important epoch in human history when we first learned the nature of the great transmissible diseases which afflict us—when Koch and Laveran threw open the gates of medical bacteriology and protozoology, and special laboratories sprang up everywhere in Europe and America, and even at last in Britain. As may be supposed from the foregoing, India was not in haste to follow, and the authorities, who had done so little for research themselves, did not trouble to utilise the researches of others. In 1883 Koch discovered the cause of cholera, that scourge of India, and the discovery should have been immediately followed by numerous official investigations. But, though the disease destroys about half a million people annually in India alone, little was done in that country, and neither the Government nor the people have, I believe, ever taken the trouble to thank Koch for his work. Ten years later, however, Hankin, of Agra, carried out his admirable researches on the mode of propagation, and enunciated his method of prevention by the treatment of wells. This again should have received close official scrutiny with a view to its general adoption or rejection, but from recent reports it appears to be still *sub judice*—as if it were not worth troubling about; and no one has ever dreamed of acknowledging indebtedness to Hankin. Tyhpoid, perhaps the principal enemy of Europeans in India, has never received adequate official inquiry as regards its modes of propagation in that country, and the discoverer of the prophylactic no longer enjoys State employment.

An amœba which is probably the cause of one form of that important disease, dysentery, was well studied for the Indian Government by Cunningham long ago, but the matter was not followed up. The cause of another form was discovered by Shiga in Japan. Some of the most prevalent and distressing complaints in many parts of India are those caused by *Filaria bancrofti*; but Manson's discovery of the carrying agent, a mosquito, though confirmed in India by Maitland, James, and others, has never, to my knowledge, been followed by sufficient practical action. The spirochaetes of relapsing fever, though finely studied by Vandyke Carter, of Bombay, many years ago, still require a determination of their carrying agent. Sprue, ankylostomiasis, beri-beri, unclassed fevers, guinea-worm, and other parasites received little official attention. The case of malaria is perhaps the most astonishing. It causes about a third of the admissions into hospital, and a mortality, directly and indirectly, possibly of some millions a year in India; while nothing does more to hamper military, engineering, and agricultural undertakings. Its cause was discovered in 1880 by Laveran in Algeria—a discovery which enabled us generally to make an immediate definite diagnosis with the microscope. Excepting Vandyke Carter's confirmation, in 1887, literally nothing of consequence was done on the subject in India for fifteen years, though during that period the Italians and others were piling research on research. Not only did these momentous advances seem to be quite unknown to the authorities, but they were almost entirely neglected in the hospitals, and not even the necessary microscopes were provided—equivalent to a failure to supply surgeons with instruments.

My own researches on this subject, commenced about 1901, gave several illustrations of these curious defects. Literature and apparatus were for the most part unobtainable, except by purchase from England, and advice or instruction on scientific details were equally hard to acquire, though arrangements for these should have been organised long previously. In 1895 a rich native State asked for my services to investigate the malaria which seriously incommoded its population, and offered to pay the expenses; but the presiding Civil Service genius vetoed the suggestion. I was even refused ordinary leave of absence to undertake researches at my own cost, although my services could easily have been spared. In 1897, just at the moment when I had at last succeeded in cultivating the parasites of malaria in gnats, and after I had reported this important fact, to my surprise I was suddenly ordered off for months to a place where malaria was almost absent. I was then, very wisely, placed on special duty to continue my work, but, a year later, after I had worked out the life-history of the parasites in mosquitoes, as I could not obtain definite assurance that my special duty would be prolonged, I left the country. Before doing so I gave advice as to the best method of dealing with malaria (by appropriate drainage), but for years no serious effort was made to act upon the advice. It is, or was, usual to thank officers who had been placed on special duty for their services if successful, but mine, I suppose, were not thought to be sufficiently important for this little *douceur*.

I have mentioned some cases of neglect to recognise work done because they involve an important general principle. A scientific administration, if it cannot afford to pay for research, would at least attempt to encourage voluntary investigations by such inexpensive methods as promotion, good conduct pensions, special thanks, and recommendations for State honours. But I cannot remember a single instance in British administration in which the two former have been given for medical researches, even of the most distinguished character (though it is done in America); while the two latter, if offered at all, are offered on the lowest scale. While soldiers, judges, and governors who have merely performed their ordinary duty are often covered with decorations in consequence, the men whose exceptional work will affect the lives of millions now and in the future are not considered good enough. Even in the medical profession it is generally the practitioner, who is already rewarded by his fees, rather than the pioneer, who is lucky if he is not ruined, who receives most of the public recognition. I may add that there are cases where men have actually suffered for their investigations. Many years ago, King, of Madras, succeeded in preparing a good vaccine from a calf inoculated with variola, but was immediately accused of trying to disseminate small-pox, was deprived of his appointment, and was not reinstated without strong efforts on the part of his friends. More recently, Haffkine, in spite of his immense services, lost his appointment because some cases of tetanus poisoning were attributed to his plague prophylactic; and still remains out of employment, although it has been clearly proved that the disaster was not possibly due to him or to his laboratory. The fact is that the public has little sense of the value of scientific investigations, and absolutely no sense of gratitude towards those who carry them out, usually at the cost of much trouble and expense to themselves.

The obvious retribution for all this childish unwisdom is that the public itself suffers on an enormous scale—millions sicken or die from diseases which a little more investigation and scientific administration would probably bring under comparatively easy control. Perhaps the most dramatic example of this was the terrible outbreak of plague in India in 1896. The people besotted with superstitions, the sanitary organisation insufficiently developed on its scientific side, and the Government knowing nothing of these matters and too weak to exert the necessary discipline, were caught unprepared. Although the disease had been raging for two years previously in Hong Kong, the authorities made no sufficient arrangements to exclude it from India, or to detect and suppress it should it effect an entry. When it came it was allowed to remain undetected for months, and was then met only with vacillating counsels and a painful feebleness of action. Only those who are utterly ignorant of the manner, and the only manner, in which epidemics must be fought against will attempt to justify such a story of ineptitude. The result for India alone has been the loss of more than four millions of lives, and the people are still dying of plague at the rate of seventy-five thousand a week!

In 1897–9 we ascertained definitely that the malarial infection was produced by the bites of mosquitoes, and this discovery immediately disclosed several methods of prevention, such as drainage of the breeding pools of the insects, protection from bites by means of gauze, and so on. Considering that the disease is a most serious, ubiquitous, and continuous pest in most tropical countries, causing an untold amount of inconvenience, expense, sickness and death, we had a right to expect that the new knowledge would be immediately acted upon everywhere for the protection of the public, as all Governments possess sanitary officials and funds specially appointed and allotted for such work. I have been watching the progress of events ever since with mingled feelings of amusement and dismay. What a tragi-comedy could be written on the subject! There were the officials, there were the funds, there was the knowledge; but to persuade the first to apply the second for the purposes of the third was often an impossibility. They said they had no funds, that they did not accept the proofs, that there was no malaria in their district, that there were no mosquitoes—any and every excuse. The simple truth was that they did not like the trouble. Years passed, but little or nothing was done. The officials remained in undisturbed possession of their leisure. We wrote, lectured, demonstrated, undertook expeditions, sent up deputations, interviewed ministers; but even now, after nearly ten years, but little has been accomplished compared with what might have been done from the first had our Governments possessed those essentials of good administration, science, and discipline. One asks why, if the State thinks it worth while to employ sanitary departments at all, it does not see that they do the work for which they are paid?

Probably a similar state of things prevails in most departments of our administration. Look, for instance, at our large cities with their unspeakable slums filled with pale, dirty, and unhealthy people lounging round the innumerable public houses, or at the crowded mud hovels of the Indian towns—a constant reproach to our systems of municipal management. Then what clearer evidence of the increasing irrationalism, irresolution, and weakness of party government could we have than that given by the successive Vaccination Acts, culminating in the ridiculous "conscientious objection" and "statutory declaration"; or by the appointment of a Royal Commission to consider the utility of experiments on animals—which is like appointing one to consider the truth of the multiplication table? Or, going into another field, we shall find that military men make precisely similar complaints about want of science and discipline in regard to their department, complaints which are certainly causing grave uneasiness among the more thoughtful of our citizens.

To what is all this attributable? In official life it is probably due to the fact that even notorious inefficiency does not always retard advancement, nor even notorious merit accelerate it, with the result that the upper grades are often filled with men of no ideas who have reached their position, not by public services, but by seniority, wire-pulling, or even by the mere inertia of their mediocrity. Going still higher, it is attributable, I think, to our system of party government, because the ministers who should be constantly engaged in a rational State with the organisation and conduct of their departments are, under party government, constantly engaged in that party warfare which, when carried to the present excess, becomes a mere idle game played for the amusement of the mob. Lastly, it is due to our defective public education, which lays too much stress on literary, philological, and dogmatic trifles, and not enough on the hard facts and still harder methods of science, so that the whole nation is tending to become irrational in thought and unpractical in action. We frequently have to look in vain for that wise and strict organisation without which the vast machine of the State cannot perform its proper work. We hear only the jangling of wheels and cranks out of gear, and the cries of the inexpert engineers who think to mend matters by belabouring each other.

Those who have not considered the subject from my point of view will certainly think that there is too much black in this picture, but I could easily cite innumerable more instances, and, personally, have no doubt of my main proposition, that British administration is generally not scientific enough and not strict enough—it does not sufficiently seek knowledge or enforce action. But I do not, of course, deny that it possesses great virtues. It is imperturbable, scrupulous, just, and pure, and, I may add, is rapidly beginning to attach more importance to science. For example, India, which formerly spent, I suppose, less than one-thousandth part of the medical budget on investigation, is now spending perhaps as much as a hundredth part. More laboratories have been equipped, and there have been official investigations on kala-azar, malaria, Malta fever, plague, typhoid, and other diseases, and on veterinary subjects; the Government has long set an example to other countries in the sale of cheap quinine in malarious areas, and something like a third of many municipal budgets is spent on sanitation, mostly water supply, conservancy, and drainage. Outside India we have recently seen very fine official researches on Malta fever and sleeping-sickness, so that matters are improving. But in my own humble opinion even this is not enough, and I think that the expenditure on research should reach 5 per cent. of that on all medical and sanitary work. Numbers of subjects, such, for example, as measles and scarlet fever in this country, remain almost untouched, greatly to the disadvantage of the public, and in a hundred directions we find action crippled by want of knowledge, and, therefore, correspondingly expensive and inefficient.

But the whole subject of science and the State possesses a most important, and indeed ominous, political significance. The invention of locomotives, by reducing the time required in travelling to about one-third or less, has, so to speak, diminished the world's diameter in the same proportion, and, by bringing the nations more closely face to face, has greatly increased the acuteness of international competition. In this competition scientific organisation becomes more and more vital to success, and in the wars of the last decade we have actually witnessed the complete collapse of two unscientific peoples before their more intelligent adversaries. Now no one will deny that the British stand in the front rank of scientific nations, but it is equally evident that this eminence is due entirely to private individuals, and not at all to the Government, that is, to the party politicians. For years they have allotted only about one three-thousandth part of the national income for scientific work, that is, for obtaining knowledge, equivalent to the annual expenditure for that purpose of six shillings and eightpence by a person possessing a thousand pounds a year; and it may be suggested that the amount of scientific intelligence and knowledge shown in our party political administration should be calculated at about the same rate. Nor can it be contended that the people at large show a much greater interest in science, a much greater knowledge of scientific facts, or a much greater proficiency in scientific habits of thought. Quite recently the Boer war gave us an explicit warning of what such nescience is likely to lead to, and we can only hope that the nation will have the sense to reform its methods in consequence before it is too late. For a full discussion of the subject, however, I must refer the reader to a recent book called "The Problem of National Defence," by my brother, Major Charles Ross, D.S.O. (Hutchinson and Co.), in which he examines from a military standpoint the same defects as I have alluded to above in connection with medical matters. The two cases are really parts of the same problem—how are we to be governed in the future by science rather than by nescience? But whether a nation so wedded to old habits will be able to change in time to save itself is another question which it is impossible to touch upon here.

I fear that some of these remarks will appear to many to be too severe, or perhaps too personal; but I can only state my own opinions, however small their value; and have attempted to do so as frankly as possible, because otherwise there is little use in writing on the subject at all. I should like to add, in conclusion, that my object is not to find fault, but to suggest lines of improvement for the future; and, unfortunately, the one cannot be attemoted without the other.

RONALD ROSS.

INCANDESCENT ELECTRIC LAMPS.[1]

THE closing months of 1906 and the opening months of 1907 are likely to be long remembered by electrical engineers as a period of a remarkable recrudescence of interest in the subject of incandescent electric lamps. For many years the familiar carbon filament lamp has been the only commercial incandescent electric lamp, in spite of its threatened extinction by the invention of the Nernst lamp in 1897–1898. The feeling of uncertainty caused by this discovery was short-lived; after a wealth of prophecy on its probable effect on the industry it was soon found out that months, even years, of experiment were necessary to perfect the Nernst lamps commercially, and the drastic changes recommended to supply engineers were postponed for a time in consequence. Finally, the lamp, capable though it proved of taking a definite place in the art of electric lighting, was found to be hardly even a serious competitor of the carbon filament lamp.

In spite, therefore, of the predictions of 1898, the electrical world settled down with the conviction that the threatened revolution was not destined to be achieved. But in the meantime inventors were busy—foreign inventors that is to say, the English manufacturers being always too busy to invent—and from time to time rumours were heard of other approaching revolutions. Rendered callous, possibly, by the history of the Nernst lamp, little attention was paid to these warnings until the introduction of first the osmium lamp of Dr. Welsbach and then the tantalum lamp of Messrs. Siemens proved the truth of the old saying connecting smoke with fire. Finally came the practical realisation of the tungsten lamp almost simultaneously by Kuzel, Just and Hannaman, and Welsbach, and this for some unknown psychological reason seems to have suddenly awakened English engineers. Once awake they atoned for their long slumber by a copious use of ink, and the technical Press of the period referred to at the beginning of this article simply teems with matter relating to the new lamp developments.

All that is valuable in these articles will be found conveniently crystallised in the papers and discussions in the Journal of the Institution of Electrical Engineers. A paper by Mr. Swinburne on the new lamps opens the latest volume; it is followed by one on light standards and the present condition of high-voltage carbon filament lamps, by Mr. C. Paterson, and the series is rounded off by a paper on carbon filament, Nernst and tantalum lamps, by Messrs. Haworth, Matthewman, and Ogley. Combining these papers with M. Rodet's excellent little book on incandescent electric lamps, the reader can obtain a very fair idea of the present position of this subject.

So far as the carbon filament lamp is concerned, the position is far from satisfactory, as the study of Mr. Paterson's paper shows. It may justly be argued that the test results shown by the author are hardly numerous enough to justify the title. Six lamps each from ten British makers is a small number on which to base a condemnation of British methods, and a lamp-maker who manufactures four or five million lamps a year may rightly complain on being judged by the performance of a chance six. But making all allowance, it must be admitted that there is still much to be desired; nor does it seem probable that a much nearer approach to perfection is likely to be attained without cooperation between manufacturers and supply engineers. To make a lamp for a given voltage to have a definite candle-power and take a definite cur-

[1] "Les Lampes à Incandescence électriques." By J. Rodet. Pp. xi + 200. (Paris: Gauthier-Villars, 1907.) Price 6 francs.
"Journal of the Institution of Electrical Engineers." Vol. xxxviii. No. 182. Pp. 211–371. London: E. and F. N. Spon, Ltd., 1907.) Price 5s.

rent involves the solution during a difficult manufacture of two simultaneous equations, and the percentage of lamps correctly solving them is small. It is the unavoidable outfalls which play such havoc with his balance-sheet, so that it is small wonder if the lamp-maker is tempted to be a trifle lax in his rating. If cooperation existed and station engineers would see the sweet reasonableness of adjusting their supply voltages in different districts or different towns, so as to afford a market for all the lamps a manufacturer produces, it would be possible for him to turn out a better article at a lower price with undeniable advantage to the industry generally.

The information concerning the new lamps is much more meagre and conjectural. It would seem that the osmium lamp is already moribund or dead, and that we have only to reckon with the tantalum and tungsten filament lamps, the former taking 2 to 2·5 watts and the latter 1 to 1·2 watts per candle. The tungsten lamp appears to have a brilliant future before it. A lamp working at a little more than 1 watt per candle brings electric lighting almost to the level of gas for cheapness. The light units, though at present large (30 candles and upwards), are no larger than the gas mantle units, and so it may reasonably be supposed that the public will not object to them, though they undoubtedly do away with one of the benefits of electric light. The chief drawback in England is the low voltage, the lamps being at present only suitable for voltages of about 100. It is conceivable, should lamp-makers fail in producing a high-voltage tungsten filament lamp, that engineers will change back to low voltage, in spite of the eagerness with which they struggled to enforce the change to high voltage a few years ago. The competition of gas is excessively severe, and in some way must be met; at present the tungsten lamp offers the only means of meeting it in interior lighting.

The next few years promise to be of exceptional interest so far as the development of electric lighting is concerned; a radical improvement has long been wanting, and there seems every reason to believe that it has at last been made. The present condition of affairs is full of possibilities, and no one can say what the position will be a few years hence. Perhaps to his interesting account of the birth of the carbon filament lamp M. Rodet may be able to add in his next edition the melancholy tale of its death.

MAURICE SOLOMON.

DR. MAXWELL T. MASTERS, F.R.S.

THE botanical and horticultural world has sustained a severe loss by the death on May 30 of Dr. Maxwell T. Masters, the well-known editor of the *Gardener's Chronicle*, and the author of many botanical works.

Dr. Masters was born in 1833, and was educated at King's College, subsequently removing to Oxford, where he became sub-curator of the Fielding Herbarium under Dr. Daubeny. He was botanical lecturer at St. George's Hospital from 1855 to 1868, and was elected to the fellowship of the Royal Society in 1870. He was a corresponding member of the Institute of France, and was also an officer of the Order of Leopold. He achieved distinction in his earlier days by the publication of his "Vegetable Teratology," a most valuable work, which has been translated into several European languages. But his most definite contributions to botany in later years were those dealing with the Coniferæ, a difficult group which had long interested him, and in which he displayed a remarkable and detailed knowledge. He contributed many papers on the structure and taxonomy of the species to the publications of the Linnean and Horticultural Societies.

But it is especially in matters appertaining to horticulture that he will be best known to most people. His position as editor of the *Gardener's Chronicle* gave him considerable influence, and he always used his best efforts with single-hearted devotion to promote the welfare of horticulture and to look after the interests of those who were engaged in gardening as the practical business of their lives.

He always took the keenest interest in the Royal Horticultural Society, and for many years presided over the Scientific Committee.

He will be sorely missed by a large circle of friends, as well as by many others in the gardening world, to whom his name has become almost a household word.

NOTES.

AT the meeting of the council of the British Association on Friday last, June 7, Mr. Francis Darwin, F.R.S., was unanimously nominated to the office of president for the year 1908–9.

WE have to deplore the deaths at Cambridge, on Friday last, June 7, of Prof. Alfred Newton, F.R.S., professor of zoology and comparative anatomy in the University, and Dr. E. J. Routh F.R.S.

THE ladies' soiree of the Royal Society will be held at Burlington House on Wednesday next, June 19.

SIR WILLIAM PERKIN, F.R.S., has been elected president of the Faraday Society for the session 1907–8.

TWELVE tablets were unveiled in the Hall of Fame of New York University on Memorial Day, May 30, among them being one in memory of Maria Mitchell, the astronomer, and another in memory of Louis Agassiz.

DR. NANSEN, president of the Social and Political Education League, will deliver his presidential address, on "Science and Ethical Ideas," at University College, Gower Street, on June 26. Sir Oliver Lodge will preside.

REUTER reports that a typhoon occurred in the Caroline Islands in the latter part of March and devastated the Olcai group of those islands. A great wave swept the land and buried it under a layer of sand.

WE learn from *Science* that Dr. C. R. Wieland, of the Peabody Museum, Yale University, has left America for a stay of five months in Europe, where he will visit the plant collections of northern and southern Europe for a special study of cycads. The results of his investigations will be published in his second volume on cycads.

A MEETING of the International Council for the Exploration of the Sea is being held in London during the present week. In the absence through illness of the president of the council, Dr. W. Herwig, his place is being taken by the vice-president, Dr. Otto Pettersson, of Stockholm. Among the members of the council and experts now present in London are Dr. P. P. C. Hoek, general secretary, and his assistant, Dr. H. M. Kyle; Dr. Lewald, Prof. Krümmel, Prof. Brandt, Prof. Heincke, Dr. Henking, and Dr. Ehrenbaum, from Germany; Mr. A. Hamman and Prof. Gilson (Belgium); Captain Drechsel, Mr. Martin Knudsen, and Dr. C. G. J. Petersen (Denmark); Dr. Homen and Mr. J. A. Sandman (Finland); Prof. Nansen, Dr. Hjort, and Dr. Helland Hansen (Norway); Prof. Max Weber, Dr. Redeke, and Dr. Wind (Holland); Prof. Otto Pettersson, Dr. F. Trybom, and Mr. G. Ekman (Sweden); Mr. Walter Archer, Prof. D'Arcy Thompson, Dr. Mill, Dr. Garstang, Dr. Masterman, Dr. H. Reid, Mr. E. W. L. Holt, Dr. Wemyss Fulton, Dr. E. J. Allen, and Mr. D. J. Matthews (Great Britain). His Majesty the King will receive the delegates at Buckingham Palace on Friday afternoon. The first formal meeting of the council takes place to-day, June 13, at the Foreign Office, when Sir Edward Grey will open the proceedings. The members of the council are being entertained at dinner during the week by Lord Carrington, the Lord Mayor, the Secretary for Scotland, the Fishmongers' Company, and the Royal Geographical Society, whilst the chairman of the council of the Marine Biological Association will give a luncheon at Christ's College, Cambridge, on June 16. On Monday, June 10, Dr. Pettersson delivered a lecture at the Royal Geographical Society on some features of the hydrographical work done in connection with the international cooperation, and Tuesday and Wednesday were occupied by meetings of various committees of the council.

THE first meeting of the science group of the Franco-British Exhibition, to take place next year, was held on Tuesday. The following were present:—Sir Norman Lockyer, K.C.B., F.R.S., in the chair, Major Baden-Powell, Sir John A. Cockburn, Captain Creak, C.B., F.R.S., Sir David Gill, K.C.B., F.R.S., Colonel Hellard, R.E., Sir Thomas Holdich, Dr. H. R. Mill, Prof. Perry, F.R.S., Mr. F. W. Rudler, Dr. W. N. Shaw, F.R.S., and Dr. T. E. Thorpe, F.R.S. The question of classification was considered under the headings of historical apparatus, instruments of observation, and methods used in exploration of the land, the sea, the air, and the heavens. Special committees were appointed to deal with these subjects.

AT the fifth annual general meeting of the British Academy, held on June 11, Lord Reay presiding, Dr. Henry Bradley, Mr. H. A. L. Fisher, Dr. J. P. Postgate, and Prof. J. Cook Wilson were elected fellows of the academy. The corresponding fellows also elected were:—M. Émile Boutroux (Paris), M. Leopold Delisle (Paris), Prof. B. L. Gildersleeve (Baltimore), Prof. Adolph Harnack (Berlin), Prof. Höffding (Copenhagen), Mr. Justice Holmes (U.S.A.), Prof. William James (Harvard), Prof. Frederick de Martens (St. Petersburg), Prof. Karl Eduard Sachau (Berlin), and Prof. Ulrich von Wilamowitz-Möllendorff (Berlin). In a valedictory address the president, Lord Reay, announced that an anonymous donor had presented to the academy the sum of 10,000*l.*, to endow a fund to be called "The Leopold Schwach Fund" for the furtherance of research in the archæology, art, history, languages, and literature of ancient civilisation, with reference to Biblical study. Lord Reay remarked that this first benefaction was of good augury, for although they might well claim aid from public funds, and maintain that the State should give encouragement to scientific studies promoted by the academy, he would repeat what he said in his first address, viz. that the academy may also stimulate private benefactors, on whose munificence we depend to a large extent in this country for the advancement of scientific knowledge. The British Academy is probably the only academy which is not State endowed, and has not even a domicile, but Lord Reay expressed the conviction that ere long it will be recognised at home as it has been recognised by the sister academies, which have assigned to the British Academy a place of distinction. Sir E. Maunde Thompson was elected president in succession to Lord Reay.

THE adjudicators of the Hanbury medal have decided to award the Hanbury gold medal this year to Mr. David Hooper, curator of the economic and art sections of the Indian Museum at Calcutta. The medal is awarded biennially for high excellence in the prosecution or promotion of original research in the chemistry and natural history of drugs. Mr. Hooper, as recipient of the medal, will also receive the sum of 50*l.*, presented in the name of the late Sir Thomas Hanbury, as an expression of his desire to be associated with the memorial to his brother. He is the author of numerous papers dealing with vegetable materia medica, his latest contribution to scientific literature dealing with the anti-opium plant, and was associated with Brigade-Surgeon Dymock (a former medallist) in the compilation of "Pharmacographia Indica."

IN connection with the celebrations of the bicentenary of Linnæus, described in another part of the present issue, the trustees of the British Museum have had specially printed in honour of the occasion "A Catalogue of the Works of Linnæus (and publications more immediately relating thereto) preserved in the Libraries of the British Museum (Bloomsbury) and the British Museum (Natural History) (South Kensington)." Copies of the catalogue were sent to accompany the addresses presented by Dr. Bather on behalf of the trustees of the British Museum to the Royal University of Uppsala and the Royal Swedish Academy of Sciences at Stockholm. The catalogue was prepared by Mr. B. B. Woodward, the assistant in charge of the general library at the Natural History Museum, with the collaboration of the general catalogue consultative committee as regards the books at South Kensington, and of Mr. W. R. Wilson, of the printed book department, as regards the books at Bloomsbury.

THE annual meeting of the Association for Maintaining the American Women's Table at the Zoological Station at Naples and for Promoting Scientific Research by Women was held on April 20 at Mount Holyoke College. Miss S. E. Doyle, of Providence, was elected president, Mrs. E. L. Clarke treasurer, and Mrs. A. W. Mead secretary. The table of the association at the Zoological Station at Naples has been occupied at different times during the past year by Miss G. Watkinson, Miss F. Peebles, and Miss A. G. Newell. It has been assigned for the spring of 1908 to Miss M. J. Hogue. Nine theses (three of them were sent from foreign countries) were received in competition for the 1000-dollar prize offered for this year. The theses showed wider range of endeavour than those received in the two previous contests, as they dealt with botanical, anatomical, morphological, physiological, and chemical problems. Several were of decided merit, but since, in the opinion of the examiners, no one was of adequate merit to deserve the award, the association decided to exercise its right to withhold the prize. The fourth prize is announced for 1909.

THE Herbert Spencer lecture, on "Probability, the Foundation of Eugenics," delivered at Oxford on June 5 by Mr. Francis Galton, has been published by the Clarendon Press. The author gives a short sketch of the history of eugenics, *i.e.* the "study of agencies under social control that may improve or impair the racial qualities of future generations, either physically or mentally," from his introduction of the word in 1883 to the organisation of the Eugenics Record Office in connection with the University of London. Passing to the application of probability to the theory of eugenics, Mr. Galton gives an interesting outline of a suggested short course of object-lessons in the methods of biometry, the meaning of averages, measures of variability, and so on being explained by reference to actual objects, such as hazel nuts or acorns arrayed like beads on a string. To most people variability implies something indefinite and capricious, and they require to be taught that it can be defined and measured. Mr. Galton then proceeds to point out that human action is guided less by certainty and by probability than by custom, prejudice, or other unreasonable influences; social opinion is the tyrant by the praise or blame of which the principles of eugenics may be expected to influence individual conduct, and public opinion may easily be directed into different channels by opportune pressure. Whenever public opinion is roused it will lead to action, and it is reasonable to expect that it will be strongly exerted in favour of eugenics when a sufficiency of evidence has been collected to make the truths on which it rests plain to all.

A LARGE meeting of people interested in the work and objects of the National League for Physical Education and Improvement was held at Devonshire House on Tuesday. The Duke of Devonshire, in the course of an address to the assembly, described the investigations made by the Physical Deterioration Committee, which collected a great deal of information of the highest importance, and made a number of suggestions of practical importance, especially in the direction of suggesting the steps which should be taken for the purpose of obtaining more accurate information as to the physical condition of the large masses of the people than are at present available. These steps are the indispensable preliminary to any effective action, either by Parliament, or by local authorities, or by the public, towards finding the remedy. One or two of the committee's recommendations relating to the medical inspection of schools and other educational subjects found a place in the Education Bill of last Session, and it is hoped that they will again find a place in an uncontroversial Bill which may be introduced in the course of the present Session. One of the objects of the league is to stimulate that public interest in the matter which seems to have been lacking, and a further object is to assist in organising local effort where it already exists, and where some beginning has been made in the direction of improvement. The meeting was also addressed by Lord Balfour, Prof. Howard Marsh, Sir Gilbert Parker, M.P., and the Bishop of Ripon.

ACCORDING to the *Daily Chronicle*, Giant's Quoit, Veryan, which figures prominently in the legendary and historical records of Cornwall, was reported on June 6, at the meeting of Truro Rural District Council, to have been destroyed by blasting and used for road metalling. The Quoit was delicately poised on a cairn, or beacon of hard rock, and with Giant's Cradle close by was of great archæological interest. A few years ago an effort was made to persuade the Government to appoint an inspector with expert knowledge whose duty it would have been to compile a record of remains of archæological interest and to take steps for their preservation. The frequency of acts of vandalism, such as that in Cornwall last week, shows the need for the appointment of an inspector with archæological knowledge to supervise these national memorials and educate local authorities as to their value.

AN excellent example of the mirage was observed on May 25 seaward of Llanelly, Carmarthenshire, by Mr. John Innes about 3, 4, and 5 p.m. The tide was about full, the day hot, and an inverted image of the land hung in the clouds.

AN auroral display was seen at Pontyates, Carmarthenshire, from 10 p.m. to 11 p.m. on June 6 by the Rev. T. Thomas. He states that the effect on houses and hedges was very weird, and closely resembled the dawn of day; there were no streamers. The phenomenon was also noted at Llanishen, near Cardiff.

THE Brighton and Hove Natural History and Philosophical Society has for fifty years had Alderman C. Clark as its honorary secretary. So long a service in a position of this kind, involving much work and expenditure of time, is very remarkable. In recognition of the active part Alderman Clark has taken in bringing the society to its present prosperous condition, a massive silver salver and an illuminated album containing the names of many past and present members was presented to him at the fifty-third annual general meeting on June 6.

THE statement as to the black tern breeding in Norfolk made in our issue of May 30 is, unfortunately, based on a mistake. It is the black-headed gull—a species still breeding in many parts of the British Isles—that has returned to its old nesting-haunts at Wells.

THE *Museums Journal* for May records the foundation at the Norwich Castle Museum of a section devoted to the study of economic biology, having for its title the Norwich Museum Association. It is desired to make this excellent museum the centre of the scientific life of the county, and to utilise its collections as a basis of instruction in subjects of importance to agriculturists, horticulturists, teachers, students, &c. A few models of insects injurious to agriculturists and horticulturists have already been installed in the central hall of the castle.

As year by year the account of the sugar-cane experiments conducted under the superintendence of Dr. F. Watts in the Leeward Islands is published, it is interesting to observe which of the seedling canes maintain their reputation, and to note the new seedlings that come into prominence. The season 1905–6 referred to in the recent publication issued by the Imperial Department of Agriculture for the West Indies was, like the previous one, characterised by drought, so that the failure in certain cases is attributed to this cause. A strong yellow cane introduced from British Guiana, known as D 625, gave the highest output, probably owing to the dry conditions surpassing such well-known varieties as B 208 and B 156.

A SERIES of analyses of the principal Indian oil seeds made by Dr. J. W. Leather form vol. i., No. 2, of the chemical series of Memoirs of the Department of Agriculture in India. The results, showing an average oil-content varying from 27 per cent. in safflower to 63 per cent. in castor seed, are of primary value to the grower and crusher. The author raises the question as to the deterioration of seed when transferred from one locality to another; thus linseed obtained from various parts of India and grown at Lyallpur in the Punjab gave a reduced proportion of oil. Other reasons may, of course, be advanced for such a reduction, but this explanation is based on the assumption that the yield becomes larger when the plants are acclimatised.

A NEW publication has been launched by the publisher of the *Rivista Geografica Italiana* as a supplement to that journal under the title of *Memorie Geografiche*. The intention is to supply a medium for the publication of monographs or original communications on the subjects of physical geography or terrestrial morphology. Italian geography will receive the preference, but contributions relative to foreign countries will be included. Each number will contain a complete memoir, and a special feature will be made of supplying illustrations and maps. The first number contains a study of the limits of altitude on the slopes of the Comelico Range, by Prof. O. Marinelli. The limits are reckoned for the snow-line, glaciers, shrubs, trees, pastures, barns, &c.

In the report for 1905–6 of the department of botanical research connected with the desert botanical laboratory at Tucson, Arizona, the director, Dr. D. T. MacDougal, refers to a number of problems that are being investigated by the resident staff or with the cooperation of other botanists. In order to test the influence of altitude and climatic factors upon vegetation, small plantations are being laid out at different localities in Arizona and north and south California, where the same plants will be grown and the various modifications noted. Water storage in plants is being studied from several aspects, and some results are already noted. Storage organs are found most abundantly in regions where a scanty rainfall is confined to a short period and during the remainder of the year the precipitation is very slight. A curious storage organ at the base of the cucurbitaceous plant *Ibervillea sonorae* was examined by Dr. MacDougal. Changes in the shape and volume of the "saguara" *Cereus giganteus* were found by Mr. E. S. Spalding to depend mainly on water-content, but partially on temperature and illumination. The development of storage organs on the roots of seedling Opuntias was discovered by Dr. W. A. Cannon.

Two papers by Mr. R. N. Hall, on the prehistoric gold mines of Rhodesia, have been reprinted from the *African Monthly*, and issued by the African Book Company, Grahamstown. In this pamphlet, of forty-five pages, Mr. Hall collects a series of statements to prove that the main working of the Rhodesian gold mines was not due to the Portuguese during the sixteenth to eighteenth centuries, nor to the Arabs and Persians between the tenth and sixteenth centuries. He therefore holds that the mines must have been worked earlier than the tenth century. He maintains that the fragments of Nankin china found in the ruins do not prove that the Zimbabwe was erected in mediæval times, as the specimens were not found under the walls of the temple, and were buried during a subsequent occupation. He emphatically re-states the conclusion that the old mining and ruined temples of Rhodesia date from ancient times, and were due to Semitic immigrants.

The enormous rainfall of 9¼ inches in about half an hour during a thunderstorm at Guinea, Caroline County, Va., on August 24, 1906, is reported in the *Monthly Weather Review* of September last. Mr. E. A. Evans, section director of the Weather Service at Richmond, states that, being much interested in establishing the facts relating to this cloud-burst, he visited Guinea and obtained the following information. There were three "measurements" made in buckets of various dimensions, all in open positions, but the term "measurements" applies only indirectly, as there were no actual measurements taken at the time; the buckets, however, were said to have been full and overflowing. As the storm approached, the lightning became severe, and at the meeting of two clouds, one moving from west and the other from north-east, the rain "poured down in solid sheets." The storm came from the west, and moved almost due northward; the wind was light, and no rain of consequence fell 1½ miles east of Guinea.

Weather in war time was the subject selected by Mr. R. Bentley as his presidential address to Royal Meteorological Society on January 16. To find a new theme after fifty-six previous addresses is of itself not easy; Mr. Bentley's task was laborious, but he showed in a most interesting manner how the operations of war, both on land and sea, were influenced by weather in more than 360 cases, dating from the earliest times. We can only quote a few of the memorable instances. Rain appears to have been the leading factor on land; in A.D. 9 the Roman legions under Quintilius Varus perished in the swamps of Lippe, in Westphalia, owing to the impossibility of moving the wagons; 1870 years later the British experienced disaster from the same cause at Isandlwana, at the hands of the Zulus. On August 13, 1870, Marshal Bazaine excused his inactivity from his inability to cross the Moselle rapidly owing to the flooding of the river after heavy rain. Snow has also played a great part; the author refers to the passage of the Alps by Hannibal, and to the retreat of the French Army from Russia in 1812, among many other instances. Ice has been frequently of assistance; perhaps the most important occasion was the invasion of Denmark in 1658, when Charles X. marched his entire army over the frozen Baltic to besiege Copenhagen. The first exemplification of the result of fog was at the battle of Barnet, on April 14, 1471, when each side outflanked the other without being aware of it; it was owing to fog that Gustavus Adolphus lost his life at Lutzen in 1632. The effect of wind at sea may be exemplified by the buffeting of the various Spanish armadas between 1588 and 1719. In November, 1854, the allied fleets were seriously damaged by the Black Sea storm. This event was one of the principal causes that led to the establishment of storm signals in this country, as a study of the storm showed that if the present system of weather telegraphy had then existed, timely notice of its approach might have been given.

We have received copies of the *plan de voyage* and programme of scientific work of the proposed second Belgian Antarctic Expedition, drawn up by M. Henryk Arctowski. It is proposed to reach the edge of the ice-pack early in the season in about long. 100° W., and to spend some months in making hydrographic and magnetic observations. At a suitable opportunity efforts will be concentrated on making a way through the pack to the Antarctic coast, trusting to the prevailing easterly winds to bring the expedition to the neighbourhood of King Edward VII. Land, where the vessel may be able to put itself *à quai* on the edge of the ice-barrier and to go into winter quarters. Efforts will be made during the following spring to penetrate southward across the ice by means of automobiles. It is intended that the expedition shall be fitted out for three summers and two winters. The scientific programme was discussed at a meeting of men of science held at Brussels on May 4, and on May 12 an enthusiastic meeting was held at Antwerp under the presidency of M. Beernaert, Minister of State, to discuss ways and means.

The Home Office has issued the first part of the general report on mines and quarries for 1906 (Cd. 3478, price 7*d*.). The report contains statistics of the persons employed, output, and accidents at mines and quarries in the United Kingdom. The total number of persons employed was 912,576. The total output of coal was 251,067,628 tons, which is an increase of 14,938,692 tons on that of 1905. The death-rate from accidents per 1000 persons employed was 1·29 at collieries, 1·19 at metalliferous mines, and 1·06 at quarries, the corresponding rates for 1905 being 1·35, 1·45, and 1·04 respectively.

In the *Annals of Mathematics* for April Prof. G. A. Miller contributes a note on the use of group theory in elementary trigonometry. It deals with the various groups of angles the sum or difference of which is a multiple of

15°, 30°, 45°, and its interest would appear to lie, not so much in the use of groups for teaching trigonometry, but rather in the possibilities of using trigonometry for illustrating the elementary study of groups.

IN a paper on the chemical actions of light, M. P. Villard describes in the *Journal de Physique* (vi., May) certain continuation phenomena. An interesting experiment is illustrated showing the effect of green light on photographic papers containing tartaric acid. A sheet of such paper was under-exposed under a stereoscopic negative; one part was then submitted to green and another to violet light. On the green part an excellent image developed, while the violet rays completely fogged the other part. The use of green glass in intensifying prints thus finds a ready explanation.

IN the Journal of the Asiatic Society of Bengal (1907, vol. iii., No. 2) Prof. P. C. Rây describes the preparation of a silver mercuroso-mercuric nitrate by the action of a solution of mercurous nitrite on silver nitrite. The compound formed has the composition $Hg''(Hg',Ag)_2(NO_3)_2$, and is of interest as showing that univalent mercury has the power isomorphously to replace silver. In an article on the "Pursuit of Chemistry in Ancient India," published in the *Modern Review* of Allahabad, Prof. Rây shows, by reference to old Sanskrit writings, the antiquity of the knowledge of chemistry in this country, particularly as regards metallurgical processes and the preparation of medicaments. The existence of an enormous wrought-iron pillar at Katub, near Delhi, which dates back to about A.D. 400, and is larger than any forged in Europe until quite recently, is a striking illustration of the high state of development of the arts in ancient India prior to their decay caused by the introduction of a new caste system under the later religious teachers.

THE uncertainty which still exists regarding the latent heat of fusion of ice forms the subject of a paper by Mr. L. F. Guttmann in No. 4 of the *Journal of Physical Chemistry*. The values obtained by Regnault (79·2) and by Bunsen (80·0) for this fundamental constant differ by more than 1 per cent., and it is contended that Bunsen's result is vitiated by the fact that the value obtained for the density of solid ice at 0° is very variable and uncertain, depending, apparently, on the age of the ice. The value 75·59, re-calculated from Regnault's determinations by introducing certain corrections for the specific heat of ice and water, is considered to represent most accurately the true value for the latent heat of fusion of ice. It would appear, however, that Mr. Guttmann, while referring to the recent work of M. Leduc on the same subject published in the *Comptes rendus* (1906, vol. cxlii., p. 46), has overlooked the more detailed account given by the same author of his investigations in the *Journal de Physique* (see NATURE, vol. lxxiv., p. 41). The difficulties raised by Mr. Guttmann were there dealt with, and, after introducing all necessary corrections, a value of 79·2 was deduced for the latent heat as being in harmony, not only with Regnault's determinations, but also with the corrected values calculated from Bunsen's data.

MESSRS. C. E. MÜLLER, ORME AND CO. have sent us their flow extraction cup apparatus. This apparatus is an improved form of the Soxhlet extractor. Two forms of cup are used; in one case the cup has a siphon, so that the substance which is being extracted is kept covered by the solvent, and a continuous flow of the pure hot solvent is kept running directly through the substance. The other cup, which has a perforated bottom, is placed in an outer cup, which is so arranged that the inner cup stands about 1 cm. above it. By this means the cup is kept continuously surrounded by the hot solvent. We have tested this apparatus, and find the extraction to be both rapid and efficient. The cups are of glass, and are therefore very convenient for weighing the substance both before and after extraction. There is also an arrangement for distilling off the solvent after the extraction is completed.

THE 1907 issue of "The Statesman's Year-book" provides, in the convenient form one has learnt to expect in this invaluable annual, the latest available statistics concerning the States of the world. In some cases the information comes up to within a few weeks of publication. One of the most important of the new features of the volume is the section, which has been entirely re-written, relating to the armies of the various States. Diagrams and tables are included exhibiting the comparative growth of the leading navies in the past with a forecast of the future. Maps are also given showing the Anglo-French Nigerian boundary, the Turko-Egyptian boundary (1906), the new boundary of Aden protectorate, and the increase in value of land and property in Great Britain. This is the forty-fourth publication of the annual, and Dr. J. Scott Keltie, its editor, is to be congratulated on maintaining its high standard of accuracy and usefulness.

A BIOGRAPHICAL sketch of the life and writings of Linnæus, by D. H. Harms, appeared in the *Naturwissenschaftliche Wochenschrift* of May 19.

OUR ASTRONOMICAL COLUMN.

COMET 1907*c* (GIACOBINI).—Circular No. 97 (June 6) from the Kiel Centralstelle gives a set of elements and an ephemeris for the faint comet discovered by M. Giacobini on June 1. From the ephemeris it is seen that the comet is travelling eastwards through Leo, and will pass about $1\frac{1}{2}$ degrees north of δ Leonis on June 14; its brightness is decreasing slowly.

MARS.—In Bulletin No. 26 of the Lowell Observatory Prof. Lowell gives the results of the observations of the south polar cap of Mars made during the favourable presentation of 1905.

Owing to the adverse tip of the planet's axis and the distance of Mars from the earth at the suitable season of the Martian year, the mapping of the southern cap has not previously been attempted. The present communication gives the latitudes of the edge of the snow in successive longitudes as determined from some two hundred drawings. The extent of the snow cap as seen during the presentations from May 10 to August 14 is shown on three diagrams.

The observations indicate that during the beginning of the opposition cloud or mist enveloped the cap, for not until May 15 was the edge of the cap continuously recognised, although snow was seen, in latitude 31°·8 S., on January 25.

In a telegram, published in Circular No. 97 from the Kiel Centralstelle, Prof. Lowell announces that Mr. Lampland has photographed the Martian canals Thoth and Astaboras.

A THIRD ASTEROID NEAR JUPITER'S ORBIT.—From a determination of the orbital elements of the minor planet 1906 VY, Herrn Vladimir Heinrich finds that in this object we have a third member of the Jupiter group of asteroids. According to the elements yet determined, the length of the semi-major axis of the orbit is about 5·19 astronomical units (*Astronomische Nachrichten*, No. 4181, p. 88, June 1).

RADIAL VELOCITIES OF ε AND ζ CYGNI.—Observations made at Bonn during 1904–5–6 indicate that the period of the radial velocity of ε Cygni is possibly shorter than that exhibited by the Lick observations of this star. Prof. Küstner finds a variation, of the radial velocity in regard to the sun, ranging from −6·1 km. (September 23, 1906) to −15·3 km. (October 29, 1904).

The velocities determined for ζ Cygni vary only from +14·3 km. to 15·7 km. (*Astronomische Nachrichten*, No. 4181, p. 87).

MINOR PLANETS DISCOVERED DURING 1906.—In No. 21 (p. 261, May 23) of the *Naturwissenschaftliche Rundschau* Prof. Berberich discusses the minor planets discovered during 1906. In all, the discovery of 126 of these objects was announced, but of these thirteen were undoubtedly objects which had been seen before, whilst sixty-nine await further observation. The orbits of twenty are now known to be elliptical, whilst twenty-one others are probably so; in three cases a circular orbit fits the observational results better. Prof. Berberich gives a comparison between the orbital elements now determined and those previously calculated for the asteroids shown to be identical with bodies discovered earlier. The magnitudes, designations, and details of discovery are also given for those probably having elliptical paths.

THE SPECTRUM OF SATURN.—The results of a photographic study of the spectrum of Saturn, made by Mr. V. M. Slipher during the autumn of 1905, appear in Bulletin No. 27 of the Lowell Observatory. The spectra were taken on plates especially sensitised to the orange-red, and extend to λ 6563. The comparison spectrum, photographed on either side of the planet's spectrum, was that of the moon at about the same altitude, so that differential effects of the earth's atmospheric absorption were eliminated. The following absorption bands appear in the Saturnian spectrum, their relative strengths being in the order given :—λλ 6193, 5430, 6145, 645, 577.

The first named is a very strong band, broad and symmetrical, and traceable down to the band at λ 6145. None of these bands is to be found in the spectra of the rings, although a much weaker absorption than that producing λ 6193 should be indicated if it existed. This points to the conclusion that if the rings possess any atmosphere at all it is much rarer than that surrounding the ball of the planet. No trace of absorption due to the presence of aqueous vapour is shown on the spectrograms.

Mr. Slipher also gives an interesting comparative table of the spectra of the four outer planets, Saturn, Jupiter, Uranus, and Neptune, which indicates that the planets which are similar telescopically have similar spectra. The excellent plate accompanying the paper shows reproductions of the spectra of these four planets taken with various comparisons.

OXFORD UNIVERSITY OBSERVATORY.—The thirty-second annual report of the Savilian professor of astronomy, dealing with the period May 1, 1906, to April 30, 1907, contains but little which is of general interest.

The proof-reading and printing of the astrographic results for the Oxford zone have occupied the time of the staff fully during the past year, and will, with the necessary re-measurement and checking, continue to do so for some few years; consequently, no other serious piece of work can be undertaken. Vols. i. (zone +31°) and ii. (zone +30°), and the greater part of vol. iii. (zone +29°), are now printed, the two former being also bound.

CELEBRATION OF THE BICENTENARY OF LINNÆUS.

THE Linné Fest[1] which has just come to an end was a complete success in every way. The meeting was admirably managed, and the delegates were treated with the most generous hospitality. At Upsala[2] they were especially indebted to the Rector of the University (Dr. Schück) and to Mr. Aksel Andersson, of the University library. The last-named gentleman was tireless in his efforts to rule his troublesome pack, and, indeed, lost his voice in that service, and became as hoarse as a huntsman after a long day. Many of the delegates arrived on May 22; the remainder reached Upsala by special train on the morning of May 23—the first day of the Fest. At the station they were met by the students of the University, looking uncommonly smart in dress coats and white caps, their fuglemen decorated with huge blue and yellow scarves. They struck us as a very fine set of young men as they marched past with their banners and saluted us. The guests were also honoured by the presence of the women students, who wore white caps like those of the men, which they removed in a masculine manner by way of salute to the assembled delegates. At mid-day was held the great meeting in the Aula of the University, when the delegates presented their addresses, heard the oration of the Rector, and listened to Holmgren's hymn in honour of Linnæus and Liljefoss's music to Snoilsky's poem "The Prince of Flowers."

The delegates of each nation formed a group, and the groups went up in alphabetical order, beginning with America and ending with Österrike (Austria), the modified *o* being the last letter in the Swedish alphabet. Each group had a leader, who made a short speech as he passed the Rector's throne, this office being performed for England by Sir Archibald Geikie with conspicuous success. It was a relief to those delegates who are not quite clear about Latin quantities to find that addresses were merely handed in. After their leader's speech the delegates descended into the body of the hall, filed passed the Crown Prince and other Royal personages with bows of varying degrees of elegance, and so got safely back to their seats.

Among the delegates were the following well-known men of science :—Profs. Farlow, Harvard; Warming, Copenhagen; Elfving, Helsingfors; Prince Roland Bonaparte, Académie des Sciences, Paris; France being also represented by MM. Flahault, Giard, and Mangin; Profs. Moll, Holland; Wille, Christiania; Borodin and Palladin, St. Petersburg; Casimir de Candolle, Geneva; Engler, Berlin; Goebel, Munich; Haeckel, Jena; Pax, Breslau; Peter, Göttingen; Pfeffer, Leipzig; Wiesner, Vienna. Halle had the distinction of being represented by a mathematician, Prof. Wangerin, who came as the president of the Leopold. Car. Academy. The delegates from "Storbritanien och Irland" were :—Sir A. Geikie, Royal Society; Dr. Bather, British Museum and Zoological Society; Mr. Carruthers, Linnean Society; Mr. F. Darwin, Cambridge and the Royal Society; Mr. Daydon Jackson, who was personally invited; Mr. Morice, Entomological Society; Prof. Poulton, Oxford; Lieut.-Colonel Prain, Kew Gardens; Dr. Rainy, College of Physicians, Edinburgh, and the University; Dr. Church, Edinburgh. The Society of Arts of London was represented by the Swedish professor Sjögren. Great Britain was in the proud position of having more delegates than any other nation. Prof. Bailey Balfour, whose name occurs on the official list, was unfortunately absent.

At the conclusion of the meeting the delegates were presented to the Crown Prince, who afterwards conferred the Order of the Polar Star on some of them, among whom were Mr. Daydon Jackson and Prof. Poulton.

The festivities were not nearly concluded. There was a concert at 4.30 p.m. given in the Botanic Garden by the students, whose remarkably finished singing was much admired.

In the evening the guests were divided between the hospitable tables of the Rector and the Archbishop. At the Rector's party, the toast of the Linnean Society was given by our host, whose generous reference to the Linnean treasures in London was warmly appreciated by the Englishmen present. The evening concluded with a grand reception in the University buildings.

On the following day (May 24) was held a great "promotion" of doctors, which by a revival of ancient custom took place in the cathedral. The building was filled with a great crowd, and the students again gave a picturesque touch by their massed white caps. The proceedings began with the creation of thirty Swedish D.D.'s named by the King and "promoted" by the Archbishop.

Then came Doctors of Law and Medicine, among the latter being Dr. Rainy, of Edinburgh. Prof. Haeckel was in a class by himself as a Jubilee Doctor. Each M.D. was presented with a remarkable headdress, being, in fact, a tall hat covered with pleated black material, and with these they were respectfully crowned by the promoter. A re-

[1] An interesting gathering took place on May 21 at Råshult, the birthplace of Linnæus, where a ceremony was arranged, including a visit to the church in which he was christened. Many delegates attended at the invitation of the Rector of the University of Lund.

[2] Modern spelling reform has converted the name to Uppsala.

markable feature in the ceremony was the firing of a cannon as each candidate was promoted. The delegates were reminded of another Scandinavian land the King of which gave command to "let the kettle to the trumpet speak, the trumpet to the cannoneer without." In Upsala the trumpet and kettle-drum seemed to be replaced by the electric button.

The Doctors in Philosophy were promoted by Dr. Tycho Tullberg, a collateral descendant of Linnæus. The ceremony consisted in placing a gold ring on the finger and a "laurel crown" on the head of each candidate; in the case of the honorary doctors the crown was made of leaves from a bay tree planted by Linnæus. The British doctors were Mr. Carruthers, Mr. F. Darwin, Sir A. Geikie, and Mr. Daydon Jackson. Among the Swedish doctors was the deservedly popular Prince Eugen, who has made for himself a reputation as an admirable landscape painter.

In the evening there was a great banquet in the Aula of the University, and an evening entertainment given by the students.

On Saturday, May 25, the delegates departed for Stockholm, where the Linné Fest was continued by the Royal Swedish Academy under the auspices of Count Mörner, the president. Here again the delegates were met with excellent arrangements and a warm welcome. A solemn meeting of the academy was held at which the delegates presented addresses, speeches were made, and a cantata was sung, of which the words were by G. Retzius, the music by Valentin. To the general satisfaction of all the delegates, and to the especial delight of those from Britain, the Linnean gold medal of the academy was awarded to Sir Joseph Hooker, and handed to Sir Rennell Rodd, the British Ambassador, for transmission to England. A beautiful bronze medal given to each delegate forms a particularly attractive memento of a memorable occasion.

In the evening a great banquet was given, at which the speeches were made by the president of the academy (Count Mörner), the Crown Prince, Prince Roland Bonaparte, and the Prime Minister. Later in the evening the students gave an entertainment at Skansen, the beautiful zoological and ethnological garden of Stockholm.

One of the most striking features of the Fest was the interest shown in it by the Royal House. The Crown Prince and Princess and other members of the Royal Family were present at the meetings and banquets both at Upsala and Stockholm. The Crown Prince mingled with the guests with a kindness that was much appreciated by the delegates, and the same may be recorded of the other members of the Royal House. A garden-party given by the Crown Prince on Sunday was somewhat marred by the break-up of the fine weather which had added so much to the effect of the Upsala gathering.

Finally must be mentioned the generosity of the authorities of Upsala and Stockholm in presenting the delegates with a valuable reproduction of the portraits of Linnæus and a reprint of his works, including a facsimile of the first edition of the "Systema Naturæ."

Celebration at the Linnean Society.

The reception held by the Linnean Society of London on Friday, June 7, as part of its celebration of the bicentenary of Linnæus, was attended by nearly three hundred guests, many of whom were ladies. The Swedish Minister, some of the Swedish Legation, and several other Swedes were amongst those present. The president of the society, Prof. Herdman, F.R.S., and Mrs. Herdman, received the guests in the library, and prominent among the exhibits were many interesting personal relics of the great naturalist—selections from his herbarium, cases of Lepidoptera, Coleoptera, fishes, and shells, including the celebrated artificial pearls produced by the native fresh-water mussel.

The beautiful medallion by Inlander, which was copied by Josiah Wedgwood, occupied a conspicuous position, and was surrounded by a laurel wreath from the recent festival held at Upsala on May 23 and 24, which was lent by one of the British representatives who received an honorary degree there. A large series of medals which had been struck at various times in honour of Linnæus also were set out in the same case; they included Count Tessin's medals of 1740 and 1758, Ljungberger's large medal, struck by command of Gustaf III. in 1778 on the death of Linnæus, and many of a later date. Recent medals were also shown, such as the Linnean medal of the society, a special copy of which had been presented to the Royal University of Upsala last month, and, latest of all, a bronze copy of the bicentenary medal, struck for the Royal Swedish Academy of Sciences, and awarded on May 25 to Sir Joseph Hooker, G.C.S.I., F.R.S. Two cases contained the correspondence between Linnæus and our own countryman, John Ellis, F.R.S., the letters on both sides being shown; manuscripts of great interest, copies of books interleaved and copiously annotated by Linnæus, his Lapland diary, and his note-book for the eventful year which witnessed his departure from Sweden to take his medical degree at Harderwijk, and the issue of his "Systema Naturæ" in 1735. The foregoing were shown by the Linnean Society, in whose possession they have been since the death of Sir J. E. Smith, the first president, in 1828.

Dr. Tempest Anderson displayed photographs showing the growth of vegetation in St. Vincent since the volcanic eruption in 1902; Prof. Dendy, preparations from his New Zealand specimens; Mr. A. D. Darbishire, Mendelian phenomena; Miss Benson and Prof. F. W. Oliver, the spermatozoid bodies in the fossil seeds of Lagenostoma and Physostoma; Prof. Farmer, apogamic growths from fern-prothallia; and the president, specimens of pearl oysters and plankton gatherings taken during the present spring. Animated photographs of plant-life were shown by Mrs. D. H. Scott, and many other objects of great interest were on view in the library and the galleries.

During the evening a series of short lectures was given in the meeting room by the following:—Prof. Poulton, Prof. Herdman (who prefaced his remarks by a short discourse on the present Linnean celebration), Lieut.-Colonel Prain, and Mr. F. J. Lewis. The rooms were not deserted until nearly midnight.

THE ROYAL OBSERVATORY, GREENWICH.

THE report of the Astronomer Royal to the Board of Visitors, on the work done at the Royal Observatory during the period May 11, 1906, to May 10, 1907, was presented on Saturday, June 8, when the annual visitation took place. A brief summary of this report is given below.

In addition to the routine observations, the transit-circle was employed on a number of stars, of the ninth magnitude and brighter, which may be used as reference stars for the Oxford astrographic zones; 7704 transits were taken during the year.

The second nine-year catalogue (epoch 1900) will probably be ready for press before the end of the current year, and will be divided into two parts, (1) fundamental and zodiacal stars, (2) astrographic reference stars.

The reflecting prism for illuminating the field of the altazimuth has been replaced by a smoothly ground reflector of opal glass, cemented on to the object-glass, and this gives a much more uniform illumination. The observations of the moon and of the lunar crater Mösting A were continued, and, discussed with the similar observations carried out at the Cape Observatory, should give an improved value for the lunar parallax.

The new working list for the 28-inch refractor primarily includes double stars discovered by Hough, and during the year 400 pairs were observed, fifty-eight of them having a separation of less than $0''.5$. The equatorial and polar diameters of Jupiter were measured by the methods described in the previous report, these measures being intended to supplement those made during the opposition of 1895–6. The diameters of the satellites were also measured on two nights with the filar micrometer.

When the 30-inch mirror on the Thompson equatorial was taken out for re-silvering, in November, 1906, it was found to be slightly loose in its cell, so, before re-mounting, twelve wedges of *lignum vitae* were inserted symmetrically round the mirror, and appear to have eliminated the slight movement.

Fifty-five photographs of the sixth, and eleven photographs of the seventh, satellite of Jupiter were secured with the 30-inch reflector, together with 170 photographs of minor planets and comets and twelve of various nebulæ. Of the latter, that of M 31 (Andromeda) and one of the Ring Nebula in Lyra are especially good.

The discussion of the photographs of Eros taken during the opposition of 1900–1 was completed, and a value for the solar parallax, in close agreement with the previously accepted value, was deduced.

With the astrographic telescope 188 supplementary photographs were taken, and 133 of them were passed as satisfactory. Positive copies of the plates covering zones 71°–74° are now completed, and of the 461 chart plates necessary to cover the remaining zones, 75° to the pole, seventy-five have to be repeated for the purpose of reproduction. Vol. ii. of the Greenwich Astrographic Catalogue is now complete, except for the introduction, which will contain the constants for the plates, and these have now been computed. For the area included in zone 81° (from 6h. to 24h.) and the zones 82° to the pole, viz. 254·7 square degrees, the 40m. exposure plates show 75,683 star images, or 297·2 per square degree; in the B.D. the corresponding area (1°) includes 15·7 stars. About 13,000 enlarged prints of the chart plates were made during the year.

During the period covered by the report, the sun was photographed on 210 days, and for 1906, including the Indian and Mauritian negatives, the daily photographic record of the sun's surface was complete except for one day. Twenty-three photographs of portions of the solar disc were secured with the 26-inch photographic refractor, fitted with a negative enlarger, the scale being such as to give a solar diameter of 30 inches.

The magnetic observations were carried on as usual, the principal results for the magnetic elements for 1906 being

Mean declination	16° 3′·6 W.
Mean horizontal force	4·0174 (in British units)
	1·8524 (in metric ,,)
Mean dip (with 3-inch needles)	66° 55′ 17″

There were no days of "great" magnetic disturbance and eight of lesser disturbance.

The mean temperature for the year ending April 30, 1907, was 50°·5, or 0°·9 above the average for 1841–1905, the highest and lowest shade temperatures recorded being 94°·3 (August 31) and 19°·8 (December 30) respectively. Of the 4457 hours that the sun was above the horizon at Greenwich, the Campbell-Stokes instrument recorded 1687 hours of bright sunshine.

The total rainfall was 0·26 inch below the average for the sixty-five years 1841–1905, being 23·86 inches, whilst the number of "rainy days" was 148.

The performance of the chronometers sent in for the annual trial was hardly up to the high standard of recent years, and of the fourteen pocket-chronometers submitted none came up to the standard of purchase. The next trial for chronometers will commence on June 15, and for chronometer watches on August 3.

In concluding his report, the Astronomer Royal refers to the threatened danger to the astronomical efficiency of the observatory occasioned by the L.C.C. generating station near by, the principal point being the recommendation of the committee appointed to consider the matter, that the conditions be reviewed after the lapse of two years. Experiments made last summer showed that the vibrations from the present installation can be effectually damped out by keeping the film of mercury in the amalgamated trough as thin as possible, but there still remains the danger that these vibrations may so cause the large telescopes to oscillate that delicate observations, such as close double-star work, may suffer materially.

A more insidious danger is that the heated gases from the chimneys may affect the accuracy of star observations on the northern meridian, and in that case the errors would not be discovered until the observations were reduced, when, possibly, it would be impracticable to repeat the observations.

TWO HEAVY SEISMOGRAPHS.

TWO new seismographs devised by Dr. Wiechert are now on sale by Spindler and Hoyer, of Göttingen. The fact which will strike most seismologists is the magnitude of the "stationary" mass employed. The horizontal pendulum uses a "stationary" mass of 17,000 kilo., nearly 17 tons. The mass is composed of barytes contained in a cylindrical sheet-iron vessel with a flat bottom. Its dimensions are 2 metres in diameter by nearly 2 metres in height, and, being intended to have freedom of movement horizontally, the vessel is suspended by three iron rods of 3 cm. diameter, the elasticity of which allows the necessary freedom. The next striking feature is the multiplication with which the thrust arm moves the indicator point, and this is 2200! It is brought about by means of four levers, multiplying $5 \times 5 \times 5 \times 17\frac{1}{2}$. The loss owing to the inertia and elasticity of the connecting system amounts to 5 per cent. only. "The instrument renders specially important service in the small European earthquakes where the rapid oscillations are more prominent." It is clear that this statement is justified. For local disturbances and extremely rapid elastic vibrations the instrument should be of great service, but, with such a multiplication, one is compelled to wonder how much the machine requires to be isolated in order to avoid the disturbance due to traffic. It is not surprising to find in a specimen seismogram tremors due to a gas engine $2\frac{1}{2}$ kilometres distant. Other drawbacks to the use of the pendulum are the price, 5000 marks, and the number of times the paper must require to be changed. These purely practical considerations must have weight with anyone who has real work in view.

The vertical seismograph has a "stationary" mass of 1300 kilograms, about one and a third tons. Even this is great as compared with the usual one to two hundred pounds. The multiplication, 160, is also large when one thinks of the usual 12 to 20. "The vertical apparatus often indicates the first movements of very distant earthquakes better than even the 17,000 kilo. pendulum, which multiplies 2000 times; so the Schlüter result is confirmed, from which follows that in the case of first indications we have to do with longitudinal movements." Thus runs the prospectus. The price of this pendulum, too, 2800 marks, is rather prohibitive, although the workmanship in both leaves little to be desired.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. Graham-Smith, Prof. Nuttall, and Prof. Woodhead have been nominated to represent the University at the International Congress of Hygiene and Demography to be held in Berlin in September.

The general board of studies has approved Alexander Scott for the degree of Doctor in Science.

Profs. E. H. Liveing and H. Louis have been nominated examiners in the application of science to the art of mining, and Mr. C. T. Heycock an examiner in metallurgy for the diploma in mining engineering for the examination to be held in the Michaelmas term, 1907.

The Balfour studentship will be vacant at Michaelmas next. The names of applicants, together with such information as they may think desirable, should be sent on or before October 1 to the secretary, J. W. Clark, Registry of the University, Cambridge. The studentship is of the net annual value of 200*l*., or such larger sum as the University may from time to time determine. The student need not be a member of the University, and during his tenure of the studentship is required to devote himself to original biological inquiry.

The Vice-Chancellor announces that the advisory committee of the Colonial Office for the tropical diseases research fund recommends that a grant of 100*l*. for two years should be made from the fund to assist in establishing a research studentship in medical entomology in Cambridge, and that Lord Elgin is prepared to approve of the proposal. Candidates for the studentship are requested to send in their applications to Prof. Nuttall, 3 Cranmer Road, Cambridge, on or before Monday, June 17.

LIVERPOOL.—Mr. J. K. Catterson-Smith has been appointed demonstrator in electrotechnology, and Dr. G. D. Hope demonstrator and assistant lecturer in organic chemistry.

From the interest of funds bequeathed to the University by the late J. L. Bowes, the council has decided to allot 100*l*. per annum towards the permanent endowment of the lectureship on organic chemistry.

Grants have been made out of funds provided by H.M. Treasury for the following researches at present being carried out in science laboratories:—for investigation of absorptive properties of vegetable fibres; for plates to illustrate a monograph on the edible crab; for materials used in the investigation of Röntgen radiation; for apparatus for research on brass annealing; for apparatus for investigating high-temperature combustion; for research on three-membered heterocyclic derivatives; for research on continuous and momentary arcs; for suction of gases in pipes; and for research on blood pressure.

The University has decided to confer the degree of D.Sc., *honoris causa*, at the forthcoming graduation in July, on the following men of science:—Prof. A. R. Forsyth, F.R.S.; Prof. F. Gotch, F.R.S.; Dr. C. L. A. Laveran, Chef de Service Honoraire of the Institut Pasteur, Paris; Sir Oliver J. Lodge, F.R.S.; Sir John Murray, K.C.B., F.R.S.; Prof. W. Osler, F.R.S.; Prof. W. Ostwald; Sir William Ramsay, K.C.B., F.R.S.; and Sir Henry E. Roscoe, F.R.S. The degree will be conferred on Dr. Laveran *in absentia*.

MANCHESTER.—His Grace the Duke of Devonshire, who for many years has held the office of president of the Owens College, and more recently of the University, has been elected Chancellor of the University upon the resignation of Earl Spencer. The installation ceremony has been fixed for July 10, and on this occasion a number of honorary degrees will be conferred. Prof. E. Rutherford, F.R.S., whose appointment as Langworthy professor of physics and director of the physical laboratories has already been noted, is now in Manchester making arrangements for taking over the duties of his office in October.

Prof. Arthur Schuster, F.R.S., has been offered, and has accepted, an appointment as honorary professor of physics; his continued cooperation in the work of the department is thus assured.

Mr. W. H. Jackson, who has for the past five years held the position of assistant lecturer in mathematics, has been appointed assistant professor of mathematics at Haverford College, Pa., U.S.A.

OXFORD.—Mr. D. L. Chapman has been selected for the official fellowship in natural science at Jesus College. Mr. Chapman was an exhibitioner of Christ Church, and since 1897 has been a demonstrator in Prof. Dixon's laboratory at the Victoria University of Manchester.

ON Thursday, June 6, the Buckinghamshire Education Committee closed all their schools so that the teachers could attend a conference, organised by Mr. C. G. Watkins, at Aylesbury, at which a number of the delegates of the Federal Conference on Education were present. Among the subjects discussed was the question as to how the rural schools might be kept in touch with the progress and development of educational life. An important difference between rural schools in the colonies and in the mother country was brought out. In the former the teachers are the best teachers, and quickly move as they are promoted according to the work that they can do. Here the best teachers go at once to the better-paid posts in towns; those in the rural districts stay where they are, as there is no system of promotion. Among those from the colonies who spoke on this and other topics were the Hon. Colin Campbell (Minister of Education, Manitoba), Mr. Frank Tate, I.S.O. (Victoria), Mr. A. Williams (South Australia), Mr. J. A. Douglas (Southern Nigeria). Mr. W. M. Webb pointed to the use that could be made of museums fixed and circulating in the training of teachers, particularly in rural districts, and he mentioned the resolutions passed at the Federal Conference with regard to a collection that should bring before teachers fresh methods and new appliances.

THE board of trustees of the University of Illinois has voted that the Engineering Experiment Station be authorised to offer ten research fellowships in the college of engineering each of an annual value of 100*l*. A pamphlet received from the University gives information concerning these fellowships, and describes the facilities for experimental work now available in the college of engineering.

WE have received a copy of a brochure, presented to the British editors on the occasion of their visit to Berlin last month, which provides an instructive account of the Handelshochschule founded by the Berlin Merchants' Corporation. It is the only institution of its kind in Germany which owes its existence to the efforts of a body of business men, and is maintained solely at their expense. The school is particularly meant for commercial students who have gone through a regular apprenticeship, and, besides, have attained that degree of general training which entitles to the privilege of serving the shorter term of one year in the German Army or Navy. Exceptions are made in the case of students otherwise suitably prepared. The object constantly held in view is "to provide instruction and opportunities for research in the sciences necessary and most useful for a commercial career." The approved course of work extends over two years. The school was opened in October, 1906, and during the first session 1371 persons were in attendance on lectures. The inauguration of the scheme serves to show that German merchants possess initiative enough themselves to supply any deficiency which may exist in the State system of education.

A DEPUTATION from the British Medical Association, the Board of Hygiene and Temperance, and the 1904 Committee of the Medical Profession, waited upon the President of the Board of Education on June 6 to urge the teaching of hygiene and temperance in all schools and training colleges under the Board, and the establishment of a medical bureau in the Education Department. Mr. McKenna, M.P., in reply, said that the chief difficulty is to obtain competent teachers, and the next is to get the teachers to teach the children. To come into immediate contact with the schools, it is necessary to have teachers to teach children in 21,000 schools, and these are not available. As to medical inspection, the Bill dealing with this subject has not yet passed through the House of Commons, but it is to be pressed, and Mr. McKenna believes it will obtain the support of the House and become law. Until the Bill is passed it would be undesirable to declare in advance what the settled policy of the Board is as to the details of carrying out the proposals of the Bill. Naturally the desire of the Board will be to have expert medical advice, if the Bill passes, upon the various topics with which it is concerned, but no definite lines could be laid down now on the proposal for the establishment of a medical bureau. On the general question, Mr. McKenna expressed himself as heartily in sympathy, as the whole of the Government are, with the objects laid before him. It is most desirable for children in elementary schools to be taught hygiene and temperance.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 18.—"On Reciprocal Innervation of Antagonistic Muscles." Tenth note. By Prof. C. S. **Sherrington**, F.R.S.

This communication furnishes fresh examples of reciprocal innervation of antagonistic muscles. These examples are taken from the great flexion-reflex of the leg. The paper shows that in that reflex the extensors of the ankle are inhibited concurrently with excitation of flexors of the ankle. It also shows that the adductors of the hip are relaxed by inhibition concurrently with reflex contraction of the abductors, and that the external rotators of the hip similarly are relaxed by inhibition concurrently with contraction of the internal rotators. These new instances of reciprocal innervation of antagonistic muscles are important, because of the desirability of seeing how far reciprocal innervation may be considered a general or widespread principle in the coordination of muscular actions.

The communication next proceeds to show that the muscles of the limbs are divisible into two groups; in one group the reflex action provocable excites the muscle itself and relaxes by inhibition its antagonist muscles. To this group belong, among others, the following muscles:—*biceps cruris, biceps brachii, gracilis, tensor fasciae femoris, semi-tendinosus, tibialis anticus*, and *gluteus minimus*. In the other group the reflex action provocable from the nerve of the muscle inhibits that muscle itself while exciting reflex contraction in the muscles antagonistic to it. In this group come the following muscles:—*vastocrureus, gastrocnemius, soleus, triceps brachii, supraspinatus scapulae* and *anconeus, adductor magnus*, and *quadratus femoris*.

The communication finally reverts to the after rebound of contraction which, as pointed out in a previous communication on this subject, very usually follows reflex inhibition of the limb muscles. It is shown that this after-rebound to contraction is of central origin, and can be produced by direct electrical excitation of the cross-section of the spinal cord itself. The rebound contraction is illustrated by a graphic record of the rebound contraction following reflex inhibition of the gastrocnemius muscle in the cat.

Geological Society, May 15.—Sir Archibald Geikie, Sec.R.S., president, in the chair.—The origin of certain cañon-like valleys associated with lake-like areas of depression: F. W. **Harmer.** In glaciated regions, as shown by Prof. P. F. Kendall, the invasion of a district by an ice-sheet would tend to obstruct the natural drainage, producing lakes, of which the outflow might take place over the advancing ice, between the ice and the hillsides, or it might escape laterally, in a direction at right angles to the longest diameter of the lake and to the course of the pre-existing stream. Overflow channels would assume a gorge-like character, and would present a comparatively recent appearance. During the Glacial epoch the North Sea ice appears to have invaded the plain of the Witham and the valleys of the Welland, Nene, and Ouse, over-riding also the higher land separating them; the Tees ice-stream moved up the Trent basin to the vicinity of Derby, and thence, inosculating with the Derwent glacier, up the Soar valley towards Leicester and Rugby; the Irish Sea ice passed into the northern part of the basin of the Lower Severn; ice from the Brecknock Beacons passed towards the Bristol Channel, and, combined with Irish Sea ice crossing Pembrokeshire from St. David's Head towards Cardiff, may have caused the accumulation of sedentary ice in the Severn valley. After considering the case of Lake Pickering and the Malton Gorge as a typical example, the author passes on to Lake Shrewsbury and the gorge at Ironbridge. Pre-glacial drainage of the upper Severn and Vyrnwy was probably northwards; when a glacial lake was first formed over the Cheshire plain it may have drained towards the Trent, possibly by Rudyard and Madeley; when these gaps were closed, the lowest outlet seems to have been towards the south, and the Severn Gorge at Ironbridge was cut. Lake Trowbridge and the gorges of Clifton and Bradford-on-Avon are next dealt with, the latter being attributed to the overflow of a glacial lake occupying the Trowbridge plain, and the former to the blocking of the Flax-Bourton valley by ice. The gaps in the Jurassic escarpment at Lincoln and Ancaster are explained as overflows from a lake caused by the damming of the Trent outlet towards the Humber. This gave rise at first to the more northern, and later to the southern gorge. Finally, Lake Oxford and the Goring Gap are dealt with in considerable detail.

Royal Microscopical Society, May 15.—Lord Avebury, F.R.S., president, in the chair.—Diffraction rings due to a circular aperture: Prof. A. W. **Porter** and P. F. **Everitt.** The differences between the theoretical and the observed radius of the first dark diffraction ring mentioned in Mr. Nelson's paper, read March 21, 1906, were considered to be due to the method of observation, because the values obtained from observations made by Mr. Everitt, under the best conditions, were in very close agreement with theory.

Zoological Society, May 28.—Dr. J. Rose Bradford, F.R.S., vice-president, in the chair.—The form of the brain in the extinct lemurs of Madagascar, with some remarks on the affinities of the Indrisinæ: Dr. G. Elliot **Smith.** This formed a supplement to the paper on recently discovered subfossil Prosimiæ from Madagascar, read before the society by Mr. H. F. Standing on March 19. From an examination of cranial casts of an extinct species of lemur and of Mesopropithecus and Palæopropithecus, and of brain casts of Nesopithecus and Megaladapis, in conjunction with information derived from the study of recent lemurs, the author had arrived at the conclusion that Propithecus, Avahis, Indris, Mesopropithecus, Nesopithecus, Palæopropithecus, Chiromys, and Megaladapis must be regarded as the diversely specialised members of one family, all of which exhibited in greater or less degree distinct evidence of retrogressive changes from a more primitive and also more pithecoid type.—Some notes on the abdominal viscera of Chlamydoselachus: Mrs. O. A. Merritt **Hawkes.** Observations on the alimentary canal, including the associated glands, the dentition, and the spiral valve of this fish. The results were compared with the accounts of these organs previously given by Garman and Günther, and attention was directed to any discrepancies which had been noted. The female reproductive organs were also examined, and evidence was cited supporting the conclusion that Chlamydoselachus was viviparous. The interesting discovery was recorded that a vestigial seventh branchial arch was present.—Second report on the batrachians and reptiles collected in South Africa by Mr. C. H. B. Grant: G. A. **Boulenger.** The report dealt with fifty-eight species—nineteen Batrachia and thirty-nine Reptilia—of which two were described as new.—Hydroids of the Cape Verde Island marine fauna collected by Mr. Cyril Crossland: J. **Ritchie.** The collection contained twenty-seven species, and added considerably to our rather meagre knowledge of the hydroid fauna of the northerly portions of the west coast of Africa. The majority of the specimens hitherto described from Cape Verde Island had been obtained in comparatively deep water, but the present collection was a littoral one, and contained examples of only one species before recorded from the locality, viz. *Sertularia versluysi*, Nutting. Of the twenty-seven species represented in the collection eighteen were already known, while the remaining nine were described as new to science. Of the new forms, the most interesting was a gymnoblast, the peculiar branching and simple gonophore of which separated it so widely from known genera that a new genus had been established for it.

Cambridge.

Philosophical Society, May 6.—Dr. Hobson, president, in the chair.—The influence of a strong magnetic field on the spark-spectra of lead, tin, antimony, bismuth, and gold: J. E. **Purvis.** The strength of the field was 40,000 units. The more important results were:—(1) Comparing the metals *separately*, there were lines belonging to the same type in having the same number of constituents, the same ratio of intensities of these constituents, the same polarisations, and the same distances apart when represented on the same scale of vibration numbers. (2) Comparing the metals *with one another*, there were lines which were comparable similarly, and this was particularly well marked amongst lines which were divided into four. (3) There were lines of Au, Sb, and Pb yielding four constituents which were essentially identical in every way with lines of the principal series in the spectra of Cu and Ag. (4) The constituents of some of the triplets of lines in the spectra of the different metals were also comparable with the constituents of some of the quadruplets in that the constituents vibrating perpendicular to the lines of force were polarised in the same direction and had the same distances apart when represented on the same scale of $d\lambda/\lambda^2$.—The β rays from potassium: N. R. **Campbell.** An account is given of an investigation into the nature of the rays from potassium which were described in a recent paper by the author and Mr. Wood. The experiments were directed mainly to showing that the rays carry a charge, and must therefore be β rays, since their penetration indicates that they cannot be α rays. For this purpose the deviation of the rays in an electrostatic field was observed and compared with that of the β rays from uranium. The conclusion reached in the earlier paper is confirmed, that the potassium rays are β rays the average velocity of which is less than that of the β rays of uranium. Incidentally, convincing proof was obtained of the photographic action of the rays. It seems beyond doubt that potassium must be classed among the radio-active elements.—The number of electrons in an atom: N. R. **Campbell.** A somewhat speculative calculation of the number of electrons in a radio-active atom based on the energy liberated in radio-active processes. The estimation of the average energy of an intra-atomic electron is based on observations of the velocity of the slow δ rays from radium. The conclusion is reached that the number of electrons is probably of the same order of magnitude as that deduced on the assumption that the whole mass of an atom is the sum of the masses of the contained electrons. General arguments are offered for the view that the number of electrons in a radium atom cannot be less than 1300, and is probably very much greater.—The longitudinal impact of metal rods with rounded ends: J. E. **Sears.** The paper deals with the determination of the velocity of propagation of elastic waves in metal rods by means of observations on the duration of their longitudinal impact. The experiments were carried out with rods of steel, copper, and aluminium, and in every case the observed value of the wave-velocity was within $\frac{1}{3}$ per cent. of that calculated from static tests by the formula $v=\sqrt{Eg/\rho}$, with the proper correction for adiabatic propagation. It was also observed that, for the exceedingly short times involved in these experiments, stresses far exceeding the elastic limit of the material can be applied without producing any permanent effects.—Selective absorption of Röntgen rays: G. W. C. **Kaye.** A Röntgen-ray bulb was constructed so that a pencil of kathode rays fell on an antikathode which was one of a batch of metals mounted on a small carriage which could be moved along inside the tube by a magnet from outside. The quantity of Röntgen rays passing through a thin aluminium window in the tube was measured by their ionising effect. Absorbing screens of different metals were placed in turn between the ionisation chamber and the aluminium window. Using a plate of aluminium as the absorber, the relation between the amount of transmitted radiation and the atomic weight of the metal used as antikathode was found to be approximately a linear one over a wide range of atomic weights. Screens of a few other metals were employed, and the results indicate that a metal is specially transparent to the Röntgen radiation from an antikathode of that metal, and that this abnormal transparency is shared in less degree by metals of atomic weight differing little from that of the antikathode. The effect seems to indicate that the Röntgen rays emerging from the interior of the antikathode to the surface undergo selective absorption, leaving the remainder specially penetrating to further layers of the same substance.—The transmission of earthquakes through the earth (second paper): Rev. O. **Fisher.**—Note on the influence of extraneous forces upon the proportion of the sexes produced by canaries: W. **Heape.** The breeding results in two aviaries are examined. In the one (N), the young produced were in the proportion of 76·99 cocks per 100 hens; in the other (G), 353·3 cocks per 100 hens were bred. This remarkable difference in the proportion of the sexes produced in these two aviaries is shown to be consistent both in detail and in the total results. Moreover, it is shown that a pair of N's birds transferred to G's aviary produced a large excess of cocks, and a pair of G's birds bred in N's aviary produced young of which the sexes were closely in accord with the average proportion obtained in the aviary that year. Examination of details regarding the food supplied and the temperature and surroundings to which the birds were subjected in these two aviaries indicates the probability that these factors exerted selective action on the generative elements dehisced by the parent birds, and may be interpreted as evidence of the exercise of extraneous forces on the proportion of the sexes produced.

PARIS.

Academy of Sciences, June 3.—M. Henri Becquerel in the chair.—The origin of the irregularities of the lunar surface: MM. **Lœwy** and **Puiseux.** A critical discussion of the theories of Laplace and G. H. Darwin concerning the moon's origin, and the present condition of its surface.—Selenium hexafluoride: Sir W. **Ramsay.** A reply to the criticisms of M. Lebeau on the selenium hexafluoride discovered by Prideaux.—Magnetic observations at Tananarivo: Ed. Él. **Colin.** The results are summarised in three tables showing the absolute measurements of declination, inclination, and the horizontal component from May, 1906, to April, 1907.—Tetramethyl-dioxyacetone: Louis **Henry.** An account of the study of the reaction between mesoxalic ester and magnesium methyl bromide by M. Joseph Lemaire. The magnesium compound being used in excess, the pentamethyl derivative $(CH_3)_2.C(OH).C(CH_3)(OH).C(OH)(CH_3)_2$ was looked for. The actual product, however, proved to be

$$(CH_3)_2.C(OH).CO.C(OH)(CH_3)_2,$$

the physical properties of which are given.—Some applications of the theorem of Landau-Picard: C. **Carathéodory.**—Integral invariants: E. **Goursat.**—An apparatus for the study of telephonic currents: Henri **Abraham** and M. **Devaux-Charbonnel.** The essential part of the apparatus is the moving coil galvanometer for alternating currents described by H. Abraham in an earlier paper. This can be arranged so as to measure, not only the amplitudes, but also the phases and strength of telephone currents.—The speaking condenser: Pierre **Sève.**—A self-recording pyrometer with fixed photographic plate: M. **Wologdine.** The time ordinate is obtained by a mirror rotating round a horizontal axis at a uniform rate.—An apparatus for the preparation of a constant stream of pure oxygen: Gustave D. **Hinrichs.** The centre bulb of a Kipp is filled with well-washed granular pyrolusite, the liquid consisting of hydrogen peroxide acidified with one-twelfth of its volume of concentrated sulphuric acid.—The action of silicon tetrachloride on silver and copper: Em. **Vigouroux.** With silver, the tetrachloride is partially reduced to the sesquichloride; the silver not converted into chloride is free from silicon. With copper, the metallic ingot remaining contains about 2·4 per cent. of silicon.—The transformation of the esters of the α-bromo-fatty acids into the corresponding α-iodo-compounds: F. **Bodroux** and F. **Taboury.** The α-bromo-ester is treated with anhydrous magnesium iodide in presence of ether. The reaction is energetic and practically quantitative.—A new method of synthesis of biprimary compounds containing an odd number of atoms of carbon: dimethoxyheptane, 1.7 $CH_3O(CH_2)_7O.CH_3$: J. **Hamonet.**—The synthesis of the auramines by means of the oxalic esters: A. **Guyot.**—The action of organo-magnesium compounds on the cyclic alkylidene ketones: Henri **de Béville.**—A new type of bisazoic compound: H. **Duval.**—An alkaline micrograpite collected at Graham's Land by Dr. Charcot's Antarctic Expedition: E. **Gourdon.**—The dehiscence of some stamens: M. **Pauchet.**—The *rôle* of comparative anatomy in the distinction between the species of the genus Cistus: M. **Gard.**—A new method of separating and estimating the organic acids in fruits and vegetables: J. M. **Albahary.**—The cultural mutation of *Solanum tuberosum*: Edouard **Heckel.**—The xylophage parasites of *Manihot Glaziovi*: P. **Lesne.**—The structure of the spinal medulla: N. A. **Barbieri.**—Fluorine in the shells of non-marine molluscs: P. **Carles.** Fluorine was found in all the non-marine molluscs examined, but in quantities much smaller than in the shells of marine molluscs.—The influence of the rapid displacements of air caused by the motor-car on the general nutrition: A. **Mouneyrat.** Both in normal and anæmic persons the number of red corpuscles in the blood is increased by moderate use of the motor-car. In neurasthenia accompanied by insomnia there is also a marked improvement.—A new method for the experimental diagnosis of tuberculosis: H. **Vallée.** Von Pirket has recently proposed the lesions arising from the application of a dilute solution of tuberculin to the skin of tuberculous subjects as a means for diagnosing tuberculosis in man. The author has studied this skin reaction with animals with results generally confirming those of Von Pirket. In healthy animals (cattle, horses, guinea-pigs) no appreciable skin reaction is produced; with tuberculous animals, on the other hand, the skin reaction is well marked.

DIARY OF SOCIETIES.

THURSDAY, JUNE 13.

ROYAL SOCIETY, at 4.30.—Some Points in the Development of *Ophiothrix fragilis*: Prof. E. W. MacBride, F.R.S.—On Certain Phenomena of Inactivation and of Inhibition exhibited by Precipitin Antisera: D. A. Welsh and H. G. Chapman.—The Inhibitory Action upon Subsequent Phagocytosis exerted on Active Normal Serum by Ioactive Normal Serum through which Bacilli have been passed: J. C. G. Ledingham.—*Miadesmia membranacea*, Bertrand; a New Palæozoic Lycopod with a Seed-like Structure: Miss M. Benson.—On the Identification of Chitin by its Physical Constants: Miss I. Sollas.

CHEMICAL SOCIETY (Extra Meeting), at 8.30.—Discourse entitled Some Borderline Problems in Botany: Prof. J. B. Farmer, F.R.S.

MATHEMATICAL SOCIETY, at 5.30.—On Partial Differential Equations of the Second Order: Prof. A. R. Forsyth.

INSTITUTION OF MINING ENGINEERS, at 11 a.m.—Improvements required in Inland Navigation: H. R. de Salis.—Bye-product Coking Plant at Clay Cross: W. B. M. Jackson.—Notes on Bye product Coke-ovens, with Special Reference to the Koppers Oven: A. V. Kochs.—Bye-product Coke-ovens: P. Schwarz.—Water Supplies by Means of Artesian-bored Tube-wells: H. F. Broadhurst.—Gypsum in Sussex: W. J. Kemp and G. A. Lewis.—The Use of Duplicate Capell Fans: G. M. Capell.

MATHEMATICAL SOCIETY, at 5.30.—Note on a Special Set of Classes of Partial Differential Equations of the Second Order: Prof. A. R. Forsyth.—Various Extensions of Abel's Lemma: Prof. T. J. I'A. Bromwich.—On the Number of Representations of a Number as a Sum of $2r$ Squares, where $2r$ does not exceed 18: Dr. J. W. L. Glaisher.—An Extension of Eisenstein's Law of Reciprocity: Mr. A. E. Western.—On Certain Singular Points of Surfaces: Mr. A. B. Basset.—The Minimum Necessary Postulates as to a Function to be Defined as Analytic over a Region: Prof. E. B. Elliott.

FRIDAY, JUNE 14.

ROYAL INSTITUTION, at 9.

ROYAL ASTRONOMICAL SOCIETY, at 5.—(1) Note on the Colours of α and o Ceti; (2) The Relation between Star Colours and Spectra: W. S. Franks.—On the "Owl Nebula," M 97, N.G.C. 3587: E. E. Barnard.—Ancient Eclipses: P. H. Cowell.—Note on the Visual Spectrum of Mira Ceti in December, 1906: Rev. A. L. Cortie.—The Spectrum of Mira Ceti in December, 1906, as Photographed at Stonyhurst College Observatory: Rev. W. PITT-RIVERS.

The Evolution of Culture and other Essays. By the late Lieut.-General A. Lane-Fox Pitt-Rivers. Edited by J. L. Myres, with an introduction by Henry Balfour. Pp. xx+232; twenty-one plates. (Oxford: The Clarendon Press, 1906.) Price 7s. 6d. net.

"IN language and in all ideas communicated by word of mouth there is a hiatus between the limits of our knowledge and the origin of culture which can never be bridged over, but we may hold in our hand the first tool ever created by the hand of man" (p. 31).

The great collection at Oxford needed this book, as a monument needs its inscription. These lectures, written during the actual collection and arrangement of the specimens, show the author's method of classification and explain the evolutionary principles which are concretely embodied in the objects themselves, from "the first tool ever created by the hand of man" to the highest effort of barbaric manufacture.

As every student of man knows, General Pitt-Rivers devoted a lifetime and a fortune to the application of the idea of evolution to the origin and development of the material arts. It was

"during his investigations, conducted with a view to ascertaining the best methods whereby the service firearms might be improved, at a time when the old Tower musket was being finally discarded, he was forcibly struck by the extremely gradual changes whereby improvements were effected. He observed that every noteworthy advancement in the efficiency, not only of the whole weapon, but also of every individual detail in its structure, was arrived at as a cumulative result of a succession of very slight modifications, each of which was but a trifling improvement upon the one immediately preceding it. Through noticing the unfailing regularity of this process of gradual *evolution* in the case of firearms, he was led to believe that the same principles must probably govern the development of the other arts, appliances, and ideas of mankind."

This extract, from Mr. Balfour's excellent introduction, puts on record a case of material inspiration very similar to that by which Darwin was led to his own great work. Colonel Lane-Fox began to put his ideas to a practical test in 1851. Evolution was in the air during the 'fifties, and it should not be forgotten that Pitt-Rivers, like E. B. Tylor in a parallel direction, worked out its principles independently of Darwin.

Taking what we may call *conscious* evolution at its first beginnings in the application of human hands and brains to the materials supplied by nature, he traces the development of utensils and weapons through savagery and barbarism into civilised culture. He takes as an axiom the principle that the earlier a weapon is the nearer it lies to some natural form. The consideration of these natural forms is extremely interesting, and the way in which, not only the form, but the material itself, flint, for instance, limited, or in some cases suggested, the use of a weapon or tool is an instructive psychological lesson. The author's analysis of variation, retardation, and other qualitative differences in the chain of continuity is full of interesting analogies with biological processes. Thus he can say that man "can no more be said to have *invented* the boomerang than he can be said to have *invented* the art of sustaining life by nourishment" (p. 124). Knowledge of the theory of projectiles renders the author's account of savage missiles scientific in the truest sense; there is nothing *a priori* about it. The evolution of the shield from the club will be strange news to the layman. A detail of development, which illustrates the interchange of use and ornament, is the following, from the lecture on "Early Modes of Navigation":—

"The *oculus*, which, on the sacred boats of the Egyptians, represented the eye of Osiris guiding the mummy of the departed across the sacred lake, is still seen eastward—in India and China—*converted* into an ornamental device, while westward it lived through the period of the Roman and Grecian *biremes* and *triremes* and has survived to this day on the Maltese rowing-boats and the *Xebecque* of Calabria, or has been *converted* into a hawser-hole in modern European craft."

The italics are not the author's, and serve to point out his tendency at times to make coincidence into causal connection. The bow of a boat is, of course, the obvious place for various gear to be put, failing which it is no less the obvious place for ornament, imaginative, as in the case of the "eye," or purely decorative. But the author did not mean that the hawser-hole of a modern ship is *sans phrase* a development from the Egyptian "eye."

The lectures deal generally with principles of classification (as applied to the Pitt-Rivers collection), the evolution of culture, primitive warfare and weapons (the largest section of the book), and early modes of navigation, and are filled with abundance of detail. Mr. Balfour in his introduction does full justice to his author's achievement and his inspiring of other workers on the same lines. A luminous example of the principles set forth in the book is given in a sketch of his own history of the origin of stringed instruments from the bow of the archer (*cf.* "The Natural History of the Musical Bow," by H. Balfour). He holds that some have taken exception to the use of the term "evolution" in connection with the development of implements and weapons, and adequately vindicates such use. So at least it seems to me; and a study of the earliest facts of "invention," so-called, would be most instructive to those who are inclined to draw too sharp a line between biological change and mental adjustments to environment. Psychologists and students of invention will find this a masterly book, and of unusual value in directing attention to many a fruitful series of facts and many examples of what Mr. Balfour well calls "hybridisation of ideas." There is no index. Many would prefer photographic process-work for the plates instead of woodcuts. Why should there not be some typical photographs of the Pitt-Rivers collection?

A. E. CRAWLEY.

THE VOICE.

La Voix, sa Culture physiologique: Théorie nouvelle de la Phonation. Conférences faites au Conservatoire de Musique de Paris en 1906. By Pierre Bonnier. Pp. 299. (Paris: Félix Alcan, 1907.) Price 3.50 francs.

THIS is an excellent work on the physiology of the voice. Nowhere have we met with a clearer exposition of the anatomical structure of the larynx, the mode of voice production, and the mechanism of breathing. The diagrammatic figures showing the action of the muscles are specially to be commended. The author rightly discredits the old-fashioned view that a vocal tone is produced by the vibrations of the margins of the true vocal cords. In a sense this is true, but it is an incomplete statement of the truth, and M. Bonnier lays stress on the variations of pressure that occur in the laryngeal cavity. The vocal cords are brought close together, and then, by an expiratory effort, the pressure below the cords becomes much greater than in the ventricles of Morgagni above the cords and in the upper part of the larynx. This increased pressure opens the chink of the glottis, and the cords are slightly stretched upwards. The air escapes, the cords again approximate, and there is a fall of pressure below the cords whilst the pressure rises in the ventricles and in the upper part of the larynx. There is thus a puff of air. This is repeated again and again according to the period of the vocal tone produced.

M. Bonnier associates the old view with the name of Helmholtz, and he so far claims the newer view as his own. This is scarcely correct. Undoubtedly Helmholtz expounded the mechanism of tone production on the "puff" theory, and he likened the acoustic action of the larynx to that of a syren. The view so ably dealt with by M. Bonnier is now almost universally taught. M. Bonnier gives an admirable account of the action of the resonating cavities in modifying quality of tone. He illustrates this by an analysis of the bass, tenor, alto, and soprano voice, and he indicates the physiological mechanism which brings out the best quality in each of these voices, a mechanism which can be trained under a competent teacher. He shows that there is a constant interplay between the muscular mechanisms and the air pressures in the larynx, so that under favourable conditions the best qualities of the voice may be produced. Accent in singing, as the effort of the singer to give emotional expression, is brought about by the action of the nervous arrangements on the muscular mechanism.

There are many excellent remarks on articulation, on the trill, on the means for, as it were, "flinging out" the voice so as to make it effective, and on the vocal registers. There is a brief account of some of the mistakes by which the voice may be injured, and the volume closes with a description of the results obtained by a clinical examination (by laryngoscope and otherwise) of forty-four voices of persons who desired to become professional singers. Of the forty-four, eight were chosen, and thirty-six were rejected as having such qualities that no amount of training could efficiently fit them for following a *carrière lyrique*. This book places voice production on a scientific basis. Many teachers have taught empirically, and with remarkable success, but they may have made mistakes. M. Bonnier conveys the scientific knowledge that is always the surest guide.

J. G. M.

THREE BOOKS ON ELEMENTARY CHEMISTRY.

A Method of Teaching Chemistry in Schools. By A. M. Hughes and R. Stern. Pp. xii+120. (Cambridge: University Press, 1906.) Price 3s. net.

Elementary Science of Common Life (Chemistry). By W. T. Boone. Pp. 252. (London: W. B. Clive, University Tutorial Press, Ltd., 1906.) Price 2s.

An Elementary Study of Chemistry. By Dr. W. McPherson and Dr. W. E. Henderson. Revised edition. Pp. viii+434. (Boston and London: Ginn and Co., n.d.) Price 6s.

THE authors of the "Method of Teaching Chemistry in Schools" claim to have discovered a new method of teaching elementary chemistry, based on the principle of working from the known to the unknown. Although one may be inclined to question the novelty of the discovery, there is no doubt of the efficacy of the principle. The book is written in the form of suggestions to the teacher. The directions are clear and concise, the illustrations are excellent, and the book is embellished by photographs of the pioneers of chemistry. But it is not the method of treatment, which is scarcely new, or the arrangement of the subject, which might conceivably be improved, which commends the book. What impresses one favourably is its manner rather than its matter. It is written by thoughtful teachers, who have striven in an attractive way to get as much out of each simple problem as it can be made to yield. For the beginner in science, the imparting of many facts or the elucidation of general theories is not wanted; what is required is the cultivation of intelligent observation and of common-sense explanations of phenomena, and if this is the aim of the little book, as we take it to be, it undoubtedly fulfils its purpose.

The modest volume on "Elementary Science of Common Life," by Mr. Boone, is one of the "Organised Science Series," and is well up to the standard of the companion volumes. There is really very little that demands anything but favourable criticism. The subject is handled in a simple fashion, the examples are well chosen, and there is wealth of verbal and graphic illustration drawn from "common life." One is inclined to ask oneself in reading a book of this type whether anything is gained by formal definitions of well-known phenomena such as heat and light. Heat and light are first realised as sensations. Later, they are recognised by certain objective effects, such as expansion in one case and chemical change in the other, and this is, of course, pointed out. But does the definition of temperature "as indicating a particular physical condition of that body while heat is the agency to which this condition is due," which is true enough, though it applies just as well to colour and light, convey information worthy of being recorded in formal language?

The "Elementary Study of Chemistry" is intended for much older students than either of the foregoing, and is an introduction to the serious study of chemistry as a separate science. The authors do not lay claim to any great originality in the treatment of their subject, and in this we must concur. At the same time, the fact that it resembles other elementary text-books does not detract from its merits. The authors have done their work thoughtfully and well. The matter is well arranged, the style is simple and concise, the paper and printing are good, and the illustrations are numerous and well executed.

As in the volume just referred to, we are soon confronted with definitions. "Physical changes," we are told, "are those which do not involve a change in the composition of the matter," but we are not told what "composition" means. "Chemical changes involve a change in the composition of matter." How would isomeric change be classified say the conversion of ammonium cyanate into urea—according to this definition? Why attempt to define where there is no clear boundary, for it is not always easy to say where physical change ends and chemical change begins?

Apart from this we have nothing but praise for the book. The information is well up to date. There are suggestive chapters on "solutions," "chemical equilibrium," and the new learning; and if the teaching is a little didactic in places and leaves many obvious questions unanswered, it must be ascribed to the highly condensed treatment of the subject.

J. B. C.

MEDICAL SCIENCE.

(1) *The Control of a Scourge, or How Cancer is Curable.* By Charles P. Childe. Pp. ix+299. (London: Methuen and Co., n.d.) Price 7*s*. 6*d*. net.

(2) *The Essential Similarity of Innocent and Malignant Tumours. A Study of Tumour Growth.* By Charles W. Cathcart. Pp. xii+79; thirty-eight plates. (Bristol: John Wright and Co.; London: Simpkin Marshall, Hamilton, Kent and Co., Ltd., 1907.) Price 9*s*. 6*d*. net.

(3) *Guy's Hospital Reports.* Edited by F. J. Steward and Herbert French. Vol. lx., being vol. xlv. of the third series. Pp. 373. (London: J. and A. Churchill, 1906.)

(1) IN "The Control of a Scourge," Mr. Childe deals with the cancer problem particularly in relation to prevention and cure. Whether the subject could not have been dealt with in a quarter of the space with equally satisfactory results as regards the general public is a question, many of the details introduced being quite unnecessary for the average man or woman to know. What is really wanted is the broadest issue of a leaflet indicating the "danger signals" warning of the development of a cancerous growth. The medical profession has naturally shrunk from doing this, savouring, as it might seem, of unprofessional advertising; but the importance of the subject warrants this being done, and there is a good precedent in the case of tuberculosis. Mr. Childe's main theme is that cancer usually indicates itself at an early stage by certain signs—"danger signals"—a lump, a sore, an abnormal discharge, &c., and that the public should be educated to understand the importance of these, so that they may seek advice at the earliest possible moment; and, this being so, cure would be possible in a much larger proportion of cases than at present. For cancer is at first a *local* disease; in four-fifths of the cases, at least, it is situated in regions eminently accessible for surgical operation, and complete removal while in the local stage would mean cure.

To the layman who wants to know all about cancer, and to the general practitioner who desires to be in a position to discuss the cancer problem with laymen, the book can be thoroughly recommended.

(2) The second work is for the professional reader, and is illustrated with some beautiful plates. It is, of course, admitted that there is no sharp line of demarcation between innocent and malignant growths, but we should take exception to the unqualified statement (p. 71) that "the same tumour may be at one time innocent and at another time malignant." Even now the minuter characters of the structure of neoplasms are by no means completely worked out, and it is surely previous to assert that tumours having an identity of structure may at one time be innocent and at another malignant. In the case of some of the infectious warts, &c., they should be regarded as infective granulomata rather than as true neoplasms. If not, it would be quite as logical to classify the granulomatous new formations of tubercule, syphilis, &c., as neoplasms.

(3) This volume of the Guy's Hospital reports contains a number (sixteen) of interesting papers, many of which have, however, been published elsewhere. Among others, Dr. F. Taylor discusses the chronic relapsing pyrexia of Hodgkin's disease, Drs. Bainbridge and Beddard discuss the mechanism of secretion by the renal tubules in the frog, and Dr. Buzzard and Mr. Allen describe observations on the effects produced by choline upon animals. The volume contains much matter of scientific value, and to old Guy's men the "school" news which is included will add to its interest.

R. T. H.

OUR BOOK SHELF.

Ightham; the Story of a Kentish Village and its Surroundings. By F. J. Bennett. Pp. viii+158; illustrated. (London: The Homeland Association, Ltd., 1907.) Price 7*s*. 6*d*. net.

THE area described lucidly in this volume is one of the most interesting in the country to the archæologist, the geologist, and the general student of nature. It comprises some sixteen square miles north of Tonbridge, lying between Maidstone and Sevenoaks, and under the unremitting observation of Mr. Benjamin Harrison, the White of Ightham, has probably been surveyed in greater detail than any other similar rural area. Much of Mr. Harrison's material is embodied in the present volume, having been personally communicated to the author and the associated contributors.

The earlier chapters deal with the physical and geological features of the area, and in them the student will find ample material for extended surveys, made easier by the careful descriptions and directions given. Debatable points are at times introduced, but where the author's conclusions run counter to those of other authorities, the actual field evidence in support thereof is submitted.

The development of flint implements, with illustrations drawn from those found by Mr. Harrison, and others, in this area, and the several epochs of the Stone age are next discussed, the seventh chapter being devoted to a description of the megalithic monuments which are to be found in the district. It is to be regretted that, in regard to the latter, more definite results have not been educed. Stone circles, dolmens, and the remains of *viae sacrae* are mentioned in a general way as being possible sites of prehistoric worship, but although the district teems with objects which may prove of the greatest value to the student of early Britain, and is situated in a home county, no one appears to have yet succeeded in discovering and elucidating alignments such as the labours of Sir Norman Lockyer have established for somewhat similar monuments in Cornwall, Devon, &c. Yet we read on p. 47 of recent vandalism which bids fair to obliterate for ever these unique traces of the early inhabitants of the district. Surely the time has now arrived when a Government which carefully preserves records of ancient Babylon and Egypt should take effective steps to protect the only records we have of prehistoric Britain.

The remainder of the book deals with the general history of the Ightham district, and is pregnant with interest both for the historian and the general reader. The illustrations are from excellent photographs taken especially for this work, and one puts the book down with a deep feeling of regret that similar records for the scores of other interesting areas in which rural England abounds are as yet unwritten.

W. E. R.

The Wit of the Wild. By E. Ingersoll. Pp. xi+288; illustrated. (London: Unwin, 1907.) Price 6s. 6d. net.

As Mr. Ingersoll is always interesting and generally accurate, his writings may be commended to the attention of the reader in a manner which would not be safe in the case of all works on popular natural history. To recapitulate the titles of the two dozen articles which go to form the present volume will be unnecessary—more especially as some of them are of a rather cryptic nature—and it must accordingly suffice to mention that they cover a wide field, ranging from an account of the jelly-fish picturesquely named the "Portuguese man-of-war" to an inquiry whether animals can rightly be charged with suicidal propensities. All have appeared in the form of periodical literature, but they are none the worse for this, especially as many were first published in America. The article in which we have been most interested is one on the death-feigning instinct in the opossum—an instinct which in this particular case the author suggests has been inherited from long dead ancestors to the animal's own disadvantage. That the "collapse" which occurs when an opossum is suddenly seized is not due to some form of hysteria the author is firmly convinced; and if it be a death-feigning instinct designed for protection it certainly fails in its object, as the unhappy creature is mauled and done to death by quite a number of animals when in this condition. The reader should, however, peruse the chapter for himself, in order to form his own judgment, and having done this he will scarcely "skip" the remainder of a very interesting volume.

(1) *Technical Electricity.* By H. T. Davidge and R. W. Hutchinson. Pp. x+502. (London: University Tutorial Press, Ltd.) Price 4s. 6d.

(2) *Elementary Electrical Engineering.* By John H. Shaxby. Pp. vii+192. (London: Blackie and Son, Ltd.) Price 3s. net.

(1) This book is intended chiefly for the use of students of electrical engineering, and covers the London City and Guilds preliminary examination in electric lighting and power, and also the necessary technical work for stage ii. of the Board of Education examination in magnetism and electricity.

The question of the various units and systems of units has been given very careful attention, and the absolute and practical units are taken side by side so as to enable the student thoroughly to understand the relationships between them, and should help to mitigate the difficulties which generally arise when dealing with these units. The same idea is applied in the description of the construction of laboratory and practical measuring instruments, all the most modern forms which are in present-day use being carefully described, both as to their construction and action.

Examples of calibration and testing are fully given, but perhaps chapter xxiv., on "indoor wiring and jointing," is one of the best. This subject is so fully dealt with and clearly explained by diagrams showing the various systems of wiring that it is one of the chief chapters in the book, although it need not be taken up for either of the examinations mentioned above.

(2) Mr. Shaxby has written a book which he hopes will assist the home reader and evening-class student. The latter mostly consist of men who during the day are employed on electrical machinery, the theory of which is little known to them. Consequently, Mr. Shaxby has written his book in the simplest and clearest manner, and mathematics are avoided as much as possible. The first part of the book deals chiefly with the theoretical side of electrical work, and the question of primary batteries is very fully gone into.

Alternating-current machinery is so very largely employed in works and mills at the present day that it does not surprise us to find the author devoting three chapters to the subject of alternating currents and alternating-current machinery. The author gives an adequate but simple explanation of their chief properties, and also supplies illustrations of modern generators and motors.

J. L. M.

Neinia, Denkversuche. By O. K. Kremer. Pp. 420. (Vienna and Leipzig: E. Beyers, 1907.)

This book is not likely to appeal to many readers of Nature. "Neinia," or Nein-Ja, represents the wish of the author to recognise any and every point of view as equally legitimate, although he personally professes to be an enemy of mystic metaphysics and a friend of materialism. He belongs to no particular philosophical school, but desires to think merely for the sake of thinking, without intending to prove any more or less unconsciously preconceived notions. This thinking cannot lead to any positive conclusion, and the book ends, characteristically enough, first with the sentence, "I believe nothing and therefore I believe everything," and then with the colophon, "U.S.W. *ad infin.*" The author claims for his book the advantage that one may begin to read it in the middle or from the end. This is no empty boast, for without wishing to depreciate a thinker who is evidently an earnest man, we cannot call his book anything but a collection of aphorisms.

Some Pages of Levantine History. By the Rev. H. T. F. Duckworth. Pp. iv+149. (London: Alexander Moring, Ltd., n.d.) Price 3*s*. 6*d*. net.

PROF. DUCKWORTH commends his book "to those of his countrymen who have either made, or intend to make, a pilgrimage to the holy places of Christian and Classical Antiquity," and it should certainly be of service to them. As he was formerly assistant chaplain representing the Eastern Church Association in Cyprus, he writes from first-hand knowledge in many of his chapters. The text is illustrated with several good plates.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Root Action and Bacteria.

MR. SPENCER PICKERING'S letter on the effect of soil sterilisation on the growth of apple trees (June 6, p. 126) is of interest in connection with experiments which have been made by Dr. Francis V. Darbishire and myself, and described in a paper read last year before the chemical section of the British Association. We find that most plants grow much better in heated than in unheated soils.

That the productiveness of a soil can be increased by heating was shown in 1888 by Frank, and has since been confirmed by other investigators besides ourselves. We have not yet been able completely to account for it. There is, beyond question, an increase in the total activity of the soil microorganisms; this is shown by the increased absorption of oxygen. There is also evidence that some chemical change takes place. Mustard grown in heated soil takes up a larger amount of nitrogen and of phosphorus, indicating an increased "availability" of some of the compounds of these two elements. One of our experiments gave the following results:—

		Yield of mustard in grams		Percentage composition of dry matter		
		Fresh weight	Dry weight	N	P_2O_5	K_2O
Heated soil	(*a*)	229·59	26·14	4·26	2·39	4·34
	(*b*)	226·15	24·04	4·80	2·01	5·07
Unheated soil	(*a*)	84·60	15·70	2·53	1·07	4·11
	(*b*)	88·70	16·05	2·09	0·92	4·29

Further, it is easy to show that heating increases the solubility both of the organic and of the inorganic matter in the soil. The actual change that takes place can only be ascertained when something more is known of the proximate constituents of the soil, and especially of the ill-defined colloidal bodies collectively known as humus.

The case is somewhat more complicated if the plant depends for part of its food on the activity of organisms which have been killed during the heating process. The increased "availability" of the plant food in the soil may or may not counteract the loss of the special organism; leguminous plants, and trees dependent on mycorrhiza, may therefore be expected to give irregular results.

A further complication may arise if the amount of calcium carbonate in the soil is insufficient. In certain circumstances humus is known to decompose and form bodies which, in absence of calcium carbonate, are injurious to plants. There is no evidence that a similar change does not take place on heating; on the contrary, one of Schulze's experiments (*Landw. Versuchs. Stat.*, 1906, lxv., 137) seems to show that it does. He found that heated pasture soil deficient in calcium carbonate gave a poorer crop of mustard than did the unheated soil, but on adding calcium carbonate the difference in crop disappeared. So far we have always worked with soils containing 3 per cent. or more of this substance, and no depressing effect has been observed, but it would be interesting to know how much was present in Mr. Pickering's soil. Unless there happened to be sufficient, the retardation in growth which he observed may well be due to some injurious body formed by heating the soil rather than to the absence of particular organisms.

EDWARD J. RUSSELL.

South-Eastern Agricultural College, Wye.

Unscientific Administration.

MAY I be allowed to offer a few words of comment on one point raised by Prof. Ronald Ross in his article appearing in this week's NATURE? No one can read his indictment of the Indian official attitude towards science without feeling that another voice crying in the wilderness is warning our administrators and governing classes of the dangers that await an unscientific nation that persists in the error of its ways. In explaining the cause of the present state of affairs, Prof. Ronald Ross says:—". . . Lastly, it is due to our defective public education." May I amend the phrase by interpolating the words "school and university" between the last two words quoted? For surely it is not the mass of the people who are to blame, but rather those who are directing the affairs of the country. Our governing classes have up till now been mostly educated at public schools and the universities of Oxford and Cambridge. To the latter institutions I will not refer. The Editor of NATURE, Prof. Turner, and Prof. Perry, not to mention the council of the Royal Society and others, have done sterling service to the cause of scientific education in their attempts to stir up public opinion; but, notwithstanding a special memorial from the Royal Society, neither university has as yet, by altering its entrance examination, acknowledged that science forms an integral part in a liberal education.

But with regard to science teaching in public schools, of which I may claim several years' experience, it is not too much to say that the outlook is far from promising. Notwithstanding the fact that governing bodies have voted money, built laboratories, and insisted on a minimum at least of science teaching, not one single public school, using the term in its usual application, has for its headmaster a man scientifically trained. The Naval College at Dartmouth and one or two grammar schools are the exceptions which prove the rule.

As a result of this, no science master can ever hope to get a headmastership, and the best men, therefore, do not enter the teaching profession. I should be far from wishing to assert that headmasters are not, as a rule, anxious to do the best they can for science, although their sympathies are with literary subjects, but they cannot do more than allow facilities for boys to learn science. The great clog to progress lies at the door of the assistant masters, who are as a body decidedly anti-scientific. What science master has not heard the opinion confidently asserted that science is only suited to the minds of a small minority of boys? They cannot and will not admit that it can be made an educational instrument of any moment. Who could not mention cases of clever boys being warned not to "waste their time" over science? Was not Darwin himself publicly rebuked for the same offence when a youth at Shrewsbury School? But if chemistry and physics are useless, biology is positively harmful. I have been told that biology should never be taught to boys, since it must turn their minds towards questions of sex about which they should be kept in perfect ignorance! Finally, it is said that the introduction of "modern" subjects such as science has only brought about mental confusion and stagnation, and the sooner we go back to the old exclusively classical curricula the better.

It is not hard to imagine what will be the attitude of mind towards science if the present generation of officials, against whom Prof. Ronald Ross brings his complaints, are succeeded by those who are now at our public schools and ancient universities. Surely it is not asking too much of some of our most distinguished men of science that they will follow in Huxley's footsteps, and once more bring home to our schools and universities the responsibility they are incurring by their attitude towards science in the education of the well-to-do classes.

Eton, June 13. M. D. HILL.

The Rainbow.

IN "Poems by Two Brothers," written by the Tennysons, and published in 1827, is a poem called "Phrenology." The following lines occur:—

> "Shall we, with Glasgow's learned Watt, maintain
> That yon bright bow is not produced by rain?
> Or deem the theory but ill surmised,
> And call it light (as Brewster) polarised?"

Can any of your readers kindly tell me (1) what view was held by James Watt about the rainbow? (2) If Brewster was the first to point out that its light is polarised? Brewster states that he observed the fact in 1812. (3) Having regard to the date (1827), what were the most probable sources of information to which the writer of the poem was indebted?

Lord Tennyson kindly informs me that the poem was probably written by Charles Tennyson.

CHAS. T. WHITMELL.

Invermay, Hyde Park, Leeds, June 5.

The Mass of the α Particle.

JUST too late to prevent the publication of my letter of last week, I perceived that the arguments contained in it are valueless. Rutherford's estimation of the number of α particles is based on the assumption that the charge on each of them is ε, and cannot be used to prove that proposition. The numbers given only show that the heat energy radiated by radium is approximately equal to the kinetic energy of the α rays, as has been pointed out by Rutherford. I regret that this foolish mistake should have led me to trespass needlessly upon your valuable space.

NORMAN R. CAMPBELL.

Trinity College, Cambridge, June 14.

Animal Messmates.

WHILE searching for marine animals on January 14, I came across some large specimens of *Ciona intestinalis*, which I kept for some time in a large bottle. After a while I noticed a small worm emerging from the larger or exhalent siphon, which, on examination by a competent authority, proved to be a small example of the nemertine worm *Drepanophorus rubrostriatus* = *Amphiporus spectabilis*, Qtrf. Other worms of the same species afterwards emerged, about ten being observed altogether. The Ciona betrayed no apparent annoyance at the egress or return of the creatures, though it withdrew its siphons at the slightest touch of any foreign objects. This observation seems to be a new instance of "animal messmates," or at any rate of the use of an ascidian's test for purposes of shelter by an active creature.

This has been confirmed on several subsequent occasions by myself and others; in one instance, a small Ciona, from which not fewer, but possibly more, than fifteen worms issued, the creature was so transparent that the worms could be observed moving about in its interior.

FRANK S. WRIGHT.

Guernsey, June 10.

Decomposition of Radium Bromide.

WITH reference to Prof. Porter's note in NATURE of June 13 (p. 151) on the odour of bromine detected on opening a sealed tube of radium bromide, it appears that the minimum quantity of bromine that is detectable by smell is between the orders 10^{-8} to 10^{-10} grams per cubic centimetre of air. This result has been obtained by the progressive dilution of a definite volume of bromine vapour. It may be mentioned that the vapour of bromine is just detectable by its odour at the temperature of liquid air.

ALFRED C. G. EGERTON.

University College, London, June 17.

THE DESTINY OF MAN.[1]

THE present volume contains three essays reprinted from two recent addresses and one article by the author. They have been slightly modified and freely illustrated for the present purpose. The first essay, "Nature's Insurgent Son," was delivered as the Romanes lecture at Oxford in 1905. It traces the history of man and his rebellion against nature, shows that his inevitable destiny is to transform rebellion into conquest, points to the causes of delay and the special responsibility for their removal which belongs to our universities.

The second essay, "The Advance of Science," served as the presidential address to the British Association at York in 1906. It gives an account of man's campaign against nature during the last twenty-five years. It is triumphantly successful in the difficult feat of rendering supremely interesting a brief general account of advance in all the great departments of science.

The third essay, "The Sleeping Sickness," reprinted from the *Quarterly Review*, gives an account of this recent terrible scourge of tropical Africa, and the attempts which have been made to deal with it. This essay is the other side of the picture presented in the second. The latter told of splendid successes in the warfare with nature; the present essay gives a startling example of those haphazard, unintelligent methods which bring terrible disaster upon man.

In attempting to give some account of this arresting and important work in the brief limits of the allotted space, I have thought it best to confine my attention to the central argument founded on man's history, rebellion and destiny. This argument, developed in the first essay, appeals strongly to the imagination, and supplies a powerful motive force which has been wanting in the case of earlier appeals for reform.

"Man is held to be a part of Nature, a product of the definite and orderly evolution which is universal; a being resulting from and driven by the one great nexus which we call Nature. He stands alone, face to face with that relentless mechanism. It is his destiny to understand and to control it."

This statement of man's origin is rightly held to contain no implied degradation—rather the reverse. It is only a superficial and ignorant view which sees in evolution the dominion of "chance." "The conclusion that Man is a part of Nature . . . is in fact a specific assertion that he is the predestined outcome of an orderly—and to a large extent 'perceptible'—mechanism." It was of importance to urge this conclusion again, a conclusion set forth, as the author states, by Tyndall in his presidential address to the British Association at Belfast in 1874, and again stated and admirably illustrated by Huxley in 1887.[2] But the error refuted in 1874 and 1887 was still alive and vigorous in 1905, and there is reason to fear that even now it is not wholly extinct.

The emergence of man—perhaps in Lower Miocene times—is shown to be the grand example of an evolution also witnessed in other animals. In many of the early Tertiary Mammalia, as well as in the ancestors of man, it is probable that mechanical form and function had reached a climax. From this point the struggle was conducted and evolution proceeded on a higher plane, and led to progressive increase in the size and powers of the brain. The author suggests the convincing hypothesis[3] that this sudden growth

1 "The Kingdom of Man." By E. Ray Lankester, F.R.S. Pp. xii+191. (London: Archibald Constable and Co., Ltd., 1907.) Price 3s. 6d. net.

2 "The Life and Letters of Charles Darwin." Edited by Francis Darwin. Vol. ii., Chapter v., Prof. Huxley on the reception of the "Origin of Species," pp. 179-201.

3 First published in "Cinquantenaire de la Société de Biologie." Pp. 43-51. (Paris, 1877.)

in the bulk of brain-substance—in animals as well as in ancestral man—signifies the substitution in large part of "educability" for a life controlled by inborn hereditary nervous mechanisms. An increased power of storing up and profiting by individual experience takes the place of all but the most fundamental and essential instinctive actions which are the inevitable outcome of inherited brain-structure. "The result is that the creature called Man emerged with an educable brain of some five or six times the bulk (in proportion to his size and weight) of that of any other surviving Simian." One of the most astonishing facts in this history is that so much of it was accomplished by early Palæolithic times, so that from this period to the present day "the bulk of his brain does not appear to have continued to increase in any very marked degree." We must, however, remember, as indeed the author reminds us, that Palæolithic man was probably not much more monkey-like than some of the existing savage races. The best implements of that age "are manufactured with great skill and artistic feeling"; they certainly go beyond the bare necessities of use as weapons or tools, and imply a life of immense complexity as compared with that of the highest animal. Although the subsequent increase in cranial capacity is surprisingly small, it is admirably shown, by two pairs of figures, to be very significant. By the courtesy of the publishers these illustrations are here reproduced. The first pair of figures, together forming the frontispiece of the work, represent above the cranial dome of Pithecanthropus, below the skull of a Greek, both seen from the left side. The former differs from the latter in the same features, but even more remarkably than do the Spey and the Neanderthal skulls.

"The three great features of difference are: (1) the great size of the eyebrow ridges (the part below and in front of A in the figures) in the Java skull; (2) the much greater relative height of the middle and back part of the cranial dome (lines *e* and *f*) in the Greek skull; (3) the much greater prominence in the Greek skull of the front part of the cranial dome—the prefrontal area or frontal 'boss' (the part in front of the line AC, the depth of which is shown by the line *d*)."

"The parts of the cranial cavity thus obviously more capacious in the Greek skull are precisely those which are small in the Apes and overlie those convolutions of the brain which have been specially developed in Man as compared with the highest Apes."

It is necessary to add a few sentences in explanation of the simple but extremely efficient set of lines by which the important differences between the skulls are indicated and can be assigned a quantitative value. The line A–B, in both skulls, is drawn from ophryon (the median point of a line drawn across the narrowest part of the frontal bone) to the extra-tentorial point between the occipital ridges. A–B thus practically represents the base-line of the cerebrum. Lines *e* and *f* are perpendiculars drawn respectively from the median point of A–B and the junction of the third with the posterior fourth of the same line.

The development of the frontal boss is clearly shown by the line A–C drawn from ophryon to bregma—the point of contact of frontal with both parietal bones. Line *d* is a perpendicular drawn from A–C to the most prominent point of the frontal boss.

The line A–B may be divided into units, and the lines *d*, *e*, *f*, indicating the depth of the brain-cavity at these three important points, expressed numerically as percentages of the ophryo-tentorial length.

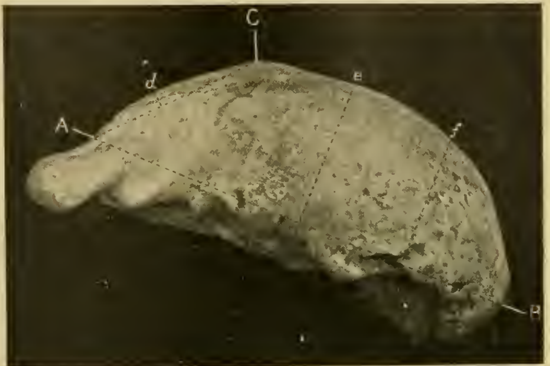

FIG. 1.—Cranial Dome of *Pithecanthropus erectus* from river gravel in Java. From "The Kingdom of Man."

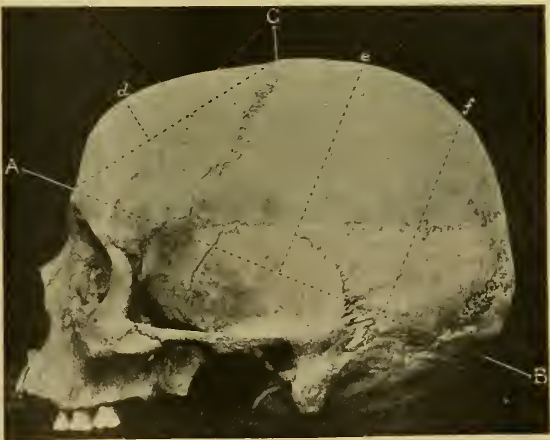

FIG. 2.—Skull of a Greek from an Ancient Cemetery. From "The Kingdom of Man."

The full significance of this method of comparison is only realised when the figures already described are considered in relation to those reproduced on the next page, Fig. 3, of course, corresponding to the upper, Fig. 4 to the lower of the preceding pair. It is here shown that line A–C—appearing as a straight line when the skulls were looked at from a little distance and placed so as to give an accurate side view—becomes when seen in front view the ovoid outline of the base of the frontal boss—the line where the frontal bone is cut by a plane at right angles to the sagittal plane, and passing through both ophryon and bregma. Similarly the line *d*, straight in the previous figures, becomes in front view the (white) line across the greatest breadth of the frontal boss. The astonishing difference between the size of this boss or prefrontal area in Pithecanthropus and that of the Greek skull is perhaps even more evident in these than it was in the former figures.

It should be mentioned that the Greek skull was selected because it happened to be a favourable example suitable for photographic reproduction, and not because of any special superiority in the crania from south-eastern Europe. Were it otherwise the author's illustrations might perhaps be called as evidence in favour of compulsory Greek!

We have directed special attention to these four figures because by their means the essential differences between the earliest known and the latest human crania are so clearly expressed; but, after all, the most striking fact that emerges is the immense size of the ancient brain and the relatively small increase which has since occurred. "The cranial capacity of many savage races and of some of the most ancient human skulls is only a little less than that of the average man of highly-civilised race. The value of the mental activities in which primitive man differs from the highest apes may be measured in some degree by the difference in the size of the man's and the ape's brain; but the difference in the size of the brain of Isaac Newton and an Australian black-fellow is not in the remotest degree proportionate to the difference in their mental qualities. Man, it would seem, at a very remote period attained the extraordinary development of brain which marked him off from the rest of the animal world, but has ever since been developing the powers and qualities of this organ without increasing its size, or materially altering in other bodily features."

It must, however, be again pointed out that, as the author states, these earliest human crania are probably Palæolithic, and thus belong to an advanced stage of human evolution with conditions not very different from those of certain savage races both existing and extinct within recent years.

The rise of the mind of man has finally led to a new "power in Nature, an *imperium in imperio*, which has profoundly modified not only man's own history but that of the whole living world and the face of the planet on which he exists." He has become "Nature's rebel," and "where Nature says 'Die!' Man says 'I will live.'" Finally, "he has advanced so far and become so unfitted to the earlier rule, that to suppose Man can 'return to Nature' is as unreasonable as to suppose that an adult animal can return to its mother's womb." But if man cannot go back he can go forward, and the author urges "the conscious and deliberate assumption of his kingdom by Man not as a matter of markets and of increased opportunity for the cosmopolitan dealers in finance—but as an absolute duty, the fulfilment of Man's destiny, a necessity the incidence of which can only be deferred and not avoided."

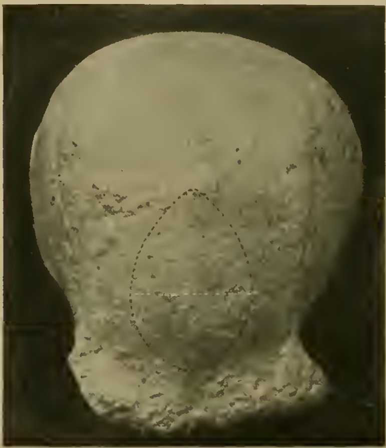

FIG. 3.—Pithecanthropus from Java.

FIG. 4.—Greek Skull.

From "The Kingdom of Man."

After tracing some of the chief lines in the past and urging the necessity for determined and active progress, the author proceeds to consider the causes of man's delay. These are found to spring from ignorance of the situation on the part of the masses of the people; and it is rightly argued that when the inevitable light shall have dawned the democracy will insist on very different qualifications in its public servants. The essay concludes by calling on the University of Oxford not to wait for the pressure that will surely come, but to take a foremost part in equipping mankind for further victories and a speedy entrance into the kingdom; and in order to play this splendid part, our ancient university is reminded that no new attitude towards learning is required, but a return to the old academic spirit which laid in Oxford the foundation of the Royal Society—this, together with some relaxation of the grip of the "present curriculum, . . . a mere mushroom growth of the last century."

It is astonishingly difficult to induce mankind to adopt fundamental changes in the methods of education. The results of education, although of boundless practical importance, are not immediately recognisable by those whose imagination has been stunted by the methods employed in their own youth. An inadequate cramping education tends to prolong itself; for youth, with all its hidden powers calling for development, must submit to the methods imposed by age. It is probable that no branch of the human race is more difficult to move than our own. The thought sometimes arises that salvation can only be found, if at all, by national disaster; and then, under modern conditions, the remedy may be too late and recovery impossible. About forty years ago Huxley delivered the powerful and eloquent addresses on education reprinted in "Lay Sermons, Addresses, and Reviews," and yet the same subject is felt to be still the paramount question of the hour when one of our foremost scientific men is invited to deliver the Romanes lecture in 1905. It is disheartening to read Huxley's admirable and convincing essays and to realise how small has been the effect. But a reformer who would achieve anything must not give way to despondency: it is only by hope and confidence in the future that mankind can be moved. And this latest appeal has one great advantage over the old. The history of man could not have been spoken of forty years ago as it can to-day; his interference with nature is also far more evident. In this latest appeal, the imagination of the author aroused by these considerations has originated the splendid argument founded on the deeds, the delay, and yet, in spite of delay, the inevitable triumphant destiny of man. It is not too much to hope that the power and the onward sweep of this great argument will carry away many an old but not time-honoured barrier, and many an obstacle built up, alas, in modern times, intervening between man and the race that is set before him. E. B. P.

INTERNATIONAL ASSOCIATION OF ACADEMIES.

A BRIEF note on the third triennial general assembly appeared in NATURE for May 30. The following academies were represented:—Amsterdam, Berlin, Brussels, Budapest, Christiania, Göttingen, Copenhagen, Leipzig, London (R.Soc.), London (B.Acad.), Madrid, Munich, Paris (Belles-Lettres), Paris (Sciences), Paris (Morales et Politiques), St. Petersburg, Rome, Stockholm, Tokio, Washington, Vienna. The English representatives mentioned in NATURE for May 30 were all present with the exception of Sir Norman Lockyer.

The proceedings opened on the morning of May 29 with a brief address from Prof. Suess, the president. Dr. Böhm-Bawerk (Vienna) was nominated vice-president, and the following as secretaries:—German, Gomperz (Vienna), von Lang (Vienna); French, de Lapparent (Paris), Senart (Paris); English, Turner (London), Gollancz (London).

M. Darboux (Paris) then announced that a medal had been struck by the French Government in honour of the first meeting at Paris. He presented the first copy to the Vienna Academy, and said that a copy would be sent to each constituent academy. The assembled representatives of science had been pictured on the medal as young girls, and, though scarcely in accord with the appearances round him at the moment, this representation had at least the merit of suggesting that science was always young.

It was decided by small majorities not to place on the agenda paper either the selection of an auxiliary language or the proposal for a symbolic nomenclature for machinery. Other questions dealt with at this meeting related to statutes and procedure.

On Thursday, May 30, the association met in two sections. In the section of science the report of the Brain Commission was received and placed on the minutes, no vote of approval being necessary since this commission has autonomous powers. A committee appointed in 1904 by the association to "consider the best method of bringing existing organisations into relation with the association" reported that they had made certain suggestions to the International Seismological Association which had been adopted, and that in consequence it had become possible for the United States, Austria, and England to join that association, while the adhesion of France was confidently expected.

Sir George Darwin presented a report on the possible cooperation of the International Geodetic Association in geological researches, by means of the study of anomalies in the value of gravity. There were difficulties (especially from lack of funds) in organising such cooperation; but the apparatus of Baron Eötvös seemed likely to give just the information desired, and it was to be hoped that the Hungarian Government would encourage experiments with this apparatus.

Prof. von Than announced that the Hungarian Government had promised a sum of 60,000 kronen annually for three years for work with the apparatus of Baron Eötvös. This announcement was naturally received with acclamation, and it was resolved to tender cordial thanks to the Hungarian Government. It was also decided to represent to the Italian Government the great importance of similar researches in the neighbourhood of active volcanoes such as Vesuvius.

A report by M. Ch. Lallemand on levelling operations urged the desirability of repeating precise levellings two or three times per century in all countries, in order to determine possible changes.

As bearing on the general importance of the work of the Geodetic Association, M. Darboux referred to the work of Prof. Milne in directing attention to the possible connection between variation of latitude and seismic phenomena.

With regard to the survey of the 30th meridian of longitude, Sir G. Darwin was able to report, on the authority of Sir David Gill, that the survey was now approaching the northern limits of British territory, where it was hoped that it would be taken over by Germany and carried through German territory. Further, that there was a good prospect that certain R.E. officers would be able to survey 2° of the meridian, in the neighbourhood of the Equator, and that Captain Lyons, F.R.S., the director of the Egyptian Survey, was hoping to begin the triangulation of the Nile Valley in the coming winter.

An interesting report of the Marey Institute was received, including the announcement of munificent assistance from the French Government and the city of Paris. Here again the Association hastened to tender cordial thanks for generous Government aid to science.

The proposal of the Royal Society for a committee on lunar nomenclature was adopted without opposition; and the following were nominated to serve on the committee, with power to add to their number:—Lœwy (chairman), Newcomb, Weiss, Franz, Saunder, and Turner.

The International Union for Solar Research successfully solicited the patronage of the association, in token whereof they were to report to it every three years, and to reserve one place on the executive committee (of three members) for a member to be nominated by the leading academy for the time being. It was unanimously decided, on the motion of Prof. Hale (Washington), respectfully to invite the Austrian

Government to consider whether, in view of the number of favourable stations existing in the neighbourhood of Vienna, they could encourage and assist solar observations.

An important resolution concerning the organisation of meteorological stations was moved by Dr. W. N. Shaw (London), and unanimously carried, as follows:—

Consideration of the distribution of meteorological stations over the globe shows that stations in the far north and on islands in the various oceans are of special importance; the International Association of Academies desires therefore to express the hope that the Governments concerned will take any necessary steps for securing the continuance of observations where they already exist; for the modification of their form, if necessary, to bring them into conformity with meteorological usage; for establishing stations where they do not yet exist; and for placing the observations at the service of science by suitable publication. As regards the far north, observations are desired from two or three stations, at least, in the north of Siberia and of the Continent of America respectively, and as regards the islands, the following list is suggested:—Greenland, Færöe Islands, Azores, Madeira, Canaries, Cape Verde, Ascension, St. Helena, Falklands, Fernando Naronha, Staten Island, Fernando Po, West Indies, Bermudas, Sandwich Islands, Carolines, Guam, Bismarck Archipelago, Samoa, Fiji, New Caledonia, Tahiti, Java, Borneo, Seychelles, Maurice, Réunion, Madagascar, Zanzibar, Socotra, Chagos Archipelago, Christmas Island, Karmaluki.

The Association reassembled in the afternoon, for a sitting which it was ultimately found necessary to adjourn until Sunday morning, June 2. The report on the publication of the works of Leibniz was received; already a catalogue of the Leibniz MSS. had been prepared and printed. The Association expressed the hope that the three academies which had prepared this catalogue (the Paris Academies of Science and of Moral and Political Science, and the Berlin Academy) would proceed to undertake and carry through a scientifically complete edition of the works of Leibniz, and that the necessary Government aid would be forthcoming.

The proceedings of the two sections were then approved in detail by the general assembly, including reports from the letters section on the international loan of MSS., on the Greek Thesaurus, and on the Corpus Medicorum Antiquorum.

It was decided to accept the invitation to hold the next meeting in Rome (1910), probably at Easter.

There were, of course, many hospitable entertainments. The Vienna Academy invited the delegates to the annual meeting on May 28; the president entertained them at dinner on May 29; there were delightful expeditions to the Semmering on June 1, and to the Schloss Kreuzenstein on June 2, which the Graf von Wilczek (the organiser of the Polar expedition which discovered Franz Josef land) has rebuilt on the old model, and filled with all the beautiful old pictures and pieces of furniture which can be collected. Finally, the delegates had the honour of being received by the Emperor in person on the evening of June 2, and of being present at the Opera on his invitation.

The success of the whole meeting was attested by the cordial words spoken at its conclusion by MM. Darboux (Paris), Schuster (London), and Kikuchi (Tokio), who joined in congratulating Prof. Suess and the Vienna Academy on the able manner in which the duties of the "leading academy" had been discharged during the last three years.

H. H. TURNER.

THE LEICESTER MEETING OF THE BRITISH ASSOCIATION.

LEICESTER people evidently intend doing their utmost to make the first visit of the British Association to their town as successful as it will be welcome, and the meeting itself promises to be both largely and influentially attended. Many foreign visitors will be entertained as guests by the local committee, the list already including representatives of science from the Cape, Canada, the United States, France, Germany, Austria, Russia, Switzerland, Holland, Prussia, Italy, Norway, Denmark, Sweden, and Greece.

The opening meeting is to be held in the Royal Opera House on Wednesday, July 31, at 8.30 p.m., when Prof. Ray Lankester, the retiring president, will vacate the chair, and Sir David Gill, K.C.B., F.R.S., assume the presidency and deliver his inaugural address. On Friday, August 2, a discourse on "The Arc and Spark in Radio-telegraphy" is to be delivered by Mr. W. Duddell in the same building, and on Monday, August 5, Dr. F. A. Dixey will discourse on "Recent Developments in the Theory of Mimicry" in the Temperance Hall. A lecture to the operative classes will be given on Saturday, August 3, also in the Temperance Hall, by Prof. H. A. Miers, F.R.S., on "The Growth of a Crystal."

Excursions are being arranged to Belvoir Castle, the seat of the Duke of Rutland; Chatsworth, the Duke of Devonshire's Midland home; Haddon Hall, and to Peterborough Cathedral, with an invitation to tea in the Palace grounds from the Bishop. In addition to a general excursion to the Charnwood Forest, there will be a special one both there and to the district of Belvoir for geologists, whilst the botanical section is also planning walks in the same district.

An interesting trip will be that over the Leicester and Swannington railway now forming part of the Midland Railway system. This is one of the earliest railways in the kingdom, and the honoured names of George and Robert Stephenson are closely associated with it. Opened for traffic in 1832, the first object of this railway was the provision of a cheap supply of coal from the district it tapped to Leicester, and there is no doubt its formation greatly influenced the prosperity of the town. From the West Bridge Station, Leicester, the line enters the Glenfield Tunnel, which is 1796 yards long, cut straight and level, 14ft. high, 12ft. 6in. wide, and built of 18in. brickwork. On the opening day a special train conveying the directors left Leicester for Bagworth. In entering the tunnel referred to the chimney of the engine, *The Comet*, was knocked down, with the result that the passengers travelled to the Glenfield end through thick smoke and dust. The train was stopped at the Glenfield Brook to permit of a general washing of faces and hands. At Bagworth an incline of 1 in 29 was originally worked by a rope 1000 yards long, 5 inches circumference, the full wagons of coal pulling up the empties. The Swannington incline, 1 in 17, has since 1833 been worked by a fixed winding engine and rope. The original engine, one of the first to be fitted with a piston-valve, is still in use. From the commencement, three passenger trains ran daily from the West Bridge Station, Leicester, and these still continue to be run, to almost the original times. It was owing to a collision at this station between an engine and a country cart, and the consequent smashing of a lot of eggs, that the engine whistle was invented for the purpose of sounding warnings. The chief boot and shoe and hosiery works in the town are to be visited, as well as the works of the water and gas and electric lighting undertakings of the Corporation. The principal Council schools will also be open for inspection.

Sectional meetings will be held on four or five days of the meeting at carefully chosen centres. The presidents of the various sections are as follows:—A (Mathematical and Physical Science), Prof. A. E. H. Love, F.R.S.; B (Chemistry), Prof. A. Smithells, F.R.S.; C (Geology), Prof. J. W. Gregory, F.R.S.; D (Zoology), Dr. W. E. Hoyle; E (Geography), Mr. G. G. Chisholm; F (Economic Science and Statistics), Prof. W. J. Ashley; G (Engineering), Prof. S. P. Thompson, F.R.S.; H (Anthropology), Mr. D. G. Hogarth; I (Physiology), Dr. A. D. Waller, F.R.S.; K (Botany), Prof. J. B. Farmer, F.R.S.; L (Educational Science), Sir Philip Magnus, M.P.

Every care is being taken in order to ensure the comfort and convenience of all attending the various meetings, and when the arrangements are completed it is anticipated that the accommodation generally will compare most favourably with that provided elsewhere. The various local secretaries are enthusiastically working with headquarters in the endeavour to make the Leicester meeting one to be long remembered for real usefulness and importance. The ladies of the town have formed a special hospitality committee, and are working to make, as they hope, ample provision for the large number of expected guests.

THE ASWAN RESERVOIR.

THE Egyptian Government has lost no time in arranging for the archæological survey of that portion of the Nile Valley which will be submerged by the Aswan reservoir when the dam has been raised seven metres above its present height.

The archæology of Nubia has not so far been very thoroughly studied, so that a comprehensive scheme of work must include:—(1) The consolidation of the foundations of ancient structures; (2) such repairs as are necessary to ensure their safety; (3) the copying of all inscriptions, and a complete photographic record of these buildings; (4) complete plans of each building, showing all structural details; (5) systematic excavation, together with the preparation of plans and photographs of all ancient sites, cemeteries, &c., which will be damaged by the increased level of the reservoir; (6) a complete topographical survey of the valley, which will also indicate all sites, buildings, &c., of archæological interest.

Under the arrangements which have been made by Sir William Garstin, G.C.M.G., Adviser of the Ministry of Public Works, the first three of these will be carried out by the Department of Antiquities; the last three sections, which constitute a survey, both topographical and archæological, will be carried out by the Egyptian Survey Department.

As the dam in its present condition admits of the water-level being raised 1·5 metres if necessary, the investigation of the area which would be affected by this will be undertaken at once, and preparations have been made to commence work in the early autumn of this year.

The recent cadastral survey of Nubia, 1:2500 reduced to the scale of 1:5000, will be utilised as the basis of the topographical survey in order to record the position of all ancient settlements, cemeteries, and structures as they are taken in hand, while the slopes of the valley will be surveyed and contoured.

The Egyptian Government has secured the services of Dr. G. Reisner, who will commence the systematic excavation of ancient sites at the end of September next at the southern limit of the area now submerged. From this point work will be carried on southwards so as thoroughly to examine the valley floor on either bank up to the future level of the reservoir (113 metres above sea-level), and as much above that as may be necessary on account of the water soaking the ground for some distance above it.

The Egyptian Government has included in the estimates for raising the dam a sum of 60,000*l.* for this work, which should suffice both for a thoroughly scientific study of the reach which is to be submerged, and for the necessary work of consolidating the foundations of temples. Facilities will be given to any archæological institutions which may wish to undertake the study of any site, and will thus facilitate the work. All other parts which have not been systematically explored by such institutions will be examined in due course by Dr. Reisner and his staff, and the results will be published so as to form a complete archæological record of this reach of the river.

PROF. ALFRED NEWTON, F.R.S.

WHILE zoological, and more especially ornithological, science has been deprived of one of its most illustrious students and exponents by the death of Alfred Newton, Cambridge has sustained an even more severe blow, both scientifically and socially. For not only has she lost in the late occupant of the chair of zoology a distinguished professor and working zoologist, and a great benefactor to her zoological museum, but likewise a social figure, whose place can never be exactly filled. For the past forty years or so the informal receptions held in term-time by Newton on Sunday evenings at his well-known rooms in Magdalene formed a unique feature in the scientific life of the university. To these gatherings not only were resident zoologists and the more advanced scientific students from all the colleges in Cambridge constant and welcome visitors, but older *alumni* re-visiting their *alma mater*, as well as zoologists educated at other seats of learning, were received and greeted by their host in that genial manner peculiarly his own. Reunions such as these must, unhappily, die with the man to whom they were due; but those in the smoky atmosphere of the old rooms at Magdalene will linger long in the memories of all the kindly old professor's former pupils and friends.

Born in Geneva on June 11, 1829, Alfred Newton belonged to an old East Anglian family, being the fifth son of William Newton, of Elveden, Suffolk, sometime M.P. for Ipswich, by Elizabeth, daughter of R. S. Milnes, of Fryston, Yorkshire, who represented his county town in Parliament. As a boy he was educated privately, but in due course he entered Magdalene College, Cambridge, as an undergraduate, and took his B.A. degree in 1853. In that year, as well as in 1852, he gained the English essay prize at Cambridge; and in 1854 he was elected to a travelling fellowship at his college, which he held until 1863. During the time that he held the travelling fellowship, Newton visited Lapland, Iceland, the West Indies, and North America, while in 1864 he accompanied Sir (then Mr.) Edward Birkbeck to Spitsbergen, then but little known zoologically. To these travels may in all probability be attributed a large proportion of his unrivalled knowledge of the distribution and habits of European birds. At a later period, during a visit to Heligoland, Newton sustained an injury in landing from a boat, which seriously increased a lameness due, we believe, to an accident in childhood. Ornithological observations were, however, continued for many years subsequently during summer yachting cruises, undertaken in company with the late Henry Evans, on the west coast of Scotland and elsewhere.

The most important and far-reaching event in the life of Newton occurred in the year 1866, when he was elected to the then newly-established professorship of zoology and comparative anatomy, a somewhat poorly paid office, which he held until his death on the 7th day of the present month, although he had for some years given up lecturing. The active part which he (in conjunction with his old friend Mr. J. W. Clark) took in the development of the Zoological and Anatomical Museum, and the energy with which he did all in his power to promote the study of zoology in the university, are known to all Cambridge biologists. As to his lectures, these, despite the fact that he was to a great extent a specialist in ornithology, covered a very wide field, in which, however, the systematic and distributional aspects of his subject loomed large.

So long ago as 1859 Newton was elected a Fellow of the Zoological Society of London; and two years later commenced a long, although, of course, interrupted, service on the council of that body, of which he was also for many years a vice-president. In 1870 he received the Fellowship of the Royal Society, and served on the council from 1879 to 1881, and again from 1889 to 1891, being also a vice-president during the latter period. From the same body he received in 1900 one of the Royal gold medals, while he was also the recipient in the same year of a gold medal from the Linnean Society, of which he was for many years a fellow. It should be added that in 1877 he was re-elected to a fellowship at his old college, which thus remained his home until the end of his days. Needless to say, the Cambridge Philosophical Society claimed him for a long period as a fellow, and subsequently as president.

Two years after his election to the professorial chair, that is to say, in 1868, Newton brought before the British Association the subject of the protection of birds; and he was subsequently for several years chairman of the close-time committee, during which period the first three Acts devoted to bird-protection were passed by Parliament. As the British Government was the first to move in this matter, Newton may be regarded as the father of bird-protection throughout the world, and, indeed, of all legislation of this nature, which had its origin in his early efforts. His endeavours to check the hideous cruelties connected with the collecting of so-called osprey plumes form another of his many claims to the gratitude of posterity. The establishment and maintenance of stations for observing the migration of birds also claimed a large share of his time and attention, and he was for many years chairman of the British Association Migration of Birds Committee. The important results which have accrued (and are still accruing) from these observations are familiar to all naturalists.

The scientific writings of Newton, which relate chiefly to ornithology, are remarkable for their finished and scholarly style, as well as for their extreme accuracy. To ensure both these attributes the author would, in the first place, defer sending his MS. to press as long as possible, and when it was in type he would go on correcting and refining until both printers and publishers must in many cases have been driven to the verge of insanity. As he was also a slow writer, the production of such of his works as were issued in parts extended over unconscionably long periods. Although, as already mentioned, characterised by the excellence of their literary style, Newton's writings in not a few instances were marked, more especially in footnotes, by criticisms of perhaps rather more caustic character than the occasion demanded.

Newton's earliest recorded paper appears to be one on the cedar-bird, published in the *Zoologist* for 1852, this being followed in the next year's issue of the same journal by one on the habits of the kiwi. His visit to the West Indies was marked by the appearance in 1859, in the first volume of the *Ibis*, of a paper on the birds of those islands. This reference to the *Ibis* affords a convenient opportunity of mentioning that Newton took a prominent part in founding that invaluable journal, of which he edited the second series (1865–70). He also took an active share in founding the *Record of Zoological Literature* (now the *Zoological Record*) a publication without which the study of zoology would now be practically impossible. To the first six volumes Newton contributed the annual record of the class Aves, while he acted as editor from 1871 to 1874 (vols. vii.–ix.). It may be added that his exertions and influence were no less important at a later period in bringing about the establishment of the British Ornithologists' Union.

The fact that during the 'sixties his brother Edward held the post of auditor-general of Mauritius (subsequently becoming governor) seems to have directed the attention of Alfred Newton to the birds, both living and extinct, of the Mascarene Islands. In 1861 and 1863 we find him, for instance, describing certain new birds from Madagascar and Mauritius; while in 1868 he and his brother communicated to the Royal Society a most important paper on the remains of the dodo-like bird from Rodriguez commonly known as the solitaire (*Pezophaps solitaria*), this paper being published in the Phil. Trans. for the following year. The same subject was continued at a later period, when Newton and Mr. J. W. Clark communicated a joint paper, published in the "Zoology of the Transit of Venus Expedition of 1874," a second paper, on the extinct birds of Rodriguez, other than the solitaire, being contributed by Dr. A. Günther and Newton to the same volume. The dodo was also a bird in which Newton was greatly interested, although the description of its remains from the Mare aux Songes was undertaken by his brother, Sir Edward Newton.

At an early period in his career Newton contributed to the *Ibis* (vol. iii., 1861) an epitome of John Wolley's investigations into the history of the extermination of the great auk, or gare-fowl; and from that time to his death the story of that bird was a subject to which his attention was constantly devoted. Indeed, we believe that at the very end of his active career he was engaged on a monograph which should comprise all that is known of that remarkable species.

One of Newton's earliest papers was "Suggestions for forming Collections of Birds' Eggs," published in London in 1860, and from that time onward the study of eggs attracted a large share of his attention. About this time he appears to have come into possession of the magnificent collection made by the late John Wolley—on condition, we believe, that he would write a descriptive catalogue embodying the collector's notes. The first part of "Ootheca Wolleyana" appeared in 1864, while the last was issued only a few months before the author's death. For a long period Newton believed that eggs might afford important clues to many vexed questions connected with avian relations; but this hope he was reluctantly compelled, in the main, to abandon. The Wolley collection of eggs, largely augmented by its late owner, is, we believe, to pass to the University of Cambridge, as is also Newton's valuable ornithological library.

To the general public the late professor is perhaps best known as editor of the first two volumes of the revised and enlarged fourth edition of "Yarrell's British Birds," the first part of which appeared in 1871, although the second volume was not completed until 1882. On the value of this work (completed by Mr. Howard Saunders) it is unnecessary to dilate.

Not less important were the contributions of Newton to the ninth edition of the "Encyclopædia Britannica," these comprising not only a large series of articles on different groups and species of birds, but likewise the article "Ornithology"; the article "Birds," it should be added, being the joint work of Newton and the late Prof. W. K. Parker. With the assistance of Prof. H. Gadow, these articles were subsequently combined by their author to form the well-known "Dictionary of Birds" (1893–1896), which forms a perfect mine of information on ornithological subjects. To this work a few articles were contributed by Dr. R. W. Shufeldt, Mr. C. S. Roy, and the present writer (by whom it was deemed a special honour to be thus associated with his former teacher). The article "Ornithology," which forms the introduction to this volume, is a perfect model of a classically written essay, and includes practically everything that there is to be said regarding the history of the subject of which it treats; while the one on "Migration" is no less important and philosophical.

As regards the other ornithological work of Newton, it must suffice to refer to a chapter on the ornithology of Iceland, issued as an appendix to S. Baring-Gould's "Iceland" (1863), to one on the birds of Greenland in the "Arctic Manual" (1875), and to a list of the birds of Jamaica in a handbook to that island, published in 1881.

To assume that Newton confined his attention to ornithology would, however, give but an inadequate idea of the scope of his knowledge. From the first he was an enthusiastic student of zoological distribution, and in 1862 he read before the Cambridge Philosophical Society a paper "On the Zoology of Ancient Europe," published the same year as a pamphlet by Messrs. Macmillan. In this he directed attention, for the first time, we believe, in this country, to the fact that the name "aurochs" belongs by right to the extinct wild ox (*Bos primigenius*), and not to the bison. His studies had also convinced him that the separation of the northern portions of the two hemispheres as distinct primary zoological regions—the Palæarctic and the Nearctic—is not supported by the facts; and at his suggestion Prof. A. Heilprin in 1882 proposed to unite them under the name of the Holarctic. That this is the true view (especially if the southern portions of the eastern and western divisions be severally cut off as the Sonoran and Mediterranean transitional regions) scarcely admits of argument. A small zoological text-book, of which the first edition appeared in 1874, likewise bears witness to the breadth of Newton's knowledge.

Although essentially conservative in all matters connected with natural history, Newton could not be termed a bigoted Tory in these matters; and when he saw occasion to change or modify his views, he had no compunction in doing so. He was an early convert to evolution, and in 1888 published a pamphlet entitled "Early Days of Darwinism"; and as evidence of the elasticity of his mind in regard to lines of investigation with which he was personally out of touch, reference may be made to his earnest support of the morphological and embryological investigations of the late F. M. Balfour, and of the Mendelian researches of the present day. As regards ornithological classification, he maintained to the last the advisability of employing generic terms in a wide sense. Whether he would ever have given his approval to modern views on nomenclature and the subdivision of species are questions which need not here be discussed.

The late professor, to quote from the obituary notice in the *Times* of June 8, "was gifted with an affectionate nature, which was not the less real because it found little verbal expression, and, possessed of old-fashioned courtesy of manner, he had the best characteristics of the race of English country gentlemen to which by birth he belonged. Stanch in his friendships, firm in his opinions, and following what he held to be right with dogged perseverance, he was a man of whom anyone might well be proud to be the friend, and one whom a very wide circle is now most genuinely mourning."

To the present writer, if he may be allowed to say so, the loss is a very real one—more so than he cares to state fully in public. R. L.

NOTES.

We regret to announce that Prof. A. S. Herschel, F.R.S., died on Tuesday, June 18, at his residence, Observatory House, Slough.

The French section of the Alliance Franco-Britannique will pay a visit to London from June 30 to July 5, and will be entertained at dinner by the British section on July 1.

The third Prehistoric Congress of France will be opened at Autun on August 12 by the president, Prof. Adrien Guébhard, and will close on August 18. Particulars may be obtained from M. Marcel Baudoin, 21 rue Linné, Paris.

Four lectures on plague are being delivered by Dr. W. J. R. Simpson as the Croonian lectures of the Royal College of Physicians. The first lecture was delivered on Tuesday, and the second is to be given to-day. The two remaining lectures will be delivered on June 25 and 27.

Science announces that at the recent session of the Pennsylvania Legislature the Senate voted 60,000*l.* to enable the American Philosophical Society to erect a memorial to Franklin, but the house did not agree to the Bill.

Mr. W. T. Hornaday has presented to the New York Zoological Society his collections of heads, horns, and tusks, comprising 131 specimens, representing 108 species. These are to form the nucleus of a collection to be exhibited at the New York Zoological Park.

A report from Santiago de Chile states that a severe shock of earthquake occurred at Valdivia on June 13. A violent earthquake was also felt at Kingston, Jamaica, on the same date, at 1.20 a.m. The earthquake was especially severe at Port Royal. A curious turbulence of the sea was noticed. An earthquake was felt at Gibraltar at 5 a.m. on June 16.

Through the generosity of several members of the Pillsbury family, of Minneapolis, Dr. Thomas G. Lee has secured, says *Science*, for the department of histology and embryology, University of Minnesota, the working library of the late Prof. W. His, of Leipzig. This collection comprises more than 8400 monographs and other papers contributed by over 2500 different authors.

An exhibition of engineering models, optical, electrical, and scientific instruments, technical education appliances, and tools, is to be held at the Royal Horticultural Hall, Vincent Square, Westminster, S.W., on October 22–26. In addition to exhibits by leading makers, there will be a loan collection of experimental and exhibition models and apparatus, and also lectures and demonstrations in various branches of applied science.

The Victoria and Albert Museum has been opened to the public exactly fifty years to-day. On June 20, 1857, Queen Victoria and Prince Albert, accompanied by the Princess Royal (afterwards the Empress Frederick), the Archduke Maximilian of Austria (afterwards Emperor of Mexico), Prince Frederick William of Prussia (afterwards German Emperor), and a numerous suite, attended in the evening the opening of the South Kensington Museum, as it was at that time styled. In it there were exhibited several miscellaneous collections of a scientific character, mainly acquired from the Exhibition of 1851. The whole of the fine art collections which had been exhibited at Marlborough House since 1852 were also removed to South Kensington, and these were supplemented by valuable loans from H.M. Queen Victoria and others. Immediately after the opening of the temporary museum the erection of permanent buildings was commenced, and various portions were completed and opened in successive years. The greater part of the original iron building was taken down in 1868, and re-erected as a branch museum at Bethnal Green. The foundation stone of the new buildings was laid by H.M. Queen Victoria on May 17, 1899, and by her late Majesty's command the name of the institution was changed to that of the Victoria and Albert Museum.

The Engineering Conference of the Institution of Civil Engineers, which began on June 18, will conclude to-morrow. On Tuesday, June 18, Dr. Francis Elgar, F.R.S., delivered the fifteenth James Forrest lecture, taking for his subject "Unsolved Problems in the Design and Propulsion of Ships." The conference was opened formally on June 19, when the president of the institution, Sir Alexander Kennedy, F.R.S., delivered his inaugural address. This evening a conversazione is to be held at the Albert Hall. The business part of the conference is being carried on in the sections, in connection with which meetings are taking place daily until 1 p.m. There are in all seven sections, which, with their chairmen, are as follows:—Section i., railways, Mr. William R. Galbraith; Section ii., harbours, docks, and canals, Sir William Matthews, K.C.M.G., who is also president-elect of the institution; Section iii., machinery, Prof. W. C. Unwin, F.R.S.; Section iv., mining and metallurgy, Mr. John Strain; Section v., shipbuilding, Dr. F. Elgar, F.R.S.; Section vi., water works, sewerage, and gas works, Sir George T. Livesey; Section vii., applications of electricity, R. E. B. Crompton, C.B. We hope to publish an article on the conference in a future issue.

Two important additions to the collection in the Natural History Museum were put on exhibition for the first time at the conversazione of the Royal Geographical Society, held in the hall of the museum on Friday last. The first is the mounted skin of a male okapi, obtained during the late Alexander-Gosling expedition on the River Welle, near Angu, in the northern part of the Congo Free State, and presented by Mr. Boyd Alexander. The second is a model of the complete skeleton of the marsupial Diprotodon, based on material obtained by Mr. E. C. Stirling in the Lake Cadibona district of south central Australia. In this skeleton some portions of the limbs and feet are represented by the original bones. Diprotodon, it will be recalled, was named many years ago on the evidence of a lower jaw described by Sir R. Owen. Now that the complete skeleton is known, there is little doubt that the creature was a gigantic relative of the wombats, retaining, perhaps, in its foot-structure evidence of arboreal ancestry. In one of the recesses on the right side of the central hall were also exhibited portraits and relics of Linnæus. The portraits of the great naturalist, represented by small woodcuts, were ten in number. Several Linnæan manuscripts sent from Bloomsbury were shown, as well as several books from the library of Linnæus (the property of the Linnean Society), and certain plants from his herbarium.

In accordance with previous announcements, the autumn meeting of the Iron and Steel Institute will be held in Vienna on September 23–25. An influential reception committee has been formed, with an executive consisting of Mr. W. Kestranek, central director of the "Prager Eisen Industrie Gesellschaft" as chairman, Max Ritter von Gutmann as vice-chairman, Mr. Richard von Schoeller as treasurer, Baron von Jüptner, A. Ritter von Kerpely, Mr. F. Schuster, and Mr. Hugo von Noot as members, and Dr. Eugen Herz and Mr. H. von Noot, jun., as honorary secretaries. The provisional programme of the meeting is as follows:—On Monday, September 23, the president, council, and members will be welcomed by the reception committee, by the Government and civic authorities, and by the president of the Society of Engineers and Architects, at the headquarters of which the meeting will be held. A selection of papers will subsequently be read and discussed. In the afternoon, members and the ladies accompanying them will be taken for a drive through Vienna and in the Prater, visiting the Municipal Museum and the Town Hall, where they will be received by the Lord Mayor of Vienna, and in the evening a special performance at the Imperial Opera House will be arranged. On Tuesday, September 24, the morning will be devoted to the reading and discussion of papers, and the afternoon to a visit to the Imperial Palace at Schönbrunn. On Wednesday, September 25, the whole day will be devoted to an excursion to the Hoch-Schneeberg. In the evening the members and ladies will be invited to a banquet at the Hall of the Musical Society. At this and at all the other functions, including the visit to the opera, the members and ladies will be the guests of the Austrian Iron Works. On Thursday, September 26, will begin the excursions to the works to be visited in (1) Bohemia; (2) Styria; and (3) Moravia and Silesia.

It is reported in the daily Press that Prof. von Leyden has arrived at the conclusion that the development of cancer is due to the diminution or absence of certain chemical substances in the liver. Further details will be awaited with interest.

In the *Bio-chemical Journal* for May (ii., Nos. 5 and 6) Drs. Garrod and Clarke describe a new case of alcaptonuria, Drs. Little and Harris discuss the metabolism in a healthy vegetarian, Dr. Barger and Mr. Dale describe the physiological action of some of the constituents of ergot, Dr. Drabble, Hilda Drabble, and Daisy Scott discuss the influence of neutral salts on the size of the cells of pleurococcus and saccharomyces, and Prof. Moore and Drs. Nierenstein and Todd publish experiments on the treatment of trypanosomiasis with atoxyl, an organic arsenical compound, followed by a mercuric salt, showing that this combination is much more successful than atoxyl alone.

At a meeting of the Pathological Society of London on June 4, Drs. Sambon and Seligman described a number of hæmogregarine parasites obtained from snakes. Dr. Pye-Smith, the president, gave a valedictory address, for the society as such ceases to exist, being merged (as the pathological section) into the new Royal Society of Medicine.

By the amalgamation of fifteen out of the twenty or twenty-five medical societies of London, the Royal Society of Medicine has been constituted, the incorporated societies forming the sections of the new society. A meeting was held on June 14 for the purpose of receiving and adopting a Royal charter. The meeting was presided over by Mr. Warrington Hayward, the president of the Royal Medical and Chirurgical Society, the wealthiest and principal society of the amalgamation, when Sir William Church was elected the first president. Each society (now a section) will carry on its special work as before. The Royal Society of Medicine will commence with a membership of 4000, an annual income of nearly 8000*l*., and possesses a library of 80,000 volumes.

A list of the palæontological type specimens in the collection of the Boston (U.S.A.) Society of Natural History, by Mr. J. A. Cushman, has been published as No. 6 of vol. xxxiii. of the Proceedings of that body.

Bulletin No. 4 of the Division of Entomology, Honolulu, is devoted to a further account of the parasites of leaf-hoppers, by Mr. R. C. L. Perkins, together with descriptions of certain new Hemiptera, by Mr. C. W. Kirkaldy, the material having been almost entirely collected in Arizona.

A paper on the ants of Saxony, by Mr. H. Viekmeyer, and one on change of function in various animal organs, by Mr. A. Jacobi, form the most important zoological contributions to the *Abhandlungen* of the Dresden Isis for the second half of 1906 (1907).

In the May number of *Naturen* Mr. O. J. Lie-Pettersen concludes his account of Scandinavian thrushes, in which special attention is directed to the dates of arrival of the migratory species. "F. V. H." figures a horse with a supplemental front toe, which was successfully removed in the Copenhagen Veterinary Institution.

"Dwellers in our Rock-pools" is the title of a small illustrated booklet describing the common littoral fauna of Folkestone. The author is Mr. F. Rutt, and the pamphlet is published by Messrs. A. Stace and Sons, of Folkestone, at the price of threepence. We have also to welcome a cheap re-issue of Mr. E. W. Wade's "Birds of Bempton Cliffs," published by Messrs. A. Brown and Sons, Ltd., of London, Hull, and York, at one shilling.

The functions of the "spiracles" in skates form the subject of an interesting article, by Mr. H. W. Rand, in the May number of the *American Naturalist*. Some time ago the author received about half a dozen skates which had been out of the water for nearly an hour, and were consequently presumed to be dead. When salt water was discharged on them from a hose, they gradually, however, showed signs of returning life, and eventually spouted copious jets of water from their spiracles. As such a phenomenon had not been previously noted by the author, he set himself to study the functions of the spiracles generally. Owing to the habit of lying flat on the sand, the spiracle, of which the primary function is to take in water, appears of much more importance to skates than to sharks. In addition to serving as an intake, it also acts as an exhalent orifice, soft substances, such as fragments of seaweed, which have gained an entrance into the gill-chamber, being expelled by spouting through the spiracles. Spouting also appears to be employed as a means of keeping the eyes clean.

In the May number of the *Zoologist* Mr. C. M. D. Stewart discusses a somewhat mythical snake known to the Zulus as "ndhlondhlo." It was reported to be of huge size, poisonous, very fierce, and furnished with a feather-like crest, while it was also asserted to utter a whistling cry. Its name forms one of the titles of the Zulu king. The main question appears to be whether the creature was a distinct species or whether we have to do with overgrown individuals of the one locally known as the black mamba (*Dendraspis angusticeps*, var.). A snake shot by the Commissioner of Zululand about 1874, measuring about 16 feet in length, and regarded by that gentleman as a black mamba, was declared by the Zulus to be a ndhlondhlo. Certainly naturalists have no knowledge of black mambas of that length, but this by no means proves that such may not have existed. The argument used by the author, that as no such giants are now known the ndhlondhlo must have been a distinct species, does not seem to us to carry much weight.

In his Huxley memorial lecture for 1903 (Nature, vol. lxviii., p. 607), Prof. Karl Pearson showed that the mental and moral characters of man are inherited in much the same manner as the physical characters. "We inherit," he said, "our parents' tempers, our parents' conscientiousness, shyness and ability, even as we inherit their stature, forearm and span." This conclusion was arrived at as the result of a prolonged investigation of fraternal resemblance between children, based on the estimates of school teachers. At the Francis Galton Laboratory for National Eugenics, University of London, the inquiry has been extended to material derived from class lists of the University of Oxford and the school lists of Harrow and Charterhouse, and the results are given in a memoir—"The Inheritance of Ability," by Edgar Schuster and Ethel M. Elderton—just published (London: Dulau and Co., price 4*s*.). The definite object of the investigation was to determine as exactly as possible the resemblance between father and son and brother and brother, as indicated by successes or failures in passing the examination for the B.A. degree at Oxford, or by their positions in school at Harrow and Charterhouse at corresponding times. The results obtained from the Oxford material show that the correlation between father and son is represented by 0·312, and that between brother and brother by 0·405, on a scale by which complete resemblance would be indicated by 1 and no resemblance by 0. The public-school material gave the value 0·398, which is in close agreement with the Oxford value, for the correlation coefficient between brother and brother. The general result of the inquiry is therefore to confirm Prof. Pearson's conclusions as to the inheritance of psychical characters in man.

A reprint has been received of an account of the development of the common mushroom, *Agaricus campestris*, contributed by Prof. G. F. Atkinson to the *Botanical Gazette* (September, 1906). Examination of the very early stages indicated that, except for the universal veil, no differentiation was noticeable until the hymenium or spore-bearing layer develops and marks off the stem and the cap. The author states that he has found two spores only arising from the basidia in cultivated varieties, whereas he has often identified four spores in normal pasture forms.

In the *Trinidad Bulletin* (April) Mr. J. H. Hart, referring to the packing of seeds for the tropics, discriminates between seeds that can be fully dried without injury, such as the seeds of temperate plants, and the seeds of many tropical plants that lose their vitality if only a small percentage of water is removed. A botanical irregularity in the shape of a nutmeg-tree bearing both staminate and pistillate flowers is recorded from the island. Allusion is also made to a variety, *longipedunculata*, of the palm *Pritchardia pacifica*, distinguished by the length of the flower stalks, of which plants have been raised from seed originally supplied from British Guiana.

An irregular series of nuclear changes in the development of the embryo-sac of *Peperomia hispidula*, differing slightly from the development in *Peperomia pellucida*, is described by Prof. D. S. Johnson. Sixteen nuclei are formed in the embryo-sac, of which two become the nuclei of the ovum and one synergid respectively, while the remaining fourteen fuse to form the endosperm nucleus; also the divisions of the endosperm nuclei are at once followed by the formation of cell-walls, so that the endosperm is cellular from the start. A preliminary notice with illustrations is published in the Johns Hopkins University Circular (March), wherein Mr. W. D. Hoyt records the observation of crops of sexual cells of *Dictyota dichotoma* at monthly intervals at Beaufort, North Carolina, as compared with fortnightly crops observed by Mr. J. Lloyd Williams at Bangor.

We have received from the Engineering Standards Committee copies of the British standard specification for ingot steel forgings for marine purposes (No. 29, price 2*s*. 6*d*. net), and of the British standard specification for steel bars for use in automatic machines (No. 32, price 2*s*. 6*d*. net). The former is based on the present specifications of the Admiralty, the Board of Trade, and the three leading registry societies, whilst the latter is based upon evidence collected from users and manufacturers. The mechanical tests and chemical analyses of steel bars for use in automatic machines are also based on the evidence obtained, supplemented by the results of actual testing. Owing to the widely different results when bars of small diameter are subjected to mechanical tests, it has been decided not to include such tests for steel bars less than half an inch in diameter.

In 1903 the Canadian Government appointed a commission to investigate the different electrothermic processes for the smelting of iron ores and the making of steel in operation in Europe. Since that date experiments have been made by Dr. P. Héroult at Sault Sainte Marie, Ontario, under Government auspices, in the smelting of Canadian ores in a specially designed electric furnace. The superintendent of mines, Dr. E. Haanel, has now issued a detailed report (Ottawa: Department of the Interior, 1907) containing in 149 pages a statement of the work done and of the results obtained, with analyses of the pig iron and slag produced and of the iron ores employed. Illustrations of the furnace and machinery used are given. The results obtained were most gratifying, and were briefly as follows:—Canadian ores, chiefly magnetites, can be smelted as economically as hæmatites in the electric furnace. Ores high in sulphur can be converted into pig iron containing only a minute proportion of sulphur. The silicon content can be varied as required for the class of pig iron to be produced. Charcoal, which can be cheaply produced from waste material, and peat-coke can be substituted for coke. Nickeliferous pyrrhotite and titaniferous iron ores containing up to 5 per cent. of titanium can be successfully treated. The far-reaching consequences of these results will be apparent. Many magnetites are too high in sulphur to be dealt with in the blast-furnace, and consequently have hitherto been of no commercial value. The introduction of electric smelting, too, will render it possible to utilise water-power that cannot at present be profitably employed for any other purpose, and to utilise peat bogs and mill refuse or sawdust, for which there has hitherto been no use. An appendix contains an account of recent improvements in electric smelting made in Sweden and in Germany.

In the *Rendiconti* of the Lombardy Institution, xl., 8, Prof. Torquato Taramelli gives a short obituary notice of the work of Dr. Benedetto Corti. This work consists largely in the study of the fossil microzoa of the Tertiary and Quaternary deposits of Lombardy, and forms an important contribution to Italian geology.

Dr. Giovanni Zappa, writing in the *Atti* of the Lincei Academy, discusses the possibility of the instruments in the observatory at Padua being affected by tides in the Adriatic. The author makes calculations of the gravitational effects, based on tide tables, using a method of triangulation as a basis of rough computation, but the results appear to be too small to have any appreciable effect even on the seismographs at Padua.

In the Bulletin of the St. Petersburg Academy of Sciences, Prince B. Galitzin describes an experimental verification of Doppler's principle for light rays, conducted in collaboration with J. Wilip. Use was made of rotating mirrors, as in the experiments of Bielopolsky, but by means of the graduated spectroscope (Stufenspektroscope) described previously by Prince Galitzin, it was possible to photograph and measure the displacements of the spectral lines of a mercury arc lamp used as the source of light. In this way quantitative results were obtained within the limits of experimental error.

Mr. C. E. Benham, writing from Colchester, June 4, points out that it is a common practice in lantern demonstrations, when it is desired to minimise the heat radiation, to interpose a cell of alum solution, though distilled water is actually more athermanous than water with alum in solution. The common belief that an alum solution is very opaque to thermal rays was disproved many years ago, but evidently has not yet quite disappeared even at the present time.

The supplement to *Mitteilungen aus den deutschen Schutzgebieten* (vol. xx., part ii.) contains the observations made in the year ended June, 1906. Taking into account the results from all stations, the rainfall was favourable, but less in amount than in the two previous years. The annual falls vary, according to position, from 27·5 inches to 0·3 inch; May to August are practically rainless months. The largest amount recorded in one day was 4·5 inches, at Seeis, in the central district, on January 30, 1906. The stations now number seventy, against sixty-seven three years previously, notwithstanding that two-thirds of them were destroyed or necessarily abandoned after the outbreak of the war.

Owing to a slight accident, Mr. Francis Galton was unable personally to deliver his Herbert Spencer lecture at Oxford, referred to in last week's Nature (p. 158), but the lecture was read by his cousin, Mr. A. Galton.

An illustrated guide to holiday resorts in the United Kingdom has been published under the title of "The Holiday Whitaker" by Messrs. J. Whitaker and Sons, Ltd. The present edition is intended as a guide to resorts for the summer season, and it is proposed to issue another and different edition for the winter season.

Accurate and interesting "guides" greatly assist the intelligent visitor to examine and understand the objects exhibited in a museum. The trustees of the British Museum are rendering a great service to natural science in ordering the publication of the excellent series of handbooks to accompany the admirable collections exhibited at the Natural History Museum, South Kensington. The most recent of these volumes is the "Guide to the Fossil Invertebrate Animals in the Department of Geology and Palæontology," which, with its seven half-tone plates and ninety-six text figures, will enable the visitor to the galleries to appreciate the significance and importance of the various fossils on view. We learn from the director's preface that the book has been written by Dr. F. A. Bather, and that the formerly published "Guide to the Fossil Invertebrates and Plants" is partly replaced by the present volume, the price of which is one shilling.

Several new volumes belonging to the concise and comprehensive series of Hoepli manuals have recently been received from the publisher, Mr. U. Hoepli, Milan. Two volumes by Prof. P. E. Alessandri, entitled "Merceologia Technica," deal respectively with natural and chemical products of commercial and industrial use. Caoutchouc and gutta-percha is the subject of a volume by Dr. L. Settimj, and the preservation of foods of one by Drs. G. B. Franceschi and G. Venturoli. Other volumes are on taxidermy, by Dr. R. Gestro; radio-activity, by Dr. G. A. Blanc: and limnology, or the scientific study of lakes, by Dr. G. P. Magrini.

Many publications of deep scientific interest have been issued by the Carnegie Institution of Washington and described in the columns of Nature. A list has just been received of ninety-two works available now or shortly which the institution has published or has in the press. Applications for the list or for copies of the works not out of print should be sent to the Carnegie Institution of Washington, D.C., U.S.A.

The Proceedings of the Anglo-Russian Literary Society for February, March, and April have now been published in one small volume. The papers read at the monthly meetings of the society, one of the objects of which is to promote the study of the Russian language and literature, are here reprinted. We notice in an obituary of the great Russian chemist, Mendeléeff, the remark, "A prophet is not without honour, save in his own country; Mendeléeff was black-balled at the elections in the Imperial Academy of Sciences."

Messrs. West, Newman and Co. have published a fifth edition of the late Rev. Joseph Greene's "Insect Hunter's Companion." The little book, which runs to 120 pages, gives instructions for collecting and preserving butterflies, moths, beetles, bees, flies, &c., and has been revised by Mr. A. B. Farn. Its price is 1*s.* 6*d.* net.

OUR ASTRONOMICAL COLUMN.

Another New Comet, 1907*d*.—A telegram from the Kiel Centralstelle announces the discovery of the fourth comet of this year by Mr. Daniel, at Princeton, on June 14. The object was of the eleventh magnitude, and at 14h. 19·1m. (Princeton M.T.) on the day of discovery its position was

R.A. = 23h. 48·53 m., dec. = 1° 8′ S.,

which lies about half-way between λ and 29 Piscium. The daily motion is given as +34′ in R.A. and +14′ in declination.

A second telegram from Kiel states that this comet was observed by Prof. Aitken at the Lick Observatory on June 13, when its position at 15h. 7·2m. (Lick M.T.) was

R.A. = 23h. 59m. 44·4s., dec. = 0° 10′ 16″ S.,

which is about 22·5m. E. and $1\frac{1}{2}$° S. of λ Piscium. This object is apparently becoming brighter at a rapid rate, for Prof. Aitken gives its magnitude as 9·5.

Titanium Flutings in the Spectrum of α Orionis.—From the examination of the spectrum of α Orionis taken with the four-prism spectrograph, Mr. Newall believes that he has discovered the presence of three titanium flutings in the red end of the spectrum of that star. The wave-lengths determined for the heads of the flutings, viz. λλ 7053, 7087, and 7124, agree fairly well with those found by Messrs. Hale and Adams in the spectrum of the titanium-arc flame, whilst collateral evidence, based on the analogy between the spectra of sun-spots and third-type stars, suggests that these bands are to be expected in stellar spectra of the α Orionis type, because they have been found in sun-spot spectra. Two other flutings, with heads at λλ 5166·8 and 5447·1 respectively, were also found, and agree with the heads of the two strongest Ti flutings found by Prof. Fowler.

An inter-comparison of sun-spot spectra and the spectrum of α Orionis shows that numerous spot lines occur in the stellar spectrum (Monthly Notices R.A.S., vol. lxvii., p. 482, May).

Tin in Stellar Atmospheres. On examining some spectrograms of α Scorpii for radial-velocity determinations, Mr. Goatcher, of the Cape Observatory, found a persistent discrepancy occurring when measurements of the wave-length of a line at about λ 4525 were reduced, this line always giving a velocity about 6 km. per second too low. This discordance was examined by Mr. Lunt, who arrived at the conclusion that it is probably due to the hitherto unsuspected presence of a tin line, the wave-length of which, according to Exner and Haschek's tables, is λ 4525·00. In the region covered by the spectrum which was examined, the latter observers give only one other tin line, and as this, according to Sir Norman Lockyer's published tables, is an enhanced line, it is not to be expected in the spectrum of α Scorpii (Antarian type). Should Mr. Lunt's conclusion be confirmed, it will be the first occasion on which tin has been shown to exist in the atmosphere of a star (Monthly Notices R.A.S., vol. lxvii., p. 487).

Non-polarisation of the Light of Prominences.—In a note appearing in No. 21 (May 27) of the *Comptes rendus*, M. Salet states that, although he was able, during the total solar eclipse of 1905, to show that the coronal radiations down to the edge of the moon were polarised, he was unable to observe any trace of polarisation in the prominence radiations. M. Salet then points out that this result appears to introduce a contradiction to the theory of Prof Julius, that the monochromatic light of a point on a prominence comes in reality from a point on the photosphere, for, according to Schmidt, such a ray would be strongly deviated by the successive refractions of the solar envelopes, and should then become partially polarised, the quantity of polarisation depending, by Fresnel's theory, only on the value of the deviation. The absence of polarisation seems, therefore, to argue that the light is not deviated, and, consequently, that it does not have to pass through the solar atmospheres from the disc.

Nova T Coronæ of 1866.—Some interesting observations concerning Nova Coronæ are made by Prof. Barnard in vol. xxv., No. 4 (p. 279, May), of the *Astrophysical Journal*. Before its outburst this star was of magnitude 9·5, then it increased to the second magnitude, finally relapsing to 9·5. Novæ generally fade away to a much less brightness than this.

Prof. Barnard has repeatedly examined this star with the 40-inch refractor, but can find no difference of focus such as usually exists between the light from faded Novæ and the stars in general. Estimations of magnitude show that the star still has essentially the same magnitude that it had before 1866; there is no definite indication of motion in the Nova. Prof. Barnard found a faint nebula in the field with the Nova, the nebula being of magnitude 14·0 or 15·0, and having a diameter of 5″ to 10″ with no nucleus.

THE SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES.

THE twelfth annual congress of the South-Eastern Union of Scientific Societies, which opened at Woolwich on June 12 and closed on June 15, was in every way a very successful gathering. At the first evening meeting, held in the New Town Hall, Mr. Francis Darwin, F.R.S., the retiring president, introduced his successor, Prof. Silvanus P. Thompson, F.R.S., who delivered the inaugural address. This was an eloquent discourse, mainly on the value of voluntary work in science—such work as is carried on non-professionally by members of local scientific societies constituting the South-Eastern Union. These societies consist chiefly of persons who may be called, in the best sense of the word, amateurs. Exposing the fallacy of the popular saying that "a little knowledge is a dangerous thing," the president advocated the cultivation of scientific hobbies, enlarged on the value of acquiring a taste for studies outside the monotonous round of daily work, and showed how science had frequently been advanced by the work of amateurs. Among examples of famous amateurs, he pointed to William Herschel, originally a teacher of music; Gilbert, of Colchester, who was a medical man; and Joule, a Manchester brewer: nor were Spottiswoode, De la Rue, and Dr. Dallinger overlooked, whilst Sir Edward Fry's study of British mosses was cited as a contribution to science by an eminent lawyer. But to an audience at Woolwich the most telling example was that of William Sturgeon, the inventor of the electromagnet, who lived at one time as a shoemaker at Woolwich. Electricity has indeed been to a large extent a layman's science.

Prof. Thompson dwelt at some length on Goethe's researches on colour, and rather startled his hearers by affirming that in the famous controversy with Newton the poet-philosopher was in some sense right. Looking at natural science with the eye of a poet, Goethe failed to comprehend the value of Newton's work, and obstinately maintained that in the prismatic analysis of light the colour was derived from the prism itself, and not from the white light. But though it is generally held that the *Farbenlehre*, in which he published his views, embodies an elaborate optical heresy, it has, strangely enough, been recently shown by Lord Rayleigh's researches that there is, after all, some truth in Goethe's contention.

As Prof. Thompson proceeded, he rather surprised the naturalists by recalling his early rambles in Yorkshire, and showing himself to be an excellent botanical observer. The preservation of our wild flowers, which are really the property of the community, is an important subject which he commended to the consideration of local societies. It would be true patriotism, he held, to establish a New Primrose League for the protection of this flower, which in some places, as in Epping Forest, has become practically extinct. Another subject which he suggested might be advantageously taken up by the societies of the South-Eastern Union was that of constructing a map of the Weald, which should show the position of all the old furnaces, forges, hammer-ponds, cinder-heaps, and other relics of the iron-making industry for which the Weald was so long famous.

It is interesting to note that by the generous action of the local committee the presidential address of Prof. Thompson was open to the public. This innovation was one of several excellent features that characterised the Woolwich congress.

As it unfortunately happened that Prof. Thompson was unable to attend after the delivery of his address, the subsequent proceedings of the congress were presided over by a former president, the Rev. T. R. R. Stebbing, F.R.S. At one of the meetings an interesting lecture on an experiment in cooperative field-work in botany was given by Prof. F. W. Oliver, F.R.S. A few years ago a party of students acquired a salt-marsh with sand dunes at Erquay, in Brittany, where they have established a laboratory. The vegetation consists chiefly of suæda grass and salicornia, backed by a growth of juncus. The observations have been directed mostly to the study of the way in which the growth of halophytes is affected by variation in the salinity of the soil.

An evening lecture was given by Mr. W. Whitaker, F.R.S., entitled "Some Ideals for Local Geologists," in which he offered excellent advice to the societies in the union, urging upon their members the necessity of cultivating habits of observation and seizing the opportunity of describing every geological section that might be exposed within their area. At other meetings Dr. Treutler, of Brighton, read a paper on Goethe as a naturalist; Mr. Norman Gray brought forward some suggestions for making local scientific societies more efficient; Mr. W. H. Griffin discussed the antiquity of the horse, with special reference to remains found in Kent; and Mr. G. F. Chambers advocated the storage and use of rain-water for domestic purposes.

In the excursions to which the afternoons were devoted Mr. Whitaker was the principal guide when geology was concerned, whilst the archæological remains were described mostly by Mr. W. T. Vincent, the president of the Woolwich Antiquarian Society, who also read a paper at the congress on local archæology.

At a reception given in the Town Hall by the Mayor of Woolwich, two illustrated lecturettes were delivered, one by Dr. G. Abbott entitled "Life in Rocks and Minerals," dealing chiefly with the formation of concretions, followed by one on xerophytes by Mrs. W. Plomer Young, of the Battersea Polytechnic.

An interesting feature of the meeting was the temporary museum, which contained an exceptionally large collection of objects illustrating natural history, under the superintendence of Mr. W. H. Griffin, of Catford. Many of the exhibits showed the results of nature-study in the elementary schools of the London County Council, and by the thoughtfulness and generosity of the local committee the children of the neighbouring schools were brought in parties to visit the museum.

It had been intended to present the delegates of the constituent societies of the union with a local handbook, similar to that sometimes issued at meetings of the British Association. But so large a number of writers had contributed essays on special subjects of local interest that the printing was delayed, and the publication necessarily deferred.

It should be remarked that the conspicuous success of the Woolwich congress was mainly due to the fact that the work of the honorary secretary, the Rev. R. Ashington Bullen, was aided by a powerful local committee, which included such enthusiastic workers as the Rev. C. H. Grinling and Mr. W. T. Vincent.

THE INSTITUTION OF MINING ENGINEERS.

THE forty-sixth general meeting of the Institution of Mining Engineers, which now numbers more than 3000 members, was held in the rooms of the Geological Society, London, on June 13 and 14, and was attended by a large and representative gathering from the various coal-mining districts. Mr. Maurice Deacon gave an admirable presidential address, in which he reviewed the recent improvements in coal-mining practice, and indicated the directions in which further progress might be sought. Mr. H. R. de Salis discussed the improvements required in inland navigation, urging that the authorities controlling the canals should be re-organised. When the works of improvement have been carried out and efficient waterways provided, the problem of mechanical haulage will soon be solved. Mr. W. B. M. Jackson described the by-product coking plant at Clay Cross, a new plant of fifty Simplex ovens with all the mechanical appliances electrically driven. Mr. A. Victor Kochs also read a paper on by-product coking, in which he described the latest forms of the Koppers oven. Water supplies by means of artesian bored tube wells were dealt with at considerable length by Mr. H. F. Broadhurst; Mr. W. J. Kemp and Mr. G. A. Lewis described the occurrence and mining of gypsum in Sussex, in the beds discovered by the sub-Wealden exploration of 1872. The mine is undoubtedly a model of modern practice. The proceedings on Thursday concluded with a paper by the Rev. J. M. Capell, the inventor of the fan bearing his name, in which he urged that the application of duplicate fans on one upcast shaft would result in great economy.

On Friday Mr. Austin Hopkinson discussed the reform of British weights and measures. Mr. J. T. Brown described the methods of working the thick coal of Warwickshire, expressing, incidentally, the opinion that coal seams exist more or less continuously, but at great depth, under the large tract of country between the South Staffordshire and East Warwickshire collieries. Mr. D. M. Chambers gave an account of the mining of ozokerite at Boryslaw, in Galicia. Mr. C. Sandberg drew some general conclusions regarding the origin of the geological structure of South Africa. His conclusions are as follows:—The main directions of mountain-folding pressures have been north and south and east and west, the result of the former being predominantly evident in the central zone and that of the latter on the periphery of South Africa. These orogenic forces worked simultaneously, and together built up the tectonic structure of South Africa, which may thus no longer be regarded and studied as the outcome of many different and local, that is, comparatively insignificant, causes, that have worked independently of one another. These systems of forces acted on all the strata of the geological systems, from the Primary upwards, either at different periods, or possibly during one long period, when there was active deposition of the younger sediments in one place and denudation of the older in another. The origin of poorten (gaps in mountain ranges), river valleys, and pans is traceable to the same causes which produced anticlines and synclines, brachy-synclines, basins or domes, that is, to fold-producing pressures, the former set of phenomena being, in fact, only modifications or diminutives of the latter.

Another paper on South African geology was contributed by Mr. A. R. Sawyer, who gave some information regarding the general geological conditions obtaining in the New Rand goldfield in the Orange River Colony. The last paper was by Mr. H. W. G. Halbaum, who discussed the contradictory formulæ given by various authorities for the strength of cast-iron tubbing, and proposed a rational formula in which the action of corrosion as well as of the pressure to which the tubbing is subject is taken into account. In connection with the meeting, visits were arranged to the generating station of the Great Western Railway at Park Royal, and to the Portland cement works at Northfleet. The next meeting of the institution will be held at Sheffield on September 4, 5, and 6.

THE PLANET SATURN.

SATURN has now become well visible as a morning star. The rings being turned nearly edgeways to the earth, the belts in both hemispheres may be observed to advantage. The irregular markings can also be satisfactorily seen, as there will be practically no interference from the rings.

This planet is perhaps more utilised as a "show" object than as a subject for critical study by observers. There is no doubt, however, that it is well calculated to repay the most diligent attention. It is true that there is rarely an outbreak of such magnitude on the disc as that which affected the N. temperate region of Saturn in the summer of 1903. In fact, it would appear that really well-marked instances of irregular spots among the dark belts or bright zones are by no means frequent. Prof. Barnard said that the spots which he discovered in 1903 were the first he had ever distinguished upon the planet, and certainly these particular markings were the first that had been clearly and satisfactorily seen by the writer, though he had been observing Saturn for more than thirty-five years.

It is extremely probable that the real surface of Saturn, like that of Jupiter, is hidden from our view. We cannot therefore determine the rotation period of the planet's actual globe, but only of the dense vapours floating above it and forming its atmosphere. These vapours are obviously influenced by great differences in velocity, the period of the N. temperate latitude being twenty-three minutes longer in 1903 than the equatorial region in 1876–7. It is very desirable to ascertain the rates of velocity of the various latitudes, as has been done in the case of Jupiter. To this end the planet should be examined frequently at every opposition, so that, whenever any visible disturbances present themselves, a large number of their transits across the central meridian may be taken. In certain years, according to the best testimony, the belts are apparently smooth and even with no interruptions or irregularities due to dark and light spots. Visible atmospheric disturbances no doubt occur on Saturn more often than is supposed. Jupiter's envelope presents very frequent evidences of eruptions and irregularities capable of producing very conspicuous and in some cases long-enduring spots. To Saturn, therefore, the most beautiful planet of our system, we may naturally look to afford us fuller information as to his surface currents if observers will but keep a critical eye upon the physical aspect of the object as seen in good telescopes.

W. F. DENNING.

THE INTERNATIONAL COUNCIL FOR THE STUDY OF THE SEA.

THE sixth meeting of the International Council for the Study of the Sea was held at the Foreign Office in London on June 13 and 14, when delegates and experts representing Norway, Sweden, Finland, Russia, Germany, Denmark, Holland, Belgium, and Great Britain were present and took part in the discussions. The meeting was formally opened at noon on June 13 by Sir Edward Grey, Secretary of State for Foreign Affairs, who was accompanied by Lord Carrington, President of the Board of Agriculture and Fisheries. Prof. Otto Pettersson, of Stockholm, vice-president of the council, occupied the chair in the absence of the president, Dr. Herwig, of Hanover.

Sir Edward Grey said that from the necessities of our geographical situation and of our associations we have a natural interest in everything that concerns the sea. We have a great interest in the practical side of the labours of the Council, and are not deficient in interest in the scientific side as well. The British Government has shown the interest which it attaches to work of this kind by continuing for another year its subscription to the work of the Council. It must be a question of increasing interest as to whether the means of capture of fish in the sea, and the increase of the demand, are tending to overtake the natural supply. It is, of course, impossible to deal with this subject adequately simply by legislation within our own territorial waters, because the territorial limits of the sea have been arranged without any special regard to the habits of the fish, and the habits of the fish have been arranged by nature without any special regard to territorial limits. Therefore, whatever measures may be taken for ourselves, and whatever separate investigations other countries may make for themselves, if any question arises as to how the protection of fish in the North Sea can be controlled, encouraged, and preserved, it must form the subject of discussion between the different countries which are interested in the high seas.

Prof. Pettersson said that five years have passed since the commencement of the international investigation of the sea and eight years since the lines of the researches were laid down by the conference in Stockholm. The bounty of the Governments has supplied the means to carry on the work of investigation on a larger scale than has perhaps ever before been employed in scientific enterprise. The Council is convinced that the statesmen of Great Britain were well advised when they engaged their country to participate in this international work, of the ultimate success of which the Council feels assured. The British Government has taken the wise and just decision to devote a year to an inquiry in order to gain a sure ground for its future action. This work the Council leaves in the hands of the British Government with the utmost confidence.

Dr. Lewald (Germany) said that the German Government was of opinion that investigations must be continued, and that some form of international cooperation was required. M. Hamman (Belgium) and Commander Drechsel (Denmark) also spoke. The subsequent proceedings of the Council were conducted in private.

In connection with the meeting of the Council, Prof.

Otto Pettersson delivered a lecture on Monday, June 10, before the Royal Geographical Society, on "Oceanic Circulation," in which he elaborated his theory of the influence of melting ice in the polar regions upon the general circulation of the oceans. In the course of the discussion which followed, Dr. Nansen gave a short account of the Norwegian hydrographical results and the nature of the actual currents which had been found to exist in the Norwegian Sea. He directed special attention to the cyclonic nature of the currents, which had been found to exist in that area. Prof. Gilson (Belgium), Prof. Homen (Finland), and Dr. Hjort (Norway) also spoke.

From June 10 to June 13 the delegates and experts were engaged on the work of the various committees of the Council, when arrangements for the conduct of the investigations during the coming year were elaborated.

The very full programme of festivities in connection with the conference, which was referred to in our last week's issue, was most successfully carried out, and it was felt by all who took part in the proceedings that much benefit would result from the friendly intercourse which took place during the week between the representatives of science on the one hand and those of the official and fishing interests on the other.

On Friday, June 14, the delegates and experts were received at Buckingham Palace by the King, who expressed his sense of the importance of the work in which they were engaged.

INTERNATIONAL CONFERENCE ON SLEEPING SICKNESS.

REUTER'S Agency announces that, at the invitation of the Colonial Office, a conference of various African colonies and protectorates has been summoned to discuss concerted international measures for dealing with sleeping sickness. This conference met at the Foreign Office for the first time on Monday, Government delegates being present from Germany, Congo Free State, France, Great Britain, Portugal, and the Sudan. The delegates are as follows:—Germany, Herr von Jacobs, Dr. Ehrlich, and Dr. Fulleborn; Congo Free State, Colonel Lantonnais, Vice-Governor General, Commandant Tonneau, M. Rutten, and Dr. van Campenhout; France, Dr. Kermorgant, Dr. Paul Gouzion, Prof. Blanchard, and Dr. Laveran; Great Britain, Lord Fitzmaurice (president), Sir W. Foster, Mr. A. W. Clarke, Mr. H. J. Read, and Sir Patrick Manson; Portugal, Dr. Correa Pinto; Sudan, Colonel Hunter and Dr. Balfour, of the Gordon College, Khartoum. The work before the conference includes the question of the holding of regular conferences, the establishment of a central bureau of information, and the assignment of definite points for investigation to particular countries or individuals. Lord Fitzmaurice, president of the conference, made the following remarks at the opening meeting to describe the objects in view:—

We are met together in the hope that it may be possible to concert measures which will enable the Powers which we represent to wage a more effective warfare against that terrible epidemic of sleeping sickness, which has already devastated so great a part of Africa, and which appears to be assuming even greater and greater proportions. This disease, as you are aware, has decimated the natives in large areas of the Congo Free State; it has levied a heavy toll on the natives of Uganda, of whom 200,000 out of a total population of 300,000 in the infected area have fallen victims to it. It has invaded portions of the French Congo and the Portuguese possessions; it has appeared the Sudan, and is now threatening German East Africa, Rhodesia, and the British Central Africa Protectorate. Already not a few Europeans have died of the disease, and many of those still alive are known to be infected.

By a bitter irony the European administration of Africa, while producing a more settled state of affairs than formerly existed, has led to more frequent and more extended travel on the part of the natives, and so helped to diffuse and spread the infection. In view of this state of affairs, which is little less than a calamity for tropical Africa, His Majesty's Government has been endeavouring, by subsidising and otherwise encouraging investigation into the nature and cause of sleeping sickness, to acquire the necessary knowledge on which to base a scheme or schemes for the prevention, and possibly the cure, of this disease. Happily these efforts have met with considerable success. It has been definitely ascertained that *Trypanosoma gambiense* is the cause of the disease, and it is all but proved, both experimentally and by analogy, and also by considerations of distribution, that this parasite is conveyed from the infected to the uninfected by at least one species of tsetse-fly (*Glossina palpalis*), and that the distribution of this fly is strictly limited to the close neighbourhood of open water. It has further been ascertained experimentally in animals, and therapeutically in man, that the infection, once acquired, can be controlled to some extent by various substances—arsenic, certain colours, dyes, and combinations of arsenic and colour dyes—*e.g.* atoxyl—and by mercury. Lastly, though sometimes difficult to diagnose in its incipient stages, symptoms have been discovered which enable the expert to recognise the earlier, and, from the point of view of infection, equally dangerous stages of the disease. It may be that we are already, in these respects, in possession of the knowledge which, if energetically applied, would enable us to prevent the spread and possibly to exterminate sleeping sickness. It is by no means improbable that there are other factors at work determining the spread of the disease, of which we are at present in ignorance, and which, if ignored, might render futile any efforts, founded on a limited knowledge, we might take.

As our several countries are responsible for the good government and prosperity of tropical Africa, His Majesty's Government, feeling sure that they would be willing to cooperate in the struggle against sleeping sickness, has asked them to send you here to devise some scheme directed to this end, and by way of initiating discussion on the subject, I would submit for your consideration the following outline:—(1) Annual or biennial conferences of delegates from the several countries interested in sleeping sickness; (2) a central bureau to extract and circulate all new literature on the subject; (3) assignment of definite points for investigation to particular countries or individuals—*e.g.* (*a*) to determine whether *Glossina palpalis* is a direct or an indirect conveyer of the trypanosome; (*b*) if the trypanosome undergoes necessary developmental changes in the *Glossina palpalis*; (*c*) if such be the case, whether the developed germ be conveyed by the original Glossina or by its larva, when the latter arrives at its imago stage; (*d*) how long an infected Glossina continues infective; (*e*) whether other species of Glossina can convey the trypanosome; (*f*) the geographical distribution of the infecting species and their habits; (*g*) the *rôle* the vertebrate fauna other than man play in the spread of the infection; (*h*) the best methods for exterminating Glossina; (*i*) the best methods for preventing the introduction of the infection into virgin country; (*j*) the best methods of controlling the spread of the disease in an infected country, including segregation of the infected and removal from the infected area of those as yet uninfected; (*k*) the experimental study on animals of drugs which destroy the trypanosome; (*l*) the therapeutical application of these drugs to man.

Doubtless other points for consideration will occur to the delegates. The foregoing have been suggested merely to start discussion. In conclusion, His Majesty's Government feels sure that, unless cooperation is secured, not only will time and labour be lost by the superfluous overlapping of the uncoordinated studies of men of science, but that it will be impossible to carry out anything like a general plan in the nature of quarantine or the restriction of the movements of the native population more immediately interested in this important disease. Much money and effort are now being expended by the different European administrations, but as there is no common plan of action there must be a considerable waste of energy. It is in the hope of organising the forces of those administrations to the best advantage against the common enemy that His Majesty's Government has invited the Powers concerned to send their representatives to this conference.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following are the speeches delivered on June 12 by the Public Orator, Dr. Sandys, in presenting the three recipients of the degree of Doctor of Science *honoris causa* :—

(1) SIR CLEMENTS MARKHAM, K.C.B., F.R.S.

Sequitur deinceps Regiae Societatis Geographicae per annos quinquaginta quidem minister indefessus, per duodecim praeses praeclarus, cuius sub ductu Societas illa diu floruit, et non modo Britannorum in doctrinae sedibus honoris locum est adeptus, sed etiam terras remotissimas, et praesertim regionem polo Australi propinquam, exploravit. Idem quot iuuenes rei naualis peritos trans maria longinqua scientiarum finibus proferendis excitauit! Quam feliciter ipse ex intimis Peruuiae penetralibus arborem contra febrium impetus ui salutari praeditam, etiam in Indiam, populi totius cum magno commodo, transtulit! Quot regiones peragrauit, peragratas litterarum lumine illustrauit! Ergo, et sibi ipsi, et collegis suis orbem terrarum totum explorantibus, nemo melius poëtarum Latinorum uerba illa potest arrogare :—

"Quae regio in terris nostri non plena laboris!"
"Viximus insignes inter utrumque"—polum.[1]

(2) COLONEL SIR THOMAS HUNGERFORD HOLDICH, K.C.M.G., K.C.I.E., C.B.

Societatis Geographicae praesidi emerito nemo potest opportunius succedere quam praesidis ipsius uicarius, miles fortissimus, Indiae totius explorator audax, qui praesertim in tellure Russorum imperio contermina, montium arduorum inter ambages, gentium barbararum inter arma, animo intrepido regionis difficillimae, regionis prope inextricabilis, fines designauit. Idem in America Australi inter respublicas duas confines controuersiam magnam de limite communi exortam, populi utriusque non sine magno commodo, terminauit. Is autem qui scientiarum doctor hodie nominabitur, itinerum suorum libris stilo facili et facundo conscriptis, non immerito etiam laudem litterarum est adeptus.

(3) PROF. SIR THOMAS RICHARD FRASER, F.R.S.

In Uniuersitate Edinensi iam per annos triginta materiam medicam est professus uir in remediorum ui et usu inuestigando iamdudum exercitatus. Abhinc annos plus quam quadraginta de magica illa faba, physostigmate uenenoso, disputauit, et propterea Franco-gallorum ab Instituto laurea insigni est coronatus. Quid dicam de pestilentia illa per Indiam quondam grassante, ab hoc uiro per triennium audacter inuestigata? Quid de serpentium ueneno ab eodem fortiter explorato? Quid de atropia et strophantho? In medicina etiam uenena nonnumquam prodesse ne antiquis quidem prorsus ignotum. Talium autem uirorum auxilio disciplina illa, "quondam paucarum scientia herbarum," "in hanc peruenit tam multiplicem uarietatem."[2]

The election of a professor of zoology and comparative anatomy will take place on Tuesday, July 23, at the University Offices, St. Andrew's Street. Candidates for the said professorship are requested to communicate with the Vice-Chancellor on or before Tuesday, July 16.

Prof. Newton has bequeathed to the University his natural history collections and library, together with the cabinets, cases, and apparatus thereto belonging, including all his copyrights, books, pictures, prints, drawings, letters, and papers relating to natural history, to be attached, so far as is convenient, to the department of zoology. He has also left the sum of 1000*l.* to apply the annual income to the keeping up and adding to the library.

The Harkness scholarship in geology and palæontology has been awarded to L. J. Wills, scholar of King's College. The Wiltshire prize in geology and mineralogy is not awarded this year.

The general board recommends that, in place of the present lectureship in physiological and experimental psychology, a university lectureship in the physiology of the senses be established from Michaelmas, 1907, in connection with the special board for biology and geology, and that a university lectureship in experimental psychology be established in connection with the special board for moral science from the same date.

It is proposed to confer the degree of Doctor of Science *honoris causa* upon Prof. W. C. Brögger, University of Christiania; Prof. H. Credner, University of Leipzig; Prof. L. Dollo, Brussels; Prof. A. de Lapparent, Paris; Prof. A. G. Nathorst, Stockholm; and Prof. H. Rosenbusch, Heidelberg, in connection with the centenary of the Geological Society, London, in September next.

OXFORD.—The following is the text of the speech delivered by Prof. Love in presenting Prof. Paul Ehrlich for the degree of D.Sc. *honoris causa* on June 18 :—

Antiquis ea erat medendi ratio ut angores levarent vel varia molestiarum genera minuerent medicamentis usi quæ affectus contrarios excitarent: recentes id propositum habent ut abdita morborum semina iam inolescentia et in vivis medullis concreta deprehendant et exstinguant. Ita non solum morbo quo quisque laboret mederi sed ipsum corpus quasi præsidiis occupare et inexpugnabile facere conantur. In maximo hoc bello quod hodie geritur contra febres varias, velut διφθερίαν quam vocant, contra cancros, vel noxiis seminibus vel ipsius carnis corruptione ortos, nemo melius vel viam munivit vel in acie præliatus est quam Paulus Ehrlich. Victoria quidem nondum reportata est: quamvis multi hostes fusi sint, restant alii mox superandi: huic certe viro summa diligentia et prudentia prædito, salubritatis patrono et præsidi, si quid bene gestum est acceptum referre debemus: huius opera et eorum qui sub eius signis militant novos triumphos reportari posse speramus.

DR. R. K. MCCLUNG, who has been senior demonstrator in physics in McGill University, Montreal, for the past three years, has been appointed to the chair of physics in Mount Allison University in Sackville, New Brunswick, Canada.

THE following recent appointments are announced:— Dr. Kriemler, to be professor of applied mechanics at the Technical College, Stuttgart; Mr. H. Maschke, to be professor, and Mr. L. E. Dickson, to be associate professor, of mathematics at Chicago University; Mr. W. L. Reid, to be professor of mathematics at Haverford College; Dr. Philipp Furtwängler, to be professor of mathematics at the Technical College, Aachen; Dr. Wilhelm Bjerknes, to be professor of mechanics and mathematical physics at Christiania; Dr. Karl Wieghardt, to be professor of mathematics and mechanics at the Technical College, Hanover.

THE Berlin correspondent of the Times reports that the German Colonial Secretary, Herr Dernburg, recently visited Hamburg to inspect the Institute for Tropical Diseases, the Botanical Museum, and the Museum for Ethnology and Anthropology with a view to ascertain whether the city possessed facilities enough for the study of colonial and tropical questions to justify the foundation of a colonial training college. Herr Dernburg decided to recommend the establishment of such an institution, and the courses at the new college are to be open to those who desire to engage in private commercial or industrial enterprise in the German colonies, as well as to Government officials. The new institute will be modelled on the plan of existing German technical colleges. The promoters of the scheme hold that the intercourse between intending officials and young business men will contribute to the benefit of the German colonies. The State of Hamburg will for the present be responsible for the scheme, and, if the results prove satisfactory, the institution will receive official recognition in the form of an Imperial subsidy.

THE King and Queen will visit Bangor on July 9, when the King will lay the foundation stone of the new buildings of the University College of North Wales. The site of the new college, at Penrallt, is at present occupied by the residence of Principal Reichel, and this interesting feature of old Bangor will have to be demolished in order to make way for the buildings. The permanent build-

[1] Virgil, *Aeneid*, i. 460; Propertius, iv. 5 (11), 46.
[2] Seneca, *Ep.* 95, § 15.

ings fund has now reached a sum that will suffice for the erection of the arts and administrative portions, and this will enable the present college buildings (formerly the Penrhyn Arms Hotel) to be handed over entirely to the requirements of science. Thus, for a time, the college will be conducted on the lines of certain foreign universities, where the faculties of arts, science, law, and medicine are housed in separate buildings. It is hoped, however, that the completion of the new college by the erection of buildings for the faculty of science will not be long delayed. A considerable moral obligation rests on the Government to assist in this matter, more especially in view of the fact that the death duties arising out of the estate of the late Lord Penrhyn, while representing a heavy financial loss to the people of North Wales, would far more than suffice to build and equip the new college.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 23.—"Chemical Reaction between Salts in the Solid State." By E. P. **Perman.** Communicated by Principal E. H. Griffiths, F.R.S.

Experiments have been made on the following pairs of salts:—lead chloride and potassium iodide, mercuric chloride and potassium iodide, sodium carbonate and barium sulphate, sodium sulphate and barium carbonate. The chief points investigated were the effect on certain of these salts of (1) traces of moisture; (2) great pressure; (3) heat.

It was found that reaction always took place unless the salts were very carefully dried, and that the reaction was accelerated by shaking the mixture, and by the application of heat or great pressure; further, that the velocity of the reaction is much influenced by the solubility and volatility of the salts.

The effect of small quantities of some other solvents was also tried. It was found that methyl alcohol caused a reaction between lead chloride and potassium iodide in the same way as water, whilst benzene, chloroform, and ammonia were without result.

Finally, it would appear that reaction between solid salts is of essentially the same nature as that between salts in solution, and it is suggested that the water (or other solvent) present forms a film on the surface of the salts, and that in this film minute quantities of the salts dissolve, and there react. In the absence of an ionising solvent there is no chemical reaction, even when the substances are heated or subjected to great pressure.

Physical Society, May 24.—Prof. J. Perry, F.R.S., president, in the chair.—The measurement of mutual inductance by the aid of a vibration galvanometer: A. **Campbell.** Carey Foster's method of comparing a mutual inductance with a capacity is one of the most convenient. The advantage gained by the use of a *vibration galvanometer* in methods for measuring capacity or inductance led the author to apply it to the Carey Foster and the Hughes-Rayleigh methods. He found it was necessary with alternating currents to modify the Carey Foster method by adding a series resistance in the condenser branch; this gave an additional formula involving the ratio of a mutual and a self-inductance. This modification has been suggested by Rowland. The modified method is convenient, the two adjustments required for a balance being independent, and the result not involving a knowledge of the frequency; the use of the vibration galvanometer is an improvement, making the method independent of the wave-form of the current used. The author discussed vibration galvanometers. They belong to the class of tuned instruments. If the detecting instrument used in a null method (with alternating current) is adjusted so that its natural period is in tune with that of the applied voltage, it will be set into strong resonance and will be enormously increased in sensitivity for this particular frequency, practically ignoring in comparison all the other components of the wave-form. Thus in any method in which the tuned instrument is used, a sine wave-form may be assumed. The author exhibited a vibration galvanometer of another type, having a moving coil controlled by an adjustable bifilar suspension. By adjusting the tension of this the tuning is easily effected. For measuring the frequency to which a tuned instrument is responding, it is convenient to use the Hughes-Rayleigh method. The author showed such an arrangement in which the slide-wire was graduated directly in frequency. The author gave results of tests of a standard mutual inductance of 0·05 henry. The Kirchhoff method with direct deflection on a ballistic galvanometer, of measured time of swing, gave a mean of 0·05014 henry, while the Carey Foster method gave 0·05009 henry; the probable error of the latter was much smaller than that of the older method.—Note on the rate of decay of the active deposit from radium: W. **Wilson** and W. **Makower.** In some experiments in which the ionisation produced by the α rays from radium C was balanced against that produced by the more penetrating β and γ rays, it was found that after a short time these two ionisations were no longer exactly equal, however carefully they had been adjusted to equality at first. A similar effect had been noticed by Brousson, and was attributed to the slowly moving β rays emitted by radium B which is present with the radium C. Since these rays are emitted by radium B, whereas the α and more penetrating β rays are emitted by radium C, it is to be expected that the rate of decay as measured by these two types of radiation will be different. The authors' experiments confirm the view that the observed difference in the rate of decay as measured in the two vessels is due to the slowly moving β rays emitted by radium B.—Apparatus for relay working of long submarine telegraph cables: S. G. **Brown.** This relay system consists of three parts:—(1) the actual relaying device or drum relay; (2) an inductive shunt with closed iron circuit for use across the receiving coil to curb the signals and straighten out the zero; and (3) a method of applying a local current possessing suitable time-lag to the receiving coil to correct the tendency of signals made up of two or more impulses of the same polarity to fall away to zero due to the charging up of the receiving condenser itself.

Faraday Society, May 28.—Prof. A. K. Huntington in the chair.—Contributions to the chemistry of gold: F. H. **Campbell.** Aurous iodide, AuI, was prepared and found to decompose at 25°, according to the equation

$$2AuI \rightleftarrows 2Au + I_2.$$

Since this equation contains only one variable, namely, the iodine, there must be a particular pressure of iodine at which AuI, Au, and I_2 are in equilibrium. This was found to be 0·943 of that of pure iodine; any solution of iodine will therefore act on gold if more than 0·943 saturated, but not if below this strength. When gold is acted on by a solution of KI and iodine, part is converted into insoluble AuI and part dissolves. The experimental results with various solutions agree with the equilibrium equations only when the gold is assumed to enter the complex ion in the monovalent condition, *i.e.* to yield AuI_2 ions. The action $3AuCl = AuCl_3 + 2Au$ was found to occur at ordinary temperatures and in absence of moisture.—Reduction of some oxides and sulphides by means of metallic calcium: Dr. F. Mollwo **Perkin.** The author first referred to the well-known powerful reducing action of aluminium, as, for example, its use in the preparation of chromium, ferrosilicon, and other metals and alloys, and its use in the form of "thermite" for welding purposes. He finds that metallic calcium is a still more powerful reducing agent than aluminium. For example, when molecular proportions of aluminium and ferric oxide are mixed together and ignited by means of a fuse of aluminium and barium peroxide, intense reaction ensues, and continues until all the oxygen has been removed from the ferric oxide, and aluminium oxide and metallic iron produced in its stead. When metallic calcium in the form of fine turnings is mixed with ferric oxide and ignited in a similar manner, the reaction is so intense that the mixture is in large part ejected from the crucible. The reaction can be brought under control by mixing 30 per cent. to 40 per cent. of calcium fluoride or 10 per cent. to 20 per cent. of calcium oxide with the contents of the crucible. Boron can be obtained by igniting a mixture of boron trioxide with the calculated quantity of calcium and 5 per cent. to 10 per cent. of calcium oxide. Attention was directed to the difficulty experienced in causing silica in the form of fine sand to react with metallic aluminium which was in the form of a rough powder. A similar difficulty was met with in the case of boric anhydride and aluminium. Galena does not yield metallic lead and calcium sulphide, but a greyish mass which gives off sulphuretted hydrogen when acted upon with acids, lead in the form of a salt being left in solution. Red phosphorus and calcium unite with explosive violence. Sulphur and calcium also react with great vigour.

Society of Chemical Industry, June 3.—Mr. R. J. Friswell in the chair.—The nature of the changes involved in the production and setting of plaster of Paris: W. A. **Davis.** The contradictory character of the present knowledge of this problem is first discussed. Data are then adduced to show that the first change occurring in the dehydration of gypsum is the formation of a new, orthorhombic form of the dehydrate, $CaSO_4,2H_2O$, which by loss of water subsequently gives the half hydrate $CaSO_4,2H_2O$ (the essential constituent of ordinary plaster). The so-called "soluble anhydrite" is produced from gypsum, not directly as supposed by van 't Hoff, but as a product of the further dehydration of the half hydrate. The conditions under which this change occurs and the manner in which it may be reversed are dealt with in detail. In the setting of plaster, gypsum is not immediately regenerated, but the second form of the dehydrate referred to above is first produced; it undergoes change into gypsum subsequently.—Analysis of white lead: W. A. **Davis** and C. A. **Klein.** The authors have investigated the sources of error in the different methods used in the analysis of white lead. These errors are much smaller in the case of dry white lead than in that of white lead ground in oil.—Calorimeter for volatile liquid fuels. Specially adapted for petrol: W. Hansen **Rawles.** A development of the Darling calorimeter. The calorimeter, which was made for the author by Messrs. A. Gallenkamp and Co., is applicable to solid and liquid fuels.—The influence of temperature of dyeing on resolution: W. P. **Dreaper** and A. **Wilson.** Basic colours are absorbed by silk fibre in two ways. Above 40° a more permanent absorption of part of the dye takes place which increases up to 100°. A similar effect is noticed with acid dyes on silk. Preliminary boiling with water or acid does not influence subsequent dyeing at low temperatures. A similar result is obtained with direct colours on cotton, so the reaction is a general one. The effect is absent when dyeing in alcohol. Fastness against light does not follow the temperature in same way.—The loss of nitre in the chamber process, part iii.: J. K. H. **Inglis.** The author, in continuation of earlier papers, has again analysed samples of the exit gases from sulphuric acid chambers by means of fractional distillation at low temperatures. Indirect analyses were almost completely avoided, and the results show the presence of small quantities of nitrous oxide and of appreciable quantities of higher oxides, the quantity of nitric oxide being considerable when the sulphur escape is high. There is still a considerable quantity of nitre unaccounted for, its loss being either due to reduction to nitrogen or to the whole of the nitric acid not being collected in this method of analysis.

MANCHESTER.

Literary and Philosophical Society, April 23.—Sir William H. Bailey, president, in the chair.—Coal mines in Sutherlandshire: Dr. M. C. **Stopes.** The mines are of Mesozoic and not of Palæozoic age, as is the case with the vast majority of coal seams.—Science and poetry: C. L. **Barnes.** The author enumerated the principal poems handed down by antiquity, enshrining the scientific knowledge of the age which gave them birth. Among these were the "Phænomena" and "Prognostica" of Aratus, originally written in Greek, but made more familiar in Latin and French translations; Lucretius, "De Rerum Natura"; the "Georgics" and "Bucolics" of Virgil; the "Astronomicon" of Manilius; Marbodus, "De Gemmis"; Alexander Neckam, "De Laudibus Divinæ Sapientiæ"; and Philippe de Thaun, "Le Livre des Créatures." Allusion was also made to the "Canon's Yeoman's Tale," Milton's "Paradise Lost" and "Natura non pati senium"; Cowley's "Plantarum Libri Duo" and "Ode to the Royal Society"; Phineas Fletcher's "Purple Island"; Erasmus Darwin's "Botanic Garden" and "Loves of the Plants"; Rowbotham's "Human Epic," and other poems of less note.

May 7.—Prof. H. B. Dixon, F.R.S., president, in the chair.—A series of photographs illustrating the flora of Corsica, particularly the characteristic bush flora of the mountain slopes: Prof. F. E. **Weiss.** This "macchia" or "Magius" is made up largely of hard-leaved shrubs, such as the arbutus, rock-rose, tree-heath, and shrubby oaks. A comparison with the bush of Table Mountain shows certain similarities between the two floras, both in the manner of growth and in the constituent orders, such as Ericaceæ, &c.—Science and poetry: C. L. **Barnes.** Conclusion of paper read on April 23. Poems were read by Prof. J. C. Maxwell, Prof. Rankine, Archbishop Whately, and others.—The compression of gases by means of hydraulic apparatus: J. E. **Petavel.**

PARIS.

Academy of Sciences, June 10.—M. Henri Becquerel in the chair.—The petrographic constitution of the volcanic *massif* of Vesuvius and Somma: A. **Lacroix.** The petrographic constitution of these rocks has hitherto been considered as extremely simple. It is found, however, that the old volcano is not simply constituted by basic rocks and their projection products. Other rocks are present in abundance, a detailed study of which is given, showing their complex nature.—Observations made at the summit of Mont Blanc from August 31 to September 5, 1906: A. **Hansky** and M. **Stefánik.** Details are given of the atmospheric conditions, attempts at the determination of the rotation of Venus, observations on the sun, Mercury, and Jupiter.—Observations concerning the form of the satellite I. of Jupiter: José Comas **Sola.** The disc of this satellite appears distinctly elongated. This was confirmed by observations made on the night of February 28, when the conditions were exceptionally favourable. The shadows of both satellites I. and II. were seen close together on the planet. The shadow of II. was clearly circular, that of I. being elongated; the flattening is fixed provisionally at $\frac{1}{4}$.—A new Giacobini comet: M. **Giacobini.** This comet was first seen on the night of June 1 at Nice. It is badly defined, 1′·5 to 2′ extent.—A new class of surfaces: G. **Tzitzéica.**—The application of the formulæ relating to molecular volumes to the calculation of the variation of the maximum pressure of water vapour with temperature: A. **Leduc.**—The electric discharge in gases: P. **Villard.**—Some oxidising and decolorising properties of graphite: Henri Louis **Dejust.** A comparison of the decolorising powers of animal charcoal, natural graphite containing 79 per cent. of carbon, and purified graphite containing 93·1 per cent. of carbon, litmus being used as the colouring matter. The activity of the graphite is reduced by purification. Graphite shows an oxidising power analogous to that noted by M. Cazeneuve for animal charcoal.—Modified nickel acetate, a new type of excitor of oxidation for hydroquinone: André **Job.** Pure nickel acetate, heated for a long time at 100° C., loses some acetic acid, but remains completely soluble in cold water. This product acts as an oxydase towards hydroquinone, its activity in this respect being greater than that of manganese acetate. The cause of this remains unknown.—Contribution to the study of the ammonio-mercuric base: H. **Gaudechon.** This base is formed at once by the action of precipitated mercuric oxide upon aqueous ammonia solution, forming hydrates of $(NHg_2)_2O$. The hydrate with one molecule of water is stable at the ordinary temperature in a dry atmosphere, that with four molecules of water stable in a moist atmosphere at 15° C. The hydrate with $5H_2O$ can only exist in the presence of water.—The combinations of hypovanadic acid with some acids containing oxygen: Gustave **Gain.**—The relation between the diagram of the binary alloys and their malleability: Léon **Guillet.**—The mechanism of the synthesis of quinoline derivatives (Döhner's reaction): L. J. **Simon** and Ch. **Manguin.**—The ether function of diphenol,  : R. **Delange.**—The action of hydroxylamine on nitriles, amides, and acetylenic esters, and on the corresponding β-ketonic compounds: Ch. **Moureu** and J. **Lazennec.**—The hydrolysis of salts: A. **Rosenstiehl.** From a consideration of the phenomena of the hydrolysis of esters and salts, the author concludes that the hypothesis of ionisation is unnecessary.—The existence of a tyrosinase in wheaten bran: Gabriel **Bertrand** and M. **Muttermilch.** Wheaten bran is shown to contain at least two ferments, tyrosinase and peroxydiastase.—The basic rocks of the Tschissapa range, northern Ural: L. **Duparc** and F. **Pearce.**—The pleural cavity in the elephant: Guillaume **Vasse.** A fully grown elephant killed in the province of Gorongoza showed on dissection lungs easily detached. There was no point of adherence.—An improved apparatus permitting of staying and working for a long time in irrespirable atmospheres: J. **Tissot.** In a previous note the author has detailed the conditions which should be realised in an apparatus of this kind. The present paper gives an account of an apparatus fulfilling these conditions, together with an account of its actual use in practice.—The digestion of chlorophyll and the stomachic excretion in rotifers: P. **de Beauchamp.**—The hypertensive action of the cortical layer of the supra-renal capsules: O. **Josué** and Louis **Bloch.** The cortical layer has been found to contain substances strongly hypertensive which are chemically different from adrenaline. It is possible that these substances are destined to form adrenaline later, and researches are being carried on to determine this point.—Radioscopy and radiography applied to the inspection of tuberculous meat: H. **Martel.** It is shown that the Röntgen rays may serve to detect tuberculous lesions in meat. The cutting into sections necessitated by the ordinary method of examinations is avoided, thus saving time and preventing the depreciation of the meat. Fat does not interfere.—The geosynclinal Miocene of southern Tell (departments of Algiers and Constantine): J. **Savornin.**—The Dinosauria of the Jurassic in Madagascar: Armand **Trévenin.**—The characteristics of the leaf trace of *Ankyropteris Bibractensis*: Paul **Bertrand.**

DIARY OF SOCIETIES.

THURSDAY, JUNE 20.

ROYAL SOCIETY, at 4.30.—Bakerian Lecture, On the Atomic Weight of Radium: Dr. T. E. Thorpe, C.B., F.R.S.—On the Origin of the Gases Evolved by Mineral Springs: Hon. R. J. Strutt, F.R.S.—On the Presence of Sulphur in Some of the Hotter Stars: Sir J. Norman Lockyer, K.C.B., F.R.S.—The Fluted Spectrum of Titanium Oxide: A. Fowler.—Preliminary Note on a New Method of Measuring Directly Double Refraction in Strained Glass: Dr. L. N. G. Filon.—Studies of the Processes Operative in Solutions, II., The Displacement of Chlorides from Solution by Alcohol and by Hydrogen Chloride, III., The Sucroclastic Action of Nitric Acid as Influenced by Nitrates; IV., The Hydrolysis of Methylic Acetate in Presence of Salts; V., The Discrimination of Hydrates in Solution: Prof. H. E. Armstrong, F.R.S., and others.

CHEMICAL SOCIETY, at 8.30.—Some Properties of Radium Emanation: A. T. Cameron and Sir W. Ramsay.—The Affinity Constants of Aminosulphonic Acids as Determined by the Aid of Methyl Orange: V. H. Veley.—Azo-derivatives of 1:3-Diphenylbarbituric Acid. Dynamic Isomerism among the Coloured Hydrazones of 1:3-Diphenylalloxan: M. A. Whiteley.—A Series of Coloured Diazo-salts Derived from p-Aminoaceto-α-naphthalide: G. T. Morgan and W. O. Wootton.—(1) Colour and Constitution of Azo-compounds, Part I.; (2) Colour and Constitution of Azo-compounds, Part II.: J. T. Hewitt and H. V. Mitchell.—The Oxidation of Hydrazines by Free Oxygen: F. D. Chattaway.—Calmatambin, a new Glucoside: F. L. Pyman.—The Decomposition of Hyponitrous Acid in Presence of Mineral Acids: P. C. Rây and A. C. Ganguli.—The Chemical Composition of Petroleum from Borneo: H. O. Jones and H. A. Wootton.—(1) The Synthesis of Phenonaphthacridines, Trimethylphenonaphthacridines; (2) The Condensation of Aldehydes with Mixtures of α-Naphthol and α-Naphthylamine; Synthesis of 7-Aryl $\begin{matrix} \alpha\text{—N—}\alpha \\ | \\ \beta\text{—CH—}\beta \end{matrix}$ Dinaphthacridines: A. Senier and P. C. Austin.—(1) An Improved Form of Apparatus for the Rapid Estimation of Sulphates and Salts of Barium; (2) The Determination of Sugar by Fehling's Solution: W. R. Lang and T. B. Allen.

LINNEAN SOCIETY, at 8.—On the Distribution of Conifers in China and Neighbouring Countries: the late Dr. M. T. Masters, F.R.S.—Lithothamnia of the *Sealark* Expedition: M. Foslie.—The Pre-Glacial Flora of Britain: Clement Reid, F.R.S., and Mrs. Reid.—Report on the Results obtained during the Cruise of the *Silver Belle*: Dr. R. Norris Wolfenden.—On a Small Collection of Amphipoda, and Two New Species: W. M. Tattersall.—On *Pyrosoma spinosum*: G. P. Farran.—Rare or Little-known Fishes taken by the *Silver Belle*: E. W. L. Holt and L. Byrne.—*Sealark* Coccidæ: E. Ernest Green.—Species and Ovicells of Tubucellaria: A. W. Waters.—Doridoeides, a New Genus of Nudibranchs, from the *Sealark*: Sir C. Eliot and T. J. Evans.—Stomatopoda of the *Sealark*: L. A. Borradaile.—On Triassic Species of Zamites and Pterophyllum: E. A. N. Arber.—Introduction to the Voyage of H.M.S. *Sealark*, Part ii.: J. Stanley Gardiner.—Cephalopoda of the Sudan: Dr. W. E. Hoyle.—Descriptions of Plants from Ruwenzori: E. G. Baker, S. Moore, and A. B. Rendle.—The Anatomy of the Julianiaceæ: Dr. E. F. Fritsch.—On Critical Freshwater Algæ: Prof. G. S. West.

TUESDAY, JUNE 25.

ANTHROPOLOGICAL INSTITUTE, at 8.15.—The Kanaka Skull: Dr. D. Waterston.—Instruments employed to obtain Contour Tracings of Different Aspects of the Skull: Prof. D. J. Cunningham, F.R.S.—Notes on Australian Aboriginal Paintings: F. S. Brockman.

FARADAY SOCIETY, at 8.—The Thermo-chemistry of Electrolysis in Relation to the Hydrate Theory of Ionisation: W. R. Bousfield and Dr. T. Martin Lowry.—The Influence of Non-Electrolytes and Electrolytes in the Solubility of Gases in Water. The Question of Hydrates in Solution: J. C. Philip.—The Dissociation of Hydrates as indicated by their Equilibrium Curves: Dr. A. Findlay.—Hydrates in Solution: Discussion of Methods proposed for determining Degree of Hydration: Dr. George Senter.—The Reading of the Papers will be followed by a General Discussion on "Hydrates in Solution."

PHYSICAL SOCIETY, at 8.

WEDNESDAY, JUNE 26.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.

THURSDAY, JUNE 27.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: On the Dynamical Theory of Gratings: The Lord Rayleigh, O.M., P.R.S.—On the Surface Tension of Liquids investigated by the Method of Jet Vibration: S. D. Pedersen.—Cases of Colour Blindness, No. VI. to No. XVIII., together with Eleven Selected Examples of Normal Colour Sensations: G. J. Burch, F.R.S.—On the Occurrence of Post-tetanic Tremor in Several Types of Muscles: Dr. D. F. Harris.—On the Pressure of Bile Secretion and the Mechanism of Bile Absorption in Obstruction of the Bile Duct: P. T. Herring and S. Simpson.—Further Studies of Gastrotoxic Serum (Progress Report): Dr. C. Bolton.—And other Papers.

FRIDAY, JUNE 28.

PHYSICAL SOCIETY, at 5.—Demonstration of the Uses of his Hot Wire Oscillographs and Hot Wire Wattmeters: I. T. Irwin.—(1) A Cosine Flicker Photometer; (2) Some Phenomena in Colour Vision: J. S. Dow.—Description and Exhibition of Students' Apparatus for Measuring Permeability and Hysteresis: Prof. W. E. Ayrton and T. Mather.—Design of Chokers: Prof. W. E. Ayrton and T. Mather.

CONTENTS.

THURSDAY, JUNE 27, 1907.

RESINS.

Die Harze und die Harzbehälter mit Einschluss der Milchsäfte. By A. Tschirch. Zweite stark erweiterte Auflage. Erster und zweiter Band. Pp. xxii+1268. (Leipzig: Gebrüder Bornträger, 1906.) Price 32 marks.

The Distillation of Resins. By Victor Schweizer. Pp. viii+183. (London: Maclaren and Sons; New York: Van Nostrand and Company, n.d.) Price 10*s.* 6*d.*

THE chemistry of resins has been very much neglected by investigators, so much so that even now the empirical formula of the best known of their constituents—abietic acid, which was isolated from ordinary rosin more than eighty years ago—is still a matter of dispute. It is difficult to account for this neglect, since many of the naturally occurring resins are readily resolved into crystalline or otherwise well-defined substances, so that the subject does not present the initial difficulties encountered by the investigators who have studied the terpenes, proteids, and similar intractable natural products. Resins should now be particularly attractive to chemical workers, since Prof. Tschirch and his collaborators have surveyed almost the whole field in a preliminary manner, and from their results it is possible to select the most promising materials for detailed investigation.

Perhaps the most important result which has accrued from this work is the possibility of classifying the constituents of the natural resins into a comparatively small number of groups of similarly reacting—and probably similarly constituted—substances.

Looked at from this general point of view, the chemical work done by Prof. Tschirch and his coadjutors can be regarded as a very satisfactory contribution to our knowledge of resin chemistry.

The publication of the second edition of this monograph affords an opportunity for a review of this work as a whole, since the book is largely a reprint, with additions and corrections, of papers published in the *Archiv der Pharmazie.*

Prof. Tschirch's usual method of investigation consists in dissolving the resin under examination in an indifferent solvent, and extracting this successively with solutions of alkali carbonates and hydroxides.

The products so isolated, and perhaps subjected to a more or less satisfactory process of purification, are in general regarded as definite substances, and though they are in the majority of cases amorphous coloured products having no constants which may be regarded safely as criteria of purity, they are analysed and have names and formulæ assigned to them. The qualifying statement that such substances may be impure is no adequate defence for such a proceeding, since the names and formulæ are liable to be copied into the literature of the subject without the disclaimer which originally accompanied them.

Similarly, when Prof. Tschirch in the course of an investigation meets with a substance resembling one already known, he does not in general ascertain definitely whether the two substances are identical, but, assuming that they are probably distinct, makes a denominator for his supposed new substance by attaching a descriptive prefix to the name of the older compound; thus *palabietic acid*, from the resin of *Pinus palustris*, has the same elementary composition and melting point as abietic acid, with which, so far as one can see, it may be identical.

The application of the terms "resinolic acid" and "resene" is also objectionable. The first of these would, under any system of nomenclature now in use among chemists, imply the presence of a hydroxyl in addition to a carboxyl group in each of the substances included in the class so designated, and similarly the termination -ene is usually reserved for hydrocarbons. Prof. Tschirch's "resinolic acids" are simple carboxylic acids, typified by abietic acid, and his "resenes" are oxygenated substances.

The book is not only a record of the results of chemical investigations, but deals with the botany and habitats of the plants from which resins are obtained, and to these branches of knowledge the author and his collaborators have made many and important contributions. Much of the information given is the result of personal observations made by Prof. Tschirch during travels in the East Indies and elsewhere, and probably no previous investigator of plant products has devoted more care to securing authentic material for investigation. The botanical part of the subject is dealt with in the second and smaller volume, which gives a *résumé* of our present knowledge of the mode of origin and distribution of resins in plants. Reference should also be made to the important section dealing with latices and the resins and rubbers obtained from them, matters which are at the present moment of great economic importance.

There are a few resinous products which have been the subject of investigation, and which, in spite of Prof. Tschirch's desire to make his monograph as complete as possible, have escaped his notice, but these are for the most part of little importance.

In spite of those unfortunate tendencies to add unduly to nomenclature and to be somewhat lax in awarding the character of a definite substance to ill-defined amorphous products, to which attention has been directed, this book is a welcome addition to the rather scanty literature dealing with the chemistry and botany of vegetable products.

Mr. Schweizer's book is intended primarily for the "practical man," and is consequently of little interest from the purely scientific point of view. The descriptions of processes and plant for the distillation of rosin and the rectification of the products obtained are lucid, and their value is enhanced by the well-printed illustrations of distilling and other apparatus, made in several instances from the author's designs.

The chapters dealing with the manufacture and uses of resinates, the preparation of lampblack, and the methods of making printing and other lampblack inks are of special interest, since much of the information given was not accessible previously.

K

In the first line of p. 22 "position" is obviously a misprint for "composition," and there are a considerable number of such slips throughout the work. A fairly full "contents list" is given, but the book would have been more useful if a comprehensive index had been provided. T. A. H.

THE WORKS OF C. F. GAUSS.

Carl Friedrich Gauss Werke. Siebenter Band. Herausgegeben von der Kön. Gesellschaft der Wissenschaften zu Göttingen. Pp. 650. (Leipzig: B. G. Teubner, 1906.) Price 30 marks.

THIS volume contains a reprint of Gauss's principal astronomical work, the "Theoria Motus Corporum Cœlestium," and his unpublished researches on planetary perturbations and on the lunar theory. In 1871 the late Prof. Schering brought out a "volume vii." without the cooperation of the Göttingen Academy of Science, containing the "Theoria Motus" and some notes from Gauss's papers; but for the sake of uniformity the academy considered it desirable to include the "Theoria" in the present volume, which has been edited by Prof. Brendel, of Göttingen.

A careful revision of the original edition of 1809 brought a few corrections to light, and a re-computation of the examples with modern tables of logarithms revealed a number of errors of one or two units of the seventh decimal (caused probably by the absence of decimals in the proportional parts of the old tables) which sometimes gave rise to greater errors in the course of the computation. A list of these corrections is given. Some notes found in Gauss's own copy of the book are added in footnotes. Next follow various notes on elliptic and parabolic motion, partly already published, partly extracted from letters and note-books. Of these the most important is a table for computing the true anomaly in a parabolic orbit; it was to have formed part of a supplement to the "Theoria Motus," dealing with the orbits of comets, which never was written.

The discovery of the first of the minor planets, Ceres, had obliged Gauss to work out a general method of computing an elliptic orbit. The next step was to determine the perturbations of the motion of Ceres and Pallas, which, particularly in the case of the latter, necessitated new methods owing to the great eccentricity and inclination; and on this work Gauss spent a great deal of time in the years 1802 to 1817. In 1805 he worked out a new method of computing the general perturbations by the variation of the elements, but he never published anything on the subject. The method is essentially the same as that proposed by Hansen in 1843 in his paper on absolute perturbations in orbits of any eccentricity and inclination.

The present volume first gives letters and computations on Ceres, after which follow 200 pages devoted to Pallas. Special perturbations by Jupiter for the years 1803–1811 were computed in 1810 and 1811, first for intervals of fifty days, after which the work was repeated with periods of 500 days, the elements for each period being taken from the first computation. The memoir on the theory of general perturbations was written in French, about the year 1815, apparently in answer to a prize question of the Paris Academy, but never finished. In 1811 Gauss began the immense labour of computing the action of Jupiter on Pallas, and finally, with the aid of Encke and Westphal, completed the work by the preparation of tables. The perturbations by Saturn were computed by Nicolai, and this work is preserved at the Heidelberg Observatory; it has naturally not been included in the present volume, but hopes are held out that it may be published elsewhere. Finally, the last part of the whole work, the action of Mars, was taken in hand, but owing to the press of other work it was never completed. It is much to be regretted that this fine piece of work, involving an enormous amount of computation, has been unknown until now, and that not even so interesting a result as the increase of the assumed mass of Jupiter was published. Already in 1814 Gauss found from the first nine oppositions of Pallas that Laplace's value, 1 : 1067·09, should be increased to 1 : 1042·86, a result which differs but little from the most recent determinations. If known to Encke, this correction of the mass would have prevented the errors of 5′ in the computed geocentric places in 1834, caused by the near approach to Jupiter in 1832 (*Astr. Nachr.*, No. 332). Needless to say, the remarkable commensurability of the mean motions of Jupiter and Pallas was noticed by Gauss at an early date.

It appears from letters written to Hansen and Bessel in 1843 that Gauss bitterly regretted having laid this great work aside. Thanks to the skilful editorship of Prof. Brendel, whose task of arranging and interpreting a vast mass of papers must have been a very difficult one, the work is now accessible in a clear and convenient form, and it is to be hoped that some competent hand will complete it.

Lastly, the volume contains the beginning of a lunar theory, dating from the second half of 1801, but soon abandoned, probably because vol. iii. of Laplace's "Mécanique Céleste" came out in the following year, and seemed to make work on the motion of the moon unnecessary at that moment. The form in which the perturbations are given is similar to that of Plana (1832).

Vols. viii. and ix. of the collected works of Gauss have already appeared. A tenth and concluding volume is announced, which is to include a general index. J. L. E. D.

NATURE AND FLORAL DESIGN.

Flowers and Plants for Designers and Schools. By Henry Irving and E. F. Strange. Pp. 95. (London: Hodder and Stoughton, 1907.) Price 10*s*. 6*d*. net.

IF designers could be produced by the study of books upon plant form there ought to be a large and flourishing crop of them, since so many elaborate works have appeared on this subject addressed to the supposed needs of such artists.

Every designer of any originality, however, feels the necessity of providing his own raw material, and what is suggestive and valuable to one may by no means prove equally so to another. The designer's best reference library is, of course, Nature; but Nature is always changing her dress, and her wealth of floral pattern is transformed with each season, so that unless we presuppose good opportunities combined with immense industry on the part of the artist, he must occasionally run short of working notes, and may be glad of the help of a herbal or a book which will give him the essential facts of the form, growth, general appearance, and structure of particular plants and flowers with which he is not familiar.

Such a practical aid and friend in need may be found in the admirable series of photographs from nature by Mr. Henry Irving and the valuable notes by Mr. E. F. Strange which constitute the volume before us.

The latter contributes a well-informed and interesting introduction to the book, as well as a series of notes upon the plants figured, which show his historic knowledge as well as his artistic sympathies.

While quite of the opinion he expresses as to the value of the study of the human form for *all* designers, it appears to be quite possible to attain great skill in purely floral draughtsmanship and design without any corresponding power over the human figure. Mr. Strange, too, hardly seems to appreciate, perhaps, the value of practice with a *firm point*—the severest test of draughtsmanship—the power of clear definition and definite expression being most necessary in all kinds of working designs intended to be carried out by some process of handicraft or manufacture. He is also a little severe upon what he describes as "brush-work"—the power of clear definition of form in the mass by means of brush and colour being also essential to a floral-designer's work, and needing much practice to gain facility and sureness of touch. The dexterity and directness of the method of Japanese artists have taught us much in this way.

Mr. Strange gives an admirable *résumé* of the treatment of plant form in the history of decorative art, and in speaking of the utility of such examples of plant form as are given in Mr. Irving's plates, he very pertinently remarks upon the beneficial effect upon a student or designer having to make their notes and drawings direct from nature or from photographs such as these, "uninfluenced by the versions, however admirable, of others."

If a designer cannot refer directly to nature, photographs are next best for most purposes, that is to say, for all superficial facts about a plant which can be disclosed without colour.

Mr. Henry Irving has made an interesting and judicious selection of plants and flowers likely to be useful to designers of all kinds, and he has been successful in presenting them by photography in a clear and tasteful way, often usefully silhouetting the stems and leaves against a light plain background, and giving the scale, and in some cases showing the seed vessels and the root. The plate of the tulip tree gives a singularly complete exposition of the characteristics of the tree—stem, leaf, bud, and full flower being given, and, moreover, quite decoratively spaced. Among the most successful plates, perhaps, may be named the wild rose, the yellow iris, the wood sorrel, the lily of the valley, the thistle, the teasle, and the catkins of the hazel.

More of the lily tribe might have been given perhaps with advantage, seeing that the structure is so beautiful and well defined, and it is the structure of plants and flowers above all that a designer needs to understand. Altogether the book may be heartily recommended to students and practical designers, and, indeed, to all interested in the beauty of plants and flowers.

WALTER CRANE.

SOME RECENT PHILOSOPHICAL WORKS.

(1) *Proceedings of the Aristotelian Society*. New Series. Vol. vi. Pp. 402. (London: Williams and Norgate, 1906.) Price 10s. 6d. net.

(2) *René Descartes' Philosophische Werke*. Erste Abteilung (Fortsetzung). Übersetzt und herausgegeben von Dr. Artur Buchenau. Pp. xviii+149. (Leipzig: Dürr'schen Buchhandlung, 1906.) Price 1.80 marks.

(3) *Herders Philosophie*. Herausgegeben von Horst Stephan. Pp. xliv+309. (Leipzig: Dürr'schen Buchhandlung, 1906.) Price 3.60 marks.

(4) *The International Scientific Series. The Mind and the Brain*. By Alfred Binet. (The authorised translation of "L'Âme et le Corps.") Pp. xii+280. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1907.) Price 5s.

(5) *Essay on the Creative Imagination*. By Th. Ribot. (Translated from the French by A. H. N. Baron.) Pp. xix+370. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1906.) Price 7s. 6d. net.

(6) *Structure and Growth of the Mind*. By W. Mitchell. Pp. xxxv+512. (London: Macmillan and Co., Ltd., 1907.) Price 10s. net.

(1) THE sixth volume (new series) of the Proceedings of the Aristotelian Society contains the papers read before the society during its twenty-seventh session, 1905–6, and is unusually bulky, as publication has now become a much more important part than formerly of the society's work. Among other articles, it contains one on teleology by Dr. Shadworth H. Hodgson, the veteran ex-president of the society; a symposium "Can Logic abstract from the Psychological Conditions of Thinking?" to which contributions are made by Messrs. Schiller, Bosanquet, and Rashdall; and the records of a controversy (on Kantian and anti-Kantian lines) between Dr. G. Dawes Hicks and Prof. Stout. Scientific readers will turn with interest and profit to a paper by Mr. T. Percy Nunn, entitled "The Aims and Achievements of Scientific Method." Mr. Nunn defines the aim of the scientific process as an endeavour to render the Objective in its actual determinations intelligible. He points out the stages of Animism and Hylozoism through which pre-scientific thought

has passed, and examines more particularly, in the case of Kepler, the struggle between the non-scientific (and commonly theological) prepossession and the purely scientific spirit—so well illustrated, for example, in Kepler's demonstration that the orbit of Mars is an ellipse, and not a circle as his "prepossession of perfection" had originally compelled him to suppose. But in all attempts at explanation, whether "the divine" is invoked or not, the primary facts are qualified by an hypothesis—in other words, they are made to form part of an apperceptive system. In this way the non-scientific attempts to render the Objective intelligible do not differ formally from the scientific, and Mr. Nunn argues that it is, in fact, difficult to declare *any* concept essentially incapable of mediating a scientific interpretation of the Objective to some thinker: he instances the use made by some scientific men of the concept of cause in the sense of transeunt action, or again the preference shown by Weber and the Continental school for the concept of action at a distance, as contrasted with the equally marked preference of the British school for the concept of an intervening medium. Finally, as for the close connection between mathematics and science, it is due simply to the fact that primary facts present themselves for the most part in series, and so "the most useful method of determining the Objective consists in correlating terms of these series with the members of the number series."

(2) and (3) These two books form part of the excellent "Philosophische Bibliothek." The Descartes volume contains (in a German translation) the "Regulae ad Directionem Ingenii" and the "Inquisitio Veritatis per Lumen Naturale." The editor, in a well-written introduction, discusses the question of dates, and reaches the conclusion that the "Regulae" were composed about the year 1628, and in Latin, as Descartes at that early age still employed the language of his instructors. The "Inquisitio," on the other hand, was probably written in French between 1644 and 1647, and translated into Latin by the unknown editor of the posthumous works published in 1701. Dr. Buchenau concludes that its fragmentary condition is due to the fact that Descartes, in 1645, had an opportunity of comparing the French translation of the "Meditations" with his own new French work, and on finding a great similarity between the two thought it unnecessary to proceed with his later effort.—Herder's works readily lend themselves to selection, and it would be a pity that we decadents should forget one who, though overshadowed by the gigantic figures of Kant and Goethe, is by no means negligible in the history of thought. The excerpts are chosen with discrimination, and include the most suggestive passages of the "Ideen." The introduction gives a good account of Herder's relation to Kant, and a useful index is provided.

(4) The title of this work is rather misleading. The International Scientific Series already contained a book entitled "Mind and Body," by Prof. Bain, and it has therefore seemed to the translator or publishers desirable, and to M. Binet tolerable, that this work in its English dress should be called "The Mind and the Brain," and not "Soul and Body" or "Mind and Body." But, for that matter, the well-known series in which it appears also contains works entitled "The Brain as an Organ of Mind," and "The Brain and its Functions," so that he who would avoid Scylla must reckon with Charybdis. And certainly, when one finds that the table of contents is boldly divided into three parts, "The Definition of Matter," "The Definition of Mind," "The Union of the Soul and the Body," it argues a certain lack of insight and imagination to fix upon a name so inappropriate as "The Mind and the Brain."

M. Binet writes in an interesting and generally a clear style, with a French lightness of touch which occasionally borders on superficiality. The subject could, in our judgment, have been better treated. The reader is often irritated by one-sided statements which are apparently, a few pages later, contradicted by one-sided statements in precisely the opposite sense. One yearns for the synoptic view, for the *cacoethes explicandi*, which will compel the writer, even at the risk of being tiresome, to burrow to the very roots of his problem. Thus, for example, on p. 25 we are told that our nervous system, which enables us to communicate with objects, prevents us from knowing their nature. Sensation has, as its unknown cause, the great X of matter. On p. 38 we find objection taken to the physicist's attempt to explain sensations of sound:—"outside our ears there exists something we do not know which excites them; this something cannot be the vibratory movement of the tuning fork, for this vibratory movement which we can see is likewise [as much as the sensation of sound] a subjective sensation"; and the airy reference on p. 39 to the hegemony of certain of our senses over others still avoids much of the difficulty. But in the light of all these statements the conclusions reached on p. 109 are little short of astonishing; they are these, that (1) there remains no reason for refusing to admit that we perceive things as they are, and that the consciousness, by adding itself to objects, does not modify them; (2) the statement that we only know our sensations, and not the excitants which produce them, is to be understood in this way that these sensations are matter—they are matter modified by other matter, viz. our nervous centres. This is perhaps skilful, but is it convincing?

(5) M. Ribot's "Essay on the Creative Imagination," which appeared in French about six or seven years ago, has now been translated into English. Like all its author's work, it is suggestive and thorough. The translation is usually well done; but is it author or translator who is responsible for the statement on p. 58 ("The Unconscious Factor") that inspiration is the result of an *underhand* process existing in men? Chatterton is said, on p. 145, to have died at the age of sixteen, some emphasis being attached to that precise number; the usual statement is that "the marvellous boy" had almost reached his eighteenth year when he died.

(6) Mr. Mitchell's work will compare very favour-

ably with the best philosophical books of recent years. At its best the exposition of the subject is very clear and engaging, and gives evidence of much reading and sound study. If it errs at all, it is perhaps in occasional over-subtlety. An excellent running analysis is given in the table of contents.

Where all is so excellent and thorough, a short notice can do little more than indicate the point of view. The first part of the volume deals with the direct explanation of the mind, *i.e.* the explanation of experience in terms of itself. The second considers Sympathetic and Æsthetic Intelligence, and contains valuable chapters on Imitation, Fellow-feeling and Individuation (with a good note on *Einfühlung* on p. 149), and Absorption in the Object. The Growth of Intelligence in its two forms, Perceptual and Conceptual, is the subject of the third part, and in the last we return to an extension of the direct explanation of experience, and to the indirect explanation or explanation in physical terms.

We note one or two small points. (i) Mr. Mitchell rounds on the materialist position thus:—

"The capacity of the brain has to be inferred from the capacity to experience. . . . Whatever is possible to the mind is possible to the brain."

(ii) While not accepting the ordinary man's use of the term "mental faculty," and not accepting the division into faculties as though they were physical, the author has a refreshing bluntness and honesty in dealing with the term faculty itself. He has no objection to its use as properly defined, and complains that too often writers on psychology have thought that, so long as they avoided the *term* faculty, they could ask any number of indefinite questions—as to whether feelings depend on thoughts, or whether reason is the slave of passion—and could, in fact, substitute for faculties "a miscellaneous collection of experiences in every kind, of processes conscious and unconscious, and even of laws, as combining to make experience or causing it somehow." "I think it a needless penance," he adds, "to use the word 'disposition' in the sense that everyone would be willing to give to 'faculty' if he understood."

THE IMPERIAL GAZETTEER OF INDIA.

The Imperial Gazetteer of India. The Indian Empire, Vol. i., Descriptive. New edition. Pp. xxxi+568. (Oxford: The Clarendon Press, 1907.) Price 6s. net.

THE completion of the census in 1901 necessitated a revised issue of "The Imperial Gazetteer of India," of which two editions had already appeared, both compiled by the late Sir W. Hunter. Hunter, while in charge of the statistical department, had gained considerable knowledge of the country and its people, and in one subject, the history of the British occupation, was a competent authority. It is true that he inclined to overestimate the importance of his labours, and that he failed to give due credit to the district authorities who provided the raw material on which his compilation was based. At the same time he performed an invaluable service in popularising India for European readers. It became clear, however, that the Gazetteer was beyond the capacity of any single man, and that it was necessary to divide the subjects among a body of specialists. In the present issue, which will be nearly double the size of the last edition, little remains of Hunter's work except the final historical chapter.

During the quarter of a century which has passed since the last edition appeared, much has been done to extend our knowledge of the country. It is significant that in its physical aspects it is now officially assumed to include those outlying territories over which the Government has extended its control, even to the southern limits of Persia, Russia, Tibet, and China. The progress in the natural sciences is marked by Sir G. Watt's unwieldy "Economic Dictionary," Sir J. Hooker's "Flora," the "Manual of the Geology of India," the series of monographs on the fauna edited by Mr. Blanford, and a great mass of special literature. Scientific anthropology was in its infancy in Hunter's day; Dr. Grierson's linguistic survey was not even dreamed of; meteorology had not begun to gather its materials from beyond the Indian Ocean; hygiene had not yet been confronted with the problem of Oriental plague. Lastly, in the domain of religion, the translation of the sacred books had only just begun, and little attention had been given to the not less important subject of the beliefs and superstitions of the peasantry.

In the present edition of this great work these stores of new learning have been summarised and interpreted. Four introductory volumes are devoted to a series of lucid articles on the various scientific and administrative questions to which reference is made in the body of the work. The first volume contains ten articles. It opens with a chapter on the physical aspects of the country by Sir T. Holdich. The natural sciences are represented by a chapter on geology by Mr. T. Holland, one on meteorology prepared from materials supplied by Sir J. Eliot, while the veteran Sir J. D. Hooker deals with botany and Mr. W. T. Blanford with zoology. The chapter on ethnology and caste is a summary of the views expressed by Sir H. Risley in his last census report; that on language is the work of Dr. Grierson. Mr. W. Crooke is responsible for religions, Mr. E. A. Gait for sociology, and Dr. A. E. Roberts for public health and vital statistics.

The volume is thus made up out of a series of essays, each the work of an expert, and each provided with an adequate bibliography. In some cases, as that of geology, the treatment is more technical than will suit the general reader, but the review within narrow limits of space of a wide and intricate subject rendered this inevitable, and the serious student is the gainer. Many of the articles, however, are eminently readable; in particular, Sir T. Holdich, dealing with Mr. Holland's materials, has so interpreted the story of rock, mountain, and river that he has produced a fresh and graphic picture of the physical aspects of the country and of the environment of its people.

The gazetteer, which is issued in excellent form and at a most moderate price, should be in the hands of all who are interested in the fortunes of India. It should remain for many years the most authoritative source of information regarding our great eastern empire. The Government of India and its official editors and contributors are to be congratulated on the completion of a work of national importance.

OUR BOOK SHELF.

The Laboratory Book of Mineral Oil Testing. By James A. Hicks, with introduction by Sir Boverton Redwood. Pp. xii+76. (London: C. Griffin and Co., Ltd., 1906.) Price 2*s*. 6*d*. net.

EMPIRIC methods of testing, however simple in principle, are just those which require exact procedure in practice; otherwise two equally skilful analysts, by slight and apparently insignificant modifications, may arrive at different results. As the flash-point and viscosity methods, applied to the testing of mineral oils, depend on specially designed apparatus used under special conditions, it is essential that every chemist should work under the same conditions, and for this reason Mr. Hicks's little book will be gratefully appreciated by those who have to do with mineral oil testing. In addition to a careful description of various flash-point and viscosity apparatus and their application, the book contains an account of colour-testing and the use of sundry apparatus for estimating pressure of naphtha vapour, detection of petroleum vapour, capillarity testing, methods for estimating melting points of paraffin, wax, and scale, and for determining the calorific value of mineral oils. There is also a table (which should be unnecessary) for converting centigrade into Fahrenheit degrees, and a list of all the apparatus required for oil testing, including the name of the firm which undertakes to supply it. The book is evidently designed to meet every requirement, and its appearance under the auspices of Sir B. Redwood should be a guarantee of its practical value and utility. J. B. C.

Theories of Chemistry. Being Lectures Delivered at the University of California in Berkeley. By Svante Arrhenius. Edited by T. Slater Price. Pp. xii+212. (London: Longmans, Green and Co., 1907.) Price 5*s*. 6*d*. net.

THE nature and aim of this work are clearly stated by the author in his preface. He writes:—"The present lectures were delivered at the University of California during the summer of 1904. I have for a long time wished to give a coherent account of the development of theories in general chemistry. This seemed to me the more desirable because the latest extensions of this science are often, both by followers and opponents, regarded as something wholly new and quite independent of the progress in the past. Many seem to hold the opinion that the new developments are the more to be admired, the less dependent they are on the older chemical theories. In my opinion, nothing could be less correct. It is just the circumstance that the new theoretical discoveries have developed organically from the old generally accepted ideas, that is to me their most promising feature."

This is a somewhat unexpected view to be held by perhaps the greatest innovator in modern chemical theory, but there is no question that it has led to the production of a most unusual and stimulating book, the perusal of which no scientific chemist can afford to neglect. A detailed enumeration of the chapters would do little to indicate their contents. The subject-matter is familiar to all chemists—it is the treatment which is of special value. The various theories and hypotheses are critically examined and exhibited in their proper relationship and subordination. The whole work bears the stamp of a mind of uncommon power applied to the matter in hand with a balance and sobriety of judgment no less rare.

Life and Flowers. By M. Maeterlinck. Translated by A. T. de Mattos. Pp. xii+312. (London: George Allen, 1907.) Price 5*s*. net.

THIS volume contains a collection of essays of which some have appeared in periodicals, others are published in English for the first time. They are all more or less directly concerned with life, from the phantasy on the sun-dial to the eulogy on the boxer's fist, but only the two last, on the intelligence of flowers and perfumes, are relevant to the subject of flowers. In the former of these, M. Maeterlinck describes in his perspicuous language some of the striking phenomena connected with fruit dispersal, flower pollination, and movement in plants. The accuracy of the word-painting bears witness to the author's first-hand observation of many of the phenomena, although, as he points out, except for his original experiments with the species of Salvia, the results of which are not sufficiently advanced to publish, the facts are taken from well-known sources. The attribution of arithmetical powers to the Rue and other such hyperboles may be regarded as the expression of a strong imaginative temperament. The account of the pollination in *Orchis pyramidalis* furnishes one of the best examples of the author's faculty of description.

LETTER TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Unscientific Administration.

IN his letter of June 20, Mr. M. D. Hill refers to the defective education of our schools and universities, and seems to suggest that it is not the mass of the people who are to blame for England's isolated position in her national neglect for science. May I point out that in the education of our future working classes equally unscientific ideals still prevail?

The recent review of Mr. Mair's book in NATURE of June 13 (p. 147) under the title "Realistic School Mathematics" shows that there is one Government department which is striving to introduce thoroughly sound and practical, and therefore scientific, methods of teaching into this country. But the training colleges in which teachers for elementary schools are educated at the expense of the State are tied down, by examination requirements, to courses which cannot be described otherwise than as useless mechanical drudgery, with the result that the student who obtains the highest class certificate of competency to teach becomes thoroughly unfitted to appreciate or even understand such a stimulating book as "A School Course of Mathematics." The children who are taught by such a teacher will in time become the electors in whose hands lies the duty of returning a Conservative or Liberal Government to power. Unless the teachers are trained on more scientific and practical lines, there is little prospect of any Government being administered scientifically.

One further point may be mentioned. In Germany and Austria the Government confers titles of honour—Geheimrat and Hofrat—on professors who have distinguished themselves by their researches. In Great Britain it is the universities which confer honorary degrees on prominent politicians. G. H. BRYAN.

LONDON BOTANIC GARDENS.[1]

THIS little work comprises in book form a series of articles contributed to the *American Journal of Pharmacy* by Mr. P. E. F. Perrédès in 1905 and 1906. Written by a pharmaceutical chemist to a pharmaceutical journal, these papers naturally devote attention primarily to the relationship of the London botanic gardens to the art of pharmacy. In tracing the origin of botanic gardens to the private gardens of the herbalists of the sixteenth and seventeenth centuries, the author shows that the cultivation of medicinal and officinal plants was the fundamental object kept steadily in view. But recognising that the modern botanic garden, while not departing from this original function, has developed other and equally important features, he has not confined himself exclusively to the pharmaceutical aspect of the London botanic gardens, but has given in a concise but comprehensive manner a review of the work accomplished by them in the domain of pure botany and in the application of the science to technical affairs. The subject has been treated throughout with a breadth of view, an insight and a sense of proportion which have too often been lacking in sketches of this nature, and the absence of which may be held accountable in a great measure for the vague ideas prevalent as to the functions of a botanic garden.

The gardens dealt with are the Chelsea Physic Garden, the Royal Botanic Gardens, Kew, the Royal Botanic Society's Garden, and the garden of the Royal Horticultural Society. The last makes no claim to rank as a botanical establishment, but in view of the close association with it of such men as Lindley, Bentham, and Fortune, and of the services rendered to botanical science by the collectors of the society, such as Don and Douglas, the author rightly feels that in a comprehensive review the Royal Horticultural Society cannot be ignored. In dealing with the three London botanic gardens proper, Mr. Perédès judiciously leaves the reader to form his own idea of their relative importance. Each is dealt with separately, from three points of view—historical, functional, and administrative.

From the historical standpoint it may almost be said that the history of these gardens is the history of systematic botany in England. In dealing with their functions, as already remarked, there has been no attempt at comparison. But the conclusion one arrives at is that, in inception at least, these respective botanic gardens were complementary rather than antagonistic or competitive. While founded on a common basis, they differed widely in scope, and though perhaps not dovetailing perfectly, there was no material overlapping. Thus the deed conveying the Chelsea Physic Garden to the Society of Apothecaries in 1722 stated that the conveyance was made "that their apprentices and others might better distinguish good and useful plants from those that bore resemblance to them, and yet were hurtful, and other the like good purposes."

The Royal Botanic Society was established, in 1839, on a somewhat wider footing "for the promotion of botany in all its branches, and its application to medicine, arts and manufactures, and also for the formation of extensive botanical and ornamental

Chelsea Physic Garden (*circa* 1850) from the river, before the construction of the Chelsea Embankment. From "London Botanic Gardens."

[1] "London Botanic Gardens." No. 62 of the Publications of the Wellcome Chemical Research Laboratories, Snow Hill, E.C. Pp. 99, with 31 plates.

gardens within the immediate vicinity of the metropolis." Both were strictly metropolitan institutions, and both were essentially educational establishments, differing only in scope. Various exigencies have at times modified, and even obscured, their primary object, but each has, so far as circumstances permitted, devoted itself to educational work. The extent and value of the services they have rendered, and continue to render, in this direction are fully detailed in the work under review.

Kew, on the other hand, can only be termed a *London* botanic garden in a strictly limited sense. As a national institution it has a much wider field, and its activities are on a correspondingly broader basis. Unlike the other gardens, it does practically no direct educational work, but "stands out prominently as a centre of botanical research, and as the cradle of botanical enterprise in India and the Colonies."

The principal aspects of Kew work are touched upon, but the limits of space have compelled the writer to treat them by way of illustration rather than exhaustively. No reference is made to the horticultural or ornamental side of Kew. While detracting in a measure from the completeness of the sketch, the omission is the less to be regretted because of the growing tendency on the part of the general public to regard this feature as fundamental rather than incidental, and to look upon botanic gardens as places of recreation rather than as scientific institutions. Mr. Perrédès's work, by directing attention to the conspicuous part that the London botanic gardens have played in the scientific and material progress of the nation, should go far towards removing the reproach that our botanic gardens are better understood and more appreciated abroad than at home, a reproach which gains point from the fact that the papers under notice were contributed to an American journal, and are only available in this country at second-hand.

The work is well illustrated, and contains a copious bibliography.

THE NATIONAL PHYSICAL LABORATORY.[1]

THE recent discussion of the affairs of the National Physical Laboratory in Parliament, and the appointment of a departmental committee of the Treasury to inquire into the working of the laboratory, with special reference to its alleged "competition with private establishments," have tended to produce amongst the newspaper-reading public an impression that the institution was not being carried on satisfactorily. It may be useful, therefore, to state in a few words what is really the position of affairs.

The laboratory was established in 1899 to serve as an independent testing authority, and to carry out researches into the properties of materials which, while necessary for the advance of the industries of the country on scientific lines, are generally too extensive and laborious to be undertaken by private individuals. It was not anticipated that it would ever be necessary to compete with the existing private institutions in the testing of materials, but nothing in the Royal Society's scheme on which the laboratory was founded limited its testing powers. Once it was equipped and staffed, the desire of industrial firms to have their materials tested by men who had already made names for themselves in the scientific world appears to have led to much work of this kind being sent to the laboratory, and it is difficult to see on what grounds it could be refused. Whether it is to be undertaken in future or not the Treasury Committee must decide.

With regard to the research work of the laboratory, there can be no two opinions. A glance through the two works under notice is sufficient to show how well it is fulfilling its task. Dr. Stanton's work on the resistance of iron and steel to reversals of stress is supplying information urgently needed, and with Dr. Carpenter's work on the structure of high-speed tool steel and on the properties of iron-nickel-manganese-carbon alloys is constituting the laboratory *the* authority in this country on the properties of the materials used by mechanical engineers. Mr. Paterson's investigations on light standards and glow lamps, communicated to the Institution of Electrical Engineers in January, supply gas and electrical engineers with information of the greatest value as to the relative merits, or rather demerits, of the various standards of light. Mr. Campbell's researches on the properties of the paper and cellulose used in telephone cables, on insulating materials suitable for high temperatures, and his hysteresis research, all bear intimately on the electrical engineering industry, as does Dr. Caspari's work on gutta-percha and balata. Dr. Harker's new bench-mark 1710° C. for the melting of platinum will serve as a starting point for a revision of all our high temperature melting points, and will introduce precision into a region in which uncertainty has been the prevailing feature. His interesting work on the Kew temperature scale may lead to Kew methods becoming international.

The testing work of the observatory department has increased, and the department appears now to turn out "hall-marked" men, *e.g.* Wood, Simpson, and Gold, as well as "hall-marked" instruments. Two important discussions, by Dr. Chree, of terrestrial magnetism and of atmospheric electricity records, and their relation to meteorological phenomena, show that there is no likelihood of the reputation of Kew as a place of research suffering now it has lost its independence.

The few investigations mentioned above serve as examples of the work that is being done in the laboratory, but they tell nothing of the good influences exerted by the laboratory through the members of its staff on the councils and at the meetings of scientific and technical societies throughout the kingdom.

Although there will always be members of the public, and even Members of Parliament, who are unable to understand why any of the nation's money should be invested outside the circle of "small profits and quick returns," no one who is anxious that our country should stand shoulder to shoulder with its neighbours in the march of scientific and industrial progress can feel other than gratified that in establishing the National Physical Laboratory we have taken a step in the right direction.

DR. EDWARD JOHN ROUTH, F.R.S.

BY the death of Dr. Routh on June 7, after a period of gradually failing health, a commanding figure in the recent history of English mathematics has been removed. Born at Quebec in 1831, the son of a distinguished British officer, he was educated in London at University College School, and subsequently studied mathematics under de Morgan at University College. He matriculated at Peterhouse in 1850, but did not drop his London connection, obtaining the gold medal in mathematics with the degree of Master of Arts in 1853, then a somewhat rare distinction. At Peterhouse he had Clerk Maxwell, who soon after migrated to Trinity, as his rival in the same year; while Tait and Steele were undergraduates of the College, and Lord Kelvin (already Prof. W. Thomson, of Glasgow) was a junior Fellow.

Not long after taking his degree, in January, 1854, being senior wrangler, and bracketed with Clerk Maxwell for the Smith's prizes, he began the career of tuition of advanced honour men in mathematics, which was soon to lead to a unique reputation as a successful teacher. From 1858 to 1888 he had, in all, between 600 and 650 pupils, of whom the great majority graduated as wranglers, twenty-seven being seniors, while forty-one were Smith's prizemen; between 1861 and 1885, when he retired from this strenuous work at the age of fifty-four, he had all the senior wranglers as pupils, with but one exception near the end of the time.[1] The number of his pupils, which was for many years about 100, was not at all unprecedented; what was unique was the fact that for all this time he directed, almost without challenge, most of the intellectual activity of the *élite* of the undergraduate mathematical side of the University. This herculean task naturally demanded methodical arrangements, and the husbanding of his resources to the utmost. What he aimed at was to impart thorough mastery of the main principles of ascertained knowledge over the field of mathematics then cultivated at Cambridge; it was clearly out of the question to stray very far into the regions of nascent science in which ordered theory gradually evolves itself in response to concentrated and specialised effort. He was in the habit of claiming that this would follow spontaneously in the case of the mathematician born, once he had learnt mastery of the resources of the science; while even when it did not follow, the record in the legal and other professions of persons who had done well in youth in mathematical studies proved their supreme value as a deductive mental discipline.

His plan was to take small classes, each of about ten men selected to run together, and to maintain an average by catechetical methods. Those who could go faster than the average had extra material provided in the form of manuscript digests for study, and especially in the institution of a weekly paper of about a dozen problems, selected from recent examination papers, or abstracted from memoirs in the home and foreign mathematical journals. An element of competition formed a stimulus in answering these papers, while written solutions were afterwards at hand for study in cases of failure to unravel them. Looking back on those times, it might be thought that there was too much problem and too little sustained theory; but no one ever accused the standard of the problems selected of being lower than it ought to be, while, on the other hand, absence of some such rigid procedure would have rendered quite impossible that focussing of undergraduate mathematical activity and ambition in one place which was a main feature of the system. Men with further ambitions would struggle with Thomson and Tait's "Natural Philosophy" or with Maxwell's "Electricity," or with brilliant and stimulating courses of lectures given on growing special subjects by the more eminent mathematical physicists, and thus learn that though in youth mastery may be rapid, yet at all times invention must be slow. It was, moreover, thus possible for the abler men to have time to spare to expand their outlook by taking up some other branch of knowledge as a relaxation from mathematics, or for joining in other activities of the University. Nowadays the field covered by the mathematical instruction offered at Cambridge is vastly wider than would have been conceived as practicable twenty years ago; but the question is still unsettled how far it is expedient to extend the preliminary undergraduate course into complex special theories.

[1] These and other facts have been taken from a valuable notice in the *Cambridge Review* signed W. W. R. B.

Whatever may be thought as regards Dr. Routh's views on postponing special research in favour of thorough preparation, it could not be urged that he did not himself, notwithstanding his other absorbing work, set an example of what research might be. Many of his earlier papers, mainly in the *Quarterly Journal of Mathematics*, related to the dynamics of rigid solids, spinning tops, rolling globes, precession and nutation, and such like, and were distinguished by the development of methods relating to moving systems of coordinate axes, and to the differentiation of vectors such as velocity and momentum with regard to them. In another connection he applied the kinematics of special systems of coordinate axes moving along a curve to problems of curvature and torsion. The advantages of these methods in differential geometry have come again into recognition, as may be seen in such works as Darboux's "Théorie des Surfaces." Afterwards, arising out of his researches on dynamical stability, which will be referred to presently in more detail, there came a series of papers in the Proceedings of the London Mathematical Society on the propagation of waves and the analysis of complex vibrations in networks of interlacing threads and in other such laminar systems, leading up to a mechanical treatment or illustration of the broad general theory of harmonic analysis, principal periods, and related topics.

In the early 'seventies, the question of the possible explanation of steady, including apparently statical, relations of material systems by the existence of latent steady motions, such as the rotations of concealed flywheels or gyrostats attached to the system, was much to the fore. The fundamental problem as regards such representations is their degree of permanence; for a state of motion which falls away, however slowly, cannot be appealed to in elucidation of secular steadiness of relations. At a later stage the ideas of the subject were crystallised by Lord Kelvin in his British Association address, Montreal, 1884, entitled "Steps towards a Kinetic Theory of Matter," and in later addresses on cognate topics, mainly reprinted in vol. i. (Constitution of Matter) of his "Popular Lectures and Addresses," culminating in a way in 1897 in his gyrostatic model of a rotationally elastic optical æther.

It is thus not surprising that the Adams prize subject at Cambridge for the period 1875–7, announced over the signatures of Challis, Clerk Maxwell, and Stokes, should have been the search for "The Criterion of Dynamical Stability." This subject suited Routh's predilections exactly; and his classical essay, "A Treatise on the Stability of a Given State of Motion, particularly Steady Motion," composed, as he states in the preface, almost entirely during the year 1876, was the result. The greater part of the work in the essay is analytical, and is concerned with the discussion of the nature of the roots of the algebraic equation determining the free period of slight vibration of the dynamical system; but where it enters upon the discussion of dynamical principles, such as the criteria connected with the Energy and the Action, the essay moves in a high plane. In particular, the burning question of how adequately to represent latent, and, therefore, unknown steady motions, such as those of concealed flywheels or gyrostats attached to the system, is solved at a stroke by the famous theorem of the "modified Lagrangian function." It was established, in fact, that the presence of concealed steady motions does not fundamentally alter the standard mode of analytical specification of dynamical interaction developed originally by Lagrange, except in the one respect that the effective Lagrangian function now involves terms linear in the velocity-components as well as quadratic terms. The procedure of Lagrange, evolved originally from the side of the Principle of Action, constituted the science of general dynamics by eliminating from the problem all variables the values of which are prescribed in terms of the remaining ones by relations of permanent constraint, thus reducing the dynamical analysis to the discussion of just as many quantities as are required to specify the state of the system. It gives cause for some surprise that nearly a century elapsed before the correlative step was taken, namely, the elimination from the analytical specification of the system of permanently steady or cyclic motions, as well as the permanent geometrical constraints above mentioned. In the hands of the analysts who treated the subject meanwhile, the requirements of the actual planetary and lunar theories were perhaps the main aim; it is only recently, and largely in the hands of the English school, notably Lord Kelvin and Clerk Maxwell, in later conjunction with Helmholtz, and building largely on the earlier work of W. Rowan Hamilton, that the subject of general dynamics has been welded into an instrument for the inductive, and in many cases speculative, exploration of physical processes in general. Anyhow, it will be evident how fundamental an advance in the principles of the dynamical interpretation of nature was involved in Routh's formulation of what he called the "modified Lagrangian function."

The problem thus solved by Routh with remarkable simplicity had already been some time in evidence. In the first edition of Thomson and Tait's "Natural Philosophy" in 1868, the equations of Lagrange had been applied in most effective manner to problems of motions of solids in fluid media, the energy function involved being determined in terms of the motions of the solids alone, and the fluid thus being *ignored* in the subsequent work. This procedure was soon challenged by Kirchhoff, as going beyond the existing conditions of validity of general dynamical theory; and a special justification for the case of motion in fluids was given by him on the basis of a Least Action analysis. Soon afterwards the same difficulty was pressed on Lord Kelvin independently by J. Purser, who also published a justification on more physical lines. This was, not unlikely, the origin of Lord Kelvin's general theory of "ignoration of coordinates," first published in 1879 in the second edition of Thomson and Tait's work, but which probably existed in manuscript anterior to Routh's essay. A report was once current that most of it was worked out in the harbour of Cherbourg, while his yacht was refitting, and the carpenters were all the time hammering overhead. This form of the theory, though more expressly suggested by the needs of physical dynamics, was less complete in one respect than Routh's, in that it did not bring the matter into direct relation with a single characteristic function (Lagrangian function of Routh, kinetic potential of Helmholtz), but simply obtained and illustrated the equations of motion that arose from the elimination of the cyclic coordinates that could be thus ignored.

Later still, Helmholtz, in his studies on monocyclic and polycyclic kinetic systems, which began in 1884 and culminated in the important memoir on the physical meaning of the Principle of Least Action in vol. c. (1886) of *Crelle's Journal*, developed the same theory more in Routh's manner, and built round it an extensive discussion of physical phenomena, so that on the Continent the whole subject is usually coupled with his name. Shortly before, the work of Routh and Kelvin had already been coordinated with the Principle of Action by more than one writer in England.

The most elaborate published result of Dr. Routh's scientific activity was the "Treatise on the Dynamics of a System of Rigid Bodies," which began as a thorough, though rather difficult, handbook in one octavo volume, but expanded in successive editions in a manner of which other classical instances readily occur to mind, until it became a sort of cyclopedia of the dynamical section of theoretical physics. In the course of an inquiry some ten years ago as to the reason why English mathematical physicists had so much practical command over the application of their knowledge, the mode of teaching in Cambridge came under review; and in particular this book was discovered by Prof. F. Klein, of Göttingen, who made arrangements for its introduction to the Continental public in a German translation, containing some brief valuable annotations such as the wide analytical outlook at Göttingen suggested. Especially was emphasis given to the great extension of the scope of abstract dynamics above described, with which Routh's name was associated, it is to be hoped permanently. Somehow the book does not seem to have attracted even yet much sustained attention in France.

Until lately, Dr. Routh's presence was a familiar and welcome one to residents in Cambridge. Though he never sought public positions, his services were in requisition in many ways, as Senator and Fellow of the University of London, as member of the University Council at Cambridge, member of council of the Royal Society, and in other activities; while he declined more prominent offices more than once. In society he was bright and attractive though somewhat retiring, simple, and entirely free from any suggestion of superiority. The respect and affection which he inspired in a long succession of distinguished pupils found expression on the occasion of his partial withdrawal from work in 1888, when at a remarkable gathering of judges, engineers, and men of science, his portrait by Herkomer was presented to Mrs. Routh, with many expressions of warm appreciation. His leisure he employed mainly in mathematical research, and in the preparation of a series of treatises on subjects of mathematical physics, of which the only criticism to be made is that his wealth of valuable material tended to convert them into cyclopedias rather than text-books. His last public action was to take the lead in opposition to the proposals for change in the system of the mathematical tripos at Cambridge. It is possible that he did not fully realise the altered circumstances of the time, and the insistent claims of other studies; anyhow, it will be matter for congratulation if the new arrangements work as well and as smoothly as did the older mathematical tripos during the long period when the practical direction was mainly in his hands.

J. L.

PROF. A. S. HERSCHEL, F.R.S.

THE death of Prof. Alexander Stewart Herschel, F.R.S., on June 18 will be deplored by many astronomers. Prof. Herschel was born in 1836, and was the second son of Sir John Herschel. He was appointed professor of physics at the Durham College of Science, Newcastle-on-Tyne, in 1871, and was honorary professor and governor of the college at the time of his death, though he left Newcastle about twenty years ago, and resided with his brother, Col. John Herschel, F.R.S., at Observatory House, Slough, which was the home of his renowned grandfather, Sir William Herschel, and of his father. Prof. Herschel was elected a Fellow of the Royal Astronomical Society in 1867, and of the Royal Society in 1884.

Inheriting an illustrious name, Prof. Herschel also inherited the love for astronomy, the indomitable perseverance and capacity for work, and much of the ability which distinguished his father and grandfather. As a mathematician, physicist, and observer, Prof. Herschel was *facile princeps*, and it was fortunate for meteoric astronomy that he devoted himself to its practical and theoretical investigation. Sir John and Sir William Herschel had swept the heavens with large telescopes in quest of nebulæ, double stars, and other objects, but Prof. Alexander Herschel appears to have preferred naked-eye observation to instrumental work. For about half a century he watched diligently for meteors, and obtained numerous and valuable results, as past volumes of the Monthly Notices of the Royal Astronomical Society and Nature fully attest.

Apart from his observational results Prof. Herschel accomplished a large amount of important work in the summation, reduction, and discussion of various other observations. In conjunction with Mr. R. P. Greg he formed several extensive catalogues of the radiant points of shooting stars, and the most important of these were published in 1868, 1872, and 1874. One of his greatest successes, though it has been little commented upon, was the prediction made in the Monthly Notices, vol. xxxii., p. 355, of the great Bielid shower of 1872 November 27. For many years he compiled the annual reports of the luminous meteor committee of the British Association, and contributed, until 1880, the yearly notes on meteoric astronomy published in the anniversary number (February) of the Monthly Notices.

Prof. Herschel was a voluminous writer, and all those who enjoyed the pleasure of corresponding with him will agree that his letters were just as interesting as they were long. The writer of this notice will always have reason to be grateful to him for kind encouragement, advice, and instruction in the earlier years of his observing career. It is not too much to say that without the deep interest incited by Prof. Herschel's letters the meteoric observations obtained at Bristol during the last thirty-five years may never have been made.

As an observer of shooting stars Prof. Herschel was remarkably accurate, and he not only recorded their apparent paths with fidelity, but accompanied his results with descriptive details marvellous in their fulness. He computed the real paths of a great many fireballs and ordinary falling stars, and very ably discussed the often discordant observations which formed the basis of these inquiries.

The present writer has often been impressed at the acumen and sound judgment he displayed in dealing with difficult materials of this character. Meteoric astronomy has indeed lost one of its ablest votaries in Prof. Herschel, and it may truly be said that the present high position of this branch of science is due in no small measure to his prolonged and able researches.

W. F. Denning.

NOTES.

A correspondent recently directed our attention to a sensational report that certain signals are regularly received at one of the Marconi wireless telegraph stations, and are believed to be communications from Mars or another planet. As Mars will be in opposition on July 6, and is well situated for observation in southern observatories, the rumour will probably be extensively circulated during the next few months. A copy of the report was sent, therefore, to Mr. Marconi, who has favoured us with the following reply:—"There is no truth whatever in the statement which has been freely published for the last year or two that mysterious signals have been received at Cape Clear from probably some distant planet. There is, in the first place, no wireless telegraph station at Cape Clear. The stray or vagrant electrical effects which do manifest themselves from time to time at wireless telegraph stations are due to atmospheric discharges or other natural causes. To attribute this phenomenon to any such source as is contemplated in these newspaper reports is, so far, purely imaginative and idle speculation."

We regret to have to record the death of the well-known ironmaster, Mr. Thomas Andrews, F.R.S., at Wortley, near Sheffield, on June 19. Mr. Andrews was born at Sheffield in 1847, and succeeded his father as proprietor of the Wortley Iron Works many years ago. He was the author of numerous papers, chiefly on metallurgical subjects, but his researches were of a varied nature, and included such widely separated subjects as the composition of river waters and the strength of railway axles. Of late years his writings dealt chiefly with the micro-structure of metals, carrying on work which originated in Sheffield. He was awarded a Telford medal and premium by the Institution of Civil Engineers in 1884, and was elected a Fellow of the Royal Society in 1888. He was also a gold medallist and Bessemer prizeman of the Society of Engineers, London.

Mr. A. W. Hill, fellow and dean of King's College, Cambridge, and university lecturer in botany, has been appointed assistant director of the Royal Gardens, Kew.

Profs. Guido Castelnuovo, of Rome, George William Hill, of New York, Camille Jordan, of Paris, and Vito Volterra, of Rome, have been elected honorary members of the London Mathematical Society.

A charter of incorporation has been granted by the King to the Society of Chemical Industry, which was founded in 1881 to promote the application of chemical science to arts and manufactures.

A committee has been appointed by the President of the Board of Agriculture and Fisheries to inquire into the nature of distemper in dogs in Great Britain and the methods of its infection, and to report whether any, and, if so, what, preventive or remedial measures, exclusive of ordinary medical treatment, can with advantage be taken with respect to it.

A conference on the prevention of infant mortality and the welfare of nursing mothers and suckling infants will be held at the Town Hall, Pancras Road, N.W., on July 1, at 3.30 p.m., to inaugurate the opening of the School for Mothers at 6 and 7 Chalton Street, Euston Road, N.W., the centre of the St. Pancras Mothers' and Infants' Society. The Mayor of St. Pancras will welcome the conference, and Lord Robert Cecil will preside.

On Monday next, July 1, at 2.30 (weather permitting), there will be a display of scientific kites and other aëronautical experiments on Chobham Common, Sunningdale, where the Aëronautical Society will hold the concluding meeting of the present session. Kites will be displayed by Mr. W. H. Dines, F.R.S., Mr. C. J. P. Cave, Mr. S. H. R. Salmon, and Mr. R. M. Balston. Mr. Cave will send up pilot balloons to determine the rate and direction of the wind at different heights, and demonstrations of the method will be given by means of a theodolite specially made from designs by M. de Quervain. Mr. Cave will also send up a *ballon-sonde* carrying self-recording instruments complete, as used by him for the international aëronautical ascents, which take place on fixed days simultaneously throughout Europe. Mr. José Weiss will perform experiments with model gliders.

As the result of an extensive correspondence with entomologists of various countries of Europe and America, it has been decided to issue, in the course of this summer, invitations for an International Congress of Entomology, to meet in 1908, probably at Brussels. The purpose of the congress is the promotion of the interests of entomology, and therefore of biology in general, by furthering cordial cooperation between the entomologists of different countries, and by stimulating research and directing it into channels where it may be most fruitful or where special research is most needed. Questions of applied entomology will likewise be dealt with in lectures and discussions, the large experience of devotees to pure entomology being applicable, with profit, to economic and hygienic entomology. Entomologists are cordially invited to advise and assist in the organisation of the congress. All communications, until further notice, should be addressed to Dr. K. Jordan, Zoological Museum, Tring (Herts).

The fifth annual meeting of the South African Association for the Advancement of Science will be held in Natal on July 10–17 next under the presidency of Dr. James Hyslop, D.S.O. The first part of the meeting, from July 10 to July 13, will be held at Pietermaritzburg, and the second part at Durban. The council of the association has revised the arrangement of the sections. Section A, the president of which this year is Mr. E. Nevill, comprises mathematics, physics, astronomy, meteorology, geodesy, and geography. Sections B and C, including chemistry, metallurgy, mineralogy and geology, engineering, mining, and architecture, will be presided over by Mr. Cathcart W. Methven. The president of Section D, Mr. H. Watkins Pitchford, will take the chair at meetings concerned with botany, zoology, agriculture and forestry, bacteriology, physiology, and hygiene. Mr. R. D. Clark is the president of Sections E and F, before which papers will be read on education, philology, psychology, history, archaeology, economics and statistics, sociology, anthropology and ethnology. It will be remembered that, in connection with the South African medal and fund, the council of the British Association adopted a resolution "that, in accordance with the wishes of the subscribers, the South African Medal Fund be vested in the names of the trustees appointed by the South African Association for the Advancement of Science; and that the dies for the medal be transferred to the association, to which in its corporate capacity the administration of the fund and the award of the medal shall be and is hereby entrusted under the conditions specified in the report of the medal committee." The council of the South African Association accepted with high appreciation the offer made by the British Association, and undertook the award of the medal and fund in accordance with the terms of the conveyance. The fund, amounting to 1376*l.*, has been invested, and rules for the award of the medal and fund are being framed and will be dealt with at the forthcoming meeting. It is intended that the first award shall be made at the 1908 meeting of the association. The assistant general secretaries are Mr. E. Hope Jones for Cape Colony and Rhodesia, and Mr. Fred Rowland for the Transvaal, Orange River Colony and Natal. They may be addressed at P.O. Box 1497, Cape Town.

The first part of a new serial, *Records of the Canterbury Museum* (N.Z.), is devoted to a list of New Zealand fishes, by Mr. E. R. Waite, based on the one in the late Captain Hutton's "Index Faunæ Novæ Zealandiæ," but containing references to the original descriptions.

Articles on the fresh-water bryozoans of the country and the plankton of the coast—the former by Dr. A. Oka and the latter by Mr. K. Okamura—are included in the latest issue (vol. vi., part ii.) of *Annotationes Zoologicae Japonenses*.

No. 10 of the Indian Forest Bulletin is devoted to an account, by Mr. E. P. Stebbing, of the ravages inflicted by a longicorn beetle (*Butocera rubus*) on fig-trees in Baluchistan. The beetles made their appearance two years ago in a garden in the Duki district noted for the size of its fig-trees, on which they have inflicted very serious injuries. It is hoped, however, that by the use of suitable remedies the plague will shortly be stayed.

According to the annual report for the year 1906, the Zoological Society of Philadelphia is in a rather unsatisfactory financial condition, owing to the increased cost of almost everything connected with the upkeep of the menagerie. The result is an account overdrawn by nearly 3000 dollars. Neither have animals been acquired so rapidly as usual, very few new to the collection having been added during the year.

Despite the plethora of popular ornithological literature, there seems certainly room for a journal devoted to the purpose of recording recent additions to our knowledge of the birds on the British list. This gap is to be supplied by *British Birds; an Illustrated Magazine devoted to the Birds on the British List*, of which the first (June) number is now before us. Edited by Mr. H. F. Witherby, with the assistance of Mr. W. P. Pycraft, the magazine is to be published monthly by Witherby and Co. at the price of one shilling. The frontispiece to the first part is an exquisite photograph of an osprey descending on its nest, the most important article in this issue being one in which Mr. Howard Saunders enumerates the species added to the British list since 1899.

In the May number of the *Quarterly Journal of Microscopical Science* Miss Georgina Sweet, of Melbourne, continues her elaborate account of the anatomy of the marsupial mole (*Notoryctes typhlops*), dealing in this instance with the structure of the skin, hair, and reproductive organs. In examining the structure of the skin of the head, certain curious modified groups of cells with a more or less definite arrangement were detected, and similar cells were also found to exist in a modified patch of skin on the rump as well as in the region of the pouch. Although direct proof of the existence of nervous function is lacking, it seems probable that these modified cells represent some form of tactile sense-organ, which would obviously be of very considerable use to a blind burrowing creature like Notoryctes. It is unfortunate that at present nothing is known with regard to the embryology and development of this remarkable animal.

To the first part of vol. xvi. of *Anales Mus. Nat. Buenos Aires* Dr. F. Ameghino contributes four interesting plates in which skeletons of the extinct Hippidium and Machaerodus (Smilodon) of Argentina are respectively contrasted with those of the modern horse and tiger. In its huge skull and short limbs the extinct horse presents a remarkable contrast to its existing representative. It may be added that, through the kind offices of Dr. Ameghino, plaster reproductions of the skeletons of the two extinct species are now exhibited in the British Museum (Natural History). In a second paper in the same issue the author records the existence of what he regards as rudimentary horns in certain members of the toxodont group. In one instance (Trigodon) the rudiment takes the form of a low median frontal boss, compared by its describer to that of the Old World Elasmotherium, but in a skull figured under the name of Ceratoxodon there appear to be at least four pairs of smaller prominences.

THE fifth annual report of the Rhodesia Museum (Bulawayo, 1907) shows that the accessions to the museum in 1906 exceeded in importance those of any previous year, and that the number of visitors was 2292. A considerable number of interesting minerals and rocks were examined during the year, the number of identifications made for prospectors having been exceptionally large. Gem-stones were especially in evidence. For the guidance of prospectors, an able essay on the mineral wealth of Rhodesia has been written by the curator, Mr. F. P. Mennell, and is appended to the report. With the appointment of Mr. E. C. Chubb, of the British Museum (Natural History), as an additional member of the staff to take charge of the zoological department, the activity of the museum cannot fail to be increased in various directions.

OF the various branches of work undertaken by the Liverpool Institute of Tropical Research, the most productive and useful have been the missions abroad, especially the two expeditions to West Africa, where the representatives of the institute had the opportunity of noting conditions and resources, and brought away valuable collections. The results are summarised by the director, Viscount Mountmorres, in the fourth number of the Quarterly Journal issued by the institute. In the same number Dr. D. Spence communicates an account of two substances prepared from the resin of *Ficus Vogelii*, leading to the conclusion that the resinous products are closely related to caoutchouc, and Mr. R. Newstead discusses three types of weevils that are found in West African grain, and the suggested methods of destruction.

A PAMPHLET has been received in which the author, Mr. P. Frazer, describes experiments undertaken with the view of tracing the sources of injury to vegetation in the neighbourhood of manufacturing works. The results are in accord with former investigations, that the poisonous effects are produced chiefly by oxides of sulphur coming into direct contact with the leaves of plants, while the acids percolating into the soil do not injure the roots. A full bibliography is appended to the paper, which was read in April at the New York meeting of the American Institute of Mining Engineers.

IT has been observed that when potato plants are grown in a very moist atmosphere, swellings or intumescences often develop on the leaves. An account of experiments undertaken by Miss E. Douglas to examine their origin and discover the causes regulating their production was published in the *Botanical Gazette* (April). The intumescences are due to the growth of the cells, generally the palisade cells of the mesophyll, that elongate and divide until they break through the epidermal layer. The experiments indicate that the growth is the result of an abnormal state of turgescence when more water is absorbed than can be transpired or used in normal growth, and this is probably caused by the accumulation of osmotically active glucose.

THE twentieth volume of the Journal of the College of Science, Tokio University, is devoted to an enumeration of flowering plants and ferns from Formosa, compiled by Prof. J. Matsumara and Mr. B. Hayata. The compilation is based on specimens collected by several Japanese botanists who have toured through the island, their routes being shown upon an accompanying map. The number of new species is not very great, and the majority are figured in the excellent plates appended. Under *Spiraea prunifolia*, a plant that with double flowers is common in Japan, the authors describe a single-flowered plant, and mention that it is the first they have seen. A new order, Alniphyllaceæ, is proposed for a plant receiving the name of *Alniphyllum pterospermum*, that bears strong affinities both to the Styraceæ and Ericaceæ.

SOME admirably planned and instructive investigations carried out by Mr. W. J. Cudworth and Mr. Wilson Worsdell on the North-Eastern Railway are described in *Engineering* of June 14. The object of the investigations, which have extended over fourteen years, was to ascertain the cause of the inequalities which from time to time develop on the surface of rails. The results, though not conclusive, are stimulating. They show that the structure of the metal is an important factor in the wear and tear of rails, the difference in structure being probably due to the varying conditions of temperature and the different speeds at which the rails are rolled. The hard knobs which develop in the course of usage on all lines may be produced by mechanical action due to vibration when the wheels are passing over the rails.

THE first report of the Royal Commission on Mines has been issued (Cd. 3548, price 1*s*. 3*d*.). The Royal Commission, of which Lord Monkswell is chairman, was appointed on June 6, 1906, to consider questions concerning the health and safety of miners. The present report, which covers fifty-two pages, is devoted to the use of breathing appliances. The Commissioners do not suggest that the use of such appliances, the compulsory provision of which would not be justified at present, is likely to lead to any considerable decrease in the number of lives lost by explosions. Apart from actual rescue work, they may, however, be of great service in making it possible to deal with underground fires safely and effectively. The use of breathing appliances is not unattended by risks, but such risks can be reduced to a minimum by a proper system of training, which could be provided by the establishment of central rescue stations. Appended to the report are reports on breathing apparatus, by Dr. Boycott; on colliery fires, by a committee of the South Yorkshire Coalowners' Association; on rescue apparatus, by a committee of the Fife and Clackmannan Coalowners' Association; and on breathing apparatus, by a French commission. For educational purposes the value of the report is enhanced by the accompanying detailed drawings of the pneumatogen, the Draeger, the Shamrock, the improved Fleuss, the Weg, and the Aërolith apparatus.

PROF. HANN presented a treatise on the daily range of temperature in the tropical regions of Asia and Australia to the Vienna Academy on April 25, being the conclusion of a laborious discussion of the daily range of temperature in the tropics. The principal object of the treatise in question was to obtain corrections for reducing to the true daily mean the means obtained from combinations of observations at various hours. The author finds that the best mean is obtained from the readings at $(7+2+9+9):4$ both for coast and inland stations, and that the mean obtained from the readings of the maximum and minimum thermometers, which is most usually adopted, is, except for higher latitudes, the worst that can be employed; a mean obtained from even two fixed hours daily would be more satisfactory than the mean of the daily extremes.

The mean and extreme meteorological values for twenty-five stations in the British Empire during the year 1905 are given in *Symons's Meteorological Magazine* for May. So far as these stations are concerned, the following high shade temperatures were recorded:—Calcutta, 106°·1 (June); Madras, 107°·9 (May); Melbourne and Coolgardie (West Australia), 108°·5 (January); Adelaide, 109°·7 (January). The lowest readings were:—Fredericton (New Brunswick), −33°·5, Winnipeg, −39°·1, Dawson, −50°·5 (all in January); the latter station had the lowest mean temperature (25°·2). Coolgardie had the highest temperature in the sun's rays, 178°·8, the lowest mean humidity, 52 per cent., and least rainfall, 7·86 inches. The greatest rainfall, 77·89 inches, was at Grenada, and the dampest station was London, 83 per cent. Similar valuable tables have been published monthly for more than twenty-five years, but it must be clearly understood that these few widely scattered stations are quite insufficient to give a complete conspectus of the climate of the vast area included in the British Empire.

The new method of lighting which has recently been installed in the courtyard of the Savoy Hotel is creating much interest, and is, we believe, the first installation of this particular system in this country. The system is the result of years of experimenting, and the results are now given by Mr. D. McFarlane Moore in his paper recently read before the American Institution of Electrical Engineers. The chief feature of the system is the automatic valve, which admits the exact quantity of air or gas required to prevent the violent spasmodic flickering due to the higher degree of vacuum in the tube causing a higher resistance, and which up to the present has prevented a perfect vacuum-tube lighting being placed on the market. The important points about the valve are its simplicity and its automatic action. The valve admits the air required about once a minute, and by changing the nature of the gas admitted the colour of the light can be arranged as required. The main objection to the system appears to be that a high pressure is required; consequently each tube must at the ends be led into a transformer. We should also like to know more about the initial cost of the installation, the length of life of the tube, efficiency, &c., than we are told by Mr. Moore in his paper. If the matters mentioned above are satisfactory in comparison with the present costs and efficiency of modern forms of lighting, the new system should prove of value for large shops, studios, and art galleries, where it is essential to have the lighting as near as possible to daylight. Further developments will be watched with interest, but fuller figures relating to tests will be required before the system can be considered seriously.

From Messrs. Hilger, Ltd., we have received a copy of their newly published "List A," in which many well-designed spectroscopes and pieces of spectroscopic apparatus are described and illustrated. The Hilger wave-length spectrometer may now be had fitted with a camera of 21 inches focal length at an additional charge of 6*l*. 10*s*. Spectroscopists will be interested, too, in the new series of six spectrographs—three of which are fitted with ultra-violet glass and three with quartz prisms and lenses—especially designed to give, with a short exposure, the whole length of spectrum, in good definition throughout, on a flat plate, and to be in permanent adjustment. The excellent results obtainable with these spectroscopes are illustrated by an enlarged copy of the spectrum of copper extending from λ 5782 to λ 2160, which we have examined. This was taken with a quartz spectrograph having two 30° prisms and lenses of 8″ focus, the distance from λ 6000 to λ 2160 on the original negative being 60 mm. ($2\frac{3}{8}$″), price 21*l*. 10*s*. The Michelson interferometer, reading to one ten-thousandth of a millimetre, is a fine instrument at the moderate price of 35*l*., as is also the Jamin refractometer at 17*l*. 10*s*. Messrs. Hilger also make a speciality of the strips of plane parallel glass for the Lummer and Gehrcke parallel-plate spectroscope. The prices range from 10*l*. for a plate 100×30×10 mm. to 39*l*. for one measuring 300×40×10 mm.

"What is Genius?" ("Che cosa è il genio?") is the title of a small book by Adolfo Padovan (Milan: U. Hoepli, 1907, second edition). The author discusses examples of genius among artists, poets, philosophers, and others; he distinguishes between genius and talent, and strongly advocates the view that genius is to be regarded as a healthy or physiological rather than a morbid or pathological quality. In this way he is led to the definition on the cover of the book: "a physiological state of exquisite and exceptional nervous sensibility."

Dr. Paul and Tatina Ehrenfest revive interest in the statistical problems of the kinetic theory in their paper on two of the objections to Boltzmann's minimum theorem in the *Physikalische Zeitschrift* (May). They deal, first, with Loschmidt's objection, based on the consideration of reversal of the motion, according to which for every possible direct motion there exists a possible reversed motion, and, secondly, with Zermelo's objection, based on the quasi-periodicity of the motion of a system of gas-molecules. The authors claim to have overcome these objections by showing that a state in which Boltzmann's function increases is statistically enormously improbable. It would, however, seem to follow, according to this view, that the existence of irreversible molecular phenomena must be regarded as due to the assumed preexistence of enormously improbable initial conditions.

Part vi. of "G. A. Fothergill's Sketch Book," which is published by Mr. James Dodds, of Darlington, continues the "History of Cleasby in Yorkshire, with Biography and Portraits of John Robinson, D.D., *The Last* Statesman-Bishop (1650 to 1723); and numerous Sketches of Blackwell Grange and Thornton Hall, Darlington, &c." Some good sketches of sundials are included in the part before us.

A lecture appreciative of the work and influence of the late Mr. Herbert Spencer, delivered by Prof. August Stadler in the Zürich Town Hall on December 6, 1906, has been published in pamphlet form by Mr. A. Muller, Zürich.

Divisional-volume ii. of "Practical Coal Mining," the first divisional-volume of which was reviewed in Nature of May 23 (p. 77), has just been published by the Gresham Publishing Co. The volume contains a continuation of section iv., on shaft-sinking, by Prof. Henry Louis; section v., on breaking ground, by Mr. H. F. Bulman; and section vi., on methods of working and timbering, by Prof. E. H. Robertson. We propose to defer any further notice of the work until the whole of the volumes have been issued.

We have received from the proprietors of the periodical called the *Young Citizen* (12 Salisbury Square, E.C.) a case containing twenty-four paper butterflies, pinned and outspread to resemble real specimens. They are, we believe, copied from a well-known work on the subject, and at a considerable distance might pass muster, but we regret that we are unable to speak favourably of the scheme. The palpi are clumsily represented, but the specimens show no trace of legs, proboscis, or even antennæ, the last deficiency being the most serious and inexcusable of all, especially as they could easily have been imitated in fine wire. We cannot suppose that so incomplete a design can have been executed by, or even submitted to, anyone with the slightest knowledge of entomology. The colouring is fairly good, though in the case of some of the white butterflies it has too greenish a shade.

The annual report of the Board of Scientific Advice for India for the year 1905–6 has reached us. It will be remembered that the Board is a central authority for the coordination of official scientific inquiry, and the object it has in view is the distribution of the work of research to the best advantage, the prevention of dissipation of energy by the useless duplication of inquiries, and its misdirection by a lack of inter-departmental cooperation. The Board by its advice also aids the Government of India in prosecuting practical research into questions of economic or applied science. During 1906 the Board appears to have held two meetings only, one at Simla in May and the other in December at Calcutta. The greater part of the report, which runs to nearly 200 pages, is made up of contributions by distinguished specialists on scientific work in various directions accomplished in India during the year under review.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in July:—

July 3. 8h. Uranus in opposition to the Sun.
6. 3h. Mars in opposition to the Sun.
7. 7h. Vesta in conjunction with Moon (Vesta 0° 15′ S.).
8. 12h. 29m. Minimum of Algol (β Persei).
10. 3h. 7m. Sun eclipsed, invisible at Greenwich.
11. 9h. 18m. Minimum of Algol (β Persei).
13. Saturn's Ring. Major axis $=42''\cdot11$, Minor $=1''\cdot72$.
15. 19h. Jupiter in conjunction with the Sun.
20. 11h. 58m. to 12h. 57m. Moon occults θ Libræ (mag. 4·3).
24. Partial eclipse of the Moon.
 13h. 59m. First contact with the penumbra.
 16h. 22m. Middle of the eclipse.
 18h. 46m. Last contact with the penumbra.
 Magnitude of the eclipse = 0·620.
 At 16h. 10m. the Moon sets at Greenwich.
27–31. Meteors numerous from Aquarius and Perseus.
28. 11h. 10m. to 12h. 14m. Moon occults 30 Piscium (mag. 4.7).
,, 13h. 4m. to 14h. 6m. Moon occults 33 Piscium (mag. 4·6).
29. 11h. 23m. to 11h. 55m. Moon occults 20 Ceti (mag. 4·9).
31. 10h. 40m. to 11h. 18m. Moon occults ξ^2 Ceti (mag. 4·3).

Comet 1907*d* (Daniel).—The following set of elements and ephemeris for comet 1907*d* have been computed by Dr. E. Strömgren, and appear in Circular No. 98 of the Kiel Centralstelle:—

Elements.

T = 1907 Sept. 2 0105 (Berlin M.T.)

$$\left.\begin{aligned}\omega &= 241^\circ\ 59'\cdot04\\ \Omega &= 143\ \ 41\cdot99\\ i &= \ \ 6\ \ 14\cdot81\end{aligned}\right\}1907\cdot0$$

$$\log q = 0\cdot11436$$

Ephemeris 12h. M.T. Berlin.

1907		α		δ		Brightness
		° ′		° ′		
June 24	...	0 31·3	...	+2 25·9	...	1·37
,, 28	...	0 44·1	...	+3 27·2	...	1·54
July 2	...	0 57·4	...	+4 29·0	...	1·73

The brightness at the time of discovery, given as equal to mag. 11·0, is taken as unity. As will be seen from the above, the comet is brightening considerably, and is travelling through Pisces, towards Aries, just south of the ecliptic. At present it rises above the eastern horizon about midnight.

Observations by Prof. Hartwig on June 15 gave the magnitude as 9·5, the diameter as 2′, and the magnitude of the nucleus as 10·0.

A Large Sun-spot.—One of the most marked features of the present year has been the large number of sun-spot groups of sufficient magnitude to be seen with the naked eye; according to the Greenwich report, fourteen such groups had been seen on the solar disc up to May 10. The accompanying photograph, taken at 2h. 30m. on June 21, shows the group of spots which appeared on

the eastern limb on Thursday, June 13, and for several days was quite an easy naked-eye object. The latitude of the group was about 17° S., and, as may be seen from the reproduction, its extreme length was about one-tenth of the solar diameter, or about 85,000 miles. The shape of the principal umbra changed considerably during the spot's progress across the disc.

The Variability of Asteroids.—A striking photograph, illustrating apparently rapid changes of brightness in an asteroid, accompanies a paper on the subject published by Mr. Joel Metcalf, of Taunton (Mass.), in No. 4, vol. xxv. (p. 264, May), of the *Astrophysical Journal.* The original negative was produced by making two exposures of equal duration on the same plate, the camera being guided so that the asteroid images are round and the images of the surrounding stars are shown as trails. The similarity of the two star trails for each star is evidence that the rating of the clock and the atmospheric conditions were constant throughout, and yet there is a marked difference in the size and density of the images of the asteroid—in this case 1906 *WE.* This plate was taken on November 6, 1906, and the two exposures had thirty-five minutes each, with an interval of a minute between them; therefore the asteroid appears to have changed considerably in magnitude during an interval of one hour eleven minutes.

Comet 1907*c* (Giacobini).—A set of elements and a daily ephemeris extending to July 11 are given for comet 1907*c* by Dr. Strömgren in No. 4183 (p. 128, June 14) of the *Astronomische Nachrichten.* Prof. Millosevich, at Rome, found this a difficult object to observe with the 38 cm. (15 inches) telescope, and, according to the ephemeris, it is decreasing in brightness.

THE ENGINEERING CONFERENCE.

THE fourth engineering conference of the Institution of Civil Engineers commenced on the morning of Wednesday, June 19, when an opening address was delivered by Sir Alexander B. W. Kennedy, F.R.S., the president of the institution. In the course of his remarks, the president referred to the essential catholicity of the aims of the institution. All and every department of industrial activity which can possibly be covered by the name engineering fell within the ken and interest of the institution. In spite of the very extended ground covered by the subjects of the sections, members of the Institution of Civil Engineers alone had been invited to take part. It was not necessary to go beyond the borders of the institution to find men, not only interested, but distinguished, in every department of engineering. The president emphasised the unity rather than the diversity of their work, and expressed the hope that members would not confine their interest and presence to those sections only with the business of which their every-day work was concerned. In conclusion, the president explained that the papers to be read were notes, intended merely to open and stimulate discussion.

The members then separated into the various sections. The discussions occupied the morning of Wednesday, Thursday, and Friday. The limitations of space permit of brief notices only of the more important matters dealt with.

Section I., Railways. Chairman, Mr. W. R. Galbraith. A discussion on the chemical composition of steel rails was opened by Mr. C. P. Sandberg, who described the effects of phosphorus, sulphur, manganese, silicon, and carbon. Mr. W. Willox stated that certain rails on the Metropolitan Railway had worn out in five months only; the Sandberg rail, he thought, would reduce the trouble considerably. In this type of rail the silicon is added in the form of silico-spiegel or ferro-silicon, which gives better results than silicon left in the steel from pig-iron during the conversion.

The subject of reinforced concrete for railway structures was introduced by Dr. C. A. Harrison. Evidence was sought of the ability of this form of construction to resist the fatigue and stress of railway traffic, and also as to whether the metal reinforcement is not liable to corrosion. Mr. W. Bell gave information regarding a building in ferro-concrete erected under his supervision for the North-Eastern Railway. He considered this building to be satisfactory, and found that, in places where it had been necessary to cut the concrete, the metal bars were clean and bright.

The use of a bituminous preparation in preference to paint wherever possible was advocated by Mr. B. Blount as being the best means of preserving iron and steel work. Mr. H. R. A. Mallock, F.R.S., contributed a note on the action between the wheel and the rail, in which he calculated from theoretical grounds that the wear on rails having a two-minute service for twelve hours a day would amount to 2·6 inches per year, a result which might be altogether avoided by somewhat increasing the tread.

Mr. W. Dawson described a system of audible signalling which has been experimented on by the Great Western Railway. The danger signal is given to the driver by means of a small steam whistle fixed to the cab of the engine, actuated by a fixed bar bolted to the sleepers. The fixed bar is electrified when it is desired to give the "all right" signal, and then has the effect of ringing a bell on the engine. Colonel Yorke expressed the importance attached by the Board of Trade to such apparatus, but stated that his department would insist on absolute trustworthiness before sanctioning its use.

In speaking on light-railway policy, Sir A. B. W. Kennedy thought that, in view of the development of motor traction, light railways had nearly reached their termination in this country, excepting in special cases.

Section II., Harbours, Docks, and Canals. Chairman, Sir William Matthews, K.C.M.G.

Lord Pirrie contributed a paper on harbour and dock requirements as affected by the development of shipping. In his opinion, finality in the size of ships had not yet been reached. The desire for greater economy and also passengers' wishes for greater comfort and luxury would lead to further developments. Owing, however, to existing conditions as regards dock accommodation and depth of channels, shipbuilders had been forced into increasing the length rather than the breadth or draught.

Ferro-concrete and reinforced concrete structures were also discussed in this section. Mr. C. S. Meik gave evidence of the strength and durability of the ferro-concrete pier at Purfleet on the Thames. Questions of dock equipment, dredging, and electric and hydraulic power for working dock machinery were dealt with. Mr. W. W. Squire considered that the tendency towards the extended use of electric appliances was on the increase.

Section III., Machinery. Chairman, Prof. W. C. Unwin, F.R.S.

The business of this section opened with a valuable and interesting discussion on the relative merits of turbines as applied to marine propulsion and of reciprocating engines. The principal point raised was the relative coal and steam consumptions. The Hon. C. A. Parsons stated that in war vessels the consumption has now been brought to substantially the same figure as with reciprocating engines, and that in pleasure steamers the turbine now showed an efficiency 5 per cent. to 15 per cent. superior to similar vessels having triple-expansion reciprocating engines. Sir Wm. White and Sir John Durston contributed to the discussion. Mr. Gerald Stoney referred to the great efficiency of the low-pressure steam turbine, and quoted instances of the successful application on land of such turbines working with the exhaust steam discharged from reciprocating engines, which steam would otherwise be wasted owing to the inability of reciprocating engines to deal economically with steam at very low pressures. Mr. Parsons was of the opinion that future development for slow-speed vessels such as cargo steamers would be in the direction of a combination of reciprocating engines for the high-pressure part of the expansion and of turbines to deal with the low-pressure part. He estimated that such an arrangement would show an improvement in coal consumption of about 12 per cent. over quadruple-expansion reciprocating engines, and from 15 per cent. to 20 per cent. over the best triple-expansion engines.

Other subjects discussed in this section were precision grinding, machine-tool design as affected by the use of high-speed cutting tools, the use of pneumatic tools, reciprocating air-compressors, and turbo-compressors for high pressures. The last subject was introduced by Prof. A. Rateau, of Paris, who described his recent work in the development of turbo-compressors. He specially directed attention to one of his machines (which consists essentially of a reversed steam turbine) placed in the mines at Bethune, which compresses the air to 6 and even 7 atmospheres, and has the further interesting feature of being driven by a steam turbine utilising the exhaust steam from one of the winding engines. The efficiency of turbo-compressors is about of the same order as piston compressors. Turbo-compressors have the advantages of simplicity of parts and the capability of being directly connected to high-speed motors.

Section IV., Mining and Metallurgy. Chairman, Mr. John Strain.

This section opened with a discussion on problems of the Witwatersrand goldfields, introduced by Mr. G. A. Denny. Questions of labour difficulties and machinery were dealt with. Shaft-sinking and shafts for deep winding were also discussed. Recent applications of the Poetsch freezing method of shaft sinking in the Durham coalfield were described by Mr. H. Louis. Arrangements of colliery surface works were described by Mr. E. M. Hann. Mr. J. E. Stead, F.R.S., introduced the subject of segregation in steel, and illustrated his remarks by reference to etched specimens. The causes of segregation and its effect on the mechanical properties were fully dealt with. Mr. B. Blount contributed a paper on electro-metallurgy, dealing with the present state of the industry and the possibilities of its application to the manufacture of steel. The subject of the education of students of mining and metallurgy was introduced by Mr. W. Rowley, who described the methods adopted in the West Riding of Yorkshire. Mr. Rowley severely criticised the present Government examination for certificates of competency, an examination which, he said, could be passed by men who have not that acquaintance with scientific principles which is desirable. The papers have often been so stereotyped that correspondence and other methods of cramming only are needed to enable a man to pass. The composition of the board of examiners had often been characterised by conspicuous absence of men qualified by scientific training and knowledge to examine candidates, however eminent might be their position in particular branches of the mining profession. Mr. Rowley emphasised his opinion that a solid foundation of a broad and liberal education was essential to the student prior to his course in applied science.

Section V., Shipbuilding. Chairman, Dr. F. Elgar, F.R.S.

A joint discussion with Section II. on harbour and dock requirements opened the work of this section. A very important discussion on the uses of high-tensile steel was opened by three papers contributed by Mr. A. E. Seaton, Mr. A. F. Yarrow, and Mr. E. W. De Rusett. High-tensile steel for structural work may be described as steel having an ultimate tensile strength of about 40 tons per square inch. In the Forth Bridge such steel was used in compression only; Mr. Seaton was of the opinion that to-day there need be no hesitation in using it under tension. By use of this material it is possible to reduce largely the weight of a given structure. Recently the huge Cunard ships have been constructed so as to withstand the heavy expected stresses by the free use of the high-tensile steel of Spencer and Colville. Mr. Yarrow quoted the present Admiralty practice of steel of 37 tons to 43 tons per square inch with specified minimum elongations in 8 inches. In his own practice a considerable reduction of dead weight had been effected by the use of high-tensile steel. Mr. E. W. De Rusett gave information as to the use of high-tensile steel in the construction of the *Mauretania*. By instruction of the authorities of Lloyd's Registry, rivets of mild ingot steel were adopted. The rivet holes in plates less than ½ inch thick were punched ⅛ inch under size and rimered out. This method was found not to interfere with the strength of the joints. Rivet holes in plates more than ½ inch thick were drilled. Sir Wm. White recommended for the proper use of high-tensile steel (*a*) thorough testing in the makers' works; (*b*) proper treatment of the material (as regards heating, &c.) in the shipbuilders' yards; (*c*) structural arrangements suitable for the new material. He was of the opinion that both mild steel and high-tensile steel can be successfully used in the same structure. Rivets of quality agreeing with the material of the plates should be employed, and such was the practice of the Admiralty. Sir P. Watts said that high-tensile steel rivets were at present used successfully in the Service. Mr. Colville gave the results of the experience of the Steel Co. of Scotland on the manufacture of high-tensile steel. Mr. Ritchie, of Parkhead Forge, quoted the case of a steam boiler of high-tensile steel working at 500 lb. per square inch pressure. Mr. Thearle, of Lloyd's, spoke of the necessity for avoiding improper heat treatment of high-tensile steel rivets. Other subjects dealt with in this section were structural details of cargo steamers, arrangements for working cargo, high-speed vessels, modern applications of superheating, and the welding of structural materials in place. In the last, methods of electric welding, welding by the oxy-hydrogen and oxyacetylene flames, and welding by the use of thermit were discussed.

Section VI., Waterworks, Sewerage, and Gasworks. Chairman, Sir George Thomas Livesey.

The first paper read in this section was on the comparative cost of pumping by steam, internal combustion engines, and electricity, based on actual working. The authors, Messrs. Charles Hawksley and Henry Davey, made out a strong case in favour of direct pumping by steam engines. Speakers in the discussion disagreed with certain figures given in the paper. Thus the authors give 1 lb. of oil per B.H.P. generally for oil engines, but the Diesel oil engine has a guaranteed consumption of 0·4 lb. of oil per B.H.P.; 1·75 lb. of coal per B.H.P. for gas engines is stated in the paper to be the engine-maker's estimate, but 1·25 lb. would be nearer. Electric current could also be obtained at a cheaper rate than that given, viz. ½*d*. per unit.

Papers on water softening and water hardening were contributed by Messrs. W. Matthews and J. Watson respectively. Softening is of value in many cases where the water is too hard to be available for supply, and the process also gives a means of defence against bacteria. The working in practice of various systems of water softening was discussed. The practice of hardening water for domestic purposes is intended to counteract acidity and neutralise peaty water possessed of lead-dissolving properties.

Applications of towns' gas as a heating agent were described in a paper by Mr. W. H. Y. Webber. The author referred to the practice now generally adopted by gas engineers of speaking of their product in terms of its calorific value rather than of its illuminating power. The domestic uses of gas for heating purposes were dealt with, and the author expressed his opinion that producer gas did not make headway against town gas at 2*s*. per 1000 cubic feet.

The distribution of gas at increased pressure was introduced by Mr. C. C. Carpenter, who described the present practice of the South Metropolitan Gas Company in using non-positive blowers giving an initial pressure of about 20 inches of water. Gas engines are preferred for driving the blowers as being more convenient. This company has 1200 miles of pipes, and finds that the unaccounted gas amounts to 4½ per cent. only.

Mr. J. D. Watson contributed a paper on sewage disposal by biological processes, in which he gave the results of the methods adopted at Birmingham, where sewage purification is effected by mechanical precipitation and septic treatment.

The relative merits of chemically treated, settled, and septic sewage in preparing the liquid for oxidising beds formed the subject of a paper by Mr. G. A. Hart. The author has compiled facts obtained from observations made on the sewage of Leeds during the last nine years. The most effective chemical precipitant was found to be a combination of 6 to 8 grains of lime and 2 grains of aluminium sulphate per gallon of sewage. Settlement is employed sufficient to reduce the suspended solids in crude sewage to an average of about 8 grains per gallon. Dealing with septic fermentation, the author stated that at a twenty-four hours' rate of flow about 30 per cent. of the suspended solids were digested in the tanks, 31 per cent. passed out with the effluent, and the balance of 39 per cent. remained as deposit.

Section VII., Applications of Electricity. Chairman, Colonel R. E. B. Crompton, C.B.

The first paper taken was on electrical transmission gears on motor vehicles, by Mr. A. A. C. Swinton. The author directed attention to the crude methods of gear changing used in petrol-driven motor vehicles, and gave short descriptions of several arrangements of electrical transmission which have been adopted. Mr. Hart gave the results of his experiments using continuous current machinery, which he had discarded in favour of polyphase alternating current. He had now an omnibus running in which the consumption of petrol amounted to one gallon per 6½ miles, the electric machinery being used for starting only, giving a smooth and rapid acceleration. Mr. W. H. Stevens advocated the use of continuous current. Mr. Swinton referred to the question of the weight of the petrol-electric equipment, which is greater than that of purely petrol machinery.

The subject of electric working of railway points and signals was opened by Mr. Ferreira, who enumerated the principal conditions considered essential in modern signalling, and discussed the various electric methods adopted for complying with these conditions.

Papers on upkeep charges on large electric generating sets and on modern applications of electricity to mines were contributed by Messrs. Burstall, Highfield and Sparks. In the last paper the application of the high-lift centrifugal pump in combination with the electric motor was mentioned as showing a great advance on previous methods of pumping.

On the evening before the formal opening of the conference, the James Forrest lecture, on "Unsolved Problems in the Design and Propulsion of Ships," was delivered by Dr. Francis Elgar, F.R.S.

During the conference the members had the privilege of visiting many works and generating stations, and these opportunities were taken advantage of to a large extent. The institution conversazione was held on Thursday evening in the Albert Hall, when a large and representative gathering met for social intercourse.

THE ROYAL SOCIETY CONVERSAZIONE.

MOST of the exhibits of scientific interest at the Royal Society on June 19, on the occasion of the soiree to which ladies as well as gentlemen are invited, were shown at the conversazione on May 8, and have been described already in NATURE (May 16, p. 57). It will be sufficient, therefore, to refer briefly to exhibits not mentioned in the previous article.

Lantern and other demonstrations were given during the evening by Prof. H. A. Miers, Prof. Flinders Petrie, and Mr. Louis Brennan. Prof. Miers showed experiments illustrating the growth of crystals in drops of solution, and indicating that the latter are of two sorts. If a solution be sufficiently strong, crystallisation may be started spontaneously by mere shaking or friction. In such a solution the crystals are apt to grow rapidly in the form of delicate needles and fronds. If the solution be supersaturated, but not strong enough to give birth to crystals in this way, they can only grow if introduced from without (by "inoculation" of the drop), and are apt to grow in symmetrical forms. A solution, as it cools, passes quite suddenly from the one state to the other. Prof. Petrie lectured on houses in ancient Egypt, and Mr. Brennan again showed and described his working model of the Brennan mono-railway.

The subjoined descriptions of the exhibits have been abridged from the official catalogue:—

Mr. A. A. Campbell Swinton: Vacuum tube phenomena. (1) Exhibition of the mechanical effects of kanal rays in causing the rotation of mill-wheels in Crookes tubes. These rays, which are positive, travel in the opposite direction to the negative rays that proceed from the kathode. They can be detected both when they are approaching the kathode, and also, if the latter is perforated, after they have passed through the apertures. (2) Photomicrographs of the bubbles that are developed by sudden heating of portions of the glass walls of Crookes tubes, owing to the occlusion by the glass of the residual gas during prolonged use. (3) Exhibition in the microscope of a special case of the above, in which the sudden heating was occasioned by an electric spark, which has thus impressed its own image on to the glass. The image is entirely made up of minute bubbles, and from its form it is clear that the spark was a positive one.—*Mr. C. E. S. Phillips:* (1) A fibre electroscope. In this electroscope the gold leaf is replaced by a fibre of electrically conductive glass which is delicately hinged so as to move very readily under the influence of a difference of potential. (2) An electroscope charger. The ease with which celluloid may be electrified by friction, together with its poor insulating property, are made use of in this apparatus. A celluloid rod is rubbed at one end by a flannel-lined split brass tube. The charge so produced slowly spreads to the opposite extremity of the rod and is there utilised. Either a positive or negative charge may be obtained with the same instrument. (3) Electrically conductive glass. The composition of this glass is as follows:—sodium silicate, thirty-two parts; borax, eight parts; Powell's flint glass, 1·25 parts. The electrical conductivity is about 500 times as great as that of any other glass, and this material is suitable for the windows of electrostatic instruments as well as for supplying the fibres used in the fibre electroscope.—*Mr. J. Mackenzie Davidson:* Stereoscopic X-ray photographs in a revolving lenticular stereoscope. A single X-ray photograph is a central projection shadow of the object placed between the Crookes tube and the photographic plate, and cannot therefore correctly indicate the real relative position of the parts—but *stereoscopic* X-ray photographs at once give a combined image which shows correctly their relative size and position. This could be observed in the series of transparencies exhibited.—*Mr. A. Kershaw:* A new visual method of measuring the speeds of photographic shutters. This consists principally of a variable-speed revolving disc with radial slits, in conjunction with a stationary illuminated slit.—*Mr. Edward Whymper:* Photographs taken in the Rocky Mountains of Canada and in the Alps.

Mr. William Burton: Pilkington's Lancastrian lustre pottery. The examples illustrate the perfecting of the old lustre process of decoration. By this method metallic vapours of silver and of copper can be driven into pottery glazes at a very low red heat under the influence of reducing gases. The surface of the metallic film so obtained glows with brilliant iridescent colours. The process has been reduced to such precision that the kilns are hermetically sealed during the firing, and no "trials" of any description are drawn from start to finish of the process. The temperature is recorded by the use of two thermocouples, placed at the bottom and top of the kiln respectively. The reducing gases are of standard composition, so that the process is so far as possible automatic.—*Hon. C. A. Parsons, F.R.S.:* Photographs of diamonds obtained from pure iron heated in a carbon crucible in an electric furnace and rapidly cooled. Scale, 150 diameters.—*Dr. Herbert Smith:* Precious stones, cut and uncut. The exhibit includes most of the mineral species that are available for jewellery purposes. The following are the more noteworthy of the specimens:—a star-twin of diamond; crystals and faceted specimens of olivine (peridot) from the Red Sea; sapphires from Montana and Ceylon; natural and "reconstructed" rubies; various opals, including opalised shells; diamonds, chrysoberyls, and topazes from Rhodesia; garnets from German East Africa; and specimens of the rare species phenakite, axinite, and diopside.—*Dr. Tempest Anderson:* Photographs illustrative of the volcanoes of Central America, and of a revisit to the Soufrière of St. Vincent. The volcanoes of the Soufrière of St. Vincent and Montagne Pelée in Martinique, both to the east of the Caribbean Sea, erupted in 1902. The volcano of Santa Maria in Guatemala, to the west of the same sea, erupted in the same year, and when it was examined this spring the eruption proves to have been of the same character.

The Royal Society: The Linnæus bicentenary—original certificate of candidature of Linnæus, dated 1753, for election into the Royal Society.—*Dr. W. A. Cunnington and Mr. C. L. Boulenger:* Examples of the fauna of the Fayûm Lake, Birket-Qurun, investigated at the request of the Egyptian Survey Department. (1) Series of the fishes, including examples of the three different kinds of Bulti (Tilapia). The females take charge of the eggs and young, which they seclude in the mouth and gill-chambers. (2) Series of the invertebrates of the lake, including examples of a new lacustrine medusa (*Moerisia lyonsi*).—*Prof. Charles Stewart, F.R.S.:* (1) Specimens illustrating alternation of generation. (2) Various invertebrates and birds showing colours due to structure; mostly thin films, and not pigment; consequently the colour is lost on crushing.—*Prof. S. J. Hickson, F.R.S.:* A collection of species of the genus Corallium, and a specimen of *Corallium maderense*, polished and mounted in silver.—*Dr. Ernst Hartert:* Birds represented in the British Isles by peculiar forms, and their Continental allies. So late as 1892 Wallace accepted only three birds as peculiar to the British Isles ("Island Life," p. 340), and even more recent works have not mentioned more than three or four. Careful investigations, however, have shown that about twenty British birds show constant and often easily recognised differences from their Continental allies. Eighteen of these are exhibited, with their allies, in order to show their differences.

Prof. Flinders Petrie, F.R.S.: Pottery soul-houses, 3000 B.C. These models, made by the Egyptians, were found at the cemetery of Rifeh in Upper Egypt, where they had been placed upon the graves. They were developed from the trays of offerings for the dead, to which a shelter was added, and further enlarged with the addition of furniture so as completely to resemble an actual house, in which the soul was supposed to dwell. Their period is from the ninth to the twelfth dynasty. Found by the British School of Archæology in Egypt, 1907.

THE CRUISE OF THE "NEPTUNE."[1]

THE cruise of the *Neptune* is the official narrative of the voyage of the Dominion Government Expedition to northern parts of Hudson Bay and the north-eastern Arctic islands in 1903–4 in charge of Mr. A. P. Low.

The Dominion Government in the spring of 1903 decided to send a cruiser to patrol the waters of Hudson Bay and those adjacent to the eastern Arctic islands, and to aid in establishing on the adjoining shores permanent stations for the collection of customs, the administration of justice, and the enforcement of the law as in other parts of Canada.

Major J. D. Moodie, of the North-West Mounted Police, was appointed acting commissioner of the unorganised north-eastern territories. The expedition carried a scientific staff.

Dr. L. E. Borden, besides being the medical officer, collected data relating to ethnology, botany, and zoology; Mr. Andrew Halkett, naturalist of the Department of Marine and Fisheries; Mr. C. F. King, who was attached from the staff of the Geological Survey, took charge of the topographical and meteorological work, assisted by Mr. C. F. Caldwell (photographer) and Mr. Ross (purser).

Mr. Low undertook the geological work. The latter writes in the preface to the book:—"The greater part of the credit for the complete and successful accomplishment of all the instructions for the voyage is due to Captain S. W. Bartlett, the officers and the crew of the *Neptune*." The latter was the largest and most powerful ship of the Newfoundland sealing fleet, 465 tons net register and engines 110 nominal horse-power.

Besides the narrative of the voyage during the seasons 1903–4, there is a short historical account of earlier explorations and discoveries in north-eastern Arctic America, a geographical sketch, and chapters dealing with the Eskimo inhabitants and the geological formation of these north-eastern territories, and a description of the important whaling and sealing industries, and opinions as to the possible navigation of Hudson Strait and Hudson Bay.

In the form of appendices are the results of the meteorological observations taken on the voyage, notes on the thickness and growth of ice, and lists of the birds, plants, and fossils collected in these northern regions. The full results, especially with regard to the determination of marine invertebrates, are promised in a future publication.

The *Neptune* wintered in Fullerton Harbour, at the entrance to Roes Welcome (latitude 64° N.). During the winter various tribes of Eskimos congregated about the ship and kept it supplied in fresh caribou meat. The two long chapters on the Eskimos are fascinating reading, and contain a mass of information for the anthropologist. In the form of an appendix there are notes on the physical condition of the Eskimos by the surgeon to the *Neptune*, Dr. L. E. Borden.

The excessive cold of the early spring practically rendered impossible any surveying or other scientific work until the month of April. The minimum temperature observed was −53° F., early in March. The really cold months were January, February, and March, the mean temperatures being respectively −23°·0 F., −27°·0 F., −20°·6 F. The thickness of the ice around the ship continued to increase until April 25, when it attained a maximum of 74 inches.

The *Neptune* broke her way out of Fullerton Harbour on July 18, after having been fast frozen for nine months, and proceeded on her summer cruise to the Arctic islands. Chapter x. contains a great deal of valuable information concerning whales and whaling. Although the capture of a right whale repays the expenditure incurred in outfitting a steam whaling ship, and if more than one is killed on the voyage it means large dividends to the owners, the chase is becoming more and more unprofitable owing to the few whales remaining and to the frequent "empty" voyages made of late years. The future of the whaling industry certainly appears to be very gloomy.

The chapters on geology are perhaps the most valuable portion of the book. Although they contain little that is absolutely new, the results of former expeditions and work of former geologists have been brought together in a concise and interesting manner.

The work is admirably written, and contains more real information than such narratives usually do. The illustrations are fairly good, and the geological map compiled by the Geological Survey of Canada to illustrate the cruise of the *Neptune* (scale, 50 statute miles to 1 inch) is probably the best of its kind published.

L. C. B.

[1] Report on the Dominion Government Expedition to Hudson Bay and the Arctic Islands on Board the D.G.S. *Neptune*, 1903–1904. By A. P. Low (officer in charge). Pp. xvii+355 and map. (Ottawa: The Government Printing Bureau, 1906.)

NATURAL HISTORY IN NORTHUMBRIA.[1]

THE third and concluding part of the first volume of the new series of the Transactions of the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne has just been issued, and it proves that the district is able to maintain its reputation as a home of eager and distinguished naturalists. In addition to the usual reports on the field meetings and the short notes on local natural history, which do not present any noteworthy features, there are six papers of more general interest which may be regarded as serious contributions to knowledge.

Among these we notice a paper by Miss M. Lebour on the larval trematodes of the Northumberland coast. Having chosen for her investigations a field of work that has unfortunately been very inadequately explored, this author is able to contribute more that is really original than her companions. A list of thirteen common littoral mollusca is given in which larval trematodes were found, and of these *Paludestrina stagnalis* was proved to be the host of no less than six different species of trematodes. Although no single complete life-history was worked out, reasons are given for supposing that the first host of *Distomum* (*Echinostomum*) *leptosomum* is *Paludestrina stagnalis*, and that encystment may take place in the same species of mollusc or in *Scrobicularia tenuis*, the final host being the dunlin. The bucephalus larva of Gasterostomum, the well-known fluke of the angler fish, was found in the cockle, this being only the second time in which the larva has been recorded in British waters. The paper is well illustrated by five plates.

In an interesting paper by Dr. Brady several species of Crustacea new to the district are recorded from a pond at Amble that has been formed by the filling up of an old quarry from the adjacent sea. The occurrence in the pond of a new ostracod for which a new genus (Proteocypris) is instituted is of special interest, as, according to the author, it is the only instance of a typically fresh-water cyprid occurring in a truly marine habit. It is to be regretted that Dr. Brady makes no statement of his opinion as to the relations of this genus or of the family to which it belongs.

The longest paper in the part is one by Mr. A. R. Jackson on the spiders of the Tyne valley. This paper will doubtless be of considerable value to arachnologists, but apart from the description of five species new to Britain, of which three species were at the time of their discovery new to science, it does not present any features of general interest.

In some interesting notes on rare local beetles, Mr. Bagnall describes his experiences in proving that the female *Epuraea angustula* enters the bores of different species of Trypodendron in order, as he believes, to deposit her eggs on those of the borer, and suggests that the staphylinid *Acrulia inflata* is similarly parasitic on Trypodendron.

Geology is represented in the part by two papers—one, on the result of the borings in the valley of the Tyne Derwent, by the Rev. A. Watts, and the other by Dr. Woolacott, on the recent landslip at Claxheugh. The photographs that illustrate this last-named paper are of permanent interest and value.

In bringing the first volume of the new series to a conclusion, the society may be congratulated on the evidence it affords of the interest taken in natural history by its members and of the valuable work they are doing.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Among the additions made during the year 1906 to the collections under the charge of the museums and lecture-rooms syndicate, special mention has been made in the forty-first annual report of the syndicate of the gift to the school of botany, by Mr. Francis Darwin, of the scientific library of his father. Dr. E. C. Stirling has presented to the museum of zoology a cast of a skeleton of the gigantic extinct marsupial *Diprotodon australis*, and the Duke of Bedford two specimens of Przewalsky's horse from the collection at Woburn Abbey. The collection of antelopes has been largely increased, principally through the donations of Mr. C. B. C. Storey, Mr. A. L. Butler, Major W. B. Emery, and Captain E. Mackenzie Murray. The executors of the late Mr. J. S. Budgett have presented a number of specimens to the museum of zoology, and certain pieces of apparatus to the zoological laboratory. The Strickland curator directs attention to the completion of the late Prof. Newton's "Ootheca Wolleyana," and to the fact that the whole of Prof. Newton's magnificent collection of palæarctic eggs becomes thereby the property of the University. Numerous anthropological gifts to the museum of human anatomy are recorded in the reports of Dr. Barclay-Smith and Dr. Duckworth.

A SUMMER school for university extension students will be held at Oxford during August. The inaugural address will be delivered in the examination schools on Thursday, August 1, at 8.30 p.m., by the Earl of Halsbury, F.R.S. The meeting will be divided into two parts, the first of which will extend from August 1 to August 14, and the second from August 15 to August 26. The lectures in the science section will be arranged with the object of illustrating the part played by Oxford in the advancement of science, particularly in the seventeenth century. Among the lecturers will be Dr. T. B. Strong, Dr. W. Osler, F.R.S., Mr. J. Wells, Dr. Brereton Baker, F.R.S., Prof. F. Gotch, F.R.S., Prof. H. H. Turner, F.R.S., Prof. E. B. Poulton, F.R.S., and Mr. J. L. Myres. There will also be special classes in practical map-making, nature-study, and principles and practice of education.

PROF. A. S. HEMMY, Government College, Lahore, writes to correct a report as to the state of science in the Punjab which appeared in the *Civil and Military Gazette*, and was summarised in NATURE of May 16 (p. 70). The local paper pointed out that comparatively few students present themselves for examinations in the science faculty of the Punjab University, and therefore suggested that scientific studies are not making much headway in India. Prof. Hemmy remarks that though the study of science in the Punjab is in a somewhat backward condition, the various laboratories being badly endowed, the article in the local paper, upon which our note was based, is misleading. The regulations of the Punjab University permit science (of a very slightly lower standard) to be taken up for the arts degree as well as for the B.Sc., and the great majority of students who take up science do so as part of the more popular B.A. course. It appears that the numbers quoted in the note only represent, therefore, a fraction of the total number studying science. For 1907, in the arts faculty, out of 3666 candidates for matriculation, 1426 took up physics and chemistry; out of 689 candidates for the intermediate, 254 took the same subject; of the 340 for the B.A., 25 took physics and 32 chemistry; while of the 52 M.A. candidates, 3 took physics and 4 chemistry.

AN exhibition of selected specimens of work of pupils in the rural schools of East Suffolk was held at the County Hall, Ipswich, on June 15. The exhibition was arranged by Alderman the Rev. C. J. Steward, chairman of the Education Committee of the East Suffolk County Council, to whose energy and enthusiasm this movement owes so much. It is clear that valuable work is being done in East Suffolk schools to train observational powers and to stimulate interest in natural phenomena. Forty-three distinct exhibits were shown, including some excellent collections of the grasses and wild plants of each district, while mounted and labelled specimens illustrating the history of common plants and animals, meteorolog... records kept and displayed in the form of charts, pl... of the villages and of the school buildings, caref... selected specimens showing the structure and growth ... common timber trees, plans of school gardens, records ... the country month by month, and excellent studies of ... changes in ditches and ponds during the year, were a... shown. In addition, there were records of bee-keeping a... illustrations of budding and grafting. East Suffolk ... made a good start in the newer teaching, and the exhi... tion itself, as well as the numbers of those who attend... from all parts of the county, shows that a genuine inter... is being taken in the matter. A selection of the exhib... is to be sent to the Royal Agricultural Society's show ... Lincoln.

A CONFERENCE will be held in Naini Tal this year, ... learn from the *Pioneer* of Allahabad, for the purpose ... considering many difficult questions connected w... technical education, and if possible to devise some prop... coordinated scheme which shall lead the way for the wh... of India. In an enlightened editorial article the *Pio*... reviews the objects the advocates of technical instruc... have in view, and indicates many of the special requ... ments of the Indian population which must be borne ... mind in devising a scheme suited to Eastern needs. ... is pointed out that for the success of any system provis... must be made for the different classes of workers engag... in modern productive industries, workmen or artisa... foremen or overseers, managers or masters, and that it ... necessary to provide grades of technical education cor... sponding to primary, secondary, and university or high... education. The lowest grade is that which presents m... difficulty in India. At the present time, the article stat... it is impossible to give instruction in elementary scie... in Indian village schools, but something might be d... to teach drawing and to give handicraft training ... means of a form of apprenticeship to village craftsm... It is proposed that the most promising of those so trai... might then be assisted to undergo a course at an indust... school in the nearest large centre, and thus the instruct... in the primary schools of the country could be brought ... touch with modern needs, and a system commenced wh... would advance any scheme of technical education fina... adopted. It is suggested that workshop practice could b... be given in India in apprenticeship schools of the Con... nental type, and that evening classes would serve t... purpose of improving the workmen and selecting th... capable of profiting from a systematic course of hig... study. No difficulty is anticipated so far as educating ... foremen is concerned, and technical institutes of the ri... kind are recommended as the best way to provide hig... technical education. Undoubtedly, the article contin... much has already been done in India to provide a syst... of technical education, and progress has been made ... means of art schools, industrial schools, and engineer... colleges, but there is a tendency to lose sight of mod... developments, and the immediate need now is a system... arrangement of the work at present undertaken.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 9.—"The Ascent of Water in Tre..." (Second paper.) By Prof. A. J. **Ewart.** Communica... by Francis Darwin, For.Sec.R.S.

The experiments detailed or quoted tend to show t... the continuous ascent of water is only possible in liv... wood, and that the power of conduction is rapidly lost ... death, without any mechanical blocking of the ves... being necessarily responsible for the change. Hence ... are forced to conclude that the living cells in tall tr... continually restore the conditions for the ascent of wa... wherever these are affected by the excessive emptying ... the vessels, and decrease the resistance to flow, as far ... possible, by maintaining continuous water columns in pa... at least of the wood. So long as these are prese... *ab initio*, a pumping action only becomes necessary in tre... more than 20 to 50 metres in height, but suspend...

columns cannot be maintained for any length of time in the vessels of tall trees without the aid of the living cells of the wood.

The energy required to pump water upwards in the tallest trees represents only a small fraction of that produced by the daily photosynthetic assimilation, and it is the feeble character and diffuseness of the pumping action which render it so difficult to demonstrate practically.

Experiments on the suction and exudation of trees at different levels and upon the influence of the entry of air and water under pressure showed that no continuous suspended water columns, or high internal tensions, existed in the conducting elements of the trees experimented on (maple and poplar) during active transpiration, or, indeed, at any period of the year.

The same was shown by direct measurements of the pressure in intact vessels of Wistaria during active transpiration. This fact, coupled with the high total resistance to flow, shows that this resistance is overcome locally from point to point, and not by any enormous tension from above or pressure from below, neither of which exists, nor could be maintained to a sufficient extent to carry on the elevation of water in a tall tree. A high tension from above leads to rapid blocking with air; a high pressure from below leads to great loss by lateral exudation from the vessels.

The surface adsorption of dissolved solids in the vessels plays a very important part in their function as translocatory channels, causing a delay in the ascent of dissolved solids, such as sugar and salts, and an accumulation of them along the outer walls of the vessels. The latter facilitates their outward diffusion, but at the same time renders the transference of small quantities of material between widely removed organs difficult or impossible.

The tallest trees in Australia do not appreciably exceed 300 feet in height, so that the values previously given for the maximal total resistance to the upward flow of sap in actively transpiring trees must be reduced to between thirty and fifty atmospheres.

May 30.—"Report of Private Expedition to Philippeville, Algeria, to View the Total Eclipse of the Sun on August 30, 1905." By Dr. T. C. **Porter** and W. P. **Colfox.**

The two observers camped out on a hill near the village of St. Charles, in lat. 36° 45′ 38″·7 N. and long. 6° 51′ 59″·1, and 690 feet above sea-level. The line of central eclipse passed directly over their station. They had magnificent weather on the day of the eclipse, and were able to carry out almost all the observations contemplated, both visual and photographic. Two simultaneous photographs were taken of the corona through two large Nicol prisms, the axes of which made angles of 45° with the horizon, and were at right angles to each other. The negatives, and also the reproductions given in the paper, show very strikingly the radial polarisation of the outer corona; one of the streamers, for example, can be traced with certainty from within 2′ 7″ to 2·2 diameters away from the moon's limb on *one* of these photos., whilst no part of it can be so traced on the other. There is unmistakable evidence in both photos. that the coronal development as a whole was more considerable on the N.E. limb of the sun, *i.e.* on the side where the great prominence was visible. The telescopic examination of the details of the inner corona on the N.E. limb proved exceptionally interesting, a superb radial "pillared" structure being seen, cut by the streamers at various angles, and limited externally by a very thin shell concentric with the sun, suggesting partial condensation and a possible differentiation of the "reversing layer" into concentric shells of vapours of varying condensability. Jets were also observed on the S.E. limb of a different colour from that of the prominences visible, their narrow stems being white, but passing into "rounded, soft-looking summits of the bluish-pink of the cyanogen flame." A photograph of the "coronium ring," taken with a specially prepared screen, revealed obvious jets, forty being easily counted on the enlarged negative, and it is shown in the paper that these must be attributed either to "coronium" itself or to some unknown element the radiation from which was capable of penetrating the screen used.

The so-called "shadow bands" were very well seen, both before and after totality, and are fully discussed in the paper. They were waved, and the waves seemed to have a motion of their own along the lines of shadow, which makes it almost certain that the true direction of travel of each band considered as a whole was *not* at right angles to its length, though at first sight the bands seemed to be so travelling. It was proved that the directions of the lengths of the bands coincided within the errors of experiment with the trace on the horizontal sheet on which they were observed of the plane passing through the cusps of the solar crescent and the sheet; the frequently observed rotation of their direction during the progress of an eclipse is accounted for. A full meteorological record was kept for a few days, both before and after the eclipse day, and the information gained is all exhibited on one chart, from which the reduced barometric height, the humidity, solar radiation, temperature of the air, direction and force of the wind, and amount and distribution of cloud, as well as its kind, can be read off for any hour of the day, and during the eclipse for every ten minutes. The total length of the certainly disturbed-barometer district at any one moment was some 5000 odd miles, the part of it *preceding* the *umbra* being some 200 miles shorter than that following it, and the barometric maximum seems to have travelled about 500 miles behind the centre of the umbra, and to have covered a region about the same number of miles in length, measured along the line of central totality. The eclipse wind is discussed, and seems to have been due to the inrush of air from all sides towards the centre of the shadow, the effect of this influx being superposed, at the station, on the northerly sea breeze. The direction of motion of the shadow bands had certainly a large northerly component, and thus their motion was also towards the line of central eclipse, thus following the general direction of the wind. A careful estimate of the height of the reflecting layers of matter in the earth's atmosphere, made by measuring the altitude of the orange glow seen near the horizon during central totality, gave six miles, a result coming very near the inferior limit given by many hundreds of observations in different latitudes by one of the observers.

The stars seen during totality were Venus, Mercury, Regulus, Spica, Arcturus, and Procyon.

"An Experimental Inquiry into the Nature of the Substances in Serum which influence Phagocytosis." (Second communication.) By George **Dean.** Communicated by Dr. C. J. Martin, F.R.S.

(1) Dilution of fresh unheated serum is not accompanied, so far as the higher concentrations are concerned, by a fall in the sensitising power for certain organisms (staphylococcus, tubercle bacillus). The diminution in this was found, as a rule, to begin at the quarter concentration.

(2) So far as the present experiments go, the points corresponding to the 1/4th, 1/8th, 1/16th, and 1/32nd dilutions of normal human serum lie on a parabola the equation of which is $y^2=4X$, *i.e.* for these dilutions the phagocytosis is proportional to the square root of the serum concentration.

(3) The phagocytic index obtained by mixing appropriate dilutions of a heated immune serum with a normal fresh serum is greater than results from the two substances acting separately.

(4) In the case of certain normal sera (guinea-pig and rabbit) previously investigated for amboceptor and complement in relation to the extra-corpuscular bacteriolysis of the typhoid bacillus (Wechsberg), an exact parallelism can be demonstrated to exist between that function and opsonisation. The normal amboceptor can be complemented by fresh serum in regard to both functions.

(5) An "anti-complement" serum, when mixed with a fresh normal serum alone or in a mixture containing heated immune serum, throws out of action the thermolabile substance, whereas it does not appear to influence the thermostable substance.

"The Correlation of the Ovarian and Uterine Functions." By E. S. **Carmichael** and Dr. F. H. A. **Marshall.** Communicated by Prof. E. A. Schäfer, F.R.S.

(1) The removal of the ovaries in young animals (rodents) prevents the development of the uterus and Fallopian tubes.

These remain in an infantile condition. The subsequent growth and general nutrition of the animals seem to be unaffected.

(2) The removal of the ovaries in adult animals (rodents) leads to fibrous degeneration of the uterus and Fallopian tubes (most marked in the mucous membrane). The animals' subsequent health and nutrition remain good.

These observations, for the most part, support the evidence obtained clinically in the human subject after surgical operation.

(3) The removal of the uterus in a young animal has no influence in preventing the further development of the ovaries. These are capable of ovulating and forming corpora lutea after adult life has been reached.

(4) The removal of the uterus in an adult animal does not give rise to any degenerative change in the ovaries, if the vascular connections of the latter remain intact.

These latter observations do not support the contentions of those surgeons who advocate subtotal hysterectomy, believing that the functional activity of the ovary is in some way dependent on the presence of the uterus.

"On Mitosis in Proliferating Epithelium." By Dr. J. O. Wakelin **Barratt.** Communicated by Prof. C. S. Sherrington, F.R.S.

(1) In epithelial proliferation brought about by scharlach R, both normal somatic and reduced mitoses occur. This statement applies to epithelium proliferating *in situ*, and also to the same implanted under the skin.

(2) In the reduction mitoses the number of chromosomes which could be counted varied from fourteen to eighteen. In the somatic form the number counted varied from twenty-eight to thirty-six.

(3) Reduction mitoses could be recognised less frequently than somatic mitoses.

(4) Post-reduction mitoses were met with.

(5) The character of the mitoses occurring was not definitely altered by implantation under the skin.

"The Solubility of Air in Fats, and its Relation to Caisson Disease." By Dr. H. M. **Vernon.** Communicated by Dr. J. S. Haldane, F.R.S.

At body temperature, fats dissolve more than five times as much nitrogen as an equal volume of water or blood plasma.

The special tendency of the fat-containing tissues (such as subcutaneous tissues, spinal cord, and peripheral nerves) of caisson workers and divers to suffer injury from the liberation of gas bubbles after rapid decompression is dependent on this great solubility.

Geological Society, June 5.—Sir Archibald Geikie, Sec.R.S., president, in the chair.—A marine fauna in the basement beds of the Bristol coalfield: Herbert **Bolton.** During exploration at the Ashton Vale Colliery, fossiliferous shales were traversed in the lowest Coal-measures resting upon the Millstone Grit. A section of the Coal-measures in this part of the coalfield is given, and the chief fossiliferous shale is localised at a depth of 84 feet below it. The feature of the fossils is their dwarfed condition. The thickness of the Millstone Grit appears to be about 980 feet. The palæontological description embodies a list of fossils from the marine horizon, which shows correspondence with the list from the marine beds associated with the gin coal of North Staffordshire, but it is not desirable to conclude that the horizons are identical until further evidence has been obtained from the Bristol area. The brachiopod fauna contains forms identical with or closely approximating to species occurring in the Cyathaxonia and Dibunophyllum zones. The description includes notes on Productus, Chonetes, Derbya, and Orthothetes, contributed by Dr. A. Vaughan, and new species of Chonetes, Raphistoma, and Loxonema.—Brachiopod morphology: Cincta, Eudesia, and the development of ribs: S. S. **Buckman.** The test ornament of brachiopods is found in three main phases, smooth, ribbed, and spinous, and of these a costate species is more advanced than a smooth one and less advanced than a spinose one. The first phase of development dealt with may be called the lenticular stage; the next phase would be the Cincta stage, in which the front margin is rounded in youth, truncate in adolescence, incipiently excavate and bilobate in the adult. The Cincta stage may develop in two directions—out of broad forms the quadrifid stage, out of narrow forms the cornute stage. The next development may be called the quadricarinate or trigonellid stage, and the fourth stage the multicarinate or *pectunculus* stage. In Eudesia there is a highly developed multicarinate stage. In degree of ribbing it is higher than Cincta, and even higher than the *pectunculus* stage, but both the ribbing and the loop forbid connection with Cincta.

Chemical Society, June 6.—Sir William Ramsay, K.C.B., F.R.S., president, in the chair.—The relation between absorption spectra and chemical constitution, part vii., pyridine and some of its derivatives: F. **Baker** and E. C. C. **Baly.** The absorption spectra of pyridine and the pyridones are consistent with the view that the nitrogen atom tends to restrain the motions of the ring, this restraint being very much lessened by the addition of acid to the solutions.—The interaction of methylene chloride and the sodium derivative of ethyl malonate: F. **Tutin.**—The constitution of the diazo-compounds: J. C. **Cain.** The author proposes for diazo-benzene chloride the quinonoid formula, which bears much analogy to the formula of quinonechloroimide, which, like diazo-salts, loses nitrogen on boiling with water.—Dibromoaminoazobenzene: J. T. **Hewitt** and N. **Walker.**—Phenol-*p*-sulphoxide: S. **Smiles** and A. W. **Bain.**—*p*-Cresol sulphoxide and sulphide: S. **Smiles** and T. P. **Hilditch.**—Molecular weight of β-naphthol in solution in solid naphthalene: E. P. **Perman** and J. H. **Davies.** It is concluded from vapour-pressure measurements that in dilute solutions β-naphthol has the same molecular weight as in the gaseous state, whilst it associates in more concentrated solutions.—Synthesis of hexatriene derivatives. (Preliminary note): Miss I. **Smedley.**—The reduction of aromatic nitro-compounds to azoxy-derivatives in acid solution: B. **Flurscheim** and T. **Simon.** The conditions which favour or prevent the formation of azoxy-products by reduction of nitro-bodies in acid solution have been determined.—Action of selenium and tellurium on arsine and stibine: F. **Jones.** It is found that the action of arsine and stibine on sulphur, selenium, and tellurium corresponds with the rise in the atomic weights of these elements, stibine being readily decomposed by sulphur, more slowly by selenium, and still more slowly by tellurium.—The double nitrites of mercury and the alkali metals: P. C. **Rây.**—Silver-mercuroso-mercuric hydroxynitrates and the isomorphous replacement of univalent mercury by silver: P. C. **Rây.**—The molecular weights of amides in various solvents: A. N. **Meldrum** and W. E. S. **Turner.**—Some experiments on the oxidising action of hydrogen peroxide: W. H. **Perkin,** jun. Brazilein, hæmatein, benzil, phenanthrenequinone, and aurin are oxidised by 30 per cent. hydrogen peroxide, yielding products which are still under investigation. Experiments are in progress with the view of determining the special conditions under which hydrogen peroxide may be employed with success in the investigation of such substances.—Action of hydroxylamine on *o*-benzoquinonediazides. 3:5-Dibromo-*o*-azoiminobenzoquinone: K. J. P. **Orton,** W. C. **Evans,** and E. **Morgan.**—Oxime formation and decomposition in presence of mineral acids: A. **Lapworth.** The conversion of stable hydroximido-compounds into the corresponding ketones or aldehydes is, as a rule, to be effected by the use of hydrochloric acid in presence of formaldehyde. The latter is converted into formic acid in the process, while the nitrogen of the oxime appears mainly as ammonium chloride. When benzaldehyde is substituted for formaldehyde, benzaldoxime and sometimes benzonitrile are formed.—Note on the constituents of the seeds of the Para rubber tree (*Hevea brasiliensis*): W. R. **Dunstan.** The kernels of the seeds of the Para rubber tree contain about 50 per cent. of a fixed oil resembling linseed oil. The seed kernels, when ground with water, evolve small quantities of hydrocyanic acid and acetone, whence it appears that a cyanogenetic glucoside is present, similar to, if not identical with, phaseolunatin. A mixture of enzymes was prepared from the seeds which probably includes, besides a lipase-like enzyme, one capable of decomposing the cyanogenetic glucoside. The nature of the fixed oil, the cyanogenetic glucoside, and the enzymes is being fully investigated in this and the related species, *Hevea pauciflora* and *Hevea confusa*.

Mineralogical Society, June 11.—Prof. H. A. Miers, F.R.S., president, in the chair.—Hamlinite from the Binnenthal: H. L. **Bowman.** A mineral occurring in small brown six-sided plates in the white dolomite, to which the name bowmanite was given by Mr. Solly in 1904, is shown by analysis to be identical with hamlinite. The crystals show a division into six biaxial sectors, and are consequently pseudohexagonal.—Faceted beads of zinc: T. V. **Barker.** The president described beads of zinc deposited on crucible lids by sublimation of zinc through oxide of tin. Some of these beads are covered with brilliant facets, and present the appearance of crystals rich in faces. Mr. Barker has found that they do not lie in zones or obey the laws of distribution of ordinary crystal faces, and cannot therefore be regarded as the faces of a single crystal. There is, however, no evidence, from etching by acid, that the bead is an aggregate of crystals. The nature of these remarkable faces is difficult to understand. A bead of platinum presenting the same peculiarities was measured by the late Prof. Miller.—Chlormanganokalite: Dr. H. J. **Johnston-Lavis** and L. J. **Spencer.** A preliminary account of this new Vesuvian mineral was given by Dr. Johnston-Lavis in NATURE on May 31, 1906. A new analysis of the mineral gives the formula $MnCl_2.4KCl$. The crystals are rhombohedral with a rhombohedral angle of 57° 36′; they are optically uniaxial with very weak positive birefringence; the refractive index is 1·59 and the specific gravity 2·31.—Mr. L. J. **Spencer** exhibited a suite of beautifully crystallised minerals, presented to the British Museum by Mr. Percy C. Tarbutt, from the Rhodesia Broken Hill mines in north-western Rhodesia. In driving a tunnel through one of the kopjes, which consist mainly of cerussite and hemimorphite, a cavern containing flint implements and bones of recent mammals was encountered, and a cavity in the bone-breccia on the floor of this cave was encrusted with magnificent groups of hopeite crystals (the rare hydrous zinc phosphate discovered by Sir David Brewster in 1823). In the vicinity of the cave, crystals of another hydrous zinc phosphate were found in association with descloizite (hydrous vanadate of lead and zinc). The crystals of this new species, for which the name *tarbuttite* is proposed, are anorthic; they possess a perfect cleavage in one direction, through which emerges obliquely the acute negative bisectrix of the optic axes. Cavities in the ordinary ore are lined with large twinned crystals of water-clear cerussite, which are encrusted with small crystals of hemimorphite.—A group of quartz crystals from British Guiana was exhibited by Mr. **Anderson,** and a fine crystal of apatite by Mr. **Gordon.**

Mathematical Society, June 13.—Prof. W. Burnside, president, in the chair.—The number of representations of a number as a sum of $2r$ squares, where $2r$ does not exceed 18: Dr. J. W. L. **Glaisher.**—An extension of Eisenstein's law of reciprocity: A. E. **Western.**—Note on a special set of classes of partial differential equations of the second order: Prof. A. R. **Forsyth.**—Various extensions of Abel's lemma: Prof. T. J. I'A. **Bromwich.** —The arithmetical nature of the coefficients of linear substitutions, third paper: Prof. W. **Burnside.**—The invariants of the quintic: Dr. H. F. **Baker.**—Informal communications were made as follows:—Certain singular points of surfaces: A. B. **Basset.**—The minimum necessary postulates as to a function to be defined as analytic over a region: Prof. E. B. **Elliott.**

Royal Astronomical Society, June 14.—Mr. H. F. Newall, president, in the chair.—The inclination of binary star orbits to the Galaxy: Prof. H. H. **Turner** and T. **Lewis.** —The illumination of the field of view, and its effect on observations with a transit instrument: Sir W. **Christie** and H. **Christie.**—The spectrum of Mira Ceti, as photographed at Stonyhurst College Observatory: Rev. W. **Sidgreaves.** The photographs were taken during the late maximum, from December 1, 1906, to January 3, 1907, with a Thorp objective prism and with a Hilger compound prism. The spectra were compared with that of the star during the previous maximum of 1897–8. The absorption spectrum was substantially the same, but the bands were much weaker in 1906, quite sufficiently so to account for the very bright maximum.—The origin of certain bands in the spectrum of sun-spots: A. **Fowler.** The bands are hazy lines, which had not hitherto been traced to their source, various experiments made in 1905–6 having given entirely negative results. The author, however, had lately found that many of the bands are part of a fluted spectrum, and can be accounted for by the presence in the umbræ of spots of a compound of magnesium and hydrogen (magnesium hydride). The identification appeared extremely probable from a comparison of visual observations, but is rendered quite certain by reference to the admirable photographs taken by Prof. Hale at the Mount Wilson Observatory. The identification supports the view that the vapours in spots are at a relatively low temperature.—Account of the instruments and work of the Mount Wilson Observatory, California: Prof. G. E. **Hale.** A large series of slides was shown on the screen, including spectroheliograph pictures of the solar surface taken in calcium and hydrogen light, comparison of which led to important conclusions as to the relative height of the flocculi. It was suggested that the areas of the flocculi should be systematically measured, and that they might furnish data for determination of the solar rotation. A series of photographic spectra of sun-spots was also shown. Prof. Hale stated that he had found that the heat of the sun caused an actual bending of the mirror employed, the front side becoming convex and the rear side concave. He proposed to obviate this disadvantage by employing mirrors of exceptional thickness, a 17-inch mirror being under construction which is as much as 13 inches thick. Other modifications in the instrumental equipment are also in progress.

PARIS.

Academy of Sciences, June 17.—M. Henri Becquerel in the chair.—The question of the origin of the lunar seas: MM. **Lœwy** and **Puiseux.** The hypothesis of the formation of the lunar seas by external collisions is discussed and shown to depend upon very uncertain hypotheses, and even then is, taken alone, insufficient to account for all the facts.—The usual mode of publication of equatorial observations and on a means of improving it: G. **Bigourdan.**—Further remarks on the obliteration of the pleural cavity of elephants: Alfred **Giard.** Referring to a recent note on this subject by G. Vasse, the author remarks that the mere fact of the lungs separating easily is no proof of the existence of a pleural cavity, and quotes recent observations by Schmaltz, Ruge, and Chapman to support his point.—The preparation of anhydrous lithium moxoxide: M. **de Forcrand.** None of the methods previously used for preparing this substance gives a pure product. Purified lithium hydroxide, placed in a platinum or silver boat, is heated to 780° C. in a current of dry hydrogen. The conversion into Li_2O is complete in one hour.—A new method of diagnosis of tuberculosis in man by the tuberculin ophthalo-reaction: A. **Calmette.** One drop of a sterilised 1 per cent. aqueous solution of tuberculin is placed in the eye. After five or six hours, conjunctivitis, accompanied by copious secretions, becomes apparent in the tuberculous subjects. In non-tuberculous subjects the tuberculin is without effect. The author suggests the use of this in clinical work as a means of diagnosis, as the reaction is prompt, and neither pain nor permanent ill effects result.—Observations of the Daniel comet (1907*d*) made with the *coudé* equatorial of the Observatory of Lyons: J. **Guillaume.**—Observations of the Giacobini comet (1907*c*) made with the *coudé* equatorial at the Observatory of Lyons: J. **Guillaume.** This comet is of thirteenth to fourteenth magnitude.—A new method for resolving several problems on the development of an arbitrary function in infinite series: W. **Stekloff.** —The surfaces engendered by a circular helix: M. **Barré.** —The mechanical integration of the hodograph: L. **Filloux.**—The displacement of the absorption bands of crystals under the action of variations of temperature: Jean **Becquerel.** The bands of tysonite, parisite, and monazite are all displaced in the direction of the smaller wave-lengths when the temperature is lowered; in xenotime, however, a large number of bands move in the opposite direction.—A new method for the production of flame spectra of metallic bodies: G. A. **Hemsalech** and C. **de Watteville.** The air supplied to the lower part of a Bunsen burner carries some of the metal in a fine state of division. To produce this the air passes through a glass bulb containing two electrodes of the metal under examination. About ten powerful sparks per second, furnished by a condenser of high capacity, are allowed to pass between the two electrodes. Sufficient of the metal is removed in this way to give a flame rich in lines. The actual quantity used, however, is extremely small, and is hardly weighable after some hours' sparking. The method is therefore peculiarly adapted for studying the spectra of rare and costly metals.—Photomicrography in colour with autochrome plates by A. and L. Lumière: Ch. A. François **Franck.**—Remark relating to the detection of calcium: H. **Baubigny.** A reclamation of priority as regards the use of an ammoniacal solution of potassium ferrocyanide as a characteristic test for calcium.—The absolute atomic weight of manganese: Gustavus D. **Hinrichs.** An application of the author's method of calculation to the experimental results of Baxter and Hines. The value 54·95 found by these workers is converted into 55 exactly by these calculations.—Arsenic acid and the methylarsenic acids: E. **Baud** and A. **Astruc.** A thermochemical paper.—The action of fluorine on selenium in the presence of glass: Paul **Lebeau.** Experimental reasons are given for assuming that the substance produced by the interaction of selenium and fluorine in the presence of glass is not pure selenium hexafluoride, but a mixture of at least two substances.—The solubility of alumina in aluminium sulphide and of magnesia in sulphide of magnesium: Marcel **Houdard.** The oxides of both magnesium and aluminium have been obtained in a crystalline form when fused with the corresponding sulphide in the electric furnace.—The alloys of nickel and tin: Em. **Vigouroux.** The alloys of nickel and tin containing up to 40 per cent. of the latter metal are feebly magnetic. Under the action of nitric acid and potash a non-magnetic alloy having the composition Ni_3Sn can be isolated.—The glycol of anethol; its transformation into anisylacetone: MM. **Tiffeneau** and **Daufresne.**—A new method of ring formation of the substituted pimelic and adipic acids: H. G. **Blanc.** The acid is converted into its anhydride by treatment with acetic anhydride, and this, followed by slow distillation, gives the corresponding cyclic ketone. The yields are very good; details are given of eleven ketones prepared according to this method.—The dimagnesium compound of 1:5-dibromopentane: V. **Grignard** and G. **Vignon.** Dibromopentane readily forms a dimagnesium compound, soluble in ether. A preliminary account is given of the reactions of this substance with carbon dioxide, ethyl acetate, and diacetyl.—The application of the method of limiting densities to the liquefiable gases: Ph. A. **Guye.** The difficulty with these is the accurate evaluation of the term A'_0, representing the deviation from Boyle's law. A linear extrapolation from densities measured at pressures between 0·5 and 1 atmosphere is not sufficiently accurate, and the three modes of parabolic extrapolation proposed by D. Berthelot do not lead to identical results. It is pointed out that, admitting the idea of a gas constant, the parabolic extrapolation will not hold good.—The kathodic phosphorescence of complex systems. The paralysing action exercised by certain exciters of the rare earth series upon others of the same series: G. **Urbain** and Clair **Scal.**—The colloidal properties of starch: E. **Fouard.**—The comparative action of extracts of barley and of malt upon the more resisting dextrins: J. **Wolff.**—The amount of oxygen in oxyhæmoglobin from the horse: MM. **Piettre** and **Vila.**—The polymorphic transformations of isomorphous mixtures of three bodies: Fred. **Wallerant.**—The inverse bundle of *Zilla macroptera*: C. **Gerber.**—The detection of invertine, sucrase, or saccharose in various organs of the vine and in some fruits: V. **Martinand.**—Protective and evasive autotomy: Henri **Piéron.**—The structure of the divided nerves in a strictly physiological evolution: N. A. **Barbieri.**—The geology of the central Sahara: R. **Chudeau.**—The presence of Carboniferous strata in the neighbourhood of Taoudeni, south-western Sahara: G. B. M. **Flamand.**—The post-helvetian eruptions anterior to the recent volcanoes in the north-west of Sardinia: M. **Deprat.**—The storm of May 22 1907, in the department of Loiret: M. **Maillard.**

THURSDAY, JULY 4, 1907.

THE CONSTRUCTION OF DYNAMOS.

The Construction of Dynamos (Alternating and Direct Current). By Tyson Sewell. Pp. xi+316. (London: Crosby Lockwood and Son, 1907.) Price 7*s.* 6*d.* net.

SO many books have already been written on the subject of the dynamo that any new publication can only be justified on one of two grounds. Either it must contain new matter of practical importance not hitherto treated in such a way as to be useful to the designer, or it must be in comparison with existing books an improvement in the way of treating old and well-known matter, so that the student and the practical engineer may have less difficulty in grasping the subject than they often have with the existing books.

A perusal of Mr. Sewell's book will leave the reader with the impression that the designer of dynamos will learn nothing from it, and that the student may with equal advantage read any of the previous publications treating of the dynamo in a popular style. The book is in this respect no better and no worse than dozens of others. As regards its use for the design of dynamos, the author himself deprecates it, for he says in the preface:—

"The examples of design are introduced by way of illustration only. The actual designing of dynamos is the work of comparatively few men, most manufacturers having standardised particular lines which, with slight modifications, meet most requirements; and in view of the labours of the Engineering Standards Committee, further developments in the direction of uniform practice may be expected."

The idea underlying this sentence seems to be that as only few men have to design dynamos, and as the Engineering Standards Committee looks after these things, it is not necessary to treat of design in books. Yet in the first sentence of the preface the author says that his work is an attempt to treat of theory, design, and construction, and several chapters are devoted to working out the details of design.

The general arrangement of the book follows well-known lines. We get first the fundamental principles of direct currents, Ohm's law, its application to the "Silvertown Set" and Evershed's "Megger," though without description of the internal arrangement and only an outside view of the box. Then come a few pages on the magnetic field and on testing iron, but the treatment is incomplete, and in one case also misleading. This is the description of the magnetometric method, where the author fails to point out that it is only applicable to thin and long wires, and not to a turned iron rod, as he says; and that the effect of the solenoid must be eliminated by a special coil. In the next chapter we get all the well-known illustration (but on a prodigiously large scale) to show lines of force, and how by cutting them an E.M.F. is produced, and the formula for the E.M.F. of a two-pole dynamo. It would have been well if the author had also given the formula for a multipole machine in this place. The chapter following deals with the fundamental principles of the alternating current, and then we get to the alternating field. Here the author introduces the hysteresis loop, and mentions that its area is a measure of the work lost per cycle, but gives no proof. The figures he gives for the hysteresis coefficient of 0·002 to 0·008 are certainly much too large, and he is also in error when he says that in dynamo work the loss due to eddy currents is very small. It is well known that the losses in iron actually occurring in the dynamo are considerably in excess of the theoretically calculated losses, and that the increase is in a large measure due to eddy currents at the burred edges of the plates. When dealing with capacity the author gives a neat hydraulic analogy to show why the charging current is a quarter phase in advance of the E.M.F.

In the chapters on construction and theory of bipolar dynamos we find the usual illustrations, but all on a large scale, so that a good deal of space is uselessly occupied and the text correspondingly restricted. Although in the illustrations the author follows well-known lines, this cannot be said as regards his way of designing. Here we find some novelty, but hardly improvement on the usual practice. Thus, in giving the design of a 400 kw. 550 v. machine, he starts with the rule that 100 kw. is a fair average allowance per pair of poles, and finds thus that eight poles is the right type. Then he calculates the number of commutator bars on the basis of 5 v. per bar, and by assuming a certain thickness he arrives at the diameter, and again by assuming a certain circumferential speed he obtains the number of revolutions per minute. This freedom in the selection of speed may be convenient, but it is certainly not the condition which prevails in practice. As a rule the speed is given, and one has to design the dynamo to suit it. Having thus found the speed, the author proceeds to find length and diameter of armature by simply applying the so-called "output formula," but as he does it without critical investigation he gets rather unusual dimensions, namely, 93 inches diameter by $15\frac{1}{2}$ inches long, whereas a little common-sense reasoning untrammelled by adherence to formula would have shown him that 80 inches by 20 inches would make a far better and cheaper machine. The number of conductors is found from a formula of circumferential current density, and so the designing goes on simply by applying formulæ without criticism, not a method to be recommended either to students or to "engineers who have occasion to deal with technical matters," as the author says in the preface.

Another claim made in the preface is only partially justified. The author says that "the available space is almost exclusively devoted to machines representing present standard practice." There are a few illustrations of the fly-wheel type of alternator, and also a turbo-alternator, and in so far standard practice is considered, but the "mono-coil-claw" type, Fig. 200, the inductor machine, Fig. 201, and the ironless machines of Mordey, Ferranti, and Crompton, are certainly not present standard practice, whilst the details of armature housing shown in Figs. 192 to 197 may be modern, but are certainly not good practice. The author's explanation why field magnets are laminated is novel, and, moreover, so peculiar that it merits verbal quotation. He says:—

"The field cores are often laminated throughout to prevent eddy currents due to any swinging of the field caused by armature reaction, and this often leads to special methods of support."

Had he said that magnets must be laminated if the stator slots are wide and open, he would have been right, but the explanation he gives is quite beside the mark. Equally misleading is his indiscriminate recommendation of damping coils as a cure for hunting. As he mentions these coils just after saying that hunting is especially the fault of gas-engine driven machines, the reader is led to conclude that the damping coils would be especially useful in such cases, whereas every expert knows that damping coils are absolutely harmful if applied to an alternator driven by a gas engine. GISBERT KAPP.

STOKES'S SCIENTIFIC CAREER AND INFLUENCE.

Memoir and Scientific Correspondence of the late Sir George Gabriel Stokes, Bart., Past Pres.R.S. Selected and arranged by Prof. Joseph Larmor, Sec.R.S. Vol. i., pp. iv+475; vol. ii., pp. vi+507. (Cambridge: The University Press, 1907.) Price 24s. net, two volumes.

IT is well known that the record of Stokes's work, splendid as it is, which is contained in the five volumes of his collected papers is far from being a complete representation of the services which during a long life he rendered to science. From his first official connection with the Royal Society in 1854 the tide of production began somewhat to slacken, and after 1868, it may almost be said, no sustained piece of work of first-rate magnitude appeared under his name, although shorter papers, often of great value, and all showing the impress of the master-hand, were given out from time to time. His energies did not relax, and his powers never showed any sign of decay, but they were diverted into somewhat different channels. Partly owing to the rigorous sense in which he construed the duties of his various official positions, and partly in consequence of his own inexhaustible good nature, he was constantly occupied in examining, advising upon, and assisting in the work of others.

This gradual change in the manner of his work has been often wondered at, and sometimes deplored, but it came about quite consistently. There is a certain type of professional *savant* to whom systematic production, or at all events publication, with due form and circumstance, is as the breath of his nostrils; it must be maintained at all hazards. With this type Stokes had never any affinity. He took to mathematical physics, in the first instance, because his interests and his powers lay that way, and he published the results of his investigations, when they seemed valuable enough, as a matter of course; but when other duties came which had, as he thought, a more immediate claim, he turned to them without a moment's regret at the diminished opportunities of personal achievement which they involved.

For a complete memorial it was therefore essential that some presentation should be made of this important phase of his work. As Prof. Larmor explains, in the preface to the two volumes now before us, the material in the shape of letters is abundant; but it is naturally very varied in character, and often fragmentary, and much of it was from one cause or another difficult to turn to account. The labour of sifting and arranging the correspondence must have been enormous, and appears to have been aggravated by the circumstance of fresh letters continually coming to hand during the printing.

The material finally selected has been dealt with as follows. In "Section II." we have an outline of Stokes's general scientific career, illustrated by a chronological series of letters, which touch upon the various topics which at different stages attracted his attention. "Section III. A" contains "special scientific correspondence" with his father-in-law, Dr. R. Robinson, Prof. Cayley, and Sir J. Norman Lockyer. These letters contain matter which is, in different ways, of great interest; the letters to Dr. Robinson are specially valuable, as they preserve many interesting notes and explanations which would otherwise have been lost. The second volume continues "Section III.," and includes letters to and from Maxwell, Joule, Rayleigh, Reynolds, Froude, Airy, and others, nearly all bearing on scientific work of the first order actually in progress. It would be hopeless, and useless, to attempt an enumeration of the various points touched upon; but it is of interest to note with what zest Stokes turns, again and again, to the early objects of his scientific affections, such as the behaviour of sea-waves, the theory of the pendulum, and the varied problems of physical optics. The collection is most of all valuable in that we are allowed a glimpse into the workshop of the master. The most expert craftsman will find much to admire, whilst the novice may derive suggestion and encouragement, more perhaps than from the contemplation of the finished work, which is often apt to beget rather feelings of despair.

These volumes include also matter of a more formal biographical character. The introductory memoir by Mrs. Lawrence Humphry is a most attractive personal record, written with admirable tact and sincerity. To this are appended "appreciations" by intimate personal friends, Prof. Liveing, Sir Michael Foster, Sir William Huggins, and the Bishop of Bristol. Considerable space is devoted to the Jubilee celebration of 1899, and to the proceedings at the unveiling of the Westminster Abbey memorial. Both these occasions greatly impressed those who had the privilege of attending them, and the record will be highly valued.

All who are interested in Stokes and his work, in other words, the whole company of followers of physical science, will feel a deep debt of gratitude to Prof. Larmor for the devoted labour which he has expended on this memorial of his great predecessor. It appears, indeed, that our obligations to him are not yet exhausted. The reader of this notice will have remarked the absence of all reference to the relations between Stokes and Lord Kelvin. We are told that this long scientific friendship is to be commemorated by a special volume of correspondence. There can be no question as to the propriety of this arrangement, and the volume will be looked for with the liveliest interest.

HORACE LAMB.

FIVE SMALL GEOGRAPHIES.

Our Own Islands. By H. J. Mackinder. Pp. xv+298. (London: George Philip and Son, Ltd., n.d.) Price 2s. 6d.

The Oxford Geographies. Vol. I. The Preliminary Geography. By A. J. Herbertson. Pp. viii+149. (Oxford: Clarendon Press, 1906.) Price 1s. 6d.

The Oxford Geographies. Vol. III. The Senior Geography. By A. J. Herbertson and F. D. Herbertson. Pp. viii+363. (Oxford: Clarendon Press, 1907.) Price 2s. 6d.

The Dominion of Man. By Ernest Protheroe. Pp. xii+215. (London: Methuen and Co., n.d.) Price 2s.

Notes upon the Island of Dominica (British West Indies). By Symington Grieve. Pp. 126. (London: A. and C. Black, 1906.) Price 2s. 6d. net.

ALTHOUGH no close comparison can be made between the two elementary reading-books in geography which Mr. Mackinder and Dr. Herbertson have given us, since the former deals with the British Isles and the latter with the whole world, yet we may note certain similarities of method. Both build up their descriptions about an imaginary journey from place to place; both endeavour to present physical and industrial geography as cause and effect; both largely use diagram-maps, partly to supplement the atlas, partly to stimulate the use of it; and both adopt, to some extent, the method of "teaching by question." While this last innovation is a step in the right direction, it is but a hesitating step. The full advantage of this method cannot be obtained by occasional interpolations of questions or suggestions for map-study amid the descriptive matter. Such interruptions are apt to be shelved until a more convenient season that may never come.

Mr. Mackinder's book is arranged on a progressive plan. While map scales and directions are taken at the outset, contour-lines are not explained until half-way through the book. Description starts with the north of England, the uplands and lowlands of which present an easy contrast. Scotland follows, then Ireland, Wales, and finally the Midlands and south and east of England. Simply and lucidly written, with many views and maps, it is a most readable book. We must, however, object to county-towns being called "capitals" (p. 143), to the coupling of Shropshire (strictly Shrewsburyshire) with Berkshire as a county name not derived from a town (p. 263), and to the printing of Macaulay's magnificent Armada lines cut in halves (p. 275).

Dr. Herbertson is unconventional in the order in which he takes the continents, starting with the Americas, because their physical and climatic conditions lend themselves best to simple generalisations, and they thus serve as a type with which Asia, Australia, Africa, and Europe are in turn contrasted. The immensity of the subject-matter renders occasional "scrappiness" of treatment inevitable, though in general this has been very successfully avoided, and attention concentrated on broad general features and contrasts. Altogether, it is a refreshing change from the old-fashioned dry text-books, but it needs supplementing with views to enable the child to realise the scenes described.

Both books have suffered a little from the troubles incidental to process-illustrations. The hemispheres on p. 3 of the "Preliminary Geography" are not all printed the right way up (this should have been avoided by processing them in pairs, instead of singly); and a phantom coalfield appears in Cheshire in Fig. 37 of "Our Own Islands."

By dividing the world into natural regions and showing how political divisions are related to these, Dr. and Mrs. Herbertson have produced an altogether admirable book. Particularly to be noticed is the treatment of the Alps as a whole, and the historical development of the Central European States in relation to them. There are only two small matters on which it occurs to us that the student needs further enlightenment—viz., the use of *Mont* for the names of passes as well as of peaks in the Western Alps (it is a common mistake to cite Mt. Cenis as a peak), and the misleading name of the first Alpine railway tunnel, taken from the Mt. Cenis carriage-route which it superseded. The historical summaries given for each country are very well done. We have noticed very few mistakes. *West* Indies, on p. 105, should surely be *East*; William the Conqueror did not march down stream from Wallingford (p. 142); and the statement on p. 68 as to the origin of Boulder-clay is rather dogmatic for so disputed a subject. It is difficult to be consistent in the spelling of European place-names, but to us at least *Luzern* looks as out-of-place in an English sentence as would Torino or Firenze. These are trivial criticisms on a book the reading of which has given us a great amount of pleasure, and which should become the standard geography for schools.

Mr. Protheroe has produced a well-arranged treatise on the commercial products of all parts of the world, on communications, towns and markets. His enthusiasm for civilisation and progress gives his style a floweriness which is occasionally overdone, but his book is very readable. It is illustrated by a well-chosen series of photographs, and while not exactly a school-book, should be very useful to teachers of geography and to those numerous persons who wish to make good the deficiencies in their knowledge of commercial geography. We have noticed a few errors, the worst being the derivation of Portland cement from Portland stone (p. 94).

Mr. Symington Grieve recently paid a visit of investigation to Dominica, in the Lesser Antilles, and now gives an interesting account of the island, its natural productions and people, illustrated by photographs taken on his expedition. To anyone intending to visit the island, whether as tourist, naturalist, or trader, the book may be recommended as an excellent guide.

A. M. D.

SOME ASPECTS OF HUMANISM.

(1) *Studies in Humanism.* By Dr. F. C. S. Schiller. Pp. xvii+492. (London: Macmillan and Co., Ltd., 1907.) Price 10s. net.

(2) *Lectures on Humanism.* By Prof. J. S. Mackenzie. (The Ethical Library.) Pp. vii+243. (London: Swan Sonnenschein and Co., Ltd., 1907.) Price 4s. 6d.

(1) LIKE the youth in "Excelsior," Mr. Schiller has a strange device upon his banner, for his motto is "Back to Protagoras." But it is on no solitary or hopeless enterprise that he is engaged, for do not all the most fruitful developments of present-day philosophy point to Pragmatism, and have not all the sages of all times, when they were talking sense, been talking Pragmatism without knowing it? Kant, of course, was of us when he gave primacy to the practical reason and when he announced as his main principle that reality is largely of our making. Even Plato, who here suffers many hard knocks, is perhaps not so complete an intellectualist as he is generally thought, if Prof. Stewart's theory can be substantiated,

"that the so-called Socratic dialogues, so far from being scientifically negligible, are really essential to the complete statement of the Ideal Theory, and should be taken as exemplifying *the function of the Concept in use*, and as supplementing the account of the *abstract* concept given in the dogmatic dialogues, on which alone the traditional descriptions of Platonism have been based."

But after all it is to the strangely misunderstood Protagoras, and his principle that man is the measure of all things, that the world owes most. If only we had his complete works and not fragments—and not Plato's caricature of his philosophy! Then many things would have happened; among others we should not have had the amusing dialogues (containing a prophetic reference to the scholars from Rhodes) which Mr. Schiller has "translated from the Greek" to fill up the gaps in our knowledge.

So it is Intellectualism in all its forms, Platonism, Hegelianism, and that tyrant who has oppressed us so many years—Absolutism—that Mr. Schiller wishes to dethrone. His criticism is always well worth reading. On the other hand, his own system contains not a few features which will give many pause—a God who is essentially finite; a reality which is always incomplete and plastic, in which laws of nature are merely the habits in which things behave; an idea of truth which involves the almost hylozoistic position that inanimate bodies *know* us in some sense (on the level of their understanding) when we operate upon them. The dust of controversy which in this volume beclouds the battlefield will have to settle before it can be decided where most of the truth lies. One wonders—it is genuine Pragmatism to know results before one states principles—what the issue will be; whether the lively Troglodyte of three decades from this will be engaged in proving that new Humanism is but old Absolutism grown more dogmatic and arrogant, or the neo-Absolutist of the period in demonstrating that Absolutism and Humanism are both partial aspects reconciled in a higher unity.

About half the essays contained in this volume have already appeared in a shorter form in various periodicals. But most of the constructive part is new, and the work does not suffer from the manifoldness of the relations in which Humanism is regarded. Certainly, if to be incisive is to be convincing, Mr. Schiller has proved his case.

(2) This volume, containing the Dunkin lectures on sociology, delivered last year at Manchester College, Oxford, runs on very different lines from Mr. Schiller's. No doubt there is the same effort to show how much of Humanism lies implicit in a large range of philosophic works; but as it does not seek to prove a thesis, this book is not written with the same verve and passion. We have sober grey in grey, and never an attempt to bring out violent contrasts. Naturally, Mr. Schiller's Humanism is for Mr. Mackenzie only Pragmatism, but in the few paragraphs devoted to it it receives only reasonable criticism.

Prof. Mackenzie's own Humanism is described as "a point of view from which human life is regarded as an independent centre of interest"—as contrasted with a Naturalism and Supernaturalism which seek the explanation of human life either in the forces around man or in some powers distinct from man and those forces.

In the light of that description the influence of Humanism in philosophy, politics, economics, education, and religion is studied, and the two closing chapters examine the limitations and implications of Humanism. Prof. Mackenzie fears that the style of treatment may be regarded as sketchy; sketchy it is, and the title of the volume perhaps induces expectations that are not realised; but undeniably the work has substantial merits.

OUR BOOK SHELF.

Euclid's Parallel Postulate: its Nature, Validity, and Place in Geometrical Systems. By Dr. J. W. Withers. Pp. x+192. (Chicago: Open Court Publishing Co.; London: Kegan Paul and Co., Ltd., 1905.) Price 4s. 6d. net.

This is a philosophical thesis by a writer who is really familiar with the subject of non-Euclidean geometry, and as such it is well worth reading. The first three chapters are historical; the remaining three deal with the psychological and metaphysical aspects of the problem; finally, there is a bibliography of fifteen pages. Mr. Withers's critique, on the whole, is quite sound, although there are a few passages either vague or disputable. For instance (pp. 80–1): "Had man's spatial experience been confined to vision alone, the struggle between Euclid and Lobatchewsky could never have been, since for vision alone there are no such things as parallel lines." This is not convincing, and the sentence that follows does not add to the force of the argument. As a matter of fact, lines that we see apparently change their inclination as we change our point of view, and diverging lines looked at in a proper direction might very well arouse the concept of parallel lines. And however freely we admit the part taken by sensation in the development of geometrical ideas, we are compelled in the last resort to see that the science of geometry is the result of a free intellectual construction. Naturally we choose a scheme that with the simplest assumptions harmonises with the greatest number of facts; this is the reason why Euclidean geometry is that of common life. As Mr. Withers points out, there is very little chance of any change in this respect; for if a series of careful experiments upon the stars were to lead to triangles with the sum of their angles different from 180°, we should be more likely to give up the hypothesis of the strictly rectilinear propagation of light than to adopt a non-Euclidean geometry as that of "actual space." On the other hand, we may some time gain experience of a new kind, presenting itself as spatial, and requiring us to assume more than three dimensions in space.

Mr. Withers sensibly steers a middle course between the extremes of pure empiricism and the *a priori* hypothesis. That we cannot form any clear conception of four-dimensional space to which three-dimensional space is related in a manner strictly analogous to that in which a line is related to a plane in which it lies, shows clearly enough that we cannot do without experience; on the other hand, the definition of a surface as a boundary between two adjacent portions of space involves a concept which cannot possibly be deduced from sense-experience, and the recent theory of sets of points gives still more striking examples. Mr. Withers's main contention is that Euclid's parallel postulate is empirical, and this may be admitted in the sense that his argument requires; at any rate, he shows the absurdity of some statements of the *à priori* school.

Die Reizleitungsvorgänge bei den Pflanzen. By Dr. H. Fitting. Pp. xv+157. (Wiesbaden: J. F. Bergmann, 1907.) Price 3.60 marks.

ALTHOUGH the phenomena of irritability in plants are in a general way easily demonstrated, their elucidation is a matter of extreme difficulty, and in spite of the numerous original experiments that have been devised, absolute proof in support of the explanations offered is rarely possible. A notable instance is furnished by the debated question whether the perception of the stimulus of gravity is localised in the tip of the root. The experiments advanced by Charles Darwin in favour of this view were speedily disputed; Czapek's ingenious glass-shoe experiments, although widely accepted as proof, have been adversely criticised, and now more definite proof is hoped to be obtainable by growing seedlings on a rapidly revolving klinostat in such a position that the tip and growing region situated on different sides of the centre of rotation are subjected to centrifugal force acting in opposite directions. The debatable character of the arguments is one hindrance to a study of the subject, to which is added the difficulty of obtaining the literature, scattered as it is through numerous journals and pamphlets.

Dr. Fitting's monograph helps but little in the matter of literature, as in many cases space does not even permit of stating the arguments put forward by investigators, but as a critical guide to the estimation of the various theories his book will be found very useful.

The book consists of three portions, dealing with the occurrence of the phenomena, the path of transmission of the stimulus, and the manner in which it is transmitted. Owing to the absence of descriptions, the first part is only suitable to the reader who has a full acquaintance with the subject or is prepared to look up the literature. The discussions of the various paths by which the stimulus may travel and of the mechanism involved are the most instructive parts of the book, and particular interest attaches to the sections on protoplasmic communications, on the fibrillar structure in cells of the root-apex, and on the electrical phenomena connected with stimulation. Dr. Fitting has himself added materially to the facts of irritability phenomena and their interpretation, so that his opinions are extremely valuable, the more so because he is a searching but unbiased critic.

Birds and their Nests and Eggs found in and near Great Towns. By G. H. Vos. Pp. xii+148; illustrated. (London: G. Routledge and Sons, Ltd., n.d.) Price 1s.

To take birds' nests and their contents with the camera is in every way a more satisfactory proceeding than egg-collecting, and if the author of this little volume succeed in aiding the new movement he ought to obtain the gratitude of all bird-lovers—not to mention the birds themselves. Two things are essential in this pursuit: first, the capacity of "spotting" nests, which seems to be an inborn art, incapable of being acquired otherwise, and, secondly, skill in manipulating the camera. In the latter accomplishment the author excels, but for the former he has had to depend on a friend; and the combination of forces has produced most satisfactory results.

The numerous photographs of nests and eggs in their natural sites are all that can be desired, and as regards these no encomiums are too high. We wish we could say the same with regard to the photographs of the parent birds, which, we are told, are taken from "characteristically stuffed typical individuals placed in natural surroundings, illustrating as nearly as possible the conditions under which they were observed." In our opinion these "faked" photographs are thoroughly unsatisfactory, the birds being obviously stuffed (whether "characteristically," in the sense in which the author evidently uses the term, or otherwise), and appearing ill at ease in their pseudo-natural surroundings. The book would be far better without them. As the nests, which include those of a considerable number of species, were all observed within a radius of sixteen miles from the City, beginners whose homes are in large towns need not be deterred by lack of material from following in the footsteps of the author, to whom amateur photographers in general are indebted for showing how much can be done at a comparatively small expenditure of time and money.

R. L.

Kinship Organisations and Group Marriage in Australia. By Northcote W. Thomas. Pp. xvi+164. (Cambridge: University Press, 1906.) Price 6s. net.

MR. THOMAS has digested everything that has been written on the Australian natives. In this volume he gives us a very useful *résumé* of all the facts of their complex social organisation, separating the attested from the doubtful—a much-needed piece of work. The account is interwoven with Mr. Lang's theory of Australian kinship and marriage evolution, perhaps the most plausible hitherto advanced, though in the matter of totemic origins it may encounter opposition. Mr. Thomas suggests some real improvements in terminology—matrilocal instead of *beena*, matrilinear and patrilinear, matripotestal and patripotestal—these should be generally adopted, as no doubt they will. The author seems to be at his best in the discussion of such a vexed question as group marriage; the argument is closely reasoned, and brings out several new points. There is an excellent index. The book will be indispensable to anthropologists, and sociologists generally will find it an admirable and convenient text-book for the study of the beginnings of social organisation.

A. E. CRAWLEY.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Absorption of the Air for Light of Short Wave-lengths.

IN his well-known work on the absorption of the air for light of very short wave-lengths, Schumann has concluded that the opacity is due to oxygen, and that this gas, in thickness of a few millimetres, absorbs *completely* all wave-lengths shorter than about 1800 tenth-metres.

I have recently been investigating the question of gas absorption in this region by means of the vacuum spectroscope which I employed in measuring the lines in the spectrum of hydrogen.

In part my results agree with those of Schumann, for I find that hydrogen, nitrogen, helium, and argon are all quite transparent to very short wave-lengths. In one very important respect, however, I cannot agree with his conclusions, for I find that oxygen is not opaque for *all* wave-lengths below a certain value, but that its absorption is represented by a band with definite limits. With a gas path of nine millimetres and a pressure of one-half an atmosphere, this band extends from 1750 to 1275 tenth-metres.

Though the investigation of the behaviour of oxygen below wave-length 1230 is hindered at present by the opacity of the fluorite windows which enclose the absorption chamber, yet it appears possible that light of even the shortest known wave-lengths may be able to penetrate air paths of more than a centimetre. The application of this result to the behaviour of ether vibrations of extremely high frequency seems important. THEODORE LYMAN.

Jefferson Physical Laboratory, Harvard University, June 21.

The Structure of the Æther.

IN the issue of NATURE of June 13 (p. 150) Dr. C. V. Burton raises an objection, raised elsewhere by Prof. Hicks and Sir Oliver Lodge, to the correlation of the magnetic vector with the velocity of the æther, on the ground that the motion of an observer relative to the æther would alter the relative velocity of the æther, and thus produce a change in the magnetic vector in the direction of the change in the observer's motion.

If it were stated definitely that the magnetic force in the free æther was proportional to the velocity of the æther relative to the observer, the objection would be valid; but this is reading into the scheme of the æther more than can legitimately be done. In the discussion the fact has been apparently overlooked that the correlation of the two vectors extends only to their rates of change in space and time, so that if identified with one another at any one point at any one instant, they will be identical at all points at every instant; otherwise they may differ by any constant, corresponding to a uniform but undetermined constant drift of the æther as a whole, or, what is the same thing, to a uniform unknown velocity of the observer through the æther.

But it should be noticed that it is not permissible to speak of the velocity of an observer relative to the æther, as though the æther were a material medium *given in advance*. Even if it were possible to isolate a fixed frame of reference in such an æther—which appears questionable in an infinite continuum—there is no physical means of determining the velocity of a system relative to it. The æther, as we know it, is defined by its electromagnetic properties, and one property is that a uniform drift of the æther as a whole has no effect on electromagnetic phenomena. It is known that the correlation between a stationary and a moving system as regards the electrodynamic equations is exact, and not only correct to the second order. The objection to Prof. Larmor's scheme of the æther does not apply if that scheme is stated accurately as follows:—"The propagation of electromagnetic effects through space, relative to a given frame of reference, may be illustrated by the propagation of disturbances in a rotationally elastic medium, it being possible *for a given frame of reference* to construct such a medium, in which the rotational displacement at any point is proportional to the electric force at that point, and the velocity relative to the frame of a point of the medium is proportional to the magnetic force." Since the velocity of a point depends on the frame of reference, it follows that the media constructed for two frames of reference moving relatively to one another with constant velocity will not be identical. The æther is, in fact, not a medium with an objective reality, but a mental image which is only unique under certain limitations (*cf.* footnote, p. 334, "Æther and Matter"). Two frames of reference imply two æthers; so long as we restrict ourselves to a single frame, the objection to Larmor's scheme does not arise. E. CUNNINGHAM.

St. John's College, Cambridge, June 28.

Root Action and Bacteria.

I DO not think that there is necessarily any antagonism between the interesting results which Dr. E. J. Russell has for some time past been obtaining and our observations on the behaviour of trees in heated soil. His deal with the growth of plants, ours with the passage of the plant from the dormant to the active condition, a process analogous to that of germination. Nevertheless, it must be freely acknowledged that, until further work on the subject has been done, the view that bacteria are concerned in the matter is a mere suggestion, and Dr. Russell's opinion that the results may be the consequence of chemical changes produced by the heating is somewhat strengthened by the fact that the soil used was poor in lime, containing only about 1 per cent. CaO. There is, however, one strong objection to accepting an explanation based on chemical change, for two of the nine trees, as I mentioned, behaved exceptionally, and showed practically no retardation in starting. These were two which had been planted in earth heated to the highest temperature, 250°, and were two out of three planted in the same batch of heated earth. It seems impossible to explain these two exceptions if the general results are due to chemical change, but they are easily explained if these results are due to bacterial action, for re-inoculation of the soil might readily occur in one case and not in another.

It may be added that, so far, the trees are behaving normally as to their growth, now that they have once started. SPENCER PICKERING.

I HAVE always carefully looked for, but never found, any retardation of germination in our experiments. The young plants all come up at about the same time, and make equal progress for some weeks; then the plants on the heated soil take on a greener colour, become larger in the leaf and thicker in the stem, and ultimately make about 100 per cent. more dry matter than the control plants in unheated soil. There is no doubt, I think, that bacterial action is involved, because the yield is depressed when I inoculate the heated soils either by watering with unsterilised well water or by adding small quantities of unheated soil. A chemical change in the soil compounds must also be involved, because of the increased "availability" of the nitrogen and phosphorus compounds indicated by the analyses quoted in my earlier letter. All non-leguminous plants we have tried so far have shown similar behaviour.

It is, I think, quite possible to explain Mr. Pickering's results on a chemical hypothesis. In certain circumstances—deficiency of lime among others—organic substances which retard germination and growth may be formed in the soil; in other circumstances, *e.g.* admission of air, they are decomposed by soil organisms. If we assume that some of these substances were formed during the heating of Mr. Pickering's soil, and further assume, with him, that in two pots re-inoculation took place, the poisonous bodies would be destroyed and growth would no longer be inhibited. These assumptions are all based on well-known facts; on this view a soil rich in calcium carbonate should behave as our soils have done and cause no retardation.

However, as Mr. Pickering says, more work is wanted before we can get much further. In the meantime, he has established the very important point that growth may be retarded in a heated soil, and the further development of his experiments will be awaited with much interest.

EDWARD J. RUSSELL.

THE SHAPE OF THE EARTH.[1]

THE most promising suggestion towards a dynamical explanation of the distribution of land and water on the surface of the globe is to be found in the theory of gravitational instability propounded by Jeans in 1903. There is always a tendency in gravitating matter, if homogeneous, to condense towards a centre, or towards an axis, or in some more complex fashion. If the matter is heterogeneous, there is always a tendency for the density to increase where it is above the average and to diminish where it is below the average. Such changes of density imply compression of the material, and they are resisted by the elastic force with which the material resists compression. In the case of a planet we may ask two questions: How small must the resistance to compression be in order that sensible condensations may take place? In respect of what changes of density can instability manifest itself? The answers depend greatly upon the size and mass of the planet, and they depend also upon its constitution.

Whatever the internal constitution of a planet may be, it is certain that, owing to the mutual gravitation of its parts, great stresses will be developed within it. A direct method of attacking the problem of gravitational instability for a planet in such a state of stress was proposed by Lord Rayleigh in 1906. The development of this method leads to the result that a homogeneous spherical planet, of the same size and mass as the earth, could not exist unless the resistance to compression of the material of which it is composed were at least half as great as that of steel. If the resistance were less than a quarter of that of steel (so that the substance was less compressible than mercury but more compressible than glass) such a planetary body would be unstable, both as regards concentration of mass towards the centre and also as regards displacements by which the density is increased in one hemisphere and diminished in the opposite hemisphere. No matter how small the resistance to compression might be, the body would not be unstable as regards any other type of displacements. If the resistance to compression were small enough for a spherically symmetrical state of aggregation to be unstable, the density of the superficial portions would be less than the mean density, and the centre of gravity would not coincide with the centre of figure. If the planet were at rest under no external forces, a shallow ocean resting upon it would be drawn permanently towards the side nearer the centre of gravity, so that there would be a land hemisphere and a water hemisphere.

The average resistance to compression of the materials of which the earth is composed can be deduced from the observed velocity of propagation of earthquake shocks, and it is found to be decidedly greater than that of any known material at the surface—a result clearly associated with the increase of resistance under great pressure. There is, therefore, no tendency to gravitational instability at the present time; but the actual excess of the mean density over the density of surface rocks, and the fact that a very large proportion of the land lies within a great circle having its centre in south-eastern Europe, suggest that the resistance to compression was once much smaller than it is now. This suggestion offers a possible dynamical explanation of the fact that the centre of gravity does not coincide with the centre of figure, and the maintenance of the Pacific Ocean on one side of the globe is due to the eccentric position of the centre of gravity.

The actual shape of the lithosphere, or rocky nucleus of the earth, and its situation relative to the geoid, or the equipotential surface which coincides with the surface of the ocean, are due to many causes, of which the eccentric position of the centre of gravity is one. Other important causes are the rotation and the attraction of the moon. The moon was once very near the earth, and the day and the month were once nearly equal. The earth was then drawn out towards the moon nearly into the form of an ellipsoid with three unequal axes. The direct result of the rotation and the attraction of the moon would be to give to the lithosphere the shape of an ellipsoid differing slightly from the ellipsoidal figure of the geoid. If the centre of gravity coincided with the centre of figure, the lithosphere would protrude from the geoid near the North and South Poles and in two equatorial regions at the opposite ends of the longest equatorial diameter of the lithosphere. If the density were in excess on one side of a diametral plane and in defect on the opposite side, the effects of the rotation, and of those irregularities of attraction which are due to the ellipsoidal figure, would be greater where the density was greater, and the surface of the lithosphere would consequently be deformed in such a way that the deviation from the ellipsoidal figure could be expressed mathematically by means of a spherical surface harmonic of the third degree. The ellipsoidal deviations from sphericity are expressed by harmonics of the second degree, and the eccentric position of the centre of gravity is equivalent to a deviation from symmetry expressed by harmonics of the first degree. We can therefore account theoretically for the presence of harmonics of these three degrees in the formula for the shape of the lithosphere and its situation relative to the geoid.

Now it is known that the actual contour-line at mean-sphere-level (1400 fathoms below sea-level) divides the surface of the globe into two regions of equal area—the continental block and the oceanic region. The continental block is practically continuous, and there are two great ocean basins, one containing the deep parts of the Atlantic and Indian Oceans, and the other the deep part of the Pacific Ocean. A spherical harmonic analysis of the distribution of land and water, account being taken of the submerged portions of the continental block, yields the result that the actual outlines of the great ocean basins at mean-sphere-level coincide very approximately with one of the contour-lines of a certain spherical harmonic containing terms of the first, second, and third degrees, but no terms of any higher degree.

It appears, therefore, that the shapes and relative situations of the great ocean basins, and their positions relative to the polar axis, can be described, at least approximately, in the statement that the lithosphere is an ellipsoid with three unequal axes, having its surface deformed according to the formula for a certain spherical harmonic of the third degree, and displaced as a whole relatively to the geoid in the direction towards south-eastern Europe. The displacement of the surface as a whole is accounted for by the eccentric position of the centre of gravity, and this eccentric position can be regarded as a survival from a past state in which the resistance to compression was too small for a spherically symmetrical configuration to be stable. The ellipsoidal figure is accounted for partly by the rotation and partly as a survival from a past state brought about by the attraction of the moon at the time when the day and the month were nearly equal. The deformation of the ellipsoid according to the formula for a spherical harmonic of the third degree is accounted

[1] Based upon a paper on "The Gravitational Stability of the Earth," by rof. A. E. H. Love, F.R.S., read before the Royal Society on March 14.

for as being due to the interaction of the two causes which gave rise to the ellipsoidal figure and to the eccentric position of the centre of gravity. The main features of the existing division of the surface into continental and oceanic regions can thus be traced to the operation of simple dynamical laws.

PRESENTATION OF THE FREEDOM OF THE CITY OF LONDON TO LORD LISTER.

IN honouring Lord Lister on June 28, the City of London acknowledged the debt humanity owes to the conscientious man of science. Lord Lister was presented with the freedom of the City "in recognition of his eminence as a surgeon, and of the invaluable services rendered to humanity by his discovery of the antiseptic system of treatment in surgery, whereby so great a progress in surgical science has been achieved, so much suffering has been alleviated, and so many valuable lives have been prolonged."

The Lord Mayor attended in state, and among those invited to be present were the President of the Royal College of Physicians, the President of the Royal College of Surgeons, Sir Henry Roscoe and Dr. Charles J. Martin (representing the Lister Institute of Preventive Medicine), Sir F. H. Lovell and Sir P. Manson (representing the London School of Tropical Medicine), Sir Norman Lockyer (representing the British Science Guild), Sir Victor Horsley, Prof. Howard Marsh (University of Cambridge), Dr. L. W. Darra Mair (representing the Chief Medical Officer of the Local Government Board), Sir W. H. Broadbent, Sir William Collins, Sir Frederick Treves, and members of the medical staffs of several of the London hospitals.

Sir Joseph Dimsdale, the City Chamberlain, in admitting Lord Lister to the freedom, remarked :—

A century ago the Corporation of London paid her tribute of honour to the great professions of which Lord Lister is so bright an ornament. In 1803 the Freedom of the City was presented to Dr. Jenner, whose name will ever be associated with the discovery of vaccination, and whose researches superseded the system of inoculation—at that time so successfully and usefully employed to combat the dread disease of small-pox by such men as Dr. Fothergill and Dr. Dimsdale. To-day we meet to do honour to one whose life-long labours mark another epoch in the history of medicine and surgery. During the last half-century the strides made both in medicine and surgery have been little short of marvellous. What was impossible a few years back is now of daily and hourly occurrence. The treatment of disease—the safety in operations—and the careful and tender nursing of the patient are a few of the many developments of our time, and throughout this period Lord Lister has held a foremost place and has been recognised as one of the greatest and most prominent among surgeons. But it is not only as a great surgeon he is known. He is equally a great man of science, and it is by blending his antiseptic treatment with modern surgery that he has made possible so much that has—until lately—been impossible. He stands out as one who has been instrumental in assuaging suffering, lessening disease, and, under God's blessing, prolonging and saving numberless lives. Few are permitted to see the full fruition of their lofty aims and aspirations, but it is with sincere pleasure we greet Lord Lister in this ancient Guildhall, and rejoice to feel that he is able to enjoy the honours conferred upon him by his Sovereign—to be the recipient of universal expressions of esteem and admiration of his work from all seats of learning; while eulogiums from every quarter of the globe proclaim the appreciation the world in general feels for his life-long labours. It remains for posterity fully to gauge and comprehend the magnitude of the legacy he bequeaths to mankind. The City of London—and through her the country—places, I venture to think, the coping stone to-day to the monument of his fame. The citizens, in expressing their deep gratitude for his great services to the human race, ask his acceptance of the highest honour it is in their power to bestow. But while they fully recognise his great work, probably the trait that touches the hearts of his fellow countrymen most is his abnegation of self, and his humble-mindedness, which, amid all his triumphs, recognises that it is under Divine blessing he has achieved so much. Well might Lord Lister in the autumn of his life take to himself the words of Lord Byron :—

> No lengthen'd scroll, no praise-encumbered stone.
> My epitaph shall be my name alone;
> If that with honour fail to crown my clay,
> Oh! may no other fame my deeds repay;
> That, only that, shall single out the spot,
> By that remember'd, or with that forgot.

The name of Lister requires no embellishment, nor is the sculptor's art needed to perpetuate it in posterity. So long as humanity exists, so long as kind and sympathetic hearts beat in the breasts of mankind, so long as the human race is capable of estimating the worth and value of the truly great and good, so long will the name of Lister live, and the memory of him who bears it remain enshrined and held in affectionate reverence by succeeding generations.

Lord Lister in reply said :—

I thank you, Sir Joseph Dimsdale, from the bottom of my heart for your overpoweringly kind words. The work which it has been my great privilege to be engaged in has been its own all-sufficient reward. Perhaps I need not say that I value in the highest degree this, the greatest civic distinction in the world. If it were possible to enhance the honour you have conferred on me to-day this has been done by the extraordinary consideration shown by you, my Lord Mayor, and your Court for my personal convenience. Had it not been for this your extreme kindness it would have been impossible for me in my very infirm state of health to have received your gift here in this historic building.

The 18-carat gold casket in which the freedom was contained bears the following inscription :—

Presented by
The Corporation of the City of London,
with the Freedom of the City,
to the Right Honourable Lord Lister, O.M., M.D., F.R.S., D.C.L., etc.,
in recognition of his eminence as a Surgeon and of the invaluable services rendered to humanity by his discovery of the Antiseptic System of Treatment in Surgery.
Guildhall, E.C., June 28, 1907.

The end panels are decorated with emblems relating to Lord Lister's career, and on the curve of the base a series of figures symbolising scientific research are embossed.

We welcome this well-deserved honour to science, and congratulate Lord Lister upon the latest distinction conferred upon him. Men of science are gratified that the Court of Common Council has shown in such an appropriate way its appreciation of the value of scientific research to the community.

THE EXTENSION OF THE BRITISH MUSEUM.

ON June 27 the King laid the foundation-stone of the new buildings forming an extension of the British Museum. A distinguished company invited to attend the ceremony included Lord Rayleigh, President of the Royal Society, Lord Avebury, Lord Kelvin, Sir John Evans, Sir Henry Howorth, Prof. E. Ray Lankester, Sir Norman Lockyer, and Sir William Ramsay. The Archbishop of Canterbury, as one of the three principal trustees, in his address to the King, detailed the circumstances which had made the extension possible. The origin of the scheme for the extension was described in the address as follows :—

Your Majesty has graciously conferred on the trustees of the British Museum a great honour in being present here this morning to lay the foundation-stone of this, the first block of buildings of the British Museum extension. The scheme of the extension was initiated twelve years ago, when, in 1895, the opportunity presented itself for acquiring from the trustees of the Duke of Bedford's estate the property immediately surrounding the north, east, and west sides of the museum. At that time your Majesty was a trustee of the British Museum, and your Majesty was pleased to take a great personal interest in the negotiations which resulted in securing the property for the purpose of the future enlargement of this great national institution. This property consisted of the sixty-nine houses forming the western side of Montague Street, the southern side of Montague Place (the site on which this present building is being erected), and the eastern side of Bedford Square and Bloomsbury Street, and covering, with their gardens, an area of $5\frac{1}{2}$ acres. The acquisition of this property, added to the existing museum premises, put the trustees in possession of a four-square area of 13 acres, which, when the scheme of the extension shall be fully carried out, will be covered by the galleries of the completed British Museum of the future. In the negotiations for the acquisition of this property the trustees of the Duke of Bedford's estate met the proposals of the trustees of the British Museum in a most liberal spirit; and the purchase was effected without difficulty for the sum of 200,000*l.*, provided by her late Majesty's Government, the Chancellor of the Exchequer then being the late Sir William Vernon Harcourt, himself an elected trustee of the British Museum, who, both on this occasion and on others, manifested his interest in the welfare of the museum by advocating liberal treatment at the hands of the Lords of the Treasury. Five years afterwards, under the will of Mr. Vincent Stuckey Lean, who bequeathed to the trustees of the British Museum the sum of 50,000*l.*, "to appropriate at their discretion to the extension and improvement of the library and reading-room," the trustees received the sum of 45,000*l.*, being the amount bequeathed, less duty. With this sum in their hands, the trustees again approached the Lords of the Treasury and submitted a scheme for erecting the galleries, of which your Majesty is about to lay the foundation-stone, on the site of the houses forming the south side of Montague Place. There were two reasons suggesting the choice of this site. In the first place, the date of the expiration of the leases of the houses was approaching; and, next, the ground on the north side of the British Museum and contiguous to the library was that which could be most conveniently utilised for complying with the wish of Mr. Lean and devoting his bequest "to the extension and improvement of the library and reading-room." The Lords of the Treasury were pleased to give favourable consideration to the trustees' proposal, with the result that, for the purposes of the new building, the sum of 150,000*l.* was scheduled in the Public Buildings Expenses Act of 1903, in augmentation of the 45,000*l.* which passed to the trustees under the Lean bequest.

In the course of his reply to the address, the King said that during the many years that he was a trustee he took the greatest interest in the scheme for extending the Museum, and he was glad that it had been found possible to acquire sufficient adjoining property to allow of a further extension of the buildings in the future.

NOTES.

SIR JOSEPH D. HOOKER, G.C.S.I., F.R.S., celebrated his ninetieth birthday on Sunday, June 30, and received the sincere congratulations of many friends. We are delighted to see that the King marked the occasion by appointing Sir Joseph Hooker to the Order of Merit.

THE long list of honours announced on the occasion of the King's birthday includes the names of a few men of scientific eminence. Prof. E. Ray Lankester, F.R.S., has been appointed a Knight Commander of the Order of the Bath, and Dr. J. A. Ewing, F.R.S., has been appointed a Companion of the same Order. Among the four new peers is Sir James Blyth, Bart., who has rendered signal service to agricultural science, and has placed two farms at the disposal of the Government for the purposes of the investigations undertaken by the Royal Commission on Tuberculosis. With the thirty-one names of new knights are those of Prof. John Rhys, professor of Celtic at Oxford; Dr. J. Donaldson, principal of the University of St. Andrews; Mr. J. Gavey, C.B., engineer-in-chief to the Post Office; and Dr. H. R. Swanzy, president of the Royal College of Surgeons in Ireland, and formerly president of the Ophthalmological Society of the United Kingdom. Sir William MacGregor, K.C.M.G., has been promoted to the rank of G.C.M.G., and Colonel W. G. Morris, C.B., C.M.G., has been promoted to the rank of K.C.M.G. for services as superintendent of the trigonometrical survey of the Transvaal and Orange River Colonies.

MR. W. P. PYCRAFT has been appointed by the principal trustees an assistant on the permanent staff of the zoological department of the British Museum.

THE Anthropological Institute has received the King's permission to change its title to that of the Royal Anthropological Institute of Great Britain and Ireland, by which name it will henceforth be known.

SOON after 9 a.m. on June 26 Holyhead and other places in the western part of the Isle of Anglesea experienced an earthquake shock which greatly alarmed the inhabitants, and in some instances threw down pictures and crockery. The shock was accompanied by a noise like thunder, which lasted about twenty seconds. The vibration is stated to have come from the north-east.

THE council of the Royal Society of Edinburgh has awarded the Keith prize for the biennial period 1903–5 to Dr. Thomas H. Bryce for his two papers on "The Histology of the Blood of the Larva of *Lepidosiren paradoxa*," published in the Transactions of the society; and the Makdougall-Brisbane prize for the biennial period 1904–6 to Dr. Jacob E. Halm for his two papers on "Spectroscopic Observations of the Rotation of the Sun" and "Some further Results obtained with the Spectroheliometer," and for other astronomical and mathematical papers published in the Transactions and Proceedings of the society.

THE Lord Mayor presided over a meeting convened by the Bread and Food Reform League at the Mansion House on June 26. This league is organised to direct attention to the great importance of the food question, to promote the healthy nutrition of the people, and to diminish many of the diseases produced by ignorance of dietetic laws. Without advocating any special system of diet, it is desired to show the nutritive and economic importance of many neglected foods of staple value. It is believed that proper knowledge of the food value of various diets will promote health and temperance, and diminish the fearful infant mortality that exists at the present time. The meeting was addressed by the Lord Mayor, Miss May Yates (the hon. secretary of the league), Sir James Crichton-Browne, Dr. Heron, Dr. J. F. Sykes, Mr. Mayo Robson, and others.

IN reply to a question asked in the House of Commons on Monday, Mr. Haldane stated that the names of the members of Lord Rayleigh's committee now considering questions arising out of defective cordite are as follows:—

Lord Rayleigh, F.R.S., Sir J. Dewar, F.R.S., Sir A. Noble, Bart., F.R.S., Sir W. Crookes, F.R.S., Dr. J. A. Ewing, F.R.S., Dr. A. Dupré, F.R.S.—absent through illness; Major-General D. D. T. O'Callaghan, president, Ordnance Committee; Rear-Admiral R. F. O. Foote, vice-president, Ordnance Committee; Lieut.-Colonel Sir F. L. Nathan, superintendent, Royal Gunpowder Factory; Captain B. H. Chevallier, assistant to Director Naval Ordnance; Captain J. H. Thomson and Major A. McN. C. Cooper Key, H.M. Inspectors of Explosives, Home Office; and Mr. R. Robertson, superintendent in Chemist Research Department.

THE New Zealand Government is about to undertake extensive trawling of an experimental nature. Mr. L. F. Ayson, Chief Inspector of Fisheries, will be in charge, and Mr. Edgar R. Waite, curator of the Canterbury Museum, Christchurch, has been appointed zoologist to the expedition. Collections will be made of all marine products, which will be investigated, so far as possible, by New Zealand naturalists, and the material obtained will be the property of the Canterbury Museum. The committee for biological and hydrographical study of the New Zealand coast, appointed by the Australasian Association for Advancement of Science, will provide certain equipment for use in the deeper waters. The *Nora Nevin*, a new steam trawler just from the stocks at Grimsby, England, built to the order of the Napier (N.Z.) Fish Supply Co., has been chartered by the New Zealand Government, and it is anticipated that operations will extend over a period of three months.

THE annual general meeting of the Society of Arts, the 153rd since the foundation of the society, was held on June 26, Sir Steuart Colvin Bayley, K.C.S.I., C.I.E., chairman of the council, being in the chair. The Prince of Wales was re-elected president of the society, an office which he has filled since 1901. It was announced that a committee has been appointed to make further investigation into the subject of the deterioration of paper, on which subject a committee reported in 1898. The council of the society is prepared to award, under the Fothergill trust, a gold medal, or a prize of 20*l*., for the best portable apparatus or appliance for enabling men to undertake rescue work in mines or other places where the air is noxious. Inventors intending to compete should send in a notice of their intention, together with a full description of their inventions, not later than March 31, 1908, to the secretary of the Society of Arts, John Street, Adelphi, London, W.C.

WE regret to see the announcement of the death, on June 28, at the age of eighty-two, of Sir William T. Gairdner, K.C.B., F.R.S., formerly professor of medicine in the University of Glasgow. Sir William Gairdner graduated as M.D. at the University of Edinburgh in 1845. He made numerous contributions to the science of medicine, more especially in the departments of pathology, public health and hygiene, and clinical medicine. He was recognised as one of the foremost physicians of his time, and his status in the medical profession is indicated by the fact that he was president of the British Medical Association in 1888. For several years he acted as the first medical officer of health for the City of Glasgow, and the measures he then initiated for securing the health of the community soon materially lowered the death-rate of the city, and have been adopted largely at home and abroad. Sir William Gairdner was appointed K.C.B. in 1889, and was elected a Fellow of the Royal Society in 1893. Among other distinctions, he received the degree of LL.D. Edin. in 1883, and that of M.D. Dublin (*honoris causa*), with the honorary Fellowship of the Royal College of Physicians of Ireland, in 1887. His principal works were "Clinical Medicine," 1862; "Public Health in Relation to Air and Water," 1862; "On some Modern Aspects of Insanity," "Lectures to Practitioners" (jointly with Dr. J. Coats), 1888; "The Physician as a Naturalist," 1888; and many papers in medical journals and in the transactions of pathological and medical societies.

THE death of Dr. Carl Braun, S.J., which we regret to have to announce, recalls the earnest efforts that Hungary has made of late years to assume a more prominent position in astronomical science. The late Archbishop of Kalocsa, who provided and equipped the observatory of that town, placed it under the charge of Dr. Braun, and here he worked indefatigably in those preliminary matters which are so necessary in a young institution. He mounted the instruments, determined the position of the observatory, and decided the course of future observation, which under Father Fenyi has been productive of such fruitful results. As a pupil of Secchi, he naturally turned to spectroscopic observation of the sun, and in this department the work of the observatory is well known. Such questions as the density of the earth also occupied him, and in the later years of his life he contributed papers on cosmogony. Indeed, his activity ranged over many subjects, and though he suffered much in the later years of his life, his colleagues speak of his untiring industry and continued perseverance. Dr. Braun was possessed of great mechanical ingenuity. This was manifested in the construction of, or rather suggestion for, a form of transit micrometer that reduced personal equation to a minimum, and of a plan for photographing the sun by monochromatic light, forestalling by many years the work of Hale and Deslandres.

THE annual meeting of the general committee of the Imperial Cancer Research Fund was held on Monday at Marlborough House, the Prince of Wales presiding. In moving the adoption of the report, Sir William Church said:—Our knowledge of the existence and frequency of cancer in various races of men is steadily increasing, and evidence is accumulating that its presence is not infrequently associated with native customs or religious rites which act as sources of chronic irritation of portions of the surface of the body and appear to determine the character and position of the cancerous growths most commonly met with. The information we have received lends no support to the view that cancer is associated with any particular kind of diet; populations living on a purely vegetable diet are apparently as subject to it as those whose food is of a mixed character. Resort to experiment must be had in order to trace more accurately the circumstances associated with the spontaneous occurrence of cancer both in individuals and in families. The removal by surgical means of cancerous tumours occurring spontaneously in mice prolongs their lives and has enabled us to breed from them; we have, therefore, now the means of observing descendants of mice of known cancerous parentage, and by successively crossing other spontaneously affected animals with the offspring of cancerous parents, we can concentrate the hereditary tendency, if it exists. This concentration in large numbers of animals of a known age and in a known amount should enable us, in the course of a few years, to determine whether there is a family or only an individual tendency to the disease. Other experimental investigations have been carried on; in former years we endeavoured by experiment to find out the essential features of cancer; during the past year we have been engaged in studying special problems, and more especially the relations of cancer-cells to those of the organism in which they occur. Considerable attention has been paid during the past year to the alleged cures for cancer which have come before us. I regret to say that it is impossible to ascribe a curative value to any of them. A further series of experiments with trypsin alone, or in conjunction with amylopsin or as pancreatic extract, have been made, and it appears in mice to exert no effect on the growth or development of the tumours.

We have received from Mr. Quaritch, of Grafton Street, a copy of the third part of a catalogue of rare and valuable works on natural history. The contents include works on various groups of invertebrates, on palæontology and geology, and on general biological subjects.

Supplemental notes on the mammals and a list of the myriopods of the Forth or Edinburgh area constitute the contents of No. 8 of vol. xvi. of the Proceedings of the Royal Physical Society of Edinburgh, both papers being by Mr. W. Evans. The additions to the mammal list include a bat and the Greenland, or harp, seal, a specimen of the latter having been taken in March, 1903, in the upper estuary of the Forth.

We have received copies of Nos. 1530–6 of the Proceedings of the U.S. National Museum. Among these, reference may be made to reviews of the loaches and sticklebacks of eastern Asia, by Mr. L. Berg (Nos. 1533, 1536), in which it is shown that *Misgurnus fossilis* (loach) and *Cobitis taenia* of the British Isles are represented by specifically identical forms in the Amur. The description of a new genus (Spherarmadillo) of terrestrial isopod crustaceans from Guatemala, by Miss H. Richardson (No. 1535), is also a matter of considerable interest.

In his report for 1906, the director of the Field Museum of Natural History, Chicago (the new title of the Field Columbian Museum), has to deplore the death of its founder, Mr. Marshall Field, which took place during the year under review. Mr. Field, although he held no official post in connection with it, was a constant visitor to the museum, where his commendation was always regarded by the officers as a high honour. In all departments the museum appears to be making steady progress, several new acquisitions and exhibits being illustrated in the report. Among the former, attention is directed to a series of meteorites from a recent fall in Kansas, and to a large number of vertebrate remains from the Loup Fork beds of Nebraska and Wyoming.

In connection with the preceding paragraph, reference may be made to the valuable series of catalogues of mammals compiled by Dr. D. G. Elliot, honorary curator of the zoological department of the Field Museum, Chicago, and published by the museum. While the previous volumes deal with the mammalian faunas of America, the one now before us is a catalogue of the specimens of mammals from all parts of the world in the collection of the Field Museum. Although simply a catalogue, with references to original descriptions, the volume contains a number of excellent illustrations of striking types of mammals, many of which students familiar with the subject will recognise as reproductions from well-known figures. The collection of mammals in the museum, now comprising about 15,000 specimens, has been mainly brought together by the energy of Dr. Elliot, and every specimen, with its full history, is catalogued in the present volume. Whether Dr. Elliot's views or nomenclature be generally accepted in their entirety or no, the work cannot fail to be of great value to naturalists, and the entire series of catalogues forms a monument to the untiring and ceaseless industry and perseverance of the author.

In the Scientific Memoirs of the Government of India, No. 27, Captain Patton, M.B., I.M.S., records the frequent occurrence of the Leishman-Donovan body in the peripheral circulation in cases of kala-azar in Madras, the parasite being seen in the leucocytes but not in the red blood cells nor free in the plasma. In certain cases of the disease, accompanied with extensive ulceration of the large intestine, the polymorphonuclear leucocytes are increased in number, and many of these cells contain the parasite. The parasite was recovered from certain lice allowed to bite patients, but not from several mosquitoes nor from a tick. In the Indian bed-bug (*Cimex macrocephalus*) the parasite was found in considerable numbers, and all stages of development, from the round body to fully developed flagellates, were observed. In Memoir No. 28, Captain Christophers, M.B., I.M.S., describes the sexual cycle of development of the hæmogregarine parasite of the dog, the *Leucocytozoon canis*, in the tick, *R. sanguineus*. Soon after the tick has ingested blood containing the parasites, free vermicules appear; some of these become embedded in the protoplasm of the gut cells and become stouter and more bulky. The bulky forms undergo fission into two, four, or even eight vermicules, some of which are large and sexually mature, conjugate, and form oocysts. The protoplasm of the oocyst then divides into sporozoits, but the means by which these reach and infect the dog have not been made out, as they have not been found in the ova of the tick.

A botanical exploration of the north-western portion of the county of Limerick, comprising the barony of Shanid, undertaken by Messrs. M. C. Knowles and C. G. O'Brien, has yielded several interesting plants and added many new species to the flora of the district. An account of their collections appears in the *Irish Naturalist* (June). Two notable discoveries were the grasses *Glyceria Foucaudi* and *Glyceria Festucaeformis*. A variety of *Rosa stylosa* was found in apparently native surroundings, and the same opinion is expressed with regard to the habitat of *Epilobium angustifolium*.

On the reproduction of trees from seedlings, a problem that offers peculiar difficulties to foresters in a hot, dry climate, several articles appear in the *Indian Forester* (April). The requirements of "sal" seedlings, *Shorea robusta*, with regard to soil, protection from frost and light are discussed by Mr. W. H. Lovegrove and Mr. E. M. Coventry, and Mr. L. S. Osmaston refers to experiments in connection with artificial methods for raising young trees. The discovery noted by Mr. E. P. Stebbing of the coccid *Lecanium capreae* on almond trees in Baluchistan provides the first record for India. A useful summary, by Dr. E. Nesbit, of Indian trees providing timber suitable for export is concluded in this number of the journal.

On the subject of the interrelation between the phases of the moon and the cutting of bamboos and other material, a correspondent writes to say that in Mexico and other American countries the belief is commonly and strongly held that material should be cut when the moon is waning if durability is desired. The statement is advanced on the evidence of an American ranchman, who offers the explanation that at the time of the full moon the bamboos are full of sap, and that the sap rises and falls with the waxing and waning of the moon. As mentioned in a paragraph in NATURE of February 14 (p. 377), Mr. E. P. Stebbing has met with the same belief in India, and refers to experiments made in southern India, but these were inconclusive. Seeing how widely the conviction is spread through the tropics, it would be interesting to obtain more evidence, but such evidence should be based on a systematic and carefully planned series of experiments.

FROM the *Agricultural News* we learn that the cultivation of new seedling sugar canes, as compared with the Bourbon and other varieties hitherto grown in British Guiana and elsewhere in the West Indies, shows considerable progress in recent years. From returns to hand, it appears that 28,801 acres were planted in British Guiana in seedling canes in 1906–7. The area in 1905–6 was 14,743 acres, and in 1904–5 9518 acres. Among the more important seedling varieties are the Demerara seedlings D. 109 and D. 625, while two Barbados seedlings, B. 208 and B. 147, are also largely cultivated. It is pointed out that an editorial note which appeared in the *International Sugar Journal* in May last (pp. 219–220) discussing the "Identity of Seedling Canes in Demerara," and stating that the seedling cane B. 208 cultivated on the well-known Diamond Plantation in Demerara "was not the original seedling of that variety," is without foundation. Samples of B. 208 from Diamond Plantation have since been submitted to a critical examination by the Imperial Department of Agriculture for the West Indies, and it is stated that they are identical with the original seedlings of that variety raised at Barbados.

THE Engineering Standards Committee has issued a new edition of the British Standard Specification for Portland Cement (report No. 12, price 2*s*. 6*d*.). Several alterations have been made with the view of extending the usefulness of the specification. The percentage of sulphuric anhydride has been slightly extended, the expansion under the Le Chatelier test has been reduced, and the maximum final settling time for the slow-setting cement has been increased. Other alterations have been made in the direction of rendering the meaning of the specification more clear.

ONE of the most interesting phases of the development of copper mines caused by the recent great demand for the metal and by the use of electric power has been the profitable mining of ores so poor that formerly they would have been regarded as valueless. A striking example of this is afforded by the mines of the Boundary District, British Columbia, which are described in detail by Mr. F. Keffler in a copiously illustrated article in the *Engineering Review* (vol. xxxiii., No. 3). In the same issue there are well-considered articles on efficiency in the burning of fuel under the steam boiler, by Mr. W. D. Ennis, and on the design of modern producers and gas engines, by Mr. R. E. Mathot.

WITH the *Engineer* of June 21 is issued a special supplement devoted to auxiliary machinery on merchant steamers. It contains seventy illustrations, and shows in a striking manner the remarkable changes that have been effected within recent years. The development of electricity on board ship for power purposes, as well as for lighting; the adoption of the turbine principle of propulsion for cross-Channel and ocean-going passenger steamers; the increase in the number and size of dead-meat carrying steamers; and the radical modifications in the general design and equipment of ships engaged in bulk-cargo carrying, with the view of extreme despatch in loading and discharging—all these are matters which have had distinct influence of late in modifying conventional and standard facilities and practice in respect of steamship auxiliary machinery.

THE *Mitteilungen* of the Berne Philosophical Society for 1906 contain observations of twilight phenomena and of the intensity of the magnificent Alpine glows at that place during the year, by P. Gruner. The glows were more frequent than usual, owing probably to the abnormally fine weather, but the cases of great intensity of colour were below the average. In "The Glaciers of the Alps" Tyndall pointed out that "the colouring must, in a great measure, be due to some variable constituent of the atmosphere"; we are glad, therefore, to learn that the author proposes to discuss the observations published since 1903, after at least a five years' series is available.

THE Egyptian Survey Department has decided to separate the meteorological work into two parts, the first dealing with the observations at Helwan Observatory and the second with the climatological stations, rainfall, and river data. These observations have now been published for 1904, and the reports for 1905–6 are promised shortly. Part ii. contains, in addition to the results of observations at the various stations in Egypt and the Soudan, a sketch of the climate of Egypt condensed from the discussion in "Physiography of the River Nile and its Basin," by Captain H. G. Lyons (see NATURE, vol. lxxv., p. 17). The chief climatological feature of the year 1904 is said to have been the failure of the north-east African monsoon, which was both late and weak. In Egypt itself the noteworthy features were the abnormally cool weather of spring and warm spell in October.

DR. G. PANCONCELLI CALZIA, of Marburg, is publishing in the *Medizinisch-pädagogische Monatsschrift* a summary of current literature on phonetics under the title "Bibliographia Phonetica." As the author points out, it has been necessary for specialists in this subject to consult literature extending over a wide range of other sciences in order to find the papers they want, the only guide in existence being the somewhat incomplete summary of the period 1876–1896 by Breymann. Dr. Calzia desires to receive copies of all papers or books bearing on phonetics for the purpose of abstracting, and rare and valuable books will be returned if desired.

A VERY suggestive article on the progress of our knowledge of the flora of North America is contributed to the *Popular Science Monthly* for June by Prof. L. M. Underwood. It is illustrated by figures reproduced from the early works of Porta (1591), Bock (1587), Cornut (1635), Plukenet, Micheli (1729), and Linnæus (1753). Perhaps the most noteworthy point emphasised in the article is the comparatively recent development of botany as a subject of university study. The late Prof. Asa Gray appears to have maintained a conservative spirit in regard to the study of systematic botany, and to have shown opposition to those who might have helped in the vast field of work required to be done. Thirty years ago America possessed only three professors of botany, and one Government botanist at Washington; now, both in the universities and in the Government stations, the botanists can be counted by hundreds.

UNDER the title "Tablettes des Cotes," M. Gaston Tarry publishes a triple entry table for the purpose of finding the prime factors of large numbers which are not divisible by 2, 3, 5, or 7. For this purpose the number in question is first expressed in the form $m. 20580 \pm (q\ 2 \cdot 10 + r)$. The tables headed with the numbers (Tablettes grillés) have slots cut in them which are placed over the columns headed with the columns r, and by following certain rules according to the sign in the above form, and noticing whether the figures ("cotes") in the subsequent lines of the columns are in dark or light type ("cotes grasses" or "cotes maigres"), it is possible to ascertain which of the prime numbers in the next adjoining column of the open tables are factors of the original number. We have verified the method, but the rules are a little difficult to apply at first. The tables are published by Gauthier-Villars, of Paris.

REFERRING to our note on the scientific uses of the kinematograph (NATURE, May 23, p. 87), Mr. W. F. Cooper, of Water Lane, Watford, writes pointing out the difficulties experienced by amateurs in obtaining sufficiently rapid films for the purposes of research. The fastest films he has been able to obtain have a speed of H. and D. 100, less than half that of ordinary snapshot plates. This speed is quite inadequate for the photography of operations, for in a case observed by Mr. Cooper an exposure of ten minutes would have been required. Mr. Cooper has been successful in recording the movements of blood corpuscle parasites, but the chief obstacle in the way of further progress is lack of general interest in the uses of the kinematograph on the part of scientific workers as opposed to professionals. He invites correspondence with others who have taken up this line of work with the view of producing a demand for films better suited to the purpose in the matter of speed and orthochromatic properties.

A SIMPLE lecture experiment to demonstrate the transformation of yellow phosphorus into the red variety is described by F. Zecchini in the *Gazzetta* (vol. xxxvii., i., p. 422). Ordinary dry phosphorus is melted in a glass tube 30 cm. long and 7–8 mm. in diameter by surrounding the tube with a bath of concentrated sulphuric acid the temperature of which is gradually raised to 180°. Sufficient phosphorus should be used to give about 10 c.c. of liquid. When the whole has melted, a minute crystal of iodine is added; as the crystal falls through the molten mass the immediate transformation of the latter into red phosphorus becomes clearly visible.

MESSRS. R. AND J. BECK, LTD., have published a pamphlet by Captain Owen Wheeler on "Telephotography Simplified for Naval, Military, and General Purposes." The price of the pamphlet is 1*s.* 3*d.*

OUR ASTRONOMICAL COLUMN.

COMET 1907*d* (DANIEL).—The daily ephemeris computed by Dr. E. Strömgren for comet 1907*d* is given up to July 10 in No. 4185 of the *Astronomische Nachrichten* (p. 155, June 21). The following is an extract therefrom:—

Ephemeris 12h. (M.T. Berlin).

1907	α (true) h. m.	δ (true) ° ′	Brightness
July 4	1 4·3	+5 0·0	
,, 6	1 11·2	+5 31·1	1·94
,, 8	1 18·3	+6 2·1	
,, 10	1 25·5	+6 32·9	2·17

An observation at Strassburg on June 17 gave corrections of +4s. and +0′·4, and the magnitude was estimated as 8·5 or 9·0. On that date the brightness, according to the ephemeris, was about 1·1. The apparent path as shown in the above ephemeris lies roughly between 80 and μ Piscium, and the comet now rises shortly after midnight.

PECULIAR SPECTRUM OF ϵ CAPRICORNI.—A note by Mr. V. M. Slipher, of the Lowell Observatory, on the spectrum of ϵ Capricorni (magnitude = 4·5) appears in No. 4, vol. xxv. (p. 285, May), of the *Astrophysical Journal*. Spectrograms taken last autumn showed bright lines, and more recent ones show that the hydrogen lines are paired—a dense dark line with a weak bright line above it. The dark hydrogen and the metallic lines indicate a radial velocity of about 45 kilometres for October 8, but on October 27 this had decreased to 35 kilometres, the lines being displaced towards the red. Broad and diffuse helium absorption lines are also shown, but do not participate in the displacement towards the red; in fact, measures of some of the sharper ones show a slight "shift" towards the violet, and it therefore seems possible that these, with the bright hydrogen lines, belong to one member of the system, whilst the dark hydrogen and the metallic lines belong to the second.

ATMOSPHERIC CURRENTS IN CELESTIAL BODIES.—A paper on the causes which produce different currents in the atmospheres of celestial bodies, such as Jupiter and Saturn, is published by Senor José Comas Solá in No. 4185 (p. 145, June 21) of the *Astronomische Nachrichten*. Senor Solá calls in the tide-raising effects of very small satellites revolving in close proximity to the primary to account for these atmospheric currents. Taking Jupiter as an example, these hypothetical satellites produce an accelerating effect in the superficial layers of the atmosphere near to the equator. The larger, more distant satellites produce a much deeper, retrograde current extending further from the equator, whilst in the circumpolar regions we see the normal rotation of the planet. Thus we get the shortest rotation period in the equatorial currents, and the slowest motion in the intermediate latitudes, where only the retrograding effect of the larger satellites is operating. This superposition of layers may account for the occasional passage of a mass of dark matter below the Red Spot, for, by the hypothesis, the latter, a superficial disturbance, is in the slower moving layer of the intermediate latitude, whilst the dark matter is a much deeper disturbance reaching down to the more quickly moving normal layer of the planet's atmosphere. Similarly, the proximity of rings of ponderable matter to Saturn and the sun may be held to account for the differential velocities observed in different zones of the atmospheres of those bodies.

OBSERVATIONS OF PLANETS.—In an account of the observations made on the summit of Mont Blanc during the period August 31 to September 5, 1906, MM. Hansky and Štefánik give details of their observations of Venus, Mercury, and Jupiter, made under nearly perfect atmospheric conditions. Difference in the markings seen near the poles of Venus and alterations in the contour of the terminator suggested a rotation of the planet, a suggestion which was apparently confirmed by the re-appearance of the same aspects after a lapse of nearly twenty-four hours. The two sets of observations made on September 3 and 4 gave the apparent rotation period as 23h. 20m. and 23h. 25m. respectively. Three dark spots, one at the middle of the terminator and two smaller ones near to the eastern limb of the planet, were seen on Mercury on September 5 at about 5h.

Numerous details of the observations of bands and spots on Jupiter are also given (*Comptes rendus*, No. 23, p. 1252, June 10).

THE MELBOURNE OBSERVATORY.—According to the report of the director, Mr. P. Baracchi, the astronomical work of the Melbourne Observatory for the period April 1, 1905, to November 30, 1906, was practically limited to meridian observations and the work for the Astrographic Catalogue. For the latter, the total number of satisfactory plates obtained was 191, of which ninety-three were triple-exposure chart plates and thirty-two were for the duplicate series of the catalogue; these bring the respective totals up to 588 and 487. The measuring bureau is the joint affair of the New South Wales and Victoria Governments, and the total numbers of plates measured to date are:—for Sydney, 551, containing 322,101 stars; for Melbourne, 836, containing 268,714 stars.

PAWNEE TRADITIONS.[1]

SOME time ago Mr. Dorsey, who is curator of anthropology at the Field Museum of Natural History, Chicago, undertook a series of investigations among the North American tribes of the Caddoan stock, to which the Pawnee among other Indians of the plains belong. The investigations were begun on behalf of the Field Museum, and have been continued for the last four years under the auspices of the Carnegie Institution. Of the results, one volume has been issued by the American Folklore Society, some detached articles have been published in the Journal of the same society and the *American Anthropologist*, and the present is the fourth volume issued by the Carnegie Institution. All materials in volume form are composed of traditional narratives, and it may at once be said that they form an important contribution to our knowledge of the aborigines.

A collection of native tales as extensive as that in the volume before us (it contains 546 quarto pages and 148 tales of varying length) must of necessity reveal incidentally much of native custom and belief. Especially is the religion abundantly illustrated, since many of the stories are connected either with the sacred objects or the sacred ceremonies. They profess to explain the origin of these, and are told, as a rule, only during the ceremonies. Moreover, they afford glimpses of the social organisation of the tribes and of their amusements, as well as of their more serious business of hunting and fighting. Pawnee is a word said to mean wolves, and the Pawnee were as noted for their bravery, their endurance, their skill, their untiring activity and relentless character as the animals the name of which they were proud to bear. Their religion was most actively concerned with the animals with which they came into contact. These animals were supposed to be organised in much the same way as themselves, and such of them as were articles of food were believed to give themselves willingly to mankind, always provided that they were treated with ceremonial respect and that dances and other rites were performed from time to time in their honour. From them and other animals human beings received magical gifts and more than natural powers if they obtained by prayer and fasting the favour of the chiefs of the animal lodges. Above the animals were a number of superior beings called "gods," most of them more or less vaguely conceived. At the head of the pantheon stood Tirawa, a quasi-creator, whose authority all the others acknowledged.

The word "mythology" on the title-page is a somewhat unfortunate choice. On the one hand, we do not get in this volume so complete a view of what may be called the sacred history of the Pawnee, apart from the origin of medicine ceremonies, as in Mr. Dorsey's previous work on the "Traditions of the Skidi Pawnee." On the other hand, many tales are included which can only be called mythology by an illegitimate extension of the meaning of that word. Such tales are not connected with the religion of the tribe, nor are they believed to be true. They are often concerned with the lower animals; and they correspond partly to our fairy-tales and partly to our apologues. Speaking of the stories in general, it may be said that the most superficial reader will at once recognise that in plot and incident they are to a large extent similar to those of the surrounding and allied peoples, are conditioned by their mode of life, and are peculiar to North America. At the same time many of the incidents, and sometimes whole chains of incident, are common to humanity. To mention only a few, we have the incident of the Magical Flight and Pursuit, the Task of Recognition to be performed by a husband who comes to find his bride, the story of Orpheus and Eurydice, the Swan-maiden Bride, the Transformation Fight. In the form in which they are presented they are so thoroughly native to the soil that it cannot be suggested that they are due to European intercourse. But in any case the old wild borrowing theory has long been given up as discredited. While it is admitted on all hands that transmission of stories does take place, students who are interested in the question seek proofs of transmission within saner limits.

[1] "The Pawnee Mythology" Part i., Collected under the Auspices of the Carnegie Institution of Washington. By George A. Dorsey. Pp. 546. (Washington, D.C.: Carnegie Institution, 1906.)

The second part of the work is not yet published. It is intended to include the music and text of the songs referred to, or given only in a free translation, in the present volume. It will also comprise a comparative study of the tales and incidents, in which they will be treated in their relation to "the tales of other tribes of the so-called Caddoan stock," and, indeed, to those of other American Indians. This is a very necessary complement to the author's other investigations. It is to be hoped he will also find opportunity then or very soon for a fuller description of the social organisation, the rites and beliefs of the stock than he has hitherto given. We want to know, for instance, what are the marriage-rules of the tribes, whether descent is traced in the male or the female line, what their clan-organisation is; we want full descriptions of their ceremonies, their taboos, and so forth. As already intimated, something may be gathered from the stories, but our inferences may be right or wrong; we need authoritative statements. Mr. Dorsey is so well qualified by life-long study, and by his eminence among American anthropologists, and he has given us in these collections of Caddoan traditions so much of interest and value, that he will pardon our demanding a key that shall unlock what at present remains closed. Our thanks to him are heartfelt, but they partake very largely of that gratitude which is a sense of (or at least an earnest hope for) favours to come.

E. SIDNEY HARTLAND.

PLANT DISEASES AND REMEDIES.

THE experiment station of the Hawaiian Sugar Planters' Association has issued as Bulletin No. 5[1] a remarkable publication which not only deals in a very comprehensive and thorough way with the fungus enemies of the sugar-cane, but also contains a series of valuable notes on associated insects and nematodes.

The volume has bound with it also Bulletin No. 4 of the same station, and by the same author. This bulletin is on some elements of plant pathology. In the course of the work mention is made of new blights found in the cane-fields of Hawaii, and of the new and threatening aspects of blights already known.

Part i. is introductory, and may be passed over. Part ii. deals with the root disease of sugar-cane. In this section, which covers eighty-five pages, we have a most accurate and interesting description of the strange Ithyphallus fungus, which is one of the causes of root disease. "Time alone can show," Mr. Cobb tells us, "what the relative importance of the Ithyphallus fungus will be among the root-diseases of cane." The serious losses caused by the fungus and its early history are first traced, and then the extraordinary fructifications are detailed and admirably illustrated. Then follows an account of the relations of insects to Ithyphallus. The author tells us that five species of flies, a beetle, and an ant frequent the fresh fructifications, and that some of the flies are so passionately fond of the sticky dark-green spore-mass that they can scarcely be driven away.

Dispersal of this fungus by their agency, especially in the excreta, is proved, and although the flies are not named generically, they were known to be Sarcophagidæ and Muscidæ. The work done in this subject is remarkable. It was shown that the spores are also carried in numbers on the feet. The spores from five of the fly tracks on glass were found to be 860,000 per track. Then follow notes on digestive power of flies, notes on defection (the number of spores found in a "fly-speck" was shown to be 22,400,000 in some instances); even the weight of a fly ration is gone into with wonderful exactness.

The use of lime as a fungicide is pointed out, and methods of cultivation given.

Parts iii. and iv. deal with the leaf-splitting blight and rind disease; the first-named is shown to be due to Mycosphærella. The pine-apple disease (*Thielaviopsis ethaceticus*) and the relation of certain insects and mites to it is detailed, and also the well-known yet little under-

[1] "Fungus Maladies of the Sugar Cane." By N. A. Cobb. (Honolulu: Hawaiian Gazette Co., Ltd., 1906.)

stood Eleau disease. Various experiments in the preparation and disinfection of cane cuttings and in testing cane varieties for their resistance to disease that have been carried out are recorded, and should prove most helpful to growers.

The ninth and concluding section deals with free-living nematodes inhabiting the soil about the roots of cane and their relation to root diseases. The root diseases are very serious, and in these soil-inhabiting nematodes we have organisms capable, through their punctures, of giving entrance to smaller parasitic organisms that would hasten the death of the plant roots.

The author describes no less than eighteen new species of these worms, and records five more found around the roots of diseased canes in Hawaii. They are included in the genera Dorylaimus, Tylenchus, Mononchus, Prismatolaimus, Cephalobus, &c., and one new genus, Anthonema, is described.

The whole work is excellent in every respect, not only from an economic point of view, but as an example of the thorough way in which such scientific investigations should be carried out.

The sixth report of the Woburn Experimental Fruit Farm deals with various washes used for the destruction of injurious insects.[1] Among the more important experimented with were the alkali washes, paraffins and emulsions, lime-sulphur and others in connection with the destruction of the mussel scale (*Mytilaspis pomorum*). The portion of the report dealing with the paraffin oils and emulsions will prove of great value, and also from a scientific point of view much else in the report. But some of the results do not at all agree with what growers have found, such, for instance, that lead arsenate wash badly scorches the leaves under certain conditions and at certain strengths. It has not, it seems, been found to do so in their hands.

Some interesting work on silver leaf is given in conclusion. As a scientific chemical work it is all that could be desired, but the reader must take certain results with care, for if "egg-counts" have been made taking into account the following sentence, "we certainly found a greater destruction of eggs by insecticides in the case of scales which had been thus bored (by Chalcididæ), than of those which were intact," then we must discount some of the results obtained. Some of the opening remarks might with advantage have been excluded by the authors.

But in spite of these few blemishes there is much useful reading, and horticulturists are indebted to the authors for their kindly interest, which we hope to see continued, for it is the first attempt at anything like sound treatment of the subject.

FRED. V. THEOBALD.

THE POSITION AND PROSPECTS OF CHEMICAL RESEARCH IN GREAT BRITAIN.[2]

The Status of Original Research.

TO all who are familiar with the influence of scientific progress on the evolution of civilisation, that is, to all students of the history of modern science, the general want of appreciation of research here cannot but be a matter of profound wonderment. It is not my intention to attempt an analysis of the causes of this public apathy on the present occasion. We must, I am afraid, deal with it as an accepted fact. Attention has from time to time been directed to this national weakness by the Press and by publicists whose influence should carry conviction to the lay mind. We can, no doubt, remember weighty utterances by statesmen such as the Duke of Devonshire, the late Lord Salisbury, Lord Rosebery, Mr. Chamberlain, Mr. Balfour, and, above all, in recent times, Mr. Haldane, who loses no opportunity of driving home the lesson of the importance of science and of scientific method to the national welfare. Nor have our scientific workers themselves failed to sound the note of alarm with all the authority of expert knowledge. But, in spite of these individual efforts, it cannot be said that we have made much headway; public interest in scientific research may still be considered to be on a low level—certainly lower here than in many other leading nations, and most decidedly lower than is desirable in the best interests of our country. A temporary flicker of excitement is caused when some sensational discovery is announced, or when some result of immediate practical (commercial) value is made known, but even in these cases the interest taken is only transitory and is narrowed down to the immediate issue; the broad cause which makes such results possible is lost sight of. The steady, plodding work which culminates in great discoveries is being carried on quite unheeded by the general public, and the workers themselves are practically unknown outside the ranks of science. Research as a "cult" is not understood; the national attitude towards the workers is one of "payment by results" in the very narrowest sense of the term.

How this state of affairs is to be remedied is a knotty question which I confess appears to me somewhat hopeless of solution at the present time. It may be that by persistent attack from within and the pressure of competition from without the country will, in fact must sooner or later, awaken to the situation. It may be that science will have to become more self-assertive and make its influence felt as a political power. There is need here, as has been often suggested, for a minister corresponding to the "Minister of Public Instruction," or the "Cultus-Minister" of other countries. The newly formed "British Science Guild" may fairly be expected in the course of time to help us in raising the level of public opinion towards the importance of research, this being, in fact, one of the primary objects for which this organisation has been founded.

The Jubilee of the Foundation of the Coal-tar Colour Industry and its Lessons.

The exaltation of scientific research into an abstract principle or "cult," which is the keynote of the remarks which I have put together for your consideration on this last opportunity when I shall have the honour of addressing you from the presidential chair, is, of course, a familiar subject to all who keep in view the objects of a society such as this. If I venture to formulate the principle somewhat more emphatically on this occasion, it is that the international gathering, which took place here last summer in honour of our distinguished past-president, Sir William Perkin, and in celebration of the jubilee of the foundation of the coal-tar colour industry, has given rise to many considerations which are intimately associated with the subject of this address. Although at that memorable assembly the voice of the nations was raised in gratitude for and in recognition of the numerous benefits arising from the establishment of a great industry, we must not forget that below the chorus of praise and congratulation, so justly sounded in honour of the founder, there was flowing an undercurrent of thought which, in some of the addresses and speeches, found verbal expression—the thought that this industry owed its existence to scientific research, and that it had been developed into its present magnitude by the never-ceasing applications of research. Speaking generally, it may be said that all the great steps, the new departures in the industry of coal-tar products, have been the outcome of pioneering work carried on in the first place without immediate reference to practical results. All honour to those who have developed these results into manufacturing operations, but honour in the first place to the scientific pioneers! This is the real lesson taught by the celebrations of last July. It may be of interest to consider in the next place how far this lesson has been learnt here on the one hand by the scientific public and on the other by the general public.

That the lesson has not been learnt by those who are most immediately concerned, the manufacturers themselves, is sufficiently apparent when we compare the enormous development of the industry in Germany with its comparatively small development here and its decadence in France, once an active centre and a successful competitor with us in the manufacture of coal-tar colouring

[1] "Sixth Report of the Woburn Experimental Fruit Farm." By the Duke of Bedford, K.G., and Spencer U. Pickering, F.R.S. Pp. v+235. (London: Eyre and Spottiswoode, 1906.) Price 4s.

[2] Abridged from the Presidential Address delivered at the annual general meeting of the Chemical Society on March 22 by Prof. Raphael Meldola, F.R.S.

matters. With respect to the public attitude, it may be said that such appreciation of Perkin's work as was expressed through our Press was just what might have been anticipated in a country where the true position of scientific research is imperfectly understood. The rejoicing was over the purely practical achievement—the discovery of the convertibility by chemical processes of so many otherwise useless tar products into saleable articles of commerce. The public cannot, as matters now exist in this country, go behind such proximate results. Moreover, the limitation of the appreciation in this way brings out very clearly the difficulties which must be encountered in any attempt to raise the status of scientific research in general, and of chemical research in particular, in the national estimation. Consider, by way of contrast, the works of the *littérateur* or artist; these appeal directly to the public or to some section of the public, and can be appreciated according to their merits. Not so the labours of the scientific investigator; his achievements are measured solely by the utilitarian standard; he is, as I said before, paid strictly by results. In other words, while literature and art have taken their position as "cults" in all civilised nations—a position to which they are fully entitled—science is judged by a lower and narrower standard, and certainly cannot be said to occupy in this country the same position as its sister branches of culture.

My contention is that scientific research, like every other branch of human culture, is worthy of national homage, whether it leads to immediately "practical" results or not—that its position in the scale of civilising agencies is not dependent upon such occasional stimulants as the jubilee of the foundation of a new industry or the announcement of a sensational discovery which furnishes materials for newspaper paragraphs. It would, I think, be generally admitted that any country which limited its appreciation of research to such branches of science as were likely to lead to industrial developments was on a low level in the scale of civilisation.

In maintaining the principle that scientific research has been, is being, and can always be carried on independently of its practical applications, I have no desire to give countenance to the view, somewhat prevalent, I fear, in this country, that there is some kind of antagonism between pure and applied science; that the scientifically trained chemist, for example, and the "practical" man, instead of being allies, as they should be, are in opposition. The days when such notions were held are, happily, passing away; if but slowly in this country much more rapidly abroad. My plea simply amounts to a claim for the re-adjustment of the positions of pure and applied science in the public estimation. The course of industrial development in the future is bound to become more and more interwoven with the development of pure science, and the perpetuation of erroneous ideas on this point cannot but act injuriously on both causes. In our own domain it is absurd to suppose that there is any antagonism between the two aspects of chemistry. Far from this being the case, it may safely be asserted from the experience furnished by the coal-tar industry that the rate of progress is actually measurable by the degree of substitution of pure science for empiricism. Those manufacturers who fail to recognise this principle do so at their own peril; those who have realised its truth cannot but admit that the more enlightened views respecting the function of science in the factory have been largely due to the influence of Perkin's work and example half a century ago.

Chemical Research in Educational and Manufacturing Centres.

I do not propose dealing in detail on this occasion with the very large question of the position of research in our universities, but putting the case broadly, we should, I think, all agree that after making allowance for the few noteworthy exceptions, the actual contributions to our science from these centres are far below the standard, both of quality and quantity, which might be expected and which we should all like to see attained. If any doubt on this point should exist, it is only necessary to call to mind the productive activity in the Continental universities as compared with our own. Judged by this standard, there can be only one conclusion—that many of our universities are distinct failures as centres of chemical research, and that the total output of work from university laboratories is by no means worthy of the great traditions of this country as a pioneering nation in scientific discovery. If these seats of the highest learning, called into existence for the dissemination and promotion of knowledge, can give such a comparatively poor account of their achievements in chemistry, it is evident that there must be deterrent causes at work. It would be going beyond my province to attempt a detailed analysis of these causes here; they are numerous and not easy to deal with in a limited time, but some of them are of the same nature as those affecting the position of chemical research in other educational centres. They may be summed up under such headings as ancient traditions, defective educational methods, want of sufficient means leading to the frittering away of the research faculty by the drudgery of "coaching," the poor outlook for chemical research as a career, and the pedantic notion that a subject requiring for its advancement something akin to manual labour is derogatory to high scholarship. Behind these causes is the general public ignorance of and apathy towards research, to which I referred at the outset, and if I may paraphrase the utterances of recent authorities in the educational world, over them all is the trail of the examining board.

If we ask whether the modern educational development brought about by the technical education movement has fulfilled our expectations with respect to the advancement of chemical science, I for one must confess to a feeling of profound disappointment. There may be better times ahead when that era of public enlightenment dawns, but at present, with a few notable exceptions, these twenty-three London polytechnics are, on the whole, so little productive that we may discount them as active centres of research. It must be remembered, moreover, that this class of institution has spread all over the country, and that the total expenditure in the way of money and teaching energy is so great in comparison with the output of original work that chemists have every right to ask why this state of affairs should exist.

Turning now to the consideration of the causes of this failure on the part of the new educational establishments, I must, in the first place, guard myself against the imputation that I am disparaging their work. The most acute form of disappointment is that which is experienced when we find weakness where we had looked for strength, and in emphasising their weakness from our standpoint I am not shutting my eyes to their usefulness in other directions. It is not a depreciation of the work which they are doing if we deplore their failure in another branch of work which they might be doing. From what I know of these institutions, and from information furnished by very good authorities, I am satisfied that in some directions, and more especially in connection with engineering and trade subjects and handicrafts—in all of which the artisan is an important element—they are doing a certain amount of good to the various industries concerned. But the danger for us is the general tendency in this country to ram the whole scheme of education into one mould, utterly regardless of the fact that the requirements of, let us say, an engineer are quite different from those of a chemist. It is for this, among other reasons, that our subject has suffered both in its scientific and industrial aspects, because the time and energy of the teachers of chemistry in these institutions are so largely frittered away in what might be called inconsequential labour on behalf of a class of student quite unprepared by previous training for assimilating the principles of our science and for the most part unable to give sufficient time to the subject to acquire any real working knowledge of it.

There is another factor to be added to those which are acting detrimentally towards the cause of research in these institutions, and that is the want of sufficient endowment. I am afraid that it is characteristic of our countrymen to neglect the most important interests until they are forcibly awakened to their danger, and then to try and make up for past neglect by rushing precipitately into the first plausible scheme that is presented. There is no doubt that the new educational development suffered much at the outset from this characteristic mode of procedure. The wrong kind of person was often allowed to frame the educational policy; the financial strength was exhausted in buildings and equipment, and the efficiency of the staff given only secondary consideration. We, of course, know that success in such educational work depends entirely upon the individual teacher—that the best mode of creating a school of chemistry, or any other subject, is to follow the advice of the late Sir William Flower with regard to the establishment of a museum: "First find a curator and let him build his museum around him." Had this principle been more generally adopted, the new institutions might by this time have been playing a really important part in the development of chemical science and chemical industry. As matters are, inadequate provision for maintenance having been made, the general standard of educational work is lowered in order that the grant-earning requirements of some examining board may be met, and as a result the establishments have to be run as purely business concerns.

There are other minor evils acting as retarding influences with respect to our subject and arising from the same cause, namely, the necessity of conducting these newer institutions, more or less, as commercial establishments. The prevalence of the "business" spirit among the committees and governing bodies gives an exaggerated importance to what may be called the office staff—the registrars and clerks. The work of the office staff is capable of being appreciated by the average committeeman, while the work of the scientific staff is generally beyond his comprehension, except so far as it can be measured by financial gain to the institution. It is not sufficiently realised that men of business and administrative ability are by no means rarities, while really good teachers of science are much scarcer, and men who combine both the qualifications of a good teacher with the inspiring zeal of an original investigator are rarest of all. Now if, as was professedly the case, the modern departure in technical education had for its object the improvement of the industries, then it is sufficiently well known to us here that the future of our subject is with the men of the latter class, and the joint exertions of all the registrars and clerks, backed by the efforts of the most skilful chemical pedagogues who get through their syllabus within the session and earn the largest grants or score the highest percentage of successful "passes," will never raise the level of this country either in chemical science or chemical industry.

It is sometimes stated that it was never contemplated that research should be carried on in these institutions—that this was the duty of the higher educational establishments. So it is the duty of the higher educational establishments, but the very fact that these are enabled to discharge their duty in a most imperfect way should have stimulated the newer institutions to make every effort to redeem our credit by making adequate provision for research. I will not venture to intrude my opinions concerning the vitalising influence of research upon other scientific subjects, but with regard to our own I have not the least hesitation in declaring the belief that a school of chemistry which is not also a centre of research is bound to degenerate and to become a mere cramming establishment not worth the cost of the maintenance. It is easy enough to follow the actual course of the degeneration process in such an institution. The teacher, who may be a man of real ability and who has entered with the hope of finding time and opportunities for research, finds himself, sooner or later, in the position of a chemical schoolmaster. The predominance of the business influence in the institution not only leads, as I have already indicated, to the lowering of the level of the instruction and to his own consequent degeneration, but he is, as a further consequence, so overweighted with business and administrative work that these, superadded to his teaching duties, leave him neither time nor energy for original work. The spirit of research within him is strangled by officialism, and his teaching faculties deadened by the monotonous toil of the annually recurring drudgery of routine teaching.

The scale of remuneration also does not enable these institutions to command the services of the best teachers, although I do not think that this is the chief deterrent cause, as there are numbers of young chemists of first-rate training and ability who would be quite willing to devote their time at the outset of their career to acquiring teaching experience in these establishments, even at some personal sacrifice, if facilities for research were given. In the present state of affairs one can only marvel at the fact that so many men of ability can be found willing to take service in these newer institutions, the more especially as, apart from the absurdly inadequate remuneration often given to the chiefs of the chemical departments, the payment of the subordinate members of the staff is generally on a scale which is nothing short of a scandal to the wealthiest of European nations. Considering the long course of training necessary to produce a competent teacher or demonstrator, and in view of the actual amount of work expected from these men who, by virtue of their attainments and position, are compelled to live up to a standard of high respectability, it seems almost incredible that the average scale of remuneration should not exceed the wages earned by an artisan, and is often below that standard.

According to the "Official List of Appointments" published by the Institute of Chemistry last year, there are on the staffs of the London and suburban polytechnics about fifty-four trained chemists. To these may be added 237 engaged in teaching in similar institutions in provincial centres throughout the United Kingdom. In one respect the hopes of those who expected great opportunities for chemists from the new departure in technical education have been realised. At the present time there are in this country in round numbers some 290 posts available for teachers of chemistry, which posts have actually been created by the latest movement in technical education. If now we ask whether the output of original work from these 130 centres is representative of the productive power of the 290 teachers, there can, I think, be only one answer, and that an emphatic negative. An examination of the lists of teachers in these centres shows that only about twelve out of the total number are carrying on research, and most of these in a desultory way. It is evident that there is justification for my complaint that there is this submergence of creative faculty going on all over the country; the nets have been spread and the capacity has been caught, but so far with comparatively little effect upon the development of new schools of chemical research.

The consideration of the question of the position of factories as centres of research is intimately bound up with the educational side of the subject, because we have to deal now with the educational establishments which are supplying the chemists for our factories. The feeders of the chemical factories are the universities and technical schools, British and foreign, and the question before us as the custodians of research is whether the absorption of the chemical talent from these sources by the factories is justified from the industrial point of view—whether these products of modern training, having entered into such careers, are being used to the best advantage. In other words, is that wastage of original faculty which, as I have endeavoured to show, is going on in the educational institutions, going on also in the factories? Whether the total number of chemists employed in our factories is what it should be is a point for the manufacturers themselves to consider. Even the extreme estimate of 1500 does not seem a very large chemical staff for the whole of the factories of Great Britain. In the German colour industry alone, according to information supplied to us seven years ago as jurors for the Paris International Exhibition, five of the great factories were employing 557 chemists—real scientific chemists, and not mere testing machines such as are dignified with the name of chemist in many of our factories.

From my own experience as head of the chemical department of a technical college, and with some knowledge of the requirements of chemical industry, I can state that the newer technical education, when conducted in the form of organised courses of day instruction extending over several years, has enabled us to capture a large amount of chemical capacity. Of the total output of trained chemists from the various institutions, a fair proportion—a number quite equal to the average in other countries—are possessed of the research faculty. We have seen what becomes of this when such men throw in their lot with the educational establishments. Are not we, the teachers, justified in asking whether the prospects of developing this faculty in our factories are such as might be reasonably expected from the known requirements of chemical industry?

In answer to this question I am afraid we must come to the conclusion that here also there is an enormous submergence of research talent going on. It is true that the position is improving—that some of our more enlightened manufacturers have realised the value of such men, and by taking advantage of their faculties have improved their various industries. But these cases are as yet exceptional, and the ideal will never be reached until the research laboratory becomes a recognised and well-staffed department in every chemical factory. Do our factories possess departments which can honestly be described as centres of research in the sense, say, of the research laboratories of the German colour factories? I am afraid not; indeed, I know of scores of young men of great promise and ability who have been swallowed up by the factories and gradually degraded, in the chemical sense, into mere machines carrying out routine work which really required no elaborate chemical education for its effective performance. There is, of course, no satisfactory means of measuring the influence of the newer education upon the chemical industries of this country, and we can only speak from individual experience concerning the careers of our own students. It is upon this experience that I base the conclusion that our country is wasting its resources in a most reckless way so far as concerns the chemical industries. There is an enormous amount of talent available if our manufacturers would only utilise it in the right way. It has frequently been pointed out how, on the Continent and in America, the educational establishments and the industries are brought into relationship by the cooperation between the manufacturers and the teachers. Here, so far as chemical industry is concerned, such cooperation is practically unknown, and, as a consequence, there exists more or less distrust where there should be confidence, and both the educational and the industrial sides of our subject are crippled. This is perhaps the most powerful influence at work in this country in checking that development which follows normally from cooperation between the representatives of science and of industry.

Checks to the Wastage of the Research Faculty; Research Funds and Scholarships.

Turning now from the consideration of the various deterrent influences, we may in the next place deal with such counteracting agencies as are available in this country. It is clear, from our point of view, that any means by which the research faculty, having once been captured, can be given free scope for development, must be a distinct gain to our cause. All who have had to do with the training of chemical students must in the course of their experience have come across young men of exceptional talent as original workers. We are concerned more particularly with the utilisation of this faculty for the promotion of our science and with the maintenance of the principle that the submergence of this faculty means so much dead loss to the national resources. Now it unfortunately happens that many of the men thus gifted come from stations in life which render it imperative that they should proceed at once from the college to some bread-winning occupation. A few may perhaps be lucky enough to find appointments in which there is scope for the development of their faculties, but I am afraid the majority do not; they undergo that process of extinction as original workers which I have already dealt with. One of the most valuable counteracting agencies, and one the importance of which, from our standpoint, cannot be overestimated, is that system of awarding research scholarships to men of proved ability so as to enable them to carry on original work after finishing their college training. The value of this most rational method of endowing research is due mainly to the fact that the right men are captured in the right way; they are not, as it were, squirted promiscuously out of an examination mould, but they are selected by the teachers who have had them under observation during the whole course of their training and who know their real as distinguished from their examinational capabilities.

The other agency working against the stream of adverse influences is to be found in the various funds from which grants are made to individual workers for the prosecution of particular researches. There are three such funds available for the promotion of chemical research, the Government Grant Fund of the Royal Society, the grants distributed annually by the British Association, and the income derived from our own research fund. Of these, the two former have to be distributed over every branch of science, and chemistry takes its chance with other subjects. The total amount available for chemical research is not very large, and all who have served on the committees of any of these funds know very well that the amount applied for is generally much in excess of the sum available for distribution. The main difficulty of administration is, in fact, the equitable pruning of the various applications.

With regard to the results obtained through the research fund of this society, the present occasion is in every way opportune for directing attention to our achievements and to our needs. The income derived from this fund has hitherto enabled us to distribute annually a sum of about 220*l.*—a very modest amount considering the number of claims and the activity of our workers. Of the value of the assistance thus given we are, of course, all thoroughly aware here, but it may not be generally realised by the outer public what an enormous amount of good work is being promoted by the judicious administration of this very modest income. In order to get at the actual facts, our assistant secretary, Mr. Carr, has been so good as to prepare a table covering the eight years from 1898 to 1905 inclusive, and setting forth for each year the sum granted, the number of grantees, the total number of papers published by the grantees in our Journal or elsewhere, and other particulars which will be found in the table itself. From this it appears that 151 grantees during that period published 203 papers, thirteen failed to publish, ten have not yet published, and eighteen grants are still in the hands of the grantees. The total amount granted was 1770*l.*, so that for this expenditure we have actually given to our science 203 papers, and more may be expected from those who still have grants in hand or who have not yet published their results. The figures as they stand, and even if nothing further is achieved, show that the grants average from 8*l.* to 9*l.* per paper, and, as we all know, each paper represents the results of at least one and frequently of several years' work. It is not going too far to say that there are no funds giving such substantial returns for so small an expenditure as these research funds, and their importance as aids to the advancement of knowledge cannot be overestimated.

With the additional capital by which our fund has been increased, the total income available for grants will be about 330*l.* per annum. In view of the demands upon that income it is obvious that even now we are possessed of but very limited means, and that the research fund committee will still be compelled, as has hitherto been the practice, to allot the grants for the purchase of materials or special apparatus. But, in addition to the promotion of research by the means indicated, there is another, and, according to my view, an equally valuable method, for assisting our workers in the prosecution of their researches, and that is the allotment of personal grants to enable the grantees to secure skilled assistance —to purchase, in fact, the services of human material as well as chemicals and apparatus. It is only want of sufficient income that has hitherto debarred the use of our fund in this way. I am so confident that an extension of our means towards this end would be productive of a most notable increase, both in the quantity and quality of the chemical research done in this country, that I have no hesitation in placing upon record the opinion that the next step taken in the forward policy of the Chemical Society ought to be in this direction. To do much good in the way of making personal grants we should, of course, require to capitalise a very large sum; we want an income of thousands instead of hundreds, and I confess that I see no immediate prospect of realising this dream. But there can be no doubt that for those who have the interests of our science at heart there could be no better method of subsidising research.

The general conclusion which appears to be justified by this inquiry into the position and prospects of chemical research is, that the position here is by no means as satisfactory as we could wish—that much more might be done if the conditions were made more favourable for our active workers. In view of the actual achievements, accomplished in spite of the existing disabilities, it appears that the prospects for this country as a home of chemical research have been improving during the last decade with greater rapidity than at any previous period in the history of our society. But it is also obvious that there is much work yet ahead of us before the environment in which our workers find themselves is properly cleared from obstructions.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—A large and brilliant company assembled in the Sheldonian Theatre on Wednesday, June 26, to celebrate the Encænia. The recently elected Chancellor, Lord Curzon, presided. Reverting to a practice which has been discontinued for some years, the authorities reserved a portion of the upper gallery for undergraduates. Honorary degrees were conferred upon a number of men of distinguished eminence. The following is the text of the speeches delivered by Prof. Love in presenting the recipients of the degree of D.Sc. *honoris causa*. Dr. Ludwig Mond, F.R.S., upon whom the honorary degree of D.Sc. was to have been conferred, was unable to be present.

SIR RICHARD DOUGLAS POWELL, BART., K.C.V.O.

Humani generis defensor contra phthisim, pestem omnium tæterrimam, inventus est Ricardus Douglas Powell. Qui vir cum medicinæ se dedisset, ac præsertim huius morbi causas cognosceret, remedia excogitaret, curandi modos quos optimos esse iudicarat re probaret, summam gloriam et scientia et scriptis assecutus est. Difficile est pro meritis eum laudare qui nihil in vita egerit nisi ut laborantibus salutem afferat: illud brevissime dixerim hunc esse quo ne reges quidem nostri carere possint, seu adversa valetudine utantur, sive prospera. Fuit enim Reginæ Victoriæ nobis nuper ereptæ medicus ordinarius, et nunc Edwardo, regi nostro dilectissimo, medicus extra ordinem est. Viri merita declarat collegarum iudicium, a quibus Regalis Collegii Medicorum Præses factus est; declarant honores inusitati a rectoribus nostris collati, qui eum Baronettum et amplissimi ordinis Victoriani militem commendatorem creaverunt; declarant tacitæ tenuiorum gratiæ, quorum necessitatibus in maximis Londinii valetudinariis hic medicorum princeps ministrat.

SIR NORMAN LOCKYER, K.C.B., F.R.S.

Inter eos qui solis stellarumque natura quæ sit optime docuerunt primarium fere locum occupat Josephus Norman Lockyer. Dies me deficiat si miracula ab eo prolata de mundorum origine, de ratione quæ inter solis maculas et orbis terræ tempestates intercedat, si legationes solis defectus observandi causa in loca remotissima missas enumerare coner. Ex tot rebus gestis sumam duas tantum. Quadraginta abhinc annos duo viri, uterque suo Marte fretus, Jannssen in Gallia, in Britannia hic noster, instrumenta effinxerunt quibus usi flammas illas ingentes, quas e sole excurrere videmus quando eius orbi luna officit, sole non obscurato cernerent. Cum ex harum flammarum observatione multum de materia e qua sol constat colligi possit, res tanti habita est ab Academia Gallica ut numismate impresso insigniretur. Altera huius viri laus est singularis quod Acta Hebdomadalia, in quibus quicquid novi in omni Scientiæ Naturalis genere a viris doctis ubique repertum est enarratur, conscribenda curabit: qua in re cum summam diligentiam et peritiam præstaret, de omnibus qui scientiæ promovendæ student optime meritus est.

SIR WILLIAM RAMSAY, K.C.B., F.R.S.

In tenebris fere incognitis quæ inter Chemiæ et Physicæ fines intercedunt nemo certius insistit quam Willelmus Ramsay. Testis est illa Baronis Rayleigh vox in hac urbe tredecim abhinc annos audita, qui, cum vaporem incognitum quendam in aere esse confirmaret, hunc virum inventi socium esse dixit. Rariora posthac metallorum genera hic noster perscrutatus est, si qua huius vaporis vestigia deprehenderet; invenit autem non ipsum quidem vaporem sed metallum quoddam quod Helium vocant: hoc in sole exstare iam notum erat, nemo ulla eius apud nos indicia umquam odoratus est: mox cum de aeris natura subtilius quaereret, tres vapores novos detexit. His annis mirae eius metalli quod Radium appellatur virtutes et mutationes multorum animos commoverunt: hic vir exstitit qui stabile illud, quod ex his mutationibus gignitur, Helium esse ostenderet: quo facto causas quibus solis calor atque lumen per sæcula innumerabilia alitur illustrare potuit.

SIR WILLIAM HENRY PERKIN, F.R.S.

E conchis, radicibus, plantis, insectis antiqui pigmenta extrahebant, Willelmus Henricus Perkin inventus est qui ex carbonibus decoctis idem faceret, tanto successu ut hodie vel plantis vel animalibus supersederi fere possit. Quid? Nitidissimi calores quibus fulgent tot formosæ, quæ circumsedunt, dominæ, Doctorumque nostrorum vestes, quæ avium silvas Indicas incolentium plumas æmulantur, unde, quæso, hic splendor omnis profectus est nisi ex invento quod hic noster fecit, cum puer esset annos septendecim natus? Multi sunt, ut hunc omittam, qui ex hoc reperto divitias comparaverint, in Germania præsertim, ubi mercatores ita doctrina instituti sint ut inventa in usum convertere possint, et ea sit vectigalium ratio ut artificia nova pecuniis publicis adiuventur. Inventor ipse satis iam locupletatus se scientiæ totum dedit: lucis quidem repercussæ et ex alia re in aliam conversæ rationem et vim occultam nemo magis intellegit.

PROF. WATSON CHEYNE, C.B., F.R.S.

Rationum Listerianarum, ut cum chirurgis loquar, quasi personam gerit Willelmus Watson Cheyne, qui et in his constituendis inventoris socius fuerit et in exercendis multo longius progressus sit. Rebus in Africa Australi turbatis hic ad bellum profectus est civilis chirurgus cuius ope et cura milites uterentur. Dolendum est eius peritiæ tantum tum patuisse campum, medendi rationibus tantum fuisse opus: illud profecto gaudendum, hunc virum præsto fuisse qui sauciorum cruciatus leniret, quique chirurgiæ ratione usuque omni instructus multorum vitam conservare posset: nullo quidem in bello antea gesto tot e vulneratis redire potuisse notum est. Hodie pace confirmata chirurgiæ rationes optimas exponit, dumque multitudinibus in magnas urbes congregatis succurrit, diligentiam peritiamque suam difficillimo belli tempore probatam vir strenuus præstat.

MANCHESTER.—At the annual degree ceremony on June 29 the honorary degrees were conferred upon Baron D. Kikuchi and Prof. G. E. Hale, the presentation addresses being delivered by Prof. A. Schuster, F.R.S. Baron Kikuchi worthily upholds the spirit of open-minded fraternity which unites the universities of the world. A graduate of Cambridge, he has occupied the chair of mathematics in the Imperial University of Tokyo, and through his studies of the older mathematicians of Japan he has taught us interesting facts as to their methods of investigation. He has held the position of president of the Imperial University, and of Minister of Education; he has represented his country at important international conferences, and taken an active part in introducing a scientific system of weights and measures into Japan. Prof. G. E. Hale was formerly director of the famous observatory of the University of Chicago, built and equipped by the late Mr. Yerkes, and is the organiser and director of the Mount Wilson Solar Observatory, on the crest of the Sierra Nevada.

It is of interest to note that the M.Sc. degree was conferred upon the exceptionally large number of sixty-three candidates. Under the new regulations, the master's degree in science is only obtainable upon satisfactory completion of post-graduate study or research, and there is thus every indication of the success of the scheme in increasing the spirit of research in the University.

MR. J. STRUTHERS, lecturer in agriculture and chemistry in the West of Scotland Agricultural College, Glasgow, has been appointed secretary and agricultural chemist in Japan to the Asociación Salitrera, and leaves in August to take up his new duties in Tokyo.

THE offer of nomination for appointment by the Crown on the governing body of the Imperial College of Science and Technology has been accepted by the Earl of Crewe, Lord President of the Council; Mr. Gerald W. Balfour; Sir Francis Mowatt, G.C.B.; Sir Julius C. Wernher, Bart.; Sir William H. White, K.C.B., F.R.S.; and Dr. MacAlister, principal of the University of Glasgow. The other persons nominated as first members of the governing body are:—by the President of the Board of Education, Mr. A. H. D. Acland; Mr. F. G. Ogilvie, C.B., a principal assistant secretary of the Board of Education; Mr. J. C. G. Sykes, an assistant secretary of the Board; and Dr. R. T. Glazebrook, F.R.S., director of the National Physical Laboratory; by the University of London, Sir E. H. Busk, past Vice-Chancellor of the University; Prof. Capper; Prof. Farmer, F.R.S.; Sir Henry E. Roscoe, F.R.S.; and Sir A. W. Rücker, principal of the University; by the London County Council, Mr. A. A. Allen, M.P.; Mr. H. Percy Harris, chairman of the Council; Sir C. Kinloch-Cooke; Mr. R. A. Robinson; and Mr. J. T. Taylor; by the City and Guilds of London Institute, the Earl of Halsbury, F.R.S., chairman of the council of the institute; Sir J. Wolfe Barry, K.C.B., F.R.S.; Sir Owen Roberts, clerk to the Clothworkers' Company; Sir Walter S. Prideaux, clerk to the Goldsmiths' Company; and Sir John Watney, hon. sec. of the institute; by the Royal Commissioners for the Exhibition of 1851, Viscount Esher, G.C.V.O., K.C.B., and Lieut.-Colonel Sir Arthur Bigge, G.C.V.O., K.C.B.; by the Royal Society, Sir Archibald Geikie, F.R.S.; by the professorial staff, Prof. Tilden, F.R.S., Prof. Gowland, and Prof. Dalby; by the Institution of Civil Engineers, Sir Alex. B. W. Kennedy, F.R.S., president of the institution; by the Institution of Mechanical Engineers, Mr. T. Hurry Riches, president of the institution; by the Institution of Electrical Engineers, Mr. R. Kaye Gray, past-president of the institution; by the Iron and Steel Institute, Sir Hugh Bell, Bart., president of the institute; by the Institution of Naval Architects, Dr. F. Elgar, F.R.S.; by the Society of Chemical Industry, Dr. E. Divers, F.R.S., past-president of the society; by the Institution of Mining Engineers, Mr. A. Sopwith, past-president of the Institution; and by the Institution of Mining and Metallurgy, Mr. W. McDermott, past-president of the institution. The draft charter for the establishment of the college will be submitted to His Majesty for approval at the council fixed for July 6.

THE Board of Education has published (Cd. 3538) a summary of figures relating to State-aided secondary schools in England. The number of schools dealt with in the summary is 600, but in addition to these there are ninety-three secondary schools provisionally recognised by the Board or seeking recognition, though these are not included. The total number of scholars, excluding pupil teachers, in the 600 schools is 104,938. About 80 per cent. of the total number of scholars are fifteen years of age or under, and the remaining 20 per cent. represent the number of pupils in State-aided secondary schools more than fifteen years of age. About a quarter of the total number of pupils in these secondary schools previously attended public elementary schools and are paying no fees in the secondary schools, while 54 per cent. of the total number previously attended public elementary schools. It is important to remember that the curriculum of secondary schools receiving grants from the Board of Education is dominated by a four years' course of work designed for children who will remain at school until they have completed their sixteenth year at least, and that no grants are paid for pupils under twelve years of age—nearly a quarter of the above total—nor for those who have completed the approved course. There seems, in fact, to be little relation between the character of the prescribed course and the special needs of the majority of the children. If 80 per cent. of the pupils finish their school life at fifteen or under, the curriculum might with advantage be modified in such a way that thoroughness and completeness in a few fundamental subjects may be secured by the majority of the pupils rather than to allow them to fritter away their few valuable years in beginning a course of work which is doomed to be left unfinished and from which little advantage can be gained.

NUMEROUS handsome bequests have been reported in *Science* during the last three months, and in addition to specially large gifts there has been a continuous record of munificence as represented by sums which are small only when judged by American standards. Among other large amounts, the following deserve special mention:—Creighton University has received 500,000*l*. under the will of the late Mr. J. A. Creighton; Teachers College, Columbia University, has been presented with 80,000*l*. by an anonymous donor, and 60,000*l*. under the will of the late Mr. F. P. Furnald. The State Legislature has provided the University of Alabama with 80,000*l*. for buildings and 5000*l*. a year for maintenance. Dartmouth College benefits to the extent of 50,000*l*. under the will of the late Captain Thomas P. Salter. The University of Chicago has received land from Mr. J. B. Rockefeller worth more than 500,000*l*. The Princeton University has received anonymously a gift of 240,000*l*.

DR. J. C. MCLENNAN, for some years director of the physical laboratory in the University of Toronto, has been elected to the professorship of physics in succession to Dr. James Loudon.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 23.—"The Relation of Thallium to the Alkali Metals: a Study of Thallium Sulphate and Selenate." By Dr. A. E. H. **Tutton**, F.R.S.

The author finds that the crystals of thallium sulphate and selenate resemble those of the analogous salts of potassium, rubidium, cæsium, and ammonium adequately closely morphologically to enable them to be classed in the same orthorhombic isomorphous series, the average difference of corresponding interfacial angles on analogous potassium and thallium salts being less than half a degree, and the maximum difference only just exceeding a degree. These differences, however, though small, are greater than those between any other of the salts, the average difference, irrespective of direction, being proportional to the higher atomic weight of thallium.

The law revealed by the author's former work, that the changes in the interfacial angles are progressive functions of the atomic weights of the interchanged metals, only applies, however, to potassium, rubidium, and cæsium, which belong strictly to the same family group of the periodic classification of the elements; for the differences in the case of thallium occur in either direction indifferently.

The molecular volumes and topic axial ratios (separation along axial directions of centres of contiguous molecules) are almost identical with those of analogous rubidium and ammonium salts, so that structurally thallium comes alongside rubidium and ammonium, intermediate between potassium and cæsium.

Optically, however, the thallium salts are quite different, the refractive indices, molecular refractions, and dispersion being far higher, indicating the essential chemical difference of thallium from the true alkali metals and ammonium.

Entomological Society, June 5.—Mr. C. O. Waterhouse, president, in the chair.—*Leioptilus carphodactylus* in Britain: Dr. T. A. **Chapman**. A living example; one of the first bred British specimens.—*Microdon mutabilis* and *Kleditoma myrmecophila*: H. St. J. **Donisthorpe**. A specimen of *Microdon mutabilis*, with the empty pupa-case, bred from a larva taken in the nest of *Formica fusca* at Porlock, April, 1907; also ♂♂ and ♀♀ of *Kleditoma myrmecophila*, n.sp., bred last month from a nest of *Lasius fuliginosus* found at Wellington College in March.—New Phytophaga from Australia: M. **Jacoby**. Examples of small beetles, new to science, of the new genus Clythridæ (Phytophaga), including *Leasia australis*, Jac.—Types of Proctotrupidæ: A. J. **Chitty**. The three types of the three species of Proctotrupidæ described by Westwood, but entirely overlooked by subsequent authors.—A parasitic South African fly: E. E. **Austen**. Examples of *Cordyloba anthropophaga*, Grunb., an African fly, parasitic in the larval stage on human beings and animals—a true Muscid—hitherto confused with another fly. The author exhibited *Bengalia depressa*, Walk., a totally different insect.—The significance of some secondary sexual characters in butterflies: Prof. E. B. **Poulton.**—Report of entomological observations made in South Africa during the visit of the British Association in 1905: Dr. F. A. **Dixey** and Dr. G. B. **Longstaff.**

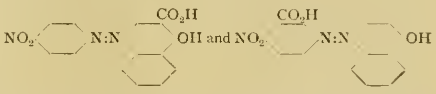
Linnean Society, June 6.—Prof. W. A. Herdman, F.R.S., president, in the chair.—Contributions to our knowledge of New Zealand Holothurians: Prof. **Dendy** and E. **Hindle.**—Report on the marine fishes collected by Mr. Stanley Gardiner in the Indian Ocean: C. Tate **Regan.** The collection contained examples of nearly 200 species, more than fifty of which were new to science, among them some remarkable new generic types. A large proportion of the new species were dredged at considerable depths, and the others chiefly belonged to genera the species of which have been supposed to be more variable and more widely distributed than proves to be the case.—The Ixodidæ collected in the above expedition: Prof. **Neumann.**

Physical Society, June 14.—Mr. H. M. Elder, vice-president, in the chair.—The electric arc: Mr. **Upson.** Arcs were described in which the electrodes consisted of carbon, copper, iron, and aluminium in different combinations, maintained in air, hydrogen, and coal-gas. With 110 volts supply, metal arcs in hydrogen took the form of a spark discharge. At that voltage the maximum length of arc it was possible to obtain, with current up to 15 amperes, was $0''.05$, except where both electrodes were of the same metal. When carbon is one of the electrodes a true arc is formed. If carbon is negative the maximum length of arc with the above voltage is $0''.07$. Volt-ampere characteristic curves were shown for arcs in air and hydrogen of length $0''.05$. The general position of the curve is determined by the material of the negative electrode. With carbon negative, in hydrogen, the curves for various positive electrodes very nearly coincide. With carbon positive, they keep the same curvature, but vary in distance apart, according to the material of the negative. In general, the position of the curve is governed by the negative, but its particular shape seems to come from the influence of the surrounding gas.—The Poulsen arc as a means of obtaining continuous electrical oscillations: Dr. J. A. **Fleming.** Dr. Fleming showed and described an apparatus for forming an electric arc in an atmosphere of coal-gas between a carbon rod kept in slow rotation and a cooled copper anode, the arc being formed in a magnetic field of 600 to 1000 C.G.S. units. The arc was supplied with continuous current at a pressure of 400–500 volts. A condenser of 0·003 mfd. capacity in series with an inductance of 200,000 cm. was shunted across the arc, and experiments shown to prove the existence of high-frequency oscillations in the condenser circuit. A long resonance helix of insulated wire was then joined to the condenser circuit, and when tuned to it created a powerful high-frequency field round it in which vacuum tubes glowed brilliantly. By vibrating or rotating a neon vacuum-tube of spectrum type near the helix, and showing that the band or disc of light was cut up by dark spaces, Dr. Fleming supported the contention that the oscillations so produced are not absolutely uninterrupted, but cut up into groups.—A direct-reading conductivity bridge for testing rods of steel or other material, where there is considerable range of conductivity between successive specimens, and where it is necessary to eliminate the resistance of end contacts: R. **Appleyard.**

Chemical Society, June 20.—Sir William Ramsay, K.C.B., F.R.S., president, in the chair.—Some properties of radium emanation: A. T. **Cameron** and Sir W. **Ramsay,** K.C.B. It has been discovered that the emanation from radium undergoes a rapid change of volume shortly after its change from the solid to the gaseous state; this is followed by a slow change corresponding with its loss of electrical activity. It has been shown by thirty sets of measurements that the emanation behaves in accordance with Boyle's law, both before and after this preliminary change. Measurements have been made of the initial volume of the emanation obtained from a solution of 87·7 milligrams of radium (metal) as bromide and sulphate. From these it would appear that, instead of the previously accepted value for the average life period of radium, 1100 years, a much shorter life must be deduced, namely, 236 years.—The affinity constants of aminosulphonic acids as determined by the aid of methyl-orange: V. H. **Veley.** The affinity constants of the aminonaphtholsulphonic acids when determined by the tintometer method show, as regards the effect of the introduction of the hydroxyl grouping in the naphthylaminesulphonic acids, relationships similar to those observed by Ostwald by the electric conductivity method for the hydroxybenzoic acids as compared with benzoic acid. One possible case of steric hindrance induced by the introduction of the hydroxyl grouping in the 8-position was noted.—Azo-derivatives of 1:3-diphenylbarbituric acid. Dynamic isomerism among the coloured hydrazones of 1:3-diphenylalloxan: Miss M. A. **Whiteley.** In order to throw some light on the structure of the compounds obtained by the action of aromatic diazonium chlorides on the 5-alkyl-substituted derivatives of 1:3-diphenylbarbituric acid, the investigation has been extended, and the action of the β-substituted derivatives of phenylhydrazine on 5:5-dibromo-1:3-diphenylbarbituric acid has been examined. The results show that the yellow compounds obtained in the first reaction are azo-derivatives, whilst the red ones obtained in the second are hydrazones.—A series of coloured diazo-salts derived from benzoyl-1:4-naphthylenediamine: G. T. **Morgan** and W. O. **Wootton.** The examination of the diazo-salts of benzoyl-*p*-phenylenediamine and benzoyl-1:4-naphthylenediamine has been continued, and it has been found that the diazo-derivatives of the latter base are extremely stable substances which are invariably coloured. These coloured salts might be regarded either as *syn*-diazo-derivatives or as equilibrium mixtures of diazonium and *syn*-diazo-derivatives, although their great stability somewhat militates against the assumption that they consist wholly or in part of *syn*-diazo-compounds.—Colour and constitution of azo-compounds, part i.: J. T. **Hewitt** and H. V. **Mitchell.** The authors recently directed attention to the very marked change in colour when *p*-nitro-derivatives of arylazo-*p*-phenols were dissolved in alkalis. The explanation was offered that, whilst benzeneazophenol forms alkaline salts of corresponding constitution, the *p*-nitro-derivatives furnish salts with the metal attached to the nitro group, and therefore diquinonoid in structure. The relationships are rendered apparent by the formulæ

$$C_6H_5.N:N.C_6H_4.OK \text{ and } KO_2N:C_6H_4:N.N:C_6H_4:O.$$

Comparison of the two carboxylic acids



indicates that the frequency of the absorbed light is lowered by increase in the length of the chain of alternate single and double linkings. The introduction of substituents may modify the length of the chain owing to the possibility of more stable salt formation in other directions.—The oxidation of hydrazines by free oxygen: F. D. **Chattaway.**—Calmatambin: a new glucoside: F. L. **Pyman.** This glucoside from the bark of a West African tree, probably *Canthium glabrifolium*, has the formula $C_{19}H_{28}O_{13},2H_2O$, contains one methoxyl group, and is readily hydrolysed by dilute acids and by emulsin forming calmatambetin, $C_{13}H_{18}O_8,\frac{1}{2}H_2O$, together with dextrose. The former is readily decomposed by the action of dilute acids, and yields a small amount of a scarlet, crystalline substance, $C_{11}H_{12}O_3$.—The decomposition of hyponitrous acid in presence of mineral acids: P. C. **Rây** and A. C. **Ganguli.** Hyponitrous acid when liberated from silver or mercurous hyponitrite by the action of dilute nitric, hydrochloric, or sulphuric acid at 25° decomposes at once according to the equations (1) $2HNO=H_2O+N_2O$, (2) $5HNO=2H_2O+HNO_3+4N$.—The chemical composition of petroleum from Borneo: H. O. **Jones** and H. A. **Wootton.** The petroleum from Borneo consists of approximately equal quantities of homologous hydrocarbons of the paraffin, *cyclo*-hexane, and aromatic series, and contains the members of the naphthalene series to the extent of about 6 per cent. to 7 per cent.—The synthesis of phenonaphthacridines: trimethylphenonaphthacridines: A. **Senier** and P. C. **Austin**.—The condensation of aldehydes with mixtures of α-naphthol and α-naphthylamine: synthesis of 7-aryl-$\begin{array}{c}\alpha\text{—N——}\alpha\\ |\\ \beta\text{—CH—}\beta\end{array}$-dinaphthacridines: A. **Senier** and P. C. **Austin**.—An improved form of apparatus for the rapid estimation of sulphates and salts of barium: W. R. **Lang** and T. B. **Allen**. The authors have simplified the apparatus of Tarugi and Bianchi for the estimation of sulphates and salts of barium by a volumetric method based on the rapid clearing of turbid solutions in tubes of narrow calibre.—The determination of sugar by Fehling's solution: W. R. **Lang** and T. B. **Allen**. The apparatus described by the authors (preceding paper) was also employed for the determination of dextrose by means of Fehling's solution.—Studies in asymmetric synthesis, vi., the asymmetric synthesis of the optically active tartaric acids: A. **McKenzie** and H. **Wren**. The asymmetric synthesis of *l*-tartaric acid was accomplished in three ways:—(1) by the oxidation of *l*-bornyl fumarate in glacial acetic acid solution by potassium permanganate; (2) by the oxidation of the potassium salt of *l*-bornyl hydrogen fumarate in aqueous solution by potassium permanganate; (3) by the oxidation of *l*-menthyl fumarate in an analogous manner. The asymmetric synthesis of *d*-tartaric acid was accomplished by the oxidation of the potassium salt of *d*-bornyl hydrogen fumarate.—Some derivatives of 2-phenyl-1:3-naphthylenediamine, part i.: N. **Lees** and J. F. **Thorpe**. Typical derivatives of the base have been prepared and investigated, and the conditions have also been determined under which it is converted into the corresponding dinaphthol and the two amino-naphthols.

EDINBURGH.

Royal Society, May 6.—Dr. Robert Munro in the chair.—Inbreeding in the Barbary sheep and in the common goat: Prof. J. C. **Ewart**, F.R.S. The herd of Barbary sheep, which had been living for about a century at Abercairney, in Perthshire, seemed to be as vigorous and prolific now as when they were first introduced, and yet there had been no fresh blood added for at least fifty years. The problem was, why should this vigour continue in spite of inbreeding? To answer this question a series of experiments had been begun in 1899 with a pair of common goats. The great-great-grandson in 1905 was as vigorous as the original male, whom he closely resembled, and his offspring with the grand-daughter of the original pair were decidedly more vigorous than the first pair of goats born in 1900. It was found that, as a rule, the offspring of immature males was weak, and that it was more important for the male to have reached his full strength than for the female to have reached maturity. One reason why inbreeding in herds did not lead to deterioration seemed to be that the weaklings were eliminated, and every now and again there was a restoration of a vigorous ancestor.—Report on fossil fishes collected by the Geological Survey in the Lower Carboniferous rocks near Gullane, East Lothian: Dr. R. H. **Traquair**, F.R.S. The list contained thirteen species, of which two were new. A comparison with the fossils of other similar shales showed that the Gullane rocks corresponded most closely with the Wardie shales, there being eight of the thirteen species in common.—Heusler's magnetic alloy: Alexander D. **Ross**. The particular alloy experimented with had a composition of manganese 25 per cent., aluminium 12·5 per cent., a trace of lead, and the remainder copper. The aim of the research was to find how the magnetic susceptibility varied under various thermal treatment, such as heating up to different high temperatures, cooling down to the temperature of liquid air, and bringing back the alloy to its original state either suddenly or gradually. When quenched at 610° C., the material showed distinct diminution in permeability, which was not so marked when the quenching was from either higher or lower temperatures. This was perhaps the most interesting among a number of other results obtained.—The physical properties of mixed solutions of independent optically active substances: Clerk **Ranken** and Dr. W. W. **Taylor**. The properties chosen for measurement were the viscosity, the density, and the electric conductivity. The optically active substances were the normal potassium tartrates and the tartar emetics, and, for the sake of comparison, potassium racemate and racemic emetic. The independent optically active substance was cane sugar, and in one set of experiments maltose. Equivalent solutions of the three *d*, *l*, and *r* substances were made, and the physical properties determined at 15° C. and 25° C. A definite weight of sugar was then added, and the measurements again made. The general conclusion was that the addition of an independent optically active substance to solutions containing optically active stereoisomers does not cause any recognisable differences.

May 20.—Dr. Traquair, vice-president, in the chair.—A new method of ascertaining twist in single threads: Thomas **Oliver**. The usual microscopic method in the case of combed yarns is fairly accurate, but is very unsatisfactory in the case of carded woollen threads. The new method depended on the relation formerly obtained by the author between the "take-up" and the turns per inch in the twisted thread, and consisted in determining the number of turns required to give the maximum length as the thread was untwisted.—The influence of twist on the strength of a thread: Thomas **Oliver**. Under tensile stress the elongation of a thread is not quite proportional to the stress. With increasing stress the increment of elongation increases. At length a certain point is reached when the increment of length for a given increment of stress becomes distinctly greater, and goes on increasing to the breaking point. This yield point was chosen as an indication of the strength, and thus it was possible to compare the strengths of the thread in different conditions of twist without breaking it. The relation between the strength *y* and the number of turns of twist per inch *x* could be represented by the equation $y = bx^2/(x^2 + b^2/k)$, where *b* and *k* are constants for each thread. The paper contained a critical examination of a formula given in 1879 by Prof. Hartig, and of some conclusions advanced by Profs. Hübner and Pope in a paper on the influence of certain reagents on the tensile strength of cotton yarn.—Notes on some oligochætes found on the Scottish Loch Survey, and also on some Turbellaria from Scottish lochs: C. H. **Martin**. The notes were chiefly concerned with the genital organs, and one new species of oligochæte worms was described. An interesting point was noted in connection with the Turbellaria. This worm feeds on the Hydra. The nematocysts are not digested, but, retaining their vitality, work out to the external skin, finally assuming the position normally occupied in the Hydra.—The composition of red clay: Dr. F. W. **Clarke**. Fifty-one specimens of red clay from various localities had been supplied by Sir John Murray. These were combined in equal weights, and the composite sample so obtained carefully analysed. In most respects the analysis agreed fairly well with the average of the original *Challenger* analyses, but showed distinctly less iron and a small quantity of a number of minor elements not hitherto reported, such as titanium, barium, strontium, vanadium, &c.—The glaciation of east Lothian, south of the Garlton Hills: Prof. **Kendall** and E. R. **Baily**. This paper gave a detailed account of the glaciation of the district described, the positions and manner of formation of the various glacial lakes and their outflows being indicated as the ice advanced and retreated. Some interesting illustrations were given of the way in which a tributary falling into a flat valley formed an accumulation of detritus which finally turned back the course of the upper tributaries into another channel and quite altered the watershed. The view which explains certain so-called raised beaches as the result of glaciation was also emphasised. The evidence of the old lake basins and of the Boulder-clay deposits led to the same conclusions.

June 3.—Prof. Crum Brown, F.R.S., in the chair.—Temperature changes occurring in fresh-water lochs: E. M. **Wedderburn**. There were three types of temperature distribution occurring in the Scottish lochs. From December to March the temperature was practically uniform throughout; from April to July the heating of the surface waters led to a distribution in which the gradient of temperature with depth was at no place very rapid, but from August to November a "discontinuity temperature layer" came into existence, the so-called *Sprungschicht* of the Austrian and German naturalists. Down to the depth of this discontinuity layer the temperature varied very slowly, and below it, down to the bottom of the loch, there was an almost constant temperature, but within the layer the temperature varied very rapidly. This the author believed to be due to the action of the winds blowing over the surface and separating out the two great masses of water of different temperature and density. The explanation was illustrated experimentally by means of a trough containing a layer of salt water with a layer of fresh water above it. A blast of varying strength could be blown along the surface, causing the fresh water to heap up towards the leeward end, and producing a back current along the bottom of the fresh-water layer. This back current drew the upper layer of the salt water after it, and set up a feeble return current in the salt-water layer in the same direction as the original current on the surface due to the wind. When the blast ceased a seich-like movement was produced in the salt-water layer, exactly similar to the temperature seiche which had been observed in the Scottish lochs.—A specimen of *Helix pomatia* with paired male organs: Dr. J. H. **Ashworth.** In addition to the normal set of reproductive organs present on the right side, this specimen possessed on the left side a set of accessory male organs. The normal and supplementary male organs were equally developed and were symmetrically placed, and the supernumerary genital aperture occupied a position on the left side exactly corresponding to that of the normal aperture on the right side. The form of the supplementary organ supports the view that the present position of the genital ducts in Helix and other Stylommatophora has been derived from a condition existing in the ancestral form in which the vas deferens and penis were connected with the primitive genital aperture by means of a lateral groove, such as still exists in Pythia.—Encystment of Tardigrada: James **Murray.** This remarkable transformation began with the forming of a cyst under the original skin of the mature animal, the skin gradually shrivelling, the feet disappearing, and the creature reverting to an embryonic state with loss of all its principal organs. After a period of rest the organs develop again, and the animal finally emerges from its case exactly as it was before the encystment began.

PARIS.

Academy of Sciences, June 24.—M. Henri Becquerel in the chair.—A new mineral species from the high temperature fumerolles of the recent eruption of Vesuvius: A. **Lacroix.** The mineral has the composition

$$PbSO_4.(K \text{ or } Na)_2SO_4,$$

and the name palmierite is proposed for it.—A new method of preparing anhydrous oxide of lithium: M. **de Forcrand.** Pure lithium carbonate is heated to a temperature of 780° C. to 800° C. in a platinum boat in a current of dry hydrogen. In about three hours the whole of the carbon dioxide is eliminated, and pure Li_2O remains. The heat of solution of pure lithium monoxide, prepared in three different ways, was found to be 31·2 calories, or more than five calories higher than the previously accepted number of M. Beketoff.—The addition of water to ethylenic oxides by means of sulphuric acid: Louis **Henry.** Now that an application of Grignard's reaction gives a means of preparing ethylene oxides in a general manner, the author has studied the mode of hydrolysis by dilute acids, and gives a series of glycols, with their boiling points, which have been prepared.—The secretary announced the death of Charles Trepied, correspondant for the section of astronomy, and A. Crova, correspondant in the section of physics.—Observations of the comets *c* and *d*, 1907, made at the Observatory of Algiers: MM. **Rambaud** and **Sy.** Observations were made on eight nights between June 5 and 19. The positions of the comparison stars and the apparent positions of the comet are given.—A species of analytical geometry of systems of additive functions: Frédéric **Riesz.**—The functional equation of M. Fredholm: A. **Korn.**—Ensembles of functions and linear operations: Maurice **Fréchet.**—The secondary kathodic emission of metals under the influence of the α-rays: Marcel **Moulin.** The existence of a secondary radiation of the α-rays, at first generally admitted, has been called in doubt by several recent workers. Preliminary experiments in favour of the hypothesis of the existence of such secondary radiations are given.—Drops formed in a magnetic field: H. **Ollivier** and Pierre **Sève.**—Thermochemical data relating to the ammonio-mercuric base and its hydrates: H. **Gaudechon.** The immediate solution effected by a solution of potassium cyanide is utilised as a means of carrying out the thermochemical measurements. The data used as a basis for the calculations are indicated in full.—The nature of sulphammonium: P. **Lebeau** and P. **Damoiseau.** A repetition of the work of Henri Moissan and of Otto Ruff and Geisel. The latter indicate a reversible reaction between sulphur and ammonia, giving rise to nitrogen sulphide and ammonium sulphide. In the present paper it is shown that if minute precautions are taken to ensure the complete absence of moisture, neither nitrogen sulphide nor ammonium sulphide is formed. The weight of sulphur recovered after evaporation of the liquid ammonia is exactly the original weight, and no trace of sulphuretted hydrogen is given off during the evaporation.—The combinations between silicon and molybdenum. Molybdenum bisilicide: Ed. **Defacqz.**—The various molecular states of anhydrous ferric sulphate and hydrated ferric sulphate: A. **Recoura.**—Cuprous iodide: Marcel **Guichard.** All attempts to prepare cupric iodide by working at low temperatures failed. Hydriodic acid, liquefied at a low temperature on cupric chloride, gives rise at once to a mixture of cuprous iodide and free iodine. The iodine appears at the commencement of the reaction, and is easily separated either by solution or sublimation. A new method of analysis of iodides is given.—A study of the alloys of cobalt and tin: F. **Ducelliez.** The method of isolation and the properties of the alloy CoSn are described.—A molybdo-uranic combination: André **Lancien.** The precipitate formed by the interaction of ammonium molybdate and uranyl nitrate has the composition of uranyl molybdate, UO_2MoO_4.—Lupeol: E. **Jungfleisch** and H. **Leroux.** A comparison of the properties of the alcohol lupeol, isolated from different samples of gutta-percha.—The action of some esters of the α-iodo-fatty acids on the iodide of magnesium phenylamine and magnesium orthotoluidine iodide: F. **Bodroux** and F. **Taboury.**—The origin of the deposits of colouring matter in red wines: A. **Trillat.** The deposit is caused by the formation of an insoluble compound of the red colouring matter with acetaldehyde. In the absence of the aldehyde the red substance is not affected by the oxygen of the air.—The synthesis of an aldehyde possessing the odour of violets, cyclo-lemonylidene-propenol: Ph. **Barbier.** Lemonal and propionic aldehyde are condensed by dilute soda in weak alcoholic solution. The resulting aldehyde is treated with 60 per cent. sulphuric acid. Two aldehydes result, both possessing an intense odour of fresh violets, and superior to that of ionone. These have the drawback of oxidising very rapidly by exposure to air, and losing their smell in consequence.—The phenomena of coloration of brown bread: Gabriel **Bertrand** and W. **Mutermilch.**—Observations on the primordial leaves of various species of the genus Achillea: Léon **Dufour.**—The fungus-cultivating ants of Madagascar: H. **Jumelle** and H. Perrier **de la Bathe.**—Some variations observed in the rose: Lucien **Daniel.**—The morphological value of the spines of coral: Louis **Roule.**—The persistence of the trocophore in a Hesionian: C. **Viguier.**—Some new ideas on the white bearded gibbon. *Hylobates leucogenys*: Louis **Boutan.**—A general table of the encephalic weights as a function of the body weight: Louis **Lapicque.**—The association of unicellular algæ with *Sarcophytum mycetoides*: Ch. **Gravier.**—The measurement of the pulmonary field and its activity: Gabriel **Arthaud.**—The physiological action of some colouring matters and their urinary excretion: Jean **Gautrelet** and Henri **Gravellat.**—The relation between oceanic whirlpools and volcanoes: E. A. **Martel.**

NEW SOUTH WALES.

Linnean Society, March 27.—Annual general meeting.—Mr. Thomas Steel, president, in the chair.—Presidential address: Some questions in terrestrial physics: T. **Steel.** The first section was devoted to a discussion of radium and the earth's internal heat, the nature of radium and the phenomena accompanying its disintegration being described. The consequences of the acceptance of the theory that the present internal heat of the earth is due to radium contained in the crust were detailed, and the immense importance of the theory in connection with the problems of geological time fully considered. The concluding portion consisted of a consideration of the question of the influence on climate of possible variations in the composition of the atmosphere, more especially with regard to its carbon dioxide content. The manner in which climate is influenced by the amount of this substance in the air was clearly described, and the causes leading up to its removal or replacement were discussed. Consideration was also given to the possibility of climate being influenced by the earth's internal heat. The address concluded with a brief account of some of the proofs of the former glaciation of the earth's surface to regions well within the tropics, and with the possible explanation of this phenomenon by mutations in climate caused by variations in the carbon dioxide in the atmosphere.—Ordinary monthly meeting, Mr. A. H. S. Lucas, president, in the chair.—Decapod Crustacea from Norfolk Island: the late F. E. **Grant** and Allan R. **McCulloch.**—Descriptions of Australian Microlepidoptera, part xix., Plutellidæ: E. **Meyrick.** In the "Handbook of British Lepidoptera," the family Plutellidæ was regarded as comprising the three groups Yponomeuta, Glyphipteryx, and Plutella. In the present paper, not without due consideration, the family receives a more extended application so as to include, in addition, Gracilaria and Zelleria, formerly included in the Tineidæ.

April 24.—Mr. A. H. S. Lucas, president, in the chair.—Descriptions of new or little-known Desmids found in New South Wales: G. I. **Playfair.** Dr. Otto Nordstedt has recorded nine species from the Blue Mountains, and Dr. M. Raciborski seventy-seven species from Centennial Park, Sydney, the papers of these two writers representing the only published contributions to a knowledge of New South Wales Desmids available at present. The material studied by the author represents about 350 species, of which 230 have been identified as forms not restricted to New South Wales, fifty require further investigation, and seventy are treated and figured in the present paper, of which fifty are regarded as previously undescribed.—Revision of the Thynnidæ (Hymenoptera), part i.: Rowland E. **Turner.** The present paper, part i., treats of the subfamilies Diamminæ and Thynninæ, the former comprising only one genus, Diamma, represented by a single species, and the latter seven genera and two subgenera, represented by 102 species, of which forty-six are described as new.—Contributions to a knowledge of Australian Foraminifera, part ii.: E. J. **Goddard** and H. I. **Jensen.** The material described in this and previous papers has been obtained from localities sufficiently far removed from one another to enable the authors to make deductions regarding the distribution of Foraminifera in Australian waters, and also to discuss the probable conditions of climate and deposition at the time the Table Cape beds were laid down.

CALCUTTA.

Asiatic Society of Bengal, May 1.—An abnormal branch of the mango (*Mangifera indica*, Linn.): I. H. **Burkill** and G. Chunder **Bose.** A young grafted mango bore two abnormal branches, which were leafy along one side, but flowering along the other. The internal anatomy of the larger branch was studied, and it was ascertained that the xylem was much more developed on the leafy than on the flowering side.—Note on the Shahin falcons (*Falco peregrinator* and *F. barbarus*): Lieut.-Colonel D. C. **Phillott.** Their habits, breeding, employment in falconry, and Eastern names.—Note on the red-headed merlin (*Æ salon chiquera*): Lieut.-Colonel D. C. **Phillott.** Its breeding, habits, and use in falconry.—Magnetic induction in spheroids: D. N. **Mallick.** This paper deals with the problem of magnetic induction in a magnetic substance in the form of a prolate spheroid, due to a current circulating in a wire wrapped round it along a part of its length.—The fats of Garcinia species: D. **Hooper.** The author enumerates four species of Garcinia the seeds of which are known to yield fixed oils, employed for lighting, edible, and medicinal purposes. Two of these have been examined by the author, who confirms the analysis of Heise in showing that the fat of *G. indica* consists chiefly of oleodistearin, and from an examination of gamboge butter, the semi-solid fat of *G. Morella*, its constitution is shown to be that of stearo-diolein.

DIARY OF SOCIETIES.

THURSDAY, JULY 4.

CHEMICAL SOCIETY, at 8.30.—*iso*Nitroso and Nitrodimethyldihydroresorcin: P. Haas.—The Structure of Carbonium Salts: F. Baker.—Studies of Dynamic Isomerism, Part VI., The Influence of Impurities on the Mutarotation of Nitrocamphor: T. M. Lowry and E. H. Magson.—The Relation between Absorption Spectra and Chemical Constitution, Part VIII., The Phenyl Hydrazones and Osazones of α-Diketones: E. C. C. Baly, W. B. Tuck, E. G. Marsden, and M. Gazdar.—Permanganic Acid: M. M. P. Muir.

ASSOCIATION OF ECONOMIC BIOLOGISTS (IMPERIAL INSTITUTE), at 11.30 a.m.—Some Notes on Ticks: C. Warburton.—A Remedy for the Spruce-gall and Larch-blight Diseases: E. R. Burdon.—Demonstration in the Public Galleries of the Imperial Institute by Mr. W. G. Freeman, the Superintendent of the Colonial Collections.—At 2 p.m.—A Note on the Cecidomyidæ or Gall-midges: W. E. Collinge.—The American Gooseberry-mildew, and the Proposed Legislative Measures: E. S. Salmon.—The Bionomics of the Calypterate Muscidæ, and their Economic Significance: C. Gordon Hewitt.

FRIDAY, JULY 5.

GEOLOGISTS' ASSOCIATION, at 8.—The Geology of the Appleby District, Westmorland: Dr. J. E. Marr, F.R.S.

CONTENTS.

THURSDAY, JULY 11, 1907.

THE WOLLEY COLLECTION OF BIRDS' EGGS.

Ootheca Wolleyana, an illustrated Catalogue of the Collection of Birds' Eggs formed by the late John Wolley, jun. Edited from the original notes by Alfred Newton. Part iv., Alcæ—Anseres; with supplement and appendix, map, and three plates. (London: R. H. Porter, 1907.) Price 25*s*. net.

THE recent death of Prof. Alfred Newton attaches a melancholy interest to this work, which, though not of a strictly scientific nature, may, in some respects, be regarded as the *magnum opus* of the editor and joint author; whilst his friends should at least take comfort in the reflection that he was spared long enough to complete it. The publication was commenced in 1864, when part i. was issued; then suspended for a period of thirty-eight years, and recommenced in 1902, when part ii. completed the first volume. Part iii. appeared in 1905, and, together with the present issue, constitutes the second volume.

Part iv. includes the divers, grebes, shearwaters, &c., and also the herons, but the most important entries relate to the swans, geese, and ducks, in which John Wolley took an especial interest on account of the difficulty of obtaining properly identified eggs of these birds. There is also a supplement and appendix, the latter containing the publications of Wolley on natural history other than those included in the text of the "Ootheca," such as papers on mammals, reptiles, batrachians, and especially on insects. The supplement is occupied with corrections, omissions, and additions, the names of species not before included being in thick type. These latter are fairly numerous, and serve to bring the work up to date, especially in those cases where the earlier collectors had been unable to discover authentic eggs. There are also some corrections in nomenclature, especially in the case of the owls, some half-dozen of which receive different names, whether of genus or of species. This reminds us of the protest of the late Dr. Bree against the generic divisions of the owls. He was writing of the Ural owl, which, by the way, is one of the new species recorded, the editor having received an egg from the Lower Danube, taken in 1866; subsequently he obtained two from Finland, as recently as 1905. Again referring to the subject of nomenclature, the editor deplores the necessity for changing the name of *Falco sacer* into that of *F. cherrug*. But Rip van Winkle rubs his eyes when he finds his old friend *Aquila imperialis* become successively *A. mogilnik* and *A. heliaca*, and is very much disposed to ask, "What next?"

Since the "Ootheca Wolleyana" is now completed, we may take a retrospective view of the entire work. The editor disclaims for it any special scientific value, and remarks that

"there is no need to observe too strictly the technicalities of science. The arrangement (I will not call it classification) of the species named is one of them. The ideal taxonomy of birds is beyond the range of my vision."

Thus he only deals with genera and species, and does not further classify under families and orders. It is obvious that in all works on natural history, authors are bound to adopt some kind of sequence. Even the alphabetical plan used in the index is not absolutely free from difficulties, since such are the changes in genera that unless one knows the name likely to have been adopted, the search is apt to be troublesome. But this is a minor matter, for the whole subject of the classification of birds is very much in the condition of the British army at the present time, viz., as we are told, "in the melting-pot." Are the Accipitres or the Passeres ultimately to have precedence?

The scope and object of the work are, however, of much more importance than any questions of classification, and, since it relates to discoveries made chiefly about the middle of the nineteenth century, the present generation of ornithologists might naturally ask for information on these points. The answer would be that it is an illustrated catalogue containing details of the most authentic and probably one of the largest collections of European and Palæarctic birds' eggs that ever was made. Practically there are two authors, since the contributions of the editor equal, if they do not exceed, the extracts from the writings of Wolley himself. John Wolley died in 1859, at the early age of thirty-six, and shortly before his death he requested that his collection of birds' eggs should be handed over to his friend and companion, Alfred Newton, who likewise became his literary executor. The "Ootheca Wolleyana" is therefore justly dedicated to the Rev. John Wolley, of Beeston, Notts (long since deceased), "as an acknowledgment of his generosity in fulfilling the last wishes of his son." The sources for the compilation of the catalogue are letters to friends, fragmentary diaries, and, above all, his "egg-book." In bringing their joint contributions into notice, the editor's method has been to print the observations of Wolley in full-sized type, whilst the editorial explanations, including references to specimens obtained since 1859, are in small type.

It should be understood that there are practically two collections, since the collection originally formed by Alfred and Edward Newton in partnership has been incorporated with the Wolley collection, and increased by subsequent additions. For a few years after his friend's decease, the editor maintained a connection with some of his principal collectors in Lapland, and thus continued the work which commenced in 1853. Moreover, the original collection was confined to European species, but the editor has chosen to extend its limits to those of the western half of the Palæarctic region. Some idea of the magnitude of the catalogue may be gathered from the fact that there are, inclusive of those in the supplement, 6076 entries or sections, consisting of one or more eggs, to which a special history is attached. The number of eggs in each entry ranges from *one* to some *twenty* or *thirty* in the case of birds breeding in colonies. The average may be a little over four, which would give a total of about 25,000 eggs. This is only a rough calculation, and may be wide of the mark. The number of species listed is approximately 650. Two samples of entries, slightly modified, are given :—

(1) *Falco Gyrfalco*, Linnæus. Sect. 192. *Four*. West Finmark, May 7, 1854. "J. W. *ipse*."

(2) *Tringa subarquata*, (Guldenstädt). Sect. 6065. *One*. Kotelny Island, New Siberian Group, June 11, 1902.

It might perhaps be objected that the collection contains too many duplicates, and this redundance receives illustration, for instance, in the case of Buffon's skua. The first egg of this species was obtained by Wolley himself near the sources of the Tana on June 20, 1857, both birds being shot, and very few additional specimens were obtained during his lifetime. But from 1860 to 1862, the latter being the great lemming-year, the number of entries, mostly of pairs, occupies about nine pages of the catalogue. The fact is that Wolley had originated a movement which could not be stopped, and his collectors, having been once put on the right track, went on collecting mechanically, as it were, and without remorse. The same thing occurred in the case of the waxwing and some other species, the eggs of which were previously unknown, or at least unauthenticated.

It must not, however, be supposed that the "Ootheca Wolleyana" is a mere list of eggs, for the notes, whether of author or editor, are copious, and both interesting and valuable, not only to collectors, but to ornithologists in general. The above calculations may serve to give some idea of the labour involved in preparing for the press this immense mass of material—a labour of love, in the words of the editor, since he regards the catalogue as largely a record of ancient friendship. Its freedom from typographical errors is remarkable, considering the constant change of type, and the number of technical names. Nor is the editor dismayed by the length of time which has elapsed since its commencement, considering that the delay has not been without its advantages, as specimens unattainable in Wolley's lifetime, and for long after his death, have been acquired, and are recorded, some in the body of the work and others in the supplement. It should also be remembered that the joint collection, of which this is the catalogue, has been given to the University of Cambridge, "in whose museum of zoology," Prof. Newton trusts, "it may long continue."

The primary object of the "Ootheca" is to record the labours of the naturalist whose name it bears, and in further fulfilment of this duty a most interesting memoir of John Wolley is added (part ii., pp. ix–xxxix) by way of introduction to vol. i. There is a good likeness of him, based on a photograph taken about a year before his death. In that likeness we recognise the calm determination which was so characteristic of a man who, in the words of Hewitson, "had become as familiar with the king of birds as others are with crows and magpies." That was in what we may call the heroic stage of his career, when he was equally prepared to scale a precipice after an eagle or to swim out to an osprey's nest in the coldest of water. Four years afterwards the birds'-nester of 1849 had made no inconsiderable progress in the study of natural history, and thus, after the example of Linnæus, as also pointed out by Hewitson, he wended his way into Central Lapland, and laid the foundation of a series of campaigns which have made his memory famous in the annals of oology. It is not so much the hardships which he endured in the quest of eggs, though these were sufficiently severe, as his powers of endurance through three winters in Lapland that astonish us. Perhaps it was this mode of life, in conjunction with his remarkable indifference to ordinary comforts, which was partly the cause of his early death, before he had time fully to work out the results of his great experience. In 1858, together with the editor, he undertook a pious pilgrimage to the last breeding-place of the great auk on Eldey, in Iceland. An abstract by the editor of Wolley's researches in Iceland respecting the great auk appeared in the third volume of the *Ibis*. The same year he became one of the original members of the British Ornithologists' Union, and contributed two classical papers to the first volume of its journal. His death, in 1859, created the first vacancy in its ranks, and it is the opinion of all who knew him that, had he been spared, he would have taken a high place amongst the leading naturalists of the second half of the nineteenth century.

As regards the collection, that portion formed by Wolley dates from the early 'forties, when he was a boy at Eton, sometimes occupied in chasing dabchicks on the Thames. The portion formed by the Newtons was commenced probably somewhat later, and continued at intervals almost to the present time. Whilst residing at Elveden, they enjoyed great advantages for working some of the best districts of East Anglia, and were not slow to profit by their opportunities. When Wolley went to Cambridge in 1843, the fens afforded very good hunting-ground, though harriers were getting scarce even then. That paradise of birds, Whittlesea Mere, was still intact, not being drained until 1850. He succeeded in obtaining eggs of all three species of harrier, though none apparently of his own taking. The other rarities of the fens, such as the grasshopper-warbler, Savi's warbler, bearded tit, &c., likewise great numbers of spotted crake and water rail, he obtained second-hand, sometimes through "Plover George" (Harvey of Baits-bight), whom he always distrusted.

It would lengthen this notice unduly if we were disposed to enter into any detail as to the eggs obtained during his famous Sutherland campaign in 1849. He succeeded in proving that it is the grey-lag goose, and not the bean goose, which breeds in the north of Scotland, whilst his success amongst the eagles was duly recorded by Hewitson, whose third edition was greatly enriched by Wolley's results, both in Scotland and in Lapland. The editor of the "Ootheca" in many cases reproduces these extracts from Wolley's letters to Hewitson, or substitutes for them the original notes from the egg-book, occasionally including passages which had been omitted.

Thus, *àpropos* of the pintail, Wolley expresses his feelings on the identification of eggs:—

"In common with some other ornithologists I had long been almost in a state of desperation about several of the ducks—about most of those, in fact, which do not, occasionally at least, breed in Great Britain. *Many a collector could produce the eggs of what ducks you please at a moment's notice, but few, very few, could give any kind of satisfactory account of them.*"

[That portion of the extract italicised was omitted by Hewitson.]

The fact is that a crisis was impending in the history of Wolley's collection. We gather from an inspection of the catalogue that many of the rarer eggs had been supplied, for the most part in single specimens, by dealers from abroad. It must in justice be said of M. Favrier, of Tangier, where Wolley paid a visit about 1845, that eggs of rare birds supplied by him were afterwards proved to be genuine on comparison with well-identified eggs obtained by Tristram's Algerian party in 1857. Subsequently to this date Wolley was enabled to supply deficiencies in his collection from the above source, partly by gifts and partly through exchange. But the problem of the nidification of birds breeding in the north of Europe he determined to solve for himself, and, as we have seen, the cream of his results went to swell the plates and pages of the third edition of "Hewitson." Those who wish to know more of this subject must consult the pages of the "Ootheca," and if we venture to deal with any particular group, by way of illustration, the Limicolæ perhaps will suit our purpose as well as any other, and a partial extract here and there must suffice. *Ex uno disce omnes.* Wolley's pæan of delight in fully identifying the eggs of jack-snipe may be quoted, partly for the purpose of illustrating his methods in Lapland.

"The next morning I went to Kharto-uoma with a good strength of beaters. I kept them as well as I could in line, myself in the middle. . . . Whenever a bird was put off its nest the man who saw it was to pass on the word, and the whole line was to stand, whilst I went to examine the eggs."

At length the expected signal was given, a nest had been discovered, and the sight of the eggs as they lay untouched raised his expectations to the highest pitch, until he succeeded in shooting "a true jack-snipe, the undoubted parent of the nest of eggs." Another most important find were the eggs of the spotted redshank, and these ultimately in considerable numbers, quite close to Muoniovara, his Lapland home. The editor doubts whether any ornithologist previous to this had ever seen a genuine specimen. Three picked eggs of this species were selected for figuring in the third edition of "Hewitson," and the editor expresses his regret that the present condition of these eggs in the collection would not justify him in figuring additional specimens. Another rare egg of this group is that of the bar-tailed godwit. A nest of four was obtained in Kittila, June 12, 1854, in time for Hewitson to figure two of them; the entire clutch is still in the collection. In 1858 and subsequently, some more complete clutches were secured, but on the whole it is probable that the bulk of these birds breed more to the eastward, as none came under Wolley's special notice. Hence eggs with "*Puna Kuovi*" in Wolley's handwriting are not to be found in many collections. Probably all the species of the Limicolæ which breed in Central Lapland were procured with their eggs, but there still remained species the nesting-places of which lie east of the White Sea, such as the grey plover, the little stint, the sanderling, the knot, and the curlew-sandpiper, the eggs of which were not added to his spoils. Their discovery is duly recorded in the "Ootheca" supplement, years after Wolley's death, and the melancholy reflection prevails that in this direction there is nothing more to be done. In the supplement the editor, *apropos* of specimens of knot and curlew-sandpiper from the New Siberian group found in 1902 and added to the collection in 1905, directs attention to an article in the *Ibis* for 1904 by Mr. Dresser. This is a translation in abstract of Dr. Walter's researches in the Taimyr peninsula, where the translator observes that

"Dr. Walter succeeded in taking eggs and young in down of the sanderling (*Calidris arenaria*), curlew-sandpiper (*Tringa subarquata*), and knot (*Tringa canutus*), the eggs of the last being especially valuable, as they are the first well-authenticated specimens yet obtained."

We presume that he is referring to eggs laid in the free state, as the editor claims to have the egg of the knot laid in the late Lord Lilford's aviary.

There are not many illustrations in part iv., but the work as a whole is sufficiently illustrated, especially part i. These illustrations are mainly of two kinds—figures principally of eggs, and lithographic landscapes. The plates of the eggs of raptorial birds by Balcombe are very successful. There are three plates devoted to eggs of the golden eagle, every one of which has a history, mainly Scotch eggs, though some came from Lapland. Nor are these all of Wolley's own taking, since both Alfred and Edward Newton personally shared in some of the Argyllshire captures. In the delineation of the eggs of the Passerines, the artist has perhaps not been quite so successful.

"Of all Mr. Wolley's discoveries," observes the editor, "the one with which his name will be especially perpetuated is his unveiling the mystery that had hitherto surrounded the breeding habits of the waxwing."

These eggs were not obtained in time for the third edition of "Hewitson," but were figured in the *Ibis* for 1861 "as Mr. Hewitson only could depict them." In the "Ootheca" an entire plate is devoted to eggs of the waxwing, which exhibit a fair amount of variety, but the figures do not compare favourably with those in the *Ibis*. One other group of eggs should be mentioned, viz., the double portraits of the seven eggs of the great auk contained in the collection, so well executed by Grönvold. The details regarding these eggs occupy about twenty pages of the catalogue, and it may interest persons who are prepared to give a high price to learn that Wolley's first great auk's egg, obtained on December 12, 1846, from Mr. D. Barclay

Bevan, cost him no more than 28s. The lithographic landscapes, especially numerous in vol. i., add greatly to the interest of this work. There are two very spirited sketches by Wolf of eagles' nests in Argyllshire, drawn to illustrate the locality previously mentioned, but the majority of these landscapes depict scenes in Lapland rendered more or less famous in connection with Wolley's exploits. The old Lapp altar near Muoniovara, the osprey's nest on the top of a Scotch fir on the Norwegian side of the watershed, and the great crane marsh, all three from original sketches by the editor, are examples of these landscapes. But perhaps the most interesting of all—certainly the most poetic—is the picture of the hooper asleep on her nest on an islet in the Patsjoki, at midnight, June 17-18, 1855; this is based on a faint sketch made by Wolley on the spot, and most skilfully interpreted by Mr. Jury. Again (Table O), there is a truly Lapland scene, where the facile golden-eye is about to deposit an egg in a *tylla*, fastened to a fir-tree, for the benefit of the wily native. A map of the country between the Gulf of Bothnia and the Arctic Ocean is added. Muoniovara occupies a fairly central position, and the district more especially exploited is comprised within the upper basins of the Muonio Elv and the Ounas Joki—a stretch of about 150 miles from S.E. to N.W. There is something very musical in the sound of many of the Finnish place-names. Those more especially associated with the great "finds" may be observed in considerable numbers in the central area of the map, and collectors who possess marked eggs from Lapland cannot fail to be interested in the topography of the district.

It is not easy to give anything like a synoptic view of a work which appears in the form of a catalogue, so that its general character can only be inferred from such extracts as we have ventured to make. There is abundance of oological lore, relating to a period when great discoveries were being made, and this matter has been carefully sifted by an editor whose critical acumen and extensive knowledge are well known. The work, therefore, cannot fail to be a valuable repertory of facts, and we are bound to admit that in the "Ootheca Wolleyana" the veteran ornithologist of Cambridge, whilst adding largely to the store of information originally acquired by Wolley, has raised a worthy monument to the memory of his long-lost friend, and we can only express our deep regret that since its completion Prof. Newton has likewise joined the majority.

W. H. H.

INDIAN MALACOLOGY.

Land and Freshwater Mollusca of India, &c. By Lieut.-Col. H. H. Godwin-Austen. Supplementary to Messrs. Theobold and Hanley's "Conchologia Indica." Vol. ii., part x. Pp. 147-238; plates ci-cxvii. (London: Taylor and Francis, 1907.)

IT is just nineteen years since the first six parts (1882-1888) of this work were noticed in these pages (NATURE, July 5, 1888, pp. 217-218), and the author is now the sole active survivor of the celebrated band of Indian malacologists that included Theobald, the Nevills, Stoliczka, Benson, Beddome, and the two Blanfords. One by one they have nearly all gone from us (Dr. W. T. Blanford's demise is still fresh in our memories), leaving, alas, no successors in the field of their labours.

This but adds to our hope that Col. Godwin-Austen may long be spared to carry on the work he has begun, but, so wide is the field, can never expect to complete, especially since of late it has been only now and then he has been able to find time for the examination of material that has come to hand. As a consequence, seven years have elapsed since the appearance of the preceding part of the work before us.

The present number is on a line with its predecessors, and like them shows no arrangement of subject, the various notes being presumably placed in the order in which they were written, and consequently deal alternately with the two families Zonitidæ and Endodontidæ, to which alone the materials treated belong.

In the former family we find one new subgenus, Dalingia, and two new genera, Sarika and Staffordia, established; while the author transfers Austenia, Girasia, and Cryptosoma from the Helicarioninæ to the Macrochlamyinæ, and places Leptodontaria and Ibycus in the Durgellinæ. He further digresses advisedly to discuss the anatomy of three Japanese species, which have been referred to Macrochlamys, but which he shows must be removed, one to a new subgenus, Petalochlamys, and the other two to Lamprocystis.

The most interesting and aberrant member of the family is Stoliczka's genus Sophina, concerning which our author has much of interest to say.

To the family Endodontidæ, which is chiefly an Australasian group, three Indian representatives are referred, namely, Thysanota, Philalanka, and Sykesia, and a new subfamily, Thysanotinæ, is created for their reception.

The wonderful similarity of these animals to Corilla (a Ceylon genus) and Plectopylis is dwelt on, but Stoliczka's idea that the latter was related to Clausilia is rejected.

To the Thysanotinæ may also possibly belong the new genus Rahula, to which the *Helix macropleuris*, Benson, with other species, some new, is referred.

Among suggestions as to topographical distribution is the hint that the fauna of the Bhutan Himalayas may possibly be rather related to that of western China than to that of India.

At the same time, the author is inclined to consider the eastern Himalayas as the centre of dispersal of the genus Macrochlamys, and points to the geological evidence as tending to show that from Sikkim eastward up to the margin of the present plains was an old land area probably coeval with that of peninsular India, and once connected with it across what is now the delta of the Ganges. The south-eastern limit of the range of the genus appears to be about Tenasserim.

So far as the Gangetic valley is concerned, there has been a natural transport southward by flood-waters of the mollusca inhabiting the mountain country, and the molluscan fauna of the great delta of the Ganges and Brahmaputra had its origin in the Himalayan slopes, although they have occupied their present quarters for sufficiently long a period to become specifically distinct. (BV)[2].

WATER AND THE PUBLIC HEALTH.

(1) *The Value of Pure Water.* By George C. Whipple. Pp. viii+84. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1907.) Price 4s. 6d. net.

(2) *The Bacteriological Examination of Water Supplies.* By Dr. William G. Savage. Pp. xvi+297. (London: H. K. Lewis, 1906.) Price 6s. 6d. net.

(1) THIS little book is planned on novel lines and deserves recognition. An extract will best serve to define its scope.

"Given two water sources equally available to a city for purposes of supply, both safe to drink, but one high coloured and soft, the other colourless and hard—which is the better selection? A water-works plant is to be appraised: structurally the system is a good one, but the quality of the water is unsatisfactory because of its excessive colour or turbidity—how much should be deducted from the value of the works because of the bad quality of the water? The water-works owned by a private company are to be purchased by the city; the city has a high typhoid fever death-rate, due unquestionably to the water supply—how much less should the city pay because of that fact? A city is using turbid river water—how much can it afford to pay to filter it? A city is using a water so heavily laden with Anabæna that it is nauseous to drink—how much can the city afford to pay to procure a new supply?"

An attempt is made from available data to establish formulæ which may be employed to calculate the allowable depreciation due to sanitary quality, physical characteristics (colour, odour, &c.), hardness, &c., of a water supply.

The following example is a calculation in the case of typhoid fever. The financial loss to the community for each death from typhoid fever is assumed from various data to be equal to 10,000 dollars. A proportion of the death-rate is due to the disease transmitted by means (shell-fish, flies, &c.) other than water. Assuming that all typhoid in excess of N is due to the water supply, that the daily consumption of water is 100 gallons per capita, and that T is the total typhoid death-rate per 100,000, then $(T-N)$ $10{,}000=$ loss to the community in dollars for $365 \times 100 \times 100{,}000$ gallons of water, or

$$D=\frac{(T-N)1000}{365}=2\cdot75(T-N),$$

where D stands for the loss in dollars per million gallons of water used. The author is quite alive to the fact that local and other conditions must modify his conclusions, and recognises that more data are required before finality is reached in the elaboration of the formulæ. The book is suggestive and stimulating reading, the various tables add to its value, and we heartily commend it to the sanitarian and water engineer.

(2) This book by Dr. Savage, who has made many important contributions to the subject on which he writes, gives an admirable survey of the present position of the bacteriology of water supplies. Successive chapters deal with the bacterial content of waters and the influences affecting it, excreta, sewage, and soil in relation to the bacteriological examination, the characters of the intestinal bacteria, bacterial evidences of pollution, and full details of the methods employed in the bacteriological examination of water. The chapter on the interpretation of results is particularly to be recommended. A full bibliography is appended. The medical officer of health, the analyst, and the bacteriologist will find this book a trustworthy and useful guide. R. T. HEWLETT.

THREE MATHEMATICAL TRACTS.

Quadratic Forms and their Classification by Means of Invariant Factors. By Prof. T. J. I'A. Bromwich, F.R.S. Pp. viii+100. (Cambridge: The University Press, 1906.) Price 3s. 6d. net.

The Axioms of Projective Geometry. By Dr. A. N. Whitehead, F.R.S. Pp. viii+64. (Cambridge: The University Press, 1906.) Price 2s. 6d.

The Axioms of Descriptive Geometry. By Dr. A. N. Whitehead, F.R.S. Pp. viii+74. (Cambridge: The University Press, 1907.) Price 2s. 6d.

THESE are Nos. 3, 4, and 5 of the Cambridge Tracts in Mathematics and Mathematical Physics, which are intended to help students by providing them with brief and readable introductions to mathematical theories which are important in themselves, and yet for various reasons do not appear in the ordinary text-books. If they serve their purpose they will induce their readers to follow up the paths they indicate, and try to explore still further the mazy garden of the mathematical muse.

The present state of the theory of quadratic forms illustrates very well how much interest there may be in the particular cases of a problem which, in its so-called "general form," has a trite and familiar solution. To put the matter into a geometrical shape; when there are four homogeneous variables, let $S=0$, $T=0$ be the equations of two quadratic surfaces; then in general the family $S+\lambda T=0$ will have a common self-conjugate tetrahedron, and by taking this as a tetrahedron of reference, S and T assume a well-known standard form. But there are thirteen other cases to consider, for each of which there is a distinct reduced form of $S+\lambda T$; for instance, if S and T intersect in a cuspidal quartic, the reduced form is

$$2(\lambda+a)xy+2yz+b(\lambda+a)z^2+c(\lambda+d)t^2.$$

If we consider the small oscillations of a dynamical system with four degrees of freedom, we are confronted by precisely the same analytical problem of reduction; the algebraical classification is the same, but certain cases are ruled out by the condition that the kinetic energy of the system is necessarily positive; still more, if the potential energy is a true minimum.

Prof. Bromwich has given an excellent account of the analytical theory, with various geometrical and dynamical illustrations, and he has added a very useful bibliography. As he has pointed out himself, he has selected Kronecker's method of proof of the invariance of the factors of the discriminant of $S+\lambda T$; and he has made no reference to the specially arithmetical form of the problem, where the coefficients of the forms are integers, and the equations of transformation have to be unitary and integral. For this, the student will consult Frobenius, Hensel, and H. J. Smith, whose memoirs, of course, Prof. Bromwich includes in his list of references.

Dr. Whitehead's chapters deal with a subject which, on the one hand, is more ancient than that of Prof. Bromwich, but, on the other, has changed its aspect recently in a much more remarkable way. Dr. Whitehead is one of the company of sappers who are reducing all the mathematical part of geometry to a system of abstract logic applied to a minimum number of undefinable entities, connected by a minimum number of undefinable relations. Put in this bald way, their work seems purely destructive and hateful, but in reality it is not so. In the tract on projective geometry it is shown how, with the help of Dedekind's axiom, and those of order, it is possible to make rigorous von Staudt's proof that all the points on a line are either reached by harmonic constructions starting from three given points, or definable as limiting points of a set of such points. This leads to definitions of numerical cross-ratios and of numerical homogeneous coordinates *which are independent of any theory of distance or measurement*, a very remarkable and far-reaching result. It is very encouraging to find that the magnificent genius of von Staudt is gradually gaining the recognition that it deserves; the interval between him and his predecessors is at least as great as that between Apollonius and Steiner.

By "descriptive" geometry Dr. Whitehead means "any geometry in which two straight lines in a plane do not necessarily intersect." Besides the discussion of preliminary axioms and definitions, his second tract falls into two principal parts; the first deals with the problem of enlarging a descriptive space into a projective space (the simplest example is that of adjoining the plane at infinity to Euclidean space), the second with the theory of displacements and measurement. The latter is based upon what is, perhaps, the only satisfactory method—that of Sophus Lie. The last chapter gives the formulæ of metrical geometry in the shape given to them by Cayley and Laguerre, so that, neglecting a constant numerical factor, a distance and an angle are each measured by the logarithm of a cross-ratio. The cross-ratio, of course, must be *projectively* defined, otherwise we should be in a vicious circle, and it is in the avoidance of this circle that the latest perfection of the theory consists.

G. B. M.

OUR BOOK SHELF.

Practical Agricultural Chemistry. By F. D. S. Robertson. Pp. x+210. (London: Baillière, Tindall and Cox, 1907.) Price 7s. 6d. net.

IN his introduction the author tells us that his book is intended as a course of laboratory practice for the use of students in agricultural chemistry. How much time does he suppose such students can give to agricultural chemistry to allow them to deal with subjects like the valuation of tea and coffee, or the determination of hop resin and glycerin in beer? To what class of readers is a paragraph like the following of use? "*The Bitter Used.* This is necessarily a tedious operation, and for full particulars the reader is referred to such books upon poisons as describe the processes of Dragendorff and others. The prepared and concentrated beer is subjected to a series of extractions with petroleum ether, benzene, chloroform, and amyl alcohol, each of which is examined in turn."

Even in the more properly agricultural parts of the book there is little evidence that the author possesses any working acquaintance with his subject, *e.g.* the chapter on the analysis of soils is the merest skeleton, possessing small reference to the methods in regular use, and containing actual errors, such as the attempt to estimate humus by solution in ammonia without a preliminary treatment of the soil with acid.

Again, in his description of the Reichert-Wollny process for estimating volatile acids in butter, the author says nothing of the official standardisation of the dimensions of the apparatus and other details, which, however, must be followed if figures are to be obtained comparable with those of other analysts, and indeed are absolutely essential if the analyst is doing public work. We cannot recommend Mr. Robertson's book.

An Episode of Flatland, or How a Plane Folk discovered the Third Dimension, to which is added An Outline of the History of Unaea. By C. H. Hinton. Pp 181. (London: Swan Sonnenschein and Co., Ltd.)

THESE plane people live on the edge of a disc which is their world. A third dimension exists only in their mathematics. Their astronomers find that a catastrophe will certainly happen. One cranky philosopher believes that there is a third dimension, and shows a scared people how their world may be tilted and the catastrophe averted. The author's characters act and make love much like three-dimensional people, and they talk of a higher dimension just as Mr. Hinton would himself talk of a fourth dimension. There never was an allegory, not even that of Bunyan, which was consistent with itself for one chapter, but Mr. Hinton's is more inconsistent with itself than any other allegory we have seen. J. P.

The Bernese Oberland. Vol. iii. Dent de Morcles to the Gemmi. By H. Dübi. Pp. xxiv+136. (London: T. Fisher Unwin, 1907.) Price 10s.

THIS conveniently arranged pocket-book is the most recent addition to the "Climbers' Guides" edited by Sir Martin Conway and the Rev. W. A. B. Coolidge. The southern limit of the region described is the Rhone Valley from Martigny to Leuk; and the northern is marked by the low passes leading from the Ormonts-Lessus glen to Kandersteg by the heads of the Grande Eau, the Sarine, the Simme, and the Kander valleys, which mark it off from the foothills. The preface of the book directs attention to the fact that the present is the jubilee year of the formation of the Alpine Club and of the ascents of the Oldenhorn and the Wildstrubel, and we are confident that the increase in the number of climbers during the last fifty years will ensure a wide popularity for this workmanlike volume of "marching orders."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Layard's Beaked Whale (Mesoplodon layardi, Flower).

ON February 17 a Layard's beaked whale was found stranded on the beach a little south of Zwartkops River, north of Port Elizabeth, by Joseph G. Crawford. The following morning I dispatched my assistant, Mr. Jas. Crawford, to inspect the carcase. He brought the tusks back, when the animal was identified as Layard's beaked whale. Immediate action was taken, with the result that the skeleton is now mounted in the Port Elizabeth Museum. As the carcase was partially decomposed when discovered, it was impossible to save the skin, but measurements and drawings were taken on the spot, and the coloration of the skin noted.

FIG. 1.—Layard's Beaked Whale, from a drawing. Engraving photographed by Mr. F. W. FitzSimons director of the Port Elizabeth Museum.

So little is known of this whale that the present specimen is of considerable importance. The skull, teeth, breast-bones, the entire skeleton, and other parts have been photographed from every point of view, while photographs have also been taken from a sketch, to scale, of the animal while lying on the beach. Any institutions requiring copies of these photographs may have them on application to me if they will defray the expense connected with their reproduction.

The following are the details:—

The animal, which was a male, measured 19 feet 2 inches in length, was entire, and showed no external injury. The colour of the back was dark brown, inclining to black on the dorsal surface, gradually merging to brown on the sides and tail, and becoming whitey-brown or dirty white on the belly. In Prof. Moseley's description there is stated to be a distinct line of demarcation between the black and the white, but in the specimen under discussion the blackish of the back gradually merged to brown on the sides, and dull white on the belly.

The flippers measured 22 inches; the dorsal fin, which is situated far back, was 13 inches wide and 11 inches high; the tail, 4 feet 6 inches across at extremes; and the interval from the point of the beak to the eye was 38 inches, and to the end of the jaw 4 feet. The exposed portion of the teeth was 11 inches long and $2\frac{1}{2}$ inches wide at the base, becoming slightly narrower towards the tip, with the conical real tooth at the front of the summit. This tooth is enamelled and sharply tipped.

In the figure of the skull given by Moseley on p. 157 of "A Naturalist on the *Challenger*," there are marked differences when compared with our specimen. Thus the lower jaw shows an upward bend in front, whilst in our specimen it is straight. The proportion of the slope in the upper jaw is also dissimilar, whilst the teeth show a kind of wearing-away slope toward the middle portion. The teeth in our whale are uniform from base to tip, showing no wearing away or indication of friction. The small real tooth at the summit of each tusk is sharp, and not wart-like. Again, though the figure given by Moseley shows the teeth uniform, and not crossed, it is stated in the text that their extremities cross. The second illustration to this article distinctly shows the absence of any crossing of the tusks. This was ascertained before they were removed from the jaws. The tusks were firmly embedded in their sockets.

In Sclater's "Fauna of South Africa," vol. ii., p. 194, is an illustration of the snout of a Layard's whale with the tusks crossed, and the drawing shows important differences when compared with the photographs of our specimen. Inspection of the muzzle proved that this whale was able to open its mouth from $4\frac{1}{2}$ inches to 5 inches at the tip. The fleshy covering of the upper jaw beneath the teeth showed no mark or abrasion, indicating that the beak was opened only so far as the teeth allowed. Moseley

FIG. 2.—Upper views of skull of Layard's Beaked Whale. From a photograph by Mr. F. W. FitzSimons, director of the Port Elizabeth Museum.

states that the hollowing-out of the central part of the tusks figured by him was caused by the friction of the snout when the animal opened its mouth. The tusks of our specimen showed no such sign, and the skin of the beak displayed no indication of coming frequently into contact with a hard body. Judging from the width of the gullet, this whale does not require to open its mouth very wide; as the gullet is only from $1\frac{3}{4}$ inches to 2 inches in diameter, it indicates that the food consists of small morsels. The sharp, enamelled tooth at the summit of the tusk is probably used for tearing and rending soft-bodied animals such as cuttle-fishes, and possibly for tearing aside seaweeds when in search of food.

The tusks are 14 inches in length, $2\frac{1}{2}$ inches wide at the jaw, $1\frac{3}{8}$ inches at the summit beneath the conical real tooth, and from $\frac{3}{8}$ inch to $\frac{1}{2}$ inch thick. On the back the blubber was 3 inches thick, and $1\frac{1}{2}$ inches on the belly. The oil was of fine quality, and had great penetrating power, almost like paraffin. Owing to the advanced state of decomposition of the viscera, the contents of the stomach were not examined.

From the foregoing it is evident either that previous drawings and data in regard to Layard's whale are more or less inaccurate, or that the present specimen indicates a new species. The drawings show that the upper lip or tip of the beak covers the lower lip, while the photographs indicate that the upper jaw slightly projects beyond the lower, the reverse being apparently the case in Sclater's and Moseley's illustrations. The lips were not horny, but rather like hardish flesh. The skull is very asymmetrical, the bulk of the frontal bones inclining from the right to the left side.

The creature had apparently been injured at some previous time, as the tongue-bones and two vertebræ showed signs of having been fractured and repaired. One of the most remarkable features of this whale is the small size of the flippers as compared with that of the body. The backward position of the dorsal fin is also noticeable. With the exception of those of the skull, the bones are remarkably light and porous. Those of the beak are, however, brittle, dense, and hard.

F. W. FITZSIMONS.

Port Elizabeth Museum, May 30.

The Radio-activity of Lead and other Metals.

IN the course of some experiments that have been recently carried out in the physical laboratory at Toronto on the natural conductivity of air confined in vessels made of different metals, a wide variation was observed in the results obtained with different samples of lead. The lowest conductivity observed with air enclosed by this metal corresponded to an average production of 23 ions per c.c. per second, and the highest to a production of 160 ions per c.c. per second. The lowest value hitherto recorded for lead appears to be that quoted by Eve in his paper in the *Phil. Mag.* of September, 1906, in which he gives 96 ions per c.c. per second as the number he obtained with this metal. The sample of lead which exhibited the low activity just referred to was a sheet which had been used as a lining in a case in the laboratory for nearly thirty years.

With zinc and aluminium receivers it was found that on the average 15 ions per c.c. were generated per second in the air which they enclosed.

From measurements made with the gamma rays from radium on the ionisation produced in air confined in a lead cylinder (1) when unlined, and (2) when lined with thin sheet aluminium, due allowance being made for absorption, it was found that the ionisation in a lead cylinder due to the gamma rays was one-half that obtained with the excited secondary radiation. On the other hand, with an aluminium cylinder, the ionisation due to the secondary radiation was found to be approximately one-half that produced by the gamma rays. Assuming these results to hold for the penetrating radiation from the earth, it follows that on the average 9 ions per c.c. per second are generated in free air by this radiation. It also follows that the difference between the natural ionisation in air observed with the aluminium cylinder, viz. 15 ions per c.c. per second, and that found with the least active lead, viz. 23 ions per c.c. per second, can be wholly explained by differences in the secondary radiation excited in the two metals. This result, combined with the observed differences in the conductivity of air enclosed in vessels made of different samples of lead, goes to show that the high activity usually observed with lead is due to the presence of active impurities in it, and not to the existence of any intrinsic activity possessed by the metal. In this connection it is interesting to note that Elster and Geitel (*Phys. Zeit.*, November, 1906, and May, 1907) have recently been able to extract from commercial lead oxide and a sample of lead an active substance which they suggest may possibly turn out to be radium F.

In the experiments described above, the measurements were made with a sensitive quadrant electrometer on air confined in cylindrical vessels 60 cm. high and 24 cm. in diameter.

University of Toronto, June 25.

Inheritance and Sex in Abraxas grossulariata.

IN February, 1906, in conjunction with the Rev. G. H Raynor, I gave a paper to the Zoological Society on the inheritance of a variety of the moth *Abraxas grossulariata* and its relation to sex (Proc. Zool. Soc., 1906, vol. i. p. 129). We found that when the var. *lacticolor* (*flavofasciata*) was crossed with the type it behaved as a Mendelian recessive, disappearing entirely in generation F. When two heterozygotes were mated together, var. *lacticolor* reappeared, but only in the female sex, roughly half the females and all the males being typical. When a heterozygous male was mated with *lacticolor* female, the variety appeared in both sexes in the offspring, viz. in about half the males and half the females. When, however, a *lacticolor* male so produced was paired with a heterozygous female, we found that all the males were typical and all the females *lacticolor*. This result was given in our paper with some hesitation, since it was founded on a rather small number of specimens (29 ♂, 11 ♀), but this year it is amply confirmed. I have reared 116 males and 74 females from six families of this mating, and every male is typical, every female *lacticolor*. Mr. Raynor has also reared equally large numbers with the same result. From a family of the converse cross, on the other hand (*lacticolor* ♀ × heterozygous ♂), I have reared 24 type ♂, 22 *lacticolor* ♂, 17 type ♀, 18 *lacticolor* ♀, a fair approach to the expected equality in each sex.

I think it may be concluded definitely that in this case

(1) The type is completely dominant.
(2) DR♀ × DR♂ gives DD♂ + DR♂, DR♀ + RR♀.
(3) R♀ × DR♂ gives DR♂ + R♂, DR♀ + R♀.
(4) DR♀ × R♂ gives DR♂, R♀.
(5) R♀ × R♂ gives R♂, R♀.

(In [2] above the absence of DD females has not been proved.)

This confirmation of our previous results seems to me to lend some support to the provisional hypothesis of sex-determination outlined in the paper referred to.

L. DONCASTER.

University of Birmingham, July 2.

THE DOUBLE-DRIFT THEORY OF STAR MOTIONS.

THE problem of determining the motion of the sun amongst the stars has undergone a great change in consequence of Prof. J. C. Kapteyn's investigations, which have recently become known. These researches indicated that the stars surrounding us do not form a simple system, but a dual one. From a discussion of the motions of the stars of Bradley's catalogue, Prof. Kapteyn demonstrated the existence of two great streams of stars passing through one another, and found the directions of motion of these streams relative to the sun and to one another. The Bradley stars, numbering about 2600, are mainly stars visible to the naked eye; they cover nearly three-quarters of the celestial sphere, and throughout the whole of this area Prof. Kapteyn found the same two streams prevailing, and it seemed probable that all the stars he examined belonged to one or other of the two streams.

The investigations with which this article more particularly deals are based on the proper motions deduced by Prof. Dyson and Mr. Thackeray from their re-reduction of Groombridge's Catalogue. The number of stars included is 4200, all confined to a region within 52° of the North Pole. About 1100 Carrington proper motions were also examined; these were all within 9° of the Pole. These two catalogues contain a large proportion of stars much fainter than those of Bradley, and enable the inquiry to be extended as far as magnitude 9·5. The same two streams are found to prevail among these faint stars, and it seems a fair conclusion that all the stars down to at least magnitude 9·5—more than half-a-million in number—are within the scope of the theory. It should, however, be remembered that only *samples* have been taken, in limited regions of the sky, for these fainter stars, so that there is a possibility of unexpected deviations from theory in the at present unexplored regions.

To indicate how it is possible to distinguish whether the stars in a given region of the sky belong to a single system or to a double system, or to something still more complex, it will be well to take an actual instance. In Fig. 1 the curve P has been drawn to

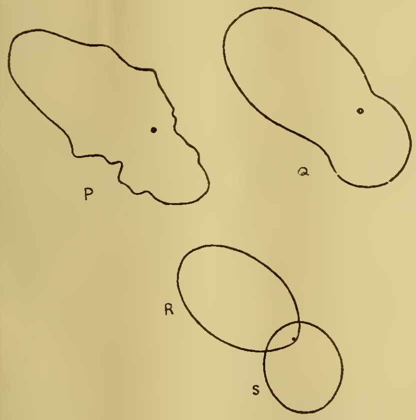

FIG. 1.—Showing the analysis of the observed motions into two simple drifts.

summarise the proper motions of the stars in a region of the sky comprising parts of the constellations Draco, Boötes and Hercules. The radius drawn from the dot to the curve in any direction represents (by its length) the number of stars moving in that direction, or rather within 5° on either side of that direction. Now the distribution of proper motions indicated by this figure cannot possibly be due to a system of stars forming a single "drift," that is, a system in which the motions of the stars *inter se* are haphazard, though the system as a whole may be in motion relative to the sun (or, as it is more usually expressed, the sun may be in motion relative to the system). The type of curve resulting from such a drift can be calculated mathematically; R and S are such curves. It is not difficult to see that, having regard to the position of the origin, no curve of this symmetrical type could be chosen which would at all approximately coincide with the observed curve P. The hypothesis of one drift, therefore, does not give even an approximation to the observed distribution of proper motions. But by combining the two drifts R and S, we obtain the curve Q, which agrees very closely with the observed curve. The differences between P and Q are, in fact, insignificant, and of a purely accidental character.

For each of seven regions into which the Groombridge stars were divided, as well as for the Carrington stars, the observed distribution of proper motions allowed itself to be dissected in this way, and exhibited as the result of two simple drifts intermingled. The agreement between the observed distribution and the theoretical distribution was not always quite so perfect as in the case illustrated. For instance, in one region the observed curve showed twenty-four stars moving where they ought not to have been; presumably they formed a local system; but such an irregularity is small compared with the two main drifts, which in that region each included more than 400 stars. Most of the regions, however, did not show even such a small irregularity as this.

The shape of the simple drift curve depends on the velocity of the drift (relative to the sun) as compared with the mean velocity of the stars of the drift relative to one another. Naturally, for high drift-velocities the curve becomes more elongated, for the tendency then is for all the stars to move nearly in the direction of the drift, the individual motions being relatively

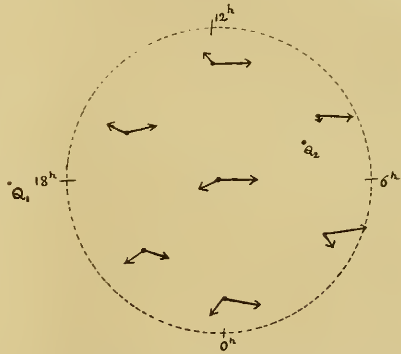

FIG. 2.—The region within 52° of the North Pole. The arrows show the magnitudes and directions of the drift velocities.

small; for low drift-velocity the curve is rounder, approaching the form of a circle about the origin for the limiting case of zero drift-velocity. The curves R and S correspond to drift velocities 1·20 and 0·45 respectively (the unit is 0·886 of the mean peculiar speed of the stars). The analysis, therefore, not only shows the directions in which the two systems of stars are moving, but also their velocities.

Fig. 2 is a diagram of the part of the sky covered by the Groombridge catalogue. At seven points (the centres of seven regions into which the area was divided) are drawn pairs of arrows representing the velocities of the two drifts in magnitude and direction, determined for each region independently, as explained above; but in each case the shorter arrow of the pair has been drawn on twice the scale of the longer one, so that the difference in velocity of the two drifts is even greater than appears from the figure. This attempt to represent a considerable portion of the sphere on a plane surface is necessarily imperfect, but it is sufficient to show that each set of arrows is directed approximately from a point, viz., the longer arrows from the point Q_1 (R.A. 18h., Decl. + 18°) on the left of the figure, and the shorter arrows from the point Q_2 (R.A. $7\frac{1}{2}$h., Decl. $+58°$). It will be convenient to refer to the two systems as Drift I. and Drift II.; Drift I. accordingly is a group of stars in rapid motion from the point Q_1, and Drift II. a group in comparatively slow motion from the point Q_2, its velocity being, in fact, not quite one-third that of Drift I. Fig. 2 also shows that the speed of Drift I. appears smaller in the regions nearest Q_1, and of Drift II. in the regions nearest Q_2. This is because that part of the drift motion which is in the line of sight has no effect on the proper motions, and cannot be detected by examining them. The component of the drift motion *across* the line of sight decreases as the apex of the drift is approached, and vanishes at the apex itself.

Another result from the mathematical analysis is that the stars are nearly equally divided between the two drifts, Drift II. having, perhaps, a slightly greater proportion. It is rather remarkable that although some parts of the sky are more than twice as rich in stars as others, the approximately equal division between the two drifts is maintained in every region.

It is natural to inquire whether there may not be some other distinction between stars of the two drifts besides their motions. The fact that the sun moves comparatively slowly relative to Drift II. rather suggests that the sun belongs to this drift. In that case it might be expected that the Drift II. stars would be nearer on the average than those of Drift I., the latter forming a sort of background. The magnitudes of the proper motions (which have up to this point not been considered) afford data for testing this point. Due allowance having been made for the fact that the true Drift II. motion has already been found to be very much less than that of Drift I., the apparent motions indicate the same mean distance for the two drifts. In fact, a mathematical calculation showed less than 5 per cent. difference between the mean distances of the two drifts (though it is improbable that the data can be trusted quite so far as this). Remembering that the two drifts divide the stars in nearly the same proportion in all the regions, it would seem that they are as completely mixed as it is possible to imagine.

One point of great interest is the distribution of the stars of different spectral types among the drifts. It has been customary to regard Secchi's two types as forming to a certain extent two systems, for Type II. stars are very evenly distributed throughout the sky, whereas those of Type I. tend to congregate in the plane of the Milky Way. It is, however, quite certain that the division into two spectral types and the division into two drifts do not correspond. If we examine Type I. stars alone, both drifts are evident; and so also if Type II. stars are examined alone. Nevertheless there is a systematic difference between the distribution of the proper motions of the Type I. and Type II. stars, which manifests itself in every region examined (including the Bradley stars). It may perhaps be interpreted as being due to a higher percentage of Type II. stars in Drift II. than in Drift I., but it now appears more probable that the difference consists in Type II. stars having larger "peculiar" motions (the haphazard individual motions) than Type I. stars. In addition to some satisfactory direct evidence, this latter explanation is supported by the fact that nearly all the "runaway" stars are of Type II., and it also agrees with the difference in distribution of Type I. and Type II. stars; the former mainly congregate in one plane, whilst the latter, perhaps originally in the same plane, would have become more uniformly distributed in consequence of their greater individual velocities.

There is no indication of any relation between magnitude and drift, except possibly in the case of the very bright stars (brighter than magnitude 4·0). These latter seem to belong principally to Drift I., but they are so few in number (in the area examined) that the result may very well be accidental.

Having determined the motions of the two drifts of stars relative to the sun, and knowing also that the stars are nearly equally divided between them, it is easy to determine the motion of the sun relative to the combined drifts—in fact, to determine the *solar apex*. In this way the solar apex is found to be at R.A. 17h. 45m., Decl. $+31°$; it is naturally fairly close to Q_1, since the velocity of Drift I. predominates. From the same stars, by Airy's method, Dyson and Thackeray found the solar apex to be at R.A. 18h. 20m., Decl. $+37°$. The somewhat greater R.A. of their determination (and of most other determinations) is probably the result of using the magnitudes of the proper motions. This position, deduced by means of the two-drift theory from the directions of the proper motions only, has the advantage of being free from all assumptions as to the distances of the stars, but the probable accidental error is large. The two-drift theory further directs attention to the true nature of the "solar motion" so determined; it is in no sense an *absolute* motion, and there is now no justification for confounding it with the motion relative to the æther, as has sometimes been done.

In conclusion, whilst Prof. Kapteyn's theory accounts in a simple manner for the very anomalous and unsymmetrical way in which the directions of motion of the stars are distributed, it is still awaiting the verdict of the spectroscopic determinations of line-of-sight velocities. The material exists in plenty for applying this test; it simply awaits examination by those who have access to it. The investigation of the motions of still fainter stars, and of regions of the sky which have not yet been explored, offers a large field for further research.

A. S. EDDINGTON.

SEVENTH INTERNATIONAL ZOOLOGICAL CONGRESS.

THE arrangements for the seventh International Zoological Congress, which will be held at Boston, August 19–23, under the presidency of Mr. Alexander Agassiz, are now well advanced. The congress will open formally on the afternoon of August 19 in the Harvard Medical School, and arrangements will then be made for the meetings of the sections. The subdivision proposed is rather elaborate, for there are to be sections on general zoology, systematic zoology, experimental zoology, marine zoology, evolution, heredity, and so on. There will be three general meetings; the International Committee on Zoological Nomenclature, under Prof. R. Blanchard, will continue its arduous labours; and numerous addresses, communications, and exhibits have already been arranged for. It need hardly be said that the arrangements for hospitality are generous. On each day of the strict congress week there will be luncheon at the invitation of the Boston local committee, and the evenings will be occupied with receptions and dinners.

On the afternoon of August 22 there will be an excursion to Wellesley College; August 24 will be devoted to a visit to the museums of Harvard University; August 25 is Woods Hole Day; August 26 Columbia University Day; August 27 the American Museum Day. On August 28 the members of the congress will visit the marine laboratory of the Brooklyn Institute of Arts and Sciences, and the Carnegie station for experimental evolution at Cold Spring Harbour. On August 29 the New York Zoological Society will receive in the morning in the New York Aquarium, and in the afternoon in the Zoological Park; in the evening there will be a reception in Columbia University library.

On Friday, August 30, Prof. Henry Fairfield Osborn invites the congress to an excursion up the Hudson to West Point and Garrison. Saturday will be devoted to the Universities of Yale and Princeton.

On Monday, September 2, the congress will move from New York to Philadelphia; there will be luncheon at the Academy of Natural Sciences, followed by inspection of the library and museum; there will be an afternoon drive to the Zoological Gardens and Fairmount Park; in the evening there will be supper at the Philadelphia Country Club.

On September 3 there will be visits to the American Philosophical Society, Independence Hall, Girard College, the University of Pennsylvania, and thereafter the congress will move on to Washington. On September 4 there will be a general meeting in the assembly hall of the Cosmos Club, Washington, at which addresses of welcome will be given by the secretary of the Smithsonian Institution, the president of the Carnegie Institution, and the president of the Washington Academy of Sciences. This will be followed by a visit to the National Zoological Park, the Congressional Library, the United States Department of Agriculture, the Hygienic Laboratory, and other points of zoological interest. In the evening there will be a reception by the Cosmos Club.

On September 5 the congress will proceed by boat on the Potomac River to Mt. Vernon, the home of George Washington, and to the United States Navy Proving Station at Indian Head. There will be dinner at Marshall Hall, and an evening reception at the United States National Museum.

On Saturday, September 7, an excursion has been arranged to Niagara Falls and across Lake Ontario to Toronto, returning to New York on Monday night or Tuesday morning.

If fifty members agree to go, there will be an excursion to Bermuda, which will give the members of the congress an opportunity of becoming acquainted with a very interesting semitropical zoological region. Members will have facilities in collecting and preserving zoological material. The expenses of the expedition for each participating member will be thirty-two dollars for return passage and about two dollars a day hotel charges while in Bermuda. After the party lands in Bermuda, the local committee will supply, free of charge, all transportation, carriages, steamers, &c., and such other incidentals as will ensure a successful expedition. It is to be hoped that this very attractive part of the programme will be carried out. The inclusive dates fixed for the expedition are September 14–22.

It may be noted that the executive committee of the Boston meeting consists of Profs. G. H. Parker (chairman), Samuel Henshaw (secretary), L. O. Howard, J. S. Kingsley, E. L. Mark, and H. F. Osborn.

If two suggestions from experience might be ventured, we would submit that outside each sectional meeting there should be a time-table board showing what precisely is going on, and that each member should wear in his button-hole a number corresponding to a printed list, so that strangers to one another may know at once who's who!

THE LEICESTER MEETING OF THE BRITISH ASSOCIATION.

Provisional Programmes of Sections.

ARRANGEMENTS for the work of the various sections are now approaching completion, and we are able to give the provisional programmes. It is evident from this list of papers and discussions, incomplete thought it is, that many matters of wide scientific interest will be brought forward at Leicester.

Among the foreign representatives who have accepted invitations to be present are the following:—Section A.: Prof. L. Natanson, Prof. D. J. Korteweg, Prof. H. G. van de Sande Bakhuyzen, Dr. Oskar Backlund, Prof. Donner, M. Ch. Féry; Section B.: Prof. R. Abegg, Prof. A. Tschitschibabin, Prof. T. W. Richards, Prof. A. Werner, Prof. F. M. Jaeger; Section C.: Prof. H. Sjögren, Prof. F. Frech, Prof. C. Diener, Prof. J. P. Iddings; Section D.: Prof. H. Simroth; Section E.: Prof. P. Vidal de la Blache, Prof. Max Eckert; Section H.: Prof. E. Naville; Section I.: Prof. N. Zuntz; Section K.: Prof. J. P. Lotsy, Prof. R. Chodat, Prof. H. Conwentz, Prof. O. Uhlworm; Section L.: Dr. Otto Anderssen, Dr. F. Rönning, Prof. M. L. Morel. Corresponding members Baron D. Kikuchi, Prof. P. H. Schoute, Prof. R. Nasini, and Prof. George F. Barker have also expressed their intention of being present.

The address of Prof. A. E. H. Love, F.R.S., the president of Section A (Mathematical and Physical Science), will be delivered on the morning of Thursday, August 1. Several discussions have been arranged. On Friday, August 2, there is to be one on the constitution of the atom, which will be opened by Prof. E. Rutherford, who will be followed by Sir O. Lodge, Mr. G. A. Schott, and others. On Monday, August 5, Dr. L. Holborn, of Charlottenburg, will open a discussion on radiation-pyrometry; he will be followed by M. C. Fery, of Paris. On August 6, a paper by Mr. W. Palin Elderton on modern methods of treating observations will consist of an exposition of the methods of Prof. Karl Pearson, chiefly as applied to meteorological phenomena. It is hoped that all will attend who are interested in the reduction of observations of any kind, and assist to make the discussion useful. The following papers have also been promised:—On the nature of ionisation, Prof. H. E. Armstrong; an analytical study of the meteorological observations made at the Glosson Moor kite station during 1906-7, Miss M. White, Mr. T. V. Pring, and Dr. J. E. Petavel; recent developments of the methods of forecasting by means of synoptic charts, Dr. W. N. Shaw; ether density, Sir O. Lodge; sæcular stability, Prof. H. Lamb; modern work on the calculus of variations, Prof. A. R. Forsyth; exhibition of models of three-dimensional sections of the regular hypersolids in space of four dimensions, Mrs. Stott; a method of obtaining the chief properties of the exponential function, Prof. A. E. H. Love; operational invariants, Major MacMahon; a property of Abelian groups, Mr. Harold Hilton; factorisation of the Pellian terms, Lt.-Col. Cunningham; on the theory of integral equations, Mr. H. Bateman; a mountain observatory in India, Prof. C. Michie Smith. The various committees connected with the section will also present their annual reports.

Section B (Chemistry) has made the following provisional arrangements:—August 1: Presidential address, Prof. A. Smithells; discussion on valency, to be opened by Prof. W. J. Pope, and in which Prof. Werner (Zürich), Prof. Abegg (Breslau), Prof. Richards (Harvard), Prof. Jaeger (Amsterdam), Prof. J. J. Thomson, Mr. W. Barlow, and others will take part. August 2: Joint discussion with Section G on explosion temperatures. The following members will take part:—Dr. Boudouard (Paris), Prof. Haber (Karlsruhe), Mr. Dugald Clerk, Prof. B. Hopkinson, Prof. H. B. Dixon, and others. August 5: Reports will be received from the research committees:—(1) The transformation of aromatic nitramines; (2) the study of hydroaromatic compounds; (3) preparation of a new series of wave-length tables of the spectra of the elements; (4) dynamic isomerism; (5) the study of isomorphous sulphonic derivatives of benzene. The following papers will be read:—The applications of Grignard's reaction, Dr. A. McKenzie; paper by Prof. Tschitschibabin (Moscow); fluid crystals, Prof. Jaeger; atomic weights, Prof. T. W. Richards; carbon suboxide, Dr. Boudouard; carbonyl compounds, Dr. H. O. Jones. August 6: Discussion on the chemistry of wheat and flour with special reference to strength, to be opened by Mr. A. E. Humphries, president of the National Association of British and Irish Millers. The following will take part:—Messrs. R. H. Biffen, T. B. Wood, A. D. Hall, Horace Brown, J. L. Baker, A. J. Banks, E. F. Armstrong, and E. S. Watkins.

The following papers, among others, will be read in Section C (Geology):—Prof. W. W. Watts and Mr. Fox Strangways will give addresses on the geology of the country round Leicester. These will be followed by papers dealing with local geology by Drs. Bennett and Stracey and Messrs. Horwood, Bosworth and Keay. A discussion on the origin and extent of the iron ores of Britain will be opened by Mr. Bennett H. Brough; and other authorities on the subject are expected to take part in it. Among other subjects to be brought forward are:—Earthquakes, Prof. Milne; pisolitic iron ores, Mr. W. G. Fearnsides; desert forms, Mr. H. Ferrar; the ancient volcanoes of Basutoland, Rev. S. S. Dornan; a remarkable occurrence of strontia near Bristol, Mr. H. Bolton; the gravels of Holderness, Messrs. Stather and Sheppard; and the occurrence of a marine peat near Liverpool, Mr. J. Lomas. Reports of various committees will be presented. On the fauna and flora of the Trias, Mr. J. Lomas; Carboniferous faunas and zones, Drs. A. Vaughan and Wheelton Hind; Anglesey Rocks, Mr. E. Greenly; terms used in geography and geology, Mr. W. G. Fearnsides; erratic blocks, Prof. P. F. Kendall; Pre-Devonian rocks of the Mendips, Prof. S. H. Reynolds; and the Kirmington Drifts, Mr. Stather. Excursions will be made to places of geological interest every afternoon during the meeting, and longer excursions have been arranged for the week-end and at the close of the meeting.

The following items have been arranged for Section D (Zoology):—Presidential address, Dr. W. E. Hoyle; discussion (in conjunction with Section of Botany) on the physical basis of heredity, to be opened by Prof. S. J. Hickson; discussion (in conjunction with the Sections of Botany and Education) on the teaching of biology in schools, to be opened by Mr. O. H. Latter, of Charterhouse; afternoon lecture by Dr. C. W. Andrews, adaptation to aquatic life in reptiles and mammals; problems in the sexual organisation of the Crustacea, Mr. G. W. Smith; Pycnogonida, Mr. T. V. Hodgson; demonstration of models, Protozoa, &c., Mr. F. R. Rowley; experiments on seasonally dimorphic forms of African Lepidoptera, Dr. F. A. Dixey; (1) classification of the Haplosporidia, (2) the movements of Spirochætes, as seen in *S. balbianii* and *S. anodontae*, Mr. H. B. Fantham; the rise and recognition of economic biology, Mr. Walter E. Collinge.

The papers offered to Section E (Geography) include the following:—The surveys of British Africa, Major C. F. Close, R.E.; the maps and methods of the present-day explorer, Captain T. T. Behrens, R.E.; the geographical evolution of transport, Prof. Vidal de la Blache (Paris); commercial geography from the modern standpoint, Prof. Max Eckert (Kiel); the hinterland of the Port of Manchester, Mr. J. McFarlane (Manchester); the Jäderin district of southern Norway, Mr. O. J. R. Howarth; Shotover Hill, a study in morphological causation, Rev. C. E. Spicer; regional geography of the Land's End peninsula, Mr. A. W. Andrews; physical geography of the Etbai desert of Egypt, Mr. H. T. Ferrar; travels in the Andes of Peru, Mr. C. R. Enock; the British Museum expedition to Ruwenzori, Mr. R. B. Woosnam; explorations in Labrador, Mrs. Leonidas Hubbard. Afternoon lectures: The Kurds, Mr. Mark Sykes; the Jamaica earthquake, Dr. Vaughan Cornish; the preservation of "Naturdenkmäle," or natural monuments, Prof. Conwentz (Danzig) (joint meeting with Sections C and K).

The programme of Section G (Engineering) is as follows:—August 1: Presidential address, Prof. S. P. Thompson; the present position of gas and petrol engines, Mr. Dugald Clerk. August 2: Joint meeting with Section B to discuss gaseous explosions with special reference to temperature. August 5 and 6: Pupin's compensated cable for telephone transmission, Sir W. H. Preece; modern machinery and its future development, Mr. H. I. Brackenbury; a machine for weighing the forces on a cutting tool, Mr. J. F. Brooks; ferro-concrete and examples of construction, Mr. J. S. E. de Vesian; examples of ferro-concrete, Mr. W. Noble Twelvetrees; the equipment of the engineering laboratory at the Finsbury Technical College, Prof. E. G. Coker; the ice problem presented in engineering work in Canada, Prof. Barnes; notes on the governing of hydraulic turbines, Mr. R. S. Ball; submarine signalling, Mr. Millet. A practical demonstration of boot and shoemaking machinery will be given by Mr. C. Bennion.

The programme of the proceedings of Section H (Anthropology) is even longer than usual, and many of the communications promise to give rise to interesting discussion. The greater part of the time of the section will be taken up by papers of an archæological character, but the communications in general ethnography, though less numerous than usual, include a number of considerable importance. On August 1 a meeting will be held in conjunction with the Section of Educational Science for the discussion of anthropometrics in schools. In archæology, Prof. W. M. Flinders Petrie will describe the results of his excavations in Egypt during the past season, and Dr. E. Naville will deal with the beginnings of Egyptian civilisation. A discussion on the early Iron age, and the different dates of inception in different areas, in which Sir John Evans has promised to take part, will be opened by Prof. W. Ridgway, and Mr. J. L. Myres will contribute a paper on the Sigynnæ of Herodotus and Cyprian spears. Prof. R. C. Bosanquet will read a paper on the scourging of the Ephebi at Sparta. Accounts of the work of the British Schools of Archæology at Athens and Rome during the past year will be given by their respective directors, Mr. R. M. Dawkins and Dr. T. Ashby. The former will deal chiefly with the excavations in Sparta. In addition, Dr. Ashby, in a paper on the ethnology of Sardinia, will urge the need of archæological and ethnographic investigation in that island for the elucidation of problems of Mediterranean ethnology, and in connection with the report of the Roman Sites Committee will describe the excavations of the past year at Caerwent. A paper by Mr. F. Newberry and Dr. T. H. Bryce deals with the "doorstep art" of Scotland, Mrs. Hobson will give the results of an examination of a large number of souterrains in Ulster, and Dr. G. A. Auden will describe a number of Scandinavian antiquities found at York. Dr. L. R. Farnell, in a communication on the development of Greek religion, will criticise Dr. Usener's theories concerning Sondergötter and Augenblick-Götter. Among the communications in general ethnography may be mentioned :—Education and evolution, the Rev. A. E. Crawley; a paper by Messrs. T. A. Joyce and E. Torday on the ethnography of the south-west Congo Free State, dealing with the migrations of the inhabitants of the territory drained by the Kwango and Kwilu Rivers; a paper by Dr. W. H. R. Rivers on Morgan's Malayan system of relationship, which adduces evidence against his concept of the "consanguineous family" as the earliest stage of the development of human society. Prof. R. J. Anderson, in a paper on racial types of Connaught, describes the chief physical types of that province, and discusses the chief influences by which they are, or have been, modified; a study of the condition of the Maoris in 1907, by Miss B. Pullen-Burry, after describing their religion and social organisation, deals with their economic and social condition. Among papers of a technical character, considerable interest attaches, in view of the present lack of agreement as to the use of anthropological terms, to a communication by Dr. Rivers in which he attempts to define the use of certain sociological terms, and to a communication by Mr. J. L. Myres on the use of the triangle in decorative art.

The provisional programme of Section I (Physiology) is as follows :—August 1: Presidential address and miscellaneous papers. The president, Dr. A. D. Waller, has been studying chloroform of late, and his address will probably take the form of a general statement on the position of anæsthetics at the present time. August 2: The morning will be devoted to papers on the electrophysiology of animals and plants. Dr. Alcock, Dr. Waller, and others will read papers. August 5: A discussion on the physiological and therapeutical uses of alcohol will be opened by Prof. Cushny. Other speakers will include Sir Victor Horsley, Dr. Dixon, Dr. Rivers, and Dr. Waller. August 6: A discussion on antitoxins will be opened by Prof. Sims Woodhead. The afternoons will be in part given to the reading of reports. There are three committees which should report, the subjects being :—(1) The investigation of the effect of climate upon health; Sir Lauder Brunton, the president of this committee, will read the report; (2) the determination of the metabolic balance-sheet of the individual tissues, president, Prof. Gotch; (3) the ductless glands, Prof. Schäfer. These reports will be presented on the afternoons of August 1, 2, and 6 respectively.

In Section K (Botany), Miss Fraser (of the Royal Holloway College) and others will communicate the results of recent investigations on the cytology of fungi, particularly in relation to sexuality and the reduction division. Mr. V. H. Blackman will take part in the discussion on this subject. Prof. F. O. Bower will communicate the results of his recent work on the embryos of Pteridophytes. Prof. Conwentz, the Prussian State Commissioner for the preservation of natural monuments, will deliver a lecture, illustrated by lantern slides, at a joint meeting of Sections C, E, and K, on the care of natural monuments. Prof. F. W. Oliver is expected to communicate the results of some recent investigations of Palæozoic seeds. Prof. Weiss will give the semi-popular lecture on pollination in recent and fossil plants. There will be a joint meeting with Section D to discuss the physical basis of heredity (opened by Prof. Hickson), and with Sections D and L to discuss the teaching of botany in schools. Prof. Armstrong will communicate a paper on the theory of enzyme-action. There will be a visit to Mr. Hurst's nurseries at Burbage to inspect his experiments in hybridisation, and a botanical excursion to Charnwood Forest.

Discussions on several important subjects have been arranged by the organising committee of Section L (Educational Science); and among the authors and speakers are leading representatives of every grade of educational activity. The chief educational associations have appointed delegates to attend the meeting. After Sir Philip Magnus's presidential address on August 1, there will be a discussion at a joint meeting with Section H (Anthropology) on anthropometrics in schools, with particular reference to the recommendations of the Physical Deterioration Committee. Among the expected speakers are Sir Victor Horsley, Mr. R. C. Lehmann, M.P., Dr. F. C. Shrubsall, Mr. J. Gray, Mr. E. Meyrick, Prof. M. E. Sadler, Dr. J. Gow, Mr. Cecil Hawkins, and Mr. S. R. Brown. Friday, August 2, will be occupied with a discussion of the scholarship system in all its aspects from the primary school to the university, with papers by Miss J. Cleghorn, Mr. A. R. Pickles, president of the National Union of Teachers; Mr. W. A. Brockington, Miss S. Heron, Mr. J. L. Paton, Mr. G. Gidley Robinson, Rev. A. A. David, Dr. H. B. Baker, Prof. H. A. Miers, and Prof. M. E. Sadler. The curricula of secondary schools will form the subject of discussion on the morning of August 5, in connection with the report of a committee appointed at the York meeting last year. Mr. R. E. Thwaites will state the results of an inquiry into science teaching in secondary schools. In the afternoon there will be a joint meeting with Sections D and K on the teaching of biology in schools, to be introduced by Mr. O. H. Latter. Other speakers will be Prof. S. J. Hickson, Prof. J. B. Farmer, Miss Lilian Clarke, Miss Laurie, Mr. M. D. Hill, Mr. E. Meyrick, and Mr. Hugh Richardson. August 6 will be devoted to scientific teaching in relation to trade classes and industrial requirements, this general description to include the consideration of domestic subjects in girls' schools, day trade schools for girls, preparation for technical training in day and evening schools, and the qualifications of teachers. Papers dealing with these subjects will be contributed by Mrs. Ramsay MacDonald, Mr. C. T. Millis, Mr. J. G. Legge, and Mr. J. H. Hawthorn.

THE KING AND HIGHER EDUCATION IN WALES.

THE foundation stone of the new buildings of the University College of North Wales was laid by the King on Tuesday, July 9. The King was accompanied by the Queen, and the ceremony was performed in the presence of a large and brilliant assembly. In his response to an address of welcome, presented by the Lord Lieutenant, the King said that the main object of his visit to Wales was to express again his belief in the necessity of affording the youths of the country the most complete educational equipment possible, both for their self-improvement and in order to enable them to acquire success in life. The King also remarked, in the course of a reply to an address presented by the Mayor and Corporation of Bangor, that "Education, and especially secondary education, is a subject the importance of which cannot be over-estimated, and which engages my cordial interest and encouragement." Replying on behalf of the Queen and himself to an address from the governors of the college, the King again referred to his interest in higher education in the following words :—

The admirable work performed by the college in its temporary buildings has been widely recognised and was well known to me when I held the office of Chancellor of the University of Wales. I feel confident that increased efficiency will result from the facilities afforded by the commodious premises of which I have to-day laid the first stone. The competition in every branch of industry, especially in those branches which depend largely on science and art, is in these days severe, and it must be met by increased application and improved methods. The world is, I believe, better for such competition, but it behoves individual nations to use every possible effort to hold their own in the struggle. For this purpose higher education is an absolute necessity. However brilliant a man's natural talents may be, he is greatly hindered by the want of early training, and as a rule only those who have enjoyed a good education are capable of acquiring such proficiency in any branch of study as will enable them to succeed. The University College of North Wales will offer to its students exceptional opportunities of instruction. Time and money, energy and perseverance, will, I am sure, not be spared in the endeavour to afford every facility to the acquirement of knowledge, and I have had sufficient opportunities of judging the intelligence of the Welsh people and their eagerness in the pursuit of knowledge to know that your young men and women will take every advantage of the instruction which is offered them.

At the close of the ceremony of laying the foundation stone, the King conferred the honour of knighthood upon Dr. H. R. Reichel, the principal of the college.

NOTES.

We regret to announce that Sir William H. Broadbent, Bart., F.R.S., physician in ordinary to the King and to the Prince of Wales, died on Wednesday, July 10, at seventy-two years of age.

The Nettleship gold medal of the Ophthalmological Society of the United Kingdom has been awarded to Dr. J. Herbert Parsons, for his work on "The Pathology of the Eye."

The council of the Institution of Civil Engineers has appointed Sir William Matthews, K.C.M.G., president of that institution, to succeed the late Sir Benjamin Baker, K.C.B., K.C.M.G., as one of their representatives on the main committee of the Engineering Standards Committee.

The annual meeting of the Victoria Institute will be held at Burlington House, Piccadilly, on Wednesday, July 17. The chair will be taken by the president, the Earl of Halsbury, F.R.S.; and an address will be given by Bishop Welldon.

The Women's Agricultural and Horticultural International Union will hold an exhibition and sale of farm and garden produce, and of nature-study teaching apparatus, in the gardens of the Royal Botanic Society, Regent's Park, on Wednesday, July 17. For the convenience of teachers, the nature-study room will be kept open until Saturday, July 20.

The vacancy in the tidal and optical departments of the National Physical Laboratory, occasioned by the appointment of Mr. J. de Graaf Hunter to the post of mathematical expert on the Indian Survey, has been filled by the appointment of Mr. T. Smith, formerly scholar of Queens' College, Cambridge.

The recent death of M. Charles Trépied, director of the Algiers Observatory, inflicts yet another severe loss on the ranks of French astronomers. In the organisation of the work of the Astrographic Catalogue and Chart he played an active and prominent part from the beginning, and it is to be deplored that he was not spared to see the completion of his labours. M. Trépied became director of the observatory at Algiers in 1880, and in the following year carried out a scheme of reorganisation. In 1883 the observatory was removed from its temporary site at Kouba to its present position at Bondzavéah, eleven kilometres from Algiers, and was further equipped with an equatorial *coudé*, and later with a photographic instrument of the standard photographic pattern. Since 1875 M. Trépied was a prolific writer on all branches of astronomy, and gave much study to the physical condition of the sun and to cometary spectra, while the observatory under his charge was always most active in observational work of all kinds. On the occasion of the solar eclipse of 1900, he extended the most generous hospitality and assistance to the foreign astronomers who visited Algiers. He was a corresponding member of the Paris Academy of Sciences.

Prof. W. J. Sollas, F.R.S., professor of geology and palæontology at Oxford, and his assistant, Mr. M. Allorge, have just taken the geological class to Belgium to study the structure of that country. In the Easter expedition of the students, Dr. Vaughan and Prof. Reynolds explained the zoning of the Carboniferous limestone in the Bristol district; and the object of the present expedition is to bring the results then obtained into comparison with the facts furnished by the Belgian limestones. The leading Belgian geologists, MM. Mourlon, Gosselet, Halet, Simoens, Lohest, Formarié, and Rutot, are acting as guides for the various visits and excursions which have been arranged. The expedition thus provides facilities for geological observations under the best conditions.

The retirement is announced of Prof. G. Lunge, at the age of sixty-eight, from the chair of technical chemistry at Zurich, a position which he has held during the past thirty-one years. Prof. Lunge's name is intimately associated with the development of chemical industry in Germany, not only on account of the influence he exerted on his many students, but more directly owing to his inventions and treatises on applied chemistry. At the time when he, as a young man, completed his studies at Heidelberg, chemical industry had hardly come into existence in Germany, so that in order to gain practical experience he found it necessary to proceed to England. In this country, in which he spent the twelve years 1864–1876, he was first actively engaged in studying the problems connected with the distillation of coal tar, but subsequently acted as manager of a large soda works at Tyneside. He was one of the founders of the Newcastle Chemical Society, a precursor of the Society of Chemical Industry. In 1876 Prof. Lunge received a call to the professorship of technical chemistry at Zurich, a position which, in spite of many inducements to pass to other universities, he continued to occupy until this year. His books on coal-tar distillation and on the manufacture of acid and alkali have, since the publication of the first volume in 1879, become almost classics in chemical technology.

An influentially signed appeal was published in the *Times* of July 5 for donations to a fund which is being raised to ensure the preservation of characteristic examples of the "grey wethers" on Marlborough Downs. These boulders are locally known as "Sarsen Stones," and are geologically the solidified boulders of a stratum of Eocene sand formerly covering the chalk which in the course of time has been denuded of the softer portions. For many generations these stones have been broken up and used for building and other purposes, but the breaking up has not been on such a scale as to make any appreciable difference in the appearance of the downs. A recent change of ownership has made it likely that the process of destruction will be greatly extended. In these circumstances representations have been made to Mr. Alec Taylor, the present owner, by the National Trust and the Wiltshire Archæological Society, who has stated that he intends to preserve the dolmen known as the Devil's Den, and has given the National Trust an option to purchase for 500*l.* about eleven acres in Pickle Dean and about nine acres in Lockeridge Dean, both of which areas are rich in "grey wethers." We trust the sum required will be forthcoming, so that examples of a unique geological phenomenon may be preserved to the nation. It is not too much to say that if British statesmen understood more fully the value and full significance of nature's "monuments," these and similar natural objects of scientific and educational importance would have been secured for the nation long ago. Donations to the fund which is being raised may be sent to Mr. Henry E. Medlicott, Potterne, Devizes; the Rev. E. H. Goddard, Clyffe Vicarage, Swindon; Mr. E. Meyrick, Thornhanger, Marlborough; or to Mr. Nigel Bond, 25 Victoria Street, Westminster.

THE thirty-sixth annual meeting of l'Association française pour l'Avancement des Sciences will be held at the lycée in Rheims on August 1–6. The president for the year is Dr. Henrot, honorary director of l'École de Médecine at Rheims. The work of the meeting will be divided among nineteen sections. The presidents in each case are as follows:—Sections 1 and 2 (Mathematics, Astronomy, Geodesy and Mechanics), Prof. C. Bourlet; Sections 3 and 4 (Navigation and Civil and Military Engineering), M. Bourguin; Section 5 (Physics), Prof. Blondin; Section 6 (Chemistry), Prof. Hugounenq; Section 7 (Meteorology), M. Luizet; Section 8 (Geology and Mineralogy), M. Peron; Section 9 (Botany), Prof. Lecomte; Section 10 (Zoology, Anatomy and Physiology), Prof. Caullery; Section 11 (Anthropology), Dr. Guelliot; Section 12 (Medical Science), Prof. Landouzy; Section 13 (Medical Electricity), Prof. Guilloz; Section 14 (Odontology), M. Francis Jean; Section 15 (Agronomy), M. Armand Walfard; Section 16 (Geography), M. Richard; Section 17 (Political Economy and Statistics), Dr. Papillon; Section 18 (Pedagogy), Dr. Bérillon; Section 19 (Hygiene), Dr. Calmette. M. Jadart is the president of the subsection dealing with archæology. On August 5 an evening lecture will be delivered by Dr. S. Leduc, his subject being "Diffusion and Osmosis." A very full programme has been arranged, and it is possible here to refer to a few of the subjects only. In the physics section the properties of the electric arc will be dealt with, and their application to the production of (*a*) luminous rays, (*b*) electric waves for use in ordinary and in wireless telegraphy, (*c*) nitric acid and nitrates from the oxygen and nitrogen of the air. In the chemistry section the progress made in the study of sugars and the action of soluble ferments on gums will be discussed. In the geology section the classification of the Tertiary beds in the neighbourhood of Rheims will be considered. Visits to places of interest have been arranged, and these include Verzenay, Épernay, Laon, Coucy, Charleville, Dinant, and the Han grottoes. Full particulars of the meeting can be obtained from the secretary to the council, 28 rue Serpente, Paris.

ACCORDING to a paper by Mr. H. Elias, published in *Gegenbaur's Morphologisches Jahrbuch*, vol. xxxvii., part i., the shrill cries of bats are, as might be expected, intimately connected with the structure of the larynx in those animals. Special features are the powerful musculature and the shortness of the glottis, the latter being the main cause of the shrillness of the cry. Details of the variation in structure of the larynx in different groups of insectivorous bats are given. In the same issue Dr. O. Brian gives an illustrated account of the so-called horny teeth on the tongue of the porcupine. These teeth form two isolated oval patches near the tip of the tongue, and although their existence has been long known, the author of the paper claims that he is the first to describe their histology.

FROM a natural history point of view, the *National Geographic Magazine* for June is an unusually interesting number. Among its contents is an article by Prof. A. Heilprin on the Guiana wilderness, in the course of which reference is made to the statement that the tropical American forest is characterised by the absence of flowers. "The picture," observes the author, "does not seem to apply to the forest of the river-banks of the Guianas. . . . The streamers of purple, red, and white which hang down over the forest-curtain easily recall in profusion and wealth of colour the flowers of the north. . . . Indeed, it would be difficult to recall in forests of the north, even as rare instances, that display of flowers which so frequently repeats itself here." Another article to which attention may be directed is one by Mr. H. M. Smith, Deputy Commissioner of U.S. Fisheries, on fish immigrants. It deals largely with the objects and results of fish-acclimatisation in the United States.

"SELECTION and Cross-breeding in Relation to the Inheritance of Coat-pigments and Coat-patterns in Rats and Guinea-pigs" is the title of a paper by Messrs. H. MacCurdy and W. E. Castle recently published by the Carnegie Institution of Washington. After a general discussion on continuous and discontinuous variation as factors in evolution, the authors point out that partial albinism displays itself in rats in a fashion quite distinct from that obtaining in guinea-pigs. In the one group the dark areas tend to become restricted to certain definite parts of the body, while in the other they become irregularly distributed everywhere. In rats pigment-reduction produces a regular series of coat-patterns, each of which breeds true within certain limits. In the case of guinea-pigs regression appears to be indicated by a reduction in the number of pigmented areas; but its occurrence could not be definitely determined in rats. If regression does occur in both groups, the main question is whether we can "with propriety consider the effects of selection permanent. . . . We consider the selection question still an open one."

AMONG several articles in the *Zeitschrift für wissenschaftliche Zoologie*, vol. lxxxvi., part iv., reference may be made to one by Mr. Hermann Jost, of Göttingen, on the developmental history of the larva of the ox-warble fly, *Hypoderma bovis.* From the absence of any reference to it in his list of literature, the author appears to be unacquainted with the paper on the same subject by Mr. A. D. Imms in vol. i., part ii., of the *Journal of Economic Biology*, of which a brief notice appeared in our columns some months ago. Mr. Imms was unable to obtain satisfactory evidence as to the manner in which the larvæ effect entrance into the bodies of the host, that is to say, whether they do so by perforating the skin or by way of the mouth. Dr. Cooper Curtice in an earlier paper came, however, to the conclusion that the young larvæ are licked up by the cattle, and thus conveyed to the alimentary canal. According to Mr. Jost, this is not quite the true explanation, as his observations lead to the conclusion that the eggs are never hatched on the exterior of their host, but are licked off from the skin by the tongue to undergo their final development in the alimentary canal. Estimates of the enormous commercial losses due to ox-warbles are given in the course of the paper.

THE rind disease of the sugar cane caused by the fungus *Melanconium sacchari* forms the subject of Bulletin No. 7 prepared by Mr. L. Lewton-Brain, of the division of pathology and physiology, and issued from the experiment station of the Hawaiian Sugar Planters' Association. The fungus can only penetrate the cane by wounds due to borers or other agents, but, having penetrated, readily forms fruiting masses from which arise the conidia that are extruded in long black threads. Reference is also made to the "red-rot" fungus, *Colletotrichum falcatum* and to the pine-apple disease induced by *Thielaviopsis ethaceticus*, a fungus that is sometimes regarded as a stage in the life of the Melanconium.

THE introduction of rubber cultivation into the Malay Peninsula has brought the Federated Malay States and the Straits Settlements into prominence, and with the view of supplying information as to their status and resources Mr. H. C. Belfield has prepared a third edition of the "Handbook of the Federated Malay States." The handbook contains much practical information, both for the settler and the tourist; an estimate of the cost of starting a rubber plantation is provided for the planter. As to other crops, the west coast from Perak to Negri Sembilan is well suited to the cultivation of cocoa-nuts, but coffee plantations will cease to exist as the interplanted rubber trees come into bearing, and owing to the wasteful methods adopted, tapioca cultivation is being discouraged. Measures are being adopted to conserve the trees yielding gutta-percha.

TWO curious substances, n'hangellite and coorongite, that have been described as mineral india-rubber or elastic bitumen, the former discovered in Portuguese East Africa, the latter in Australia, are the subject of an article in the Kew Bulletin (No. 5). After examination, Mr. L. A. Boodle arrives at the conclusion that they have been derived chiefly from masses of a gelatinous blue-green alga, and that the bituminous character is due to chemical changes. An account of the method of preparing amber-coloured biscuits of Funtumia rubber in Uganda is based upon a communication by Mr. H. Hesketh-Bell. On the subject of mud-binding grasses that might be utilised to reclaim sand and mud-flats, information is provided with regard to the growth of species of Spartina in Southampton Water. A long list of moths collected during the season of 1906, supplementary to the species recorded in the special volume of the Kew Bulletin on the wild fauna and flora of the gardens, is contributed by Mr. A. L. Simmons.

THE University of California, from funds supplied by Mrs. P. A. Hearst, has added to its series of monographs on American ethnology an account of the language of the Yokuts in the south central region. This tribe, the name of which means "men," inhabits the southern portion of the San Joaquin basin. It includes some forty sub-tribes, each with a distinct dialect, differences of vocabulary being probably due, partly, as among the Nagas of Assam, to inter-tribal feuds, and partly to the taboo of words connected with the dead. The Yokuts are now gradually disappearing, and the author of this monograph, Mr. A. L. Kroeber, has found much difficulty in collecting the materials for a comparative grammar and chrestomathy, the latter including some interesting tribal legends and folk-lore, more complete versions of which he proposes to publish in a subsequent volume.

THE weather still continues most persistently cold for the time of year over the whole of the British Islands, and, indeed, over nearly the whole of western Europe. Rain is falling with considerable frequency, but the measurements are not generally large. The principal feature is the large amount of cloud and the consequent small amount of sunshine. According to the summary of the weather issued by the Meteorological Office for the week ended July 6, the maximum temperature recorded anywhere in the British Islands was 68°, in the Midland counties. The defect of temperature on the mean for the period was mostly from 6° to 8°, whilst the bright sunshine was deficient over the whole of Great Britain. At Greenwich the highest shade temperature for the first nine days of July was 68°, and the observations since 1841 fail to show any other year for the same period with so persistently low a temperature, the previous years always having had a temperature of 70°, and commonly a temperature of 80° or even 90°. The mean highest temperature for the first nine days is rather below 65°, which is in agreement with the average conditions in the middle of May or the end of September. The aggregate rainfall at Greenwich for the first nine days of July is less than 0·2 inch, but rain has fallen on six days. The aggregate rainfall at the London reporting station of the Meteorological Office since the commencement of the year is 8·8 inches, which is about 1·5 inches less than the normal, and April is the only month with an excess of rain. The present outlook promises a further continuance of cool and unsettled weather.

THE Deutsche Seewarte has just published vol. xiv. of *Deutsche Ueberseeische Meteorologische Beobachtungen*, containing summaries of the meteorological observations made at thirty-eight foreign stations for various periods between 1892 and 1904. The first part includes the records from twenty-six stations where the observations were made three times a day, the stations being well scattered over the globe. Labrador, West Indies, Brazil, Morocco, Liberia, Siberia, China, Corea, and the Pacific Islands are all represented. The value of these otherwise good observations is marred by the fact that only from eight of the stations can a continuous record be got for so short a period as three years. The second part contains the results of hourly observations at stations which are all in German East Africa, and deals with the period 1900–4. Here again is the same trouble of discontinuity.

"DISTRIBUTION of Temperature and Air Pressure over the Globe in the 'Polar Year' 1882–3" is the title of the inaugural dissertation chosen by S. B. Ehrhart on obtaining his doctor's degree at Erlangen. It was a gigantic undertaking, and the results of observations at 924 stations have been utilised in preparing isothermal and isobaric charts for each month from September, 1882, to August, 1883; the charts for January and July, 1883, accompany the dissertation. The author states that, on the whole, the charts for this particular year exhibit the same general features as those drawn from means for a series of years, and show that the temperature conditions of any one month influence the pressure conditions of the following month, *e.g.* areas of high temperature favour the development of barometric minima, and *vice versâ*. We fail to find any reference to the synchronous weather charts of the North Atlantic published by the Meteorological Office for that year, which, although not dealing with mean values, constitute the greatest investigation of synchronous meteorology ever undertaken by any country.

THE paper on the theory of thermoelectricity contributed by Shizuwo Sano to the Proceedings of the Tokyo Mathematico-Physical Society, iv., 1 (February number, recently received), cannot fail to throw light or suggest ideas in connection with this difficult and controversial subject. It is usual to apply to thermoelectric phenomena the equations of reversible thermodynamics which would hold good in the absence of such irreversible phenomena as the Joule effect or conduction of heat, but the author, following on the lines indicated by Boltzmann in 1887, considers that the reversible and irreversible effects may be mutually interdependent. The paper does not claim to be free from assumptions which are not altogether justified, and in particular the deduced property of potential difference in relation to temperature may be open to question. The theory deserves careful consideration; but would it not be possible to throw it into a less analytical form?

THE first part has appeared of the *Rivista di Scienza*, of which a preliminary notice has been already given in these columns. It is an international journal somewhat similar in appearance and arrangement to the present series of *Science Progress*. From the nature of the case the articles necessarily take a somewhat broader view of the progress of science than is possible in a journal published in a country specially characterised by its national apathy to scientific work, and the expectations that were raised by the prospectus have been more than realised in the present number. The character of the journal will best be inferred from the following table of contents:—E. Picard, "La mécanique classique"; W. Ostwald, "Zur modernen Energetik"; G. Ciamician, "Problemi di chimica organica"; F. Raffaele, "Il concetto di specie in biologia"; H. E. Ziegler, "Die natürliche Zuchtmahl"; C. Scipino, "Il carattere delle leggi economiche"; W. Cunningham, "Impartiality in History"; J. Tannéry, "Questions pédagogiques, l'Enseignement secondaire"; in addition to a large number of reviews, notes on physics and physiology, a "review of reviews," and notes. The price of each part is 7*s*. 6*d*. net; Messrs. Williams and Norgate are the London agents. The editorial office is at Milan, 16 Via Aurelio Saffi. The list of forthcoming articles is sufficient to fill a large number of volumes, and nearly every nationality is represented among the contributors.

OF all the numerous publications issued by the United States Geological Survey, none is of greater interest than the volumes dealing with the "mineral resources of the United States," a series of which we have just received the twenty-second annual issue (Washington: Government Printing Office, 1906). Each chapter in this report is a census of the production of the industry under discussion during the calendar year 1905. Although printed in smaller type, the volume is considerably larger than that of the previous year, covering as it does no less than 1403 pages. The publication of the volume has been anticipated to a great extent by the issue in advance, in pamphlet form, of the several chapters which compose it. The volume is edited by Dr. D. T. Day, and the various chapters are written by different statistical experts. The figures dealt with are stupendous. In 1905, for the seventh time, the total value of the United States mineral production exceeded the enormous sum of 200,000,000*l*. The exact figures for 1905 are 324,775,422*l*., iron ore and coal being, as heretofore, the most important of the minerals produced. The arrangement and scope of the volume are practically the same as in previous issues. The production of carbonic acid, especially at Saratoga Springs, New York, is, however, discussed for the first time, and statistics are given of the production and consumption of water-gas. A report is also included directing attention to peat in the United States, and to its great possibilities as a source of fuel. There is, too, a chapter devoted to tin, although, as a matter of fact, during 1905 no metallic tin was made in the United States, and merely an insignificant quantity of ore was obtained from the placers of Buck Creek, Alaska.

IN a paper published in the *Verhandlungen* of the German Physical Society (No. 8, p. 175), Messrs. P. Nordmayer and A. L. Bernoulli give the results of a series of determinations of the specific heat of a large number of substances, both elementary and compound, between the temperatures $-185°$ C. and $+20°$ C. The method used was to ascertain the weight of liquid air evaporated on adding a known weight of the substance in question, the heat required to evaporate 1 gram of liquid air being taken as 50 calories. The results obtained show that, whereas the specific heat of a compound substance such as water or benzene in the solid state diminishes very rapidly as the temperature falls, the specific heat of most solid elements is subject to a much smaller variation. The change of specific heat with temperature is most marked in the case of elements of low atomic weight, for example, sodium and magnesium. For the metals molybdenum, tungsten, and tantalum, the specific heat is almost constant for all temperatures between $-200°$ C. and $+250°$ C.

THE conditions which are essential in order to obtain accurate results in the estimation of potassium by the well-known method based on the precipitation of the metal in the form of its chloroplatinate are studied in a paper by M. J. Morozewicz in the Bulletin of the Cracow Academy of Sciences (1906, No. 9, p. 796). Fresenius recommended that in presence of sodium the chloroplatinate should be precipitated in 70 per cent. to 80 per cent. alcohol, but subsequent workers have advised the use of absolute alcohol instead; it is, however, shown that if absolute alcohol be used, a much larger proportion of platinum chloride is required to ensure the complete transformation of sodium chloride into its chloroplatinic salt. The results obtained are, moreover, generally high, owing to the co-precipitation of some of the sodium chloride. It is therefore advisable to adhere to Fresenius's original procedure.

IN NATURE of June 20 (p. 184) Prince B. Galitzin's experimental verification of Doppler's principle for light rays was briefly noted; and the paragraph stated that use was made of "the graduated spectroscope (Stufenspektroscope)." Mr. J. Twyman, of Messrs. A. Hilger, Ltd., writes to point out that "Stufenspektroscope" is the accepted designation of a spectroscope wherein a "Stufengitter" or echelon diffraction grating is employed.

THE British Sports Publishing Company, Ltd., have issued in their Spalding's Athletic Library the "Lawn Tennis Annual for 1907," edited by H. R. M., and "Spalding's Golfers' Annual for 1907," edited by Mr. Henry Leach. Both books are illustrated by reproductions of action photographs depicting well-known players. The price of the annuals is 6*d*. net each.

WE have received from Marconi's Wireless Telegraph Company, Ltd., a copy of a catalogue dealing with

Röntgen ray and high-frequency apparatus, instruments, and accessories. The list provides full particulars as to a variety of induction coils made by the company, interrupters, fluorescent screens, portable accumulators, and high-frequency sets. The information given as to light baths, vibration apparatus, the Finsen lamp and light, and the orthodiagraph, should appeal specially to medical men. The list is conveniently arranged and admirably illustrated.

A new edition of "Bradshaw's Through Routes to the Chief Cities of the World" has just been published. This comprehensive handbook of colonial and foreign travel, besides giving descriptive routes of the chief railways, ocean lines, and caravan tracks, supplies an abundance of maps and plans and some useful vocabularies. The volume has been edited by Prof. A. H. Keane and Mr. Stanley Read, and its price is 5*s*. net. The route numbered 50, dealing with tours round the world, is of special interest, showing as it does the increased facilities for travel since Jules Verne wrote "Round the World in Eighty Days." The actual minimum time required for an all-round journey from London, provided no delay occurred in missing train or boat connections, is 38 days 10 hours, and Lieut.-Colonel Burnley-Campbell recently completed the circuit of the world in 40 days 19·5 hours, following the route Liverpool, Quebec, Vancouver, Yokohama, Tsaruga, Vladivostok, Harbin, Irkutsk, Moscow, Warsaw, Berlin, Ostend, Dover; but the usual quick rate of travel is still 53 days. The book may be commended to teachers as an interesting example of applied geography.

OUR ASTRONOMICAL COLUMN.

Transits of Saturn's Satellite Titan and Shadow.—In the Publications of the Astronomical Society of the Pacific, vol. xix., p. 125, Hermann Struve gives the following central transits of Titan and shadow during ensuing months:—

1907		G.M.T. h. m.	Distance from centre ″	Semi-duration of transit h.
July 17	Shadow	8 16	0·5 S.	3·0
July 17	Titan	13 48	7 0 N.	1·6
Aug. 2	Shadow	7 30	0·2 N.	3·0
Aug. 2	Titan	12 6	6·3 N.	2·0
Aug. 18	Shadow	6 43	0 9 N.	3·0
Aug. 18	Titan	9 51	5·0 N.	2·5
Sept. 3	Shadow	5 59	1·6 N.	3·0
Sept. 3	Titan	7 42	3·2 N.	2·8
Sept. 19	Titan	5 14	1·3 N.	3·0
Sept. 19	Shadow	5 15	2·3 N.	2·9
Oct. 5	Titan	2 48	0·7 S.	3 0

Comet 1907*d* (Daniel).—A new set of elements and a daily ephemeris for comet 1907*d* are published by Dr. Strömgren in No. 4187 (p. 191, June 29) of the *Astronomische Nachrichten*. A part of the ephemeris is given here; and, in order to facilitate the location of the object, the daily positions, with respect to the surrounding stars, are marked on the accompanying chart:

Ephemeris 12h. (M.T. Berlin).

1907	α (true) h. m.	δ (true) ° ′	log *r*	log Δ	Brightness
July 10	1 39·0	+ 7 35·1	0·1318	0·0216	3·50
12	1 49·0	+ 8 16·7			
14	1 59·5	+ 8 58·8	0·1133	9·9977	4·25
16	2 10·5	+ 9 41·2			
18	2 22·0	+10 23·6	0·0942	9·9756	5·14
20	2 34·1	+11 5·9			
22	2 46·7	+11 47·8	0·0744	9·9558	6·17

According to Dr. Strömgren's elements, perihelion will occur on September 9·4.

Apparent path of Comet 1907*d*, July 5–22, 1907.

As will be seen from the above ephemeris, the comet is brightening rapidly, and may yet become a faint naked-eye object. At present it is an easy object, when found, in a 3-inch refractor. It has a distinct stellar nucleus which, according to Dr. Zappa, of Rome, was centrally placed and of magnitude 8·5 on June 16. A faint fan-shaped tail was seen on June 21.

Mars: the Duplication of the Solis Lacus.—In Bulletin No. 28 of the Lowell Observatory, Prof. Lowell records that the Solis Lacus showed double on May 18, this being the first time that it has appeared divided since the summer of 1894. This is not a case of gemination, for the two portions are not alike either in shape or size, nor were they in 1894. Among the canals which emerge from the eastern part, a new one was detected for the first time on May 18, and has been designated Ichor. The South Polar cap has retreated southward since the last presentation, leaving dark ground behind it, and it is noticeable that the canals connecting with the Solis Lacus on the south are darker and more easily seen than those proceeding from it towards the north, although the tilt of the planet's axis should render the former the more difficult to detect. As the snow has left dark ground behind it, darker than is the case in this region in the later part of the Martian year, Mr. Lowell argues that water, and not CO_2, is concerned. As a consequence, it follows that the temperature in this region—lat. 42°–52°—was already higher than 0° C. on May 18, or, in the Martian year, on a date corresponding to March 13 of our calendar.

Variable Stars.—*Astronomische Nachrichten*, No. 4186 (June 28), contains several important communications concerning variable stars. The first is by Messrs. Müller and Kempf, of the Potsdam Observatory, on the peculiar variable X Persei, which they have now observed regularly for twenty years. The present paper gives the observational record since September, 1899, and is accompanied by a light curve showing the peculiar fluctuations of magnitude which this star undergoes.

In the second paper M. Luizet records some maxima and minima of several long-period variables, among the stars dealt with being *o* Ceti, R Leonis, and S Coronæ.

The third communication is from the Harvard College

Observatory, and gives the designations, positions, magnitudes, magnitude ranges, and spectral classification of fifteen new variable stars discovered in the regions covered by the Harvard maps Nos. 31 and 62.

NAMES FOR THE THREE JOVIAN ASTEROIDS.—Drs. Wolf and Kopff have chosen the three names Achilles, Hector, and Patroclus, respectively, to designate the three important minor planets (588) [1906 TG], [1907 XM], and [1906 VY] discovered by them at Heidelberg. Readers of these columns will remember that the orbits of these three bodies have been found to extend as far from the sun as that of Jupiter (*Astronomische Nachrichten*, No. 4187, p. 192, June 29).

THE MIRA MAXIMUM OF 1906–7.—From a series of observations made at Utrecht, and extending from July 25, 1906, to March 4, 1907, Prof. Nijland found that the maximum brightness of Mira occurred on December 7, when the magnitude was 2·0. The preceding minimum was recorded on August 7, and, as seen from the curve, was a very flat one, from which a sharp rise to an exceptionally bright maximum took place. The previous maximum took place on January 3, 1906, so that the period between these two successive maxima was 338 days (*Astronomische Nachrichten*, p. 113, No. 4183, June 14).

SOLAR PROMINENCE OBSERVATIONS IN 1906.—The annual summary of the results of the prominence observations made at Catania, for 1906, is published by Prof. Riccò in No. 5, vol. xxxvi. (p. 73), of the *Memorie della Società degli Spettroscopisti Italiani*. The daily record is reproduced, and then analysed, under the heads of the extension, height and frequencies of the prominences, in the two hemispheres for each month and quarter and for the year. The similarity of the size and distribution of the prominences recorded to those of the previous year indicates a stationary point characteristic of the maximum, whilst the greater frequency during March points to that month as being the actual month of solar prominence maximum.

CONGRESS OF THE ROYAL INSTITUTE OF PUBLIC HEALTH.

THE congress of the Royal Institute of Public Health, held this year at Douglas, Isle of Man, from June 29 to July 5, was presided over by Lord Raglan, the Lieutenant-Governor of the island, who, in the course of his presidential address, gave a cordial welcome to the members of the congress. He referred to the progress of sanitation during the Victorian era, but pointed out that England was handicapped in the hygienic struggle as compared with Continental nations owing to our exaggerated ideas of personal liberty.

Sir James Barr, in the course of his presidential address in the preventive medicine section, urged medical practitioners to take as deep an interest in sanitation as sanitarians. The health of a nation was its most valuable asset, and he would like to see all his adult countrymen able to handle a rifle and take part in the defence of their country should occasion arise, and he would encourage the military spirit as the best means of developing the moral and physical qualities of the nation. He urged that there should be State aid if needed for every child under sixteen to be properly fed and cared for. Huge trusts and millionaires were a danger to society, and part of their wealth should be appropriated by the State.

Prof. Sims Woodhead, in the section of bacteriology and chemistry, delivered an address on the subject of "anti-bodies," in which he traced the rise and development of bacteriology, and adduced statistical evidence on the value of diphtheria anti-toxin. Dr. Warrington, of Liverpool, introduced a discussion on cerebro-spinal fever, in which he advocated the isolation of cases and the disinfection of places in which the disease had occurred. Dr. Prudence Gaffitien read a paper on the causes of infantile mortality. She said the high infant death-rate was due to the ignorance of mothers, and advocated the prohibition of the use of soothing syrups, &c. The Infant Life Protection Act was worse than useless; the State should provide for the inspection of foster or nurse children.

Prof. Hele Shaw delivered an address in the engineering and architectural section on road locomotion and the public health. He dealt chiefly with the new conditions occasioned by the advent of motor-cars; he admitted that the public had grievances arising from dust, odour, noise, and vibration, but claimed that much was being done to lessen these.

Dr. Sergeant, of the Lancashire County Council, opened a discussion on the milk supply, and a resolution was passed affirming the desirability of dairy regulations being made compulsory by the Local Government Board.

Many valuable papers were read on notification, tuberculosis, and sanatoria.

The social part of the congress was all that could be desired, and many excursions were made to the places of interest in the beautiful island. The congress dinner was presided over by Lord Raglan, and there was a garden-party at Government House.

RECENT CONTRIBUTIONS TO ELECTRIC WAVE TELEGRAPHY.[1]

PROF. FLEMING said that the achievements of electric-wave telegraphy had not yet ceased to interest the public mind. In little more than eight years from the time when Mr. Marconi sent his first messages across the English Channel, it had become an indispensable implement in naval warfare, and also a means of communication between ships and the shore, greatly adding to the safety of life and property at sea. At the present time practically the whole of the first- and second-class battleships of the British Navy are equipped with apparatus for electric-wave telegraphy, and about 130 cruisers and smaller craft as well. The Marconi Company alone have fitted with their instruments nearly 100 Atlantic liners and other mercantile vessels, and have an elaborate organisation by which all these ships are constantly in communication with the mainland during their voyage from port to port. Concurrently with this, an immense amount of scientific investigation has been carried on having for its object further improvements and the quantitative study of the phenomena. The object of the discourse was to make known some of these recent additions to knowledge.

A cardinal feature of electric-wave telegraphy is the vertical wire or wires at the transmitting and receiving stations, called the antenna. At the transmitting station high-frequency electric currents are set up in the sending antenna, and these create rapidly alternating electric and magnetic forces in the space around, which are propagated outwards from point to point with the velocity of light. Hence at certain distances, called a wave-length, these forces are reversed in the same way at the same instant. In electric-wave telegraphy the wave-lengths used lie between 200 feet and 20,000 feet or so, covering about eight octaves. The measurement of this wave-length is important. Prof. Fleming described an instrument of his own invention, called a cymometer, used for this purpose. It consists of a spiral of wire in series with a sliding tubular condenser, the circuit being completed by a copper bar. Across the terminals of the condenser is placed a neon vacuum tube. If the bar of the cymometer is placed near the transmitting antenna and the handle of the instrument moved, its capacity and inductance can be altered until it comes into tune with the antenna circuit. When this is the case the oscillations in the antenna create violent sympathetic oscillations in the cymometer, and the neon tube glows brilliantly. An index pointer moving over a scale then shows the wave-length of the waves radiated. The same instrument may be used to measure the wave-length of the arriving waves. Also it can be used to determine the decay of the oscillations in a train.

In spark telegraphy the oscillations are set up in the antenna by an electric discharge, and at each spark a group of oscillations takes place. These may come at the rate of ten to fifty groups per second, and each group may contain from ten to 100 decadent oscillations. The cymometer can be used to draw a resonance curve by which the rate of decay and the number of the oscillations in a

[1] Abstract of a discourse delivered at the Royal Institution on Friday, May 24, by Prof. J. A. Fleming, F.R.S.

train are determined. Methods have now been devised for creating undamped or nearly undamped oscillations. One method suggested is by the use of a high-frequency alternator, but the difficulty of constructing such a machine for a sufficiently high frequency is very considerable, and as yet only machines of small power have been made.

Prof. Elihu Thomson in 1892 patented a plan for producing a continuous current electric arc between metal terminals which was acted upon by an air jet or magnetic field. He found that when the metal poles or spark balls were connected by a condenser in series with an inductance high-frequency oscillations were created in the latter circuit.

Mr. Duddell showed in 1900 that continuous undamped oscillations could be obtained when using, in place of the spark balls, an electric arc made between solid carbons. In 1903 Mr. Poulsen went a step farther. He formed the arc between a carbon terminal (negative) kept in rotation and a cold metal terminal (positive), and enclosed them in an atmosphere of hydrogen or coal gas and placed a strong magnetic field across the arc. The arc terminals being then shunted by a small condenser and an inductance, we have undamped high-frequency oscillations suitable for wireless telegraphy created in this latter circuit. Prof. Fleming gave an explanation of the reason for this effect, and showed that it was due to the form of the characteristic curve of the metal carbon arc. He compared the action to that of an organ pipe in which the energy is supplied by a steady jet of air corresponding to the continuous current arc, and this is made to set up aërial vibrations in the resonant organ pipe, equivalent to the condenser circuit, the vibrations in the pipe controlling and drawing their energy from the air jet. In applying the Poulsen method to wireless telegraphy, an antenna circuit is connected either inductively or directly with the condenser circuit.

Experiments were shown illustrating the production of high-frequency undamped electric oscillations in a long wire wound on an ebonite rod. Incidentally it was proved by an ingenious experiment with a neon vacuum tube that the oscillations are not really continuous, but cut up into irregular groups. In reference to the application of the Poulsen method to wireless telegraphy, Prof. Fleming said that the apparatus was more complicated and less easy to use than that for spark telegraphy. It was not true that undamped waves could not be picked up or tapped, and he proved that such advantages as the use of undamped waves in telegraphy might present were not due only to the transmitter, but to the conjoint use of a slightly damped receiver circuit.

Prof. Fleming did not agree with the opinion, confidently expressed in some quarters, that telegraphy by undamped waves would destroy spark telegraphy. Further, he pointed out that the electric arc was not the only method for producing undamped waves. He said that for some months past Mr. Marconi had been working out a purely mechanical method of producing continuous trains of electric waves suitable for wireless telegraphy, and had obtained considerable success. The method was exceedingly simple, and by means of it any existing station for spark telegraphy could be converted easily into a station sending out undamped electric-wave trains instead of intermittent damped trains.

The lecturer then passed on to explain some recent forms of electric-wave detector. When the waves sent out from the sending antenna fall on a receiving antenna they create in it secondary high-frequency oscillations, and these are detected by the use of some device called a wave detector. In addition to the coherer and the Marconi magnetic detector, the latter exclusively used in long-distance work, a receiver called an electrolytic detector is now much used. It consists of a vessel containing nitric acid in which is placed a platinum plate and an exceedingly fine platinum wire as the pair of electrodes. This cell is connected in series with a telephone and a voltaic battery, and when electric oscillations are passed through the cell they annul more or less the polarisation of the small electrode and create an increase of current, which in turn makes an audible signal in the telephone.

Signals are thus sent on the Morse code by interrupting the oscillations in the sending antenna. It has, however, recently been found that this electrolytic detector, in conjunction with undamped-wave trains, affords a means of transmitting, not merely *dots* and *dashes*, but articulate speech sounds, and hence we have now electric-wave wireless telephony as an accomplished fact. Between Nauen and Berlin, a distance of about sixteen miles, successful experiments were recently carried out. From the transmitter continuous undamped waves of constant wave-length are sent out. The antenna is shunted by a microphone, so that words spoken to its diaphragm vary the intensity of the wave train, but not its wave-length. At the receiving station an electrolytic detector is used, and the words spoken to the transmitter are reproduced at the receiving telephone. It is almost practicable at the present moment to speak audibly across the English Channel by wireless telephony, and within the bounds of possibility that at some time we may telephone without wires to a ship in the middle of the Atlantic.

Another new form of electric-wave detector is a glow-lamp detector. A small carbon filament glow lamp has a metal cylinder placed in its bulb so as to surround, but not touch, the filament. This cylinder is connected to third terminal by a wire sealed through the glass. When the filament is rendered incandescent by a continuous current it throws off negatively charged corpuscles or electrons. The space between the filament and the cylinder will pass negative electricity from the filament to the cylinder, but not in the opposite direction. If, then, the oscillatory current in the receiving antenna, or secondary currents induced by them, are passed through the bulb from the carbon filament to the cylinder, only one constituent of the oscillation passes, or the bulb rectifies the oscillations. We can then insert in series with the bulb either a telephone or galvanometer sensitive only to continuous currents and cause it to be affected.

This glow-lamp detector or oscillation valve has already proved itself to be a most sensitive long-distance receiver for wireless telegraphy. It is of great use in connection with undamped electric waves, as it affords a ready means for converting the high-frequency alternating current created in the receiving antenna into a continuous current detectable by a galvanometer or telephone. Prof. Fleming showed by an experiment that it enabled him to revive in another form electromagnetic induction telegraphy.

In the form in which this older system of wireless telegraphy was practised by Trowbridge, Preece, Lodge, and others, a closed primary circuit was traversed by a rather low-frequency alternating current, viz. one of which the frequency lay within the limits of audible sound. In the modification proposed, a closed primary circuit earthed at one point is traversed by a very high-frequency current produced by the electric arc or other mechanical method. With high frequencies, say of 100,000 or so, no disturbance would be created in other earthed neighbouring telephonic or telegraphic circuits. The receiving circuit is a similar closed and syntonised circuit having a glow-lamp detector or oscillation valve and telephone inserted in it. The primary circuit affects the secondary circuit by magnetic induction, and also acts like a Fitzgerald closed magnetic oscillator, and throws off magnetic waves. With these modifications it is possible that induction telegraphy may be extended in range and free from the objection of disturbing neighbouring telephonic circuits.

The lecturer then passed on to consider some advances made in directing electric waves in any required direction. All methods employing mirrors or reflectors are out of the question when long telegraphic electric waves are under consideration. Two methods at the present time presented practical advantages. In one, due to Mr. Marconi, the vertical upright antenna wires are replaced by antennæ having a short part vertical and their greater part horizontal. Such a bent antenna radiates best in the opposite direction to that in which its free or insulated end points. Hence, in accordance with the law of exchanges, which applies to electric radiators, a bent antenna absorbs best electric waves coming from a direction opposite to that to which its free end points. Making use of such bent receiving and transmitting antennæ, Mr. Marconi has been able to limit the radiation in undesired directions, and also to locate the direction of invisible sending stations.

Another method, different in principle, has been devised by Prof. Braun, of Strassburg, who employs three vertical antennæ placed at equal distances, and sets up in these oscillations having certain assigned differences of phase. Hence, by the interference of these oscillations, the resultant radiation is made a maximum in a certain direction and zero in an opposite one.

In conclusion, some questions were dealt with concerning the varying opacity of our atmosphere to long electric waves and the effects of sunlight and radio-active matter in hindering their transmission. Although much valuable invention and discoveries in connection with this subject have rewarded the labours of workers in many lands, a glance round shows innumerable unsolved problems still remaining. Having regard to its importance for naval and maritime communication, scientific research in connection with wireless telegraphy is not merely desirable, but a positive duty, and it is to be hoped that the tendency to legislate for it by Acts of Parliament or international conferences will not impose shackles upon the freedom of investigation or of commercial work which alone can conduct us to the satisfactory solution of the difficulties and problems which yet remain.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Mr. S. S. Dawson has been appointed to the chair of accounting vacated by Prof. Dicksee.

A sum of about 1000*l*. has been given by the Birmingham Chamber of Commerce to found a scholarship in the faculty of commerce.

MANCHESTER.—During recent years, with the increasing number of students who come from other parts of the country and from abroad, the accommodation in the two halls of residence for men students has had to be extended on several occasions. The opening of the new buildings of Hulme Hall in Victoria Park on July 6, which are to displace the older buildings in Plymouth Grove, marks an important advance, and rooms are immediately available for forty students, whilst this hall will later be extended to accommodate sixty.

ST. ANDREWS.—An important addition to the equipment of the Gatty Marine Laboratory has just been made by the presentation of the late Mrs. Alfred Gatty's extensive collection of British and foreign marine algæ by her daughter, Mrs. Horatio Eden, of Rugby. Begun in 1848 at Hastings, this important collection was constantly added to during the life of the accomplished author of the "British Seaweeds." Moreover, Miss Catherine Cutley, of Exmouth, a well-known algologist, Prof. W. Harvey, Prof. Agardh, and others, largely increased its value by liberal donations. The collection is arranged, though not completely, according to Prof. Harvey's "Index Generum Algarum," and is accompanied by a valuable series of books of reference, many of them finely illustrated, by Greville, Harvey, Turner, Agardh, J. E. Gray, Frauenfeld, Mrs. Gatty, and others. The foregoing, with the collections of algæ by Mrs. McIntosh, Charles Howie, W. Knight, Dr. Drummond, &c., previously in the laboratory, will, with the rich living series in the bay, give workers in algology facilities of no ordinary kind.

THE King will open the new buildings of University College School, in Frognal, Hampstead, on Friday, July 26.

THE Right Hon. Ailwyn Fellowes will distribute the diplomas and prizes on Wednesday, July 24, at the South-Eastern Agricultural College, Wye, Kent.

DR. S. G. RAWSON has been appointed principal of the Battersea Polytechnic in succession to Mr. Sidney H. Wells, who has been principal since the foundation of the institute in 1893, and is resigning to take up the position of director-general of the Department of Agriculture and Technical Education for Egypt. Dr. Rawson is at present director of education for Worcestershire, and was formerly principal of the Technical College, Huddersfield, and lecturer at Liverpool University.

A COMMITTEE has been appointed by the Treasury to inquire and report upon the character of the work accomplished by the University of Wales and its constituent colleges, the financial position and lines of development of the colleges, and their probable requirements for staff or otherwise. The members of the committee are:—Sir T. Raleigh, K.C.S.I. (chairman); Sir John Rhys, Principal of Jesus College, Oxford; Principal D. MacAlister, Glasgow University; Mr. F. G. Ogilvie, C.B.; Prof. W. S. McCormick; and Dr. Alexander Hill, Master of Downing College, Cambridge. Mr. G. L. Barstow, of the Treasury, will act as secretary to the committee.

THE Board of Education has issued its regulations for next session in connection with the work of technical schools, schools of art, and other day and evening schools and classes for further education. A prefatory memorandum directs attention to the changes introduced; but, before enumerating these, some remarks are made on the general condition of the work of the schools concerned. The experience of towns which have provided systematic and graded courses of instruction shows that a good supply of well-considered educational facilities may be made to foster a demand for these advantages without the application of compulsion in the matter of attendance. Another interesting fact is to find it specifically stated that it is regarded as one of the functions of the Board's inspectors to advise educational authorities, where evening and other schools are not so popular as they might be, as to the changes which would probably lead to improvement and to inform them where successful schools may be found. A note has been added to the regulations with the object of making clear to local authorities that the classification of subjects and courses is in no sense a restriction upon the free adjustment of the subject-matter and methods of instruction in any class to the particular circumstances of the students. The necessity for keeping rural interests well in view throughout all educational work in country districts is now fully recognised, and the continuing need for Saturday and holiday courses for teachers who desire to improve their qualifications for duty in such areas is again pointed out.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 2.—"The Spontaneous Crystallisation of Binary Mixtures. Experiments on Salol and Betol." By Prof. H. A. **Miers**, F.R.S., and Miss F. **Isaac**.

The authors have inferred from their experiments upon certain salts that a cooling supersaturated solution can at first only be made to crystallise by inoculation with a crystal of the solute, until a perfectly definite temperature is attained at which a mechanical stimulus, *e.g.* shaking or friction, will suffice to produce crystallisation. The temperature of this "spontaneous crystallisation" depends upon the strength of the solution as determined by a curve which they name the "supersolubility curve." They have now traced the complete freezing-point curve, and also the supersolubility curves for mixtures in all proportions of salol and betol, choosing these substances merely because they melt at convenient temperatures and do not form compounds or isomorphous mixtures. Salol melts at $42\frac{1}{2}°$, betol at 92°. The eutectic contains 78 per cent. salol, and freezes at $32\frac{1}{2}°$ by inoculation only.

Salol freezes spontaneously at 33°, betol at 79°; the supersolubility curves of their mixtures meet in the "hypertectic" mixture, containing 74 per cent. salol, for which the two substances freeze together spontaneously at 15°.

The freezing-point curve was determined by immersing a minute crystal in the cooling liquid and noting the temperature at which it just ceased to dissolve and began to grow.

The temperatures of spontaneous crystallisation were determined (1) by the crystallisation of the liquid on shaking or scratching when enclosed in a sealed tube, and also (2) by the dense shower of crystals which appears at the same temperature when the liquid is stirred in an open vessel.

The actual change of constitution of the liquid in the crystallising mixture was traced by means of the refractive index.

These experiments show that a binary mixture has, in general, four freezing points. For example, the mixture containing 90 per cent. salol may yield crystals of salol by inoculation at 38°, and by stirring at 28°; crystals of betol by inoculation at $17\frac{1}{2}$°, and by stirring at $10\frac{1}{2}$°.

The actual temperatures of crystallisation in binary mixtures are given by the supersolubility curves.

May 23.—"Studies on Enzyme Action. X.—The Nature of Enzymes." By Henry E. **Armstrong** and E. Frankland **Armstrong**.

The study of enzymes has now reached a stage at which it appears to be desirable to consider what is established and to direct attention to some of the principal issues which remain to be elucidated. The action which each enzyme exercises is clearly specific and limited to compounds of a particular type; the apparent exceptions to this statement in the case of sucroclastic enzymes have been investigated and eliminated: there is little doubt that maltase is capable of hydrolysing α-glucosides alone, whilst emulsin hydrolyses only β-glucosides. Further experiments have been made with carefully purified materials to ascertain what substances control the action of each sucroclastic enzyme; the evidence that enzyme and hydrolyte must be in complete correlation appears to be little short of absolute.

A special study has been made of the hydrolysis of cane sugar by invertase: apparently, glucose and fructose alone retard the action of this enzyme; it would seem to follow that it is so constituted that it can adapt itself to both sections of the biose. Cane sugar, though a derivative of α-glucose, is not a simple α-glucoside, nor is it an α-fructoside: consequently there is little room for doubt that the action of invertase is altogether peculiar and that the enzyme extends its influence over the whole of the cane-sugar molecule. Maltose and lactose differ from cane sugar in that they are hydrolysed by enzymes which also act on the corresponding simple glucosides.

It is conceivable that the enzymes themselves are subject to hydrolysis and simplification—in other words, that a biose may give rise to a monase. The existence of monases in admixture with biases is therefore to be expected. There can be little doubt that the sucroclastic enzymes are products of hydrolytic changes in the protoplasm conditioned by enzymes—mainly proteoclasts.

"Studies on Enzyme Action. IX.—The Enzymes of Yeast: Amygdalase." By R. J. **Caldwell** and S. L. **Courtauld**.

Amygdalin, which on complete hydrolysis yields two molecular proportions of glucose, is only partially hydrolysed by the enzymes extracted from dried yeast, mandelonitrile glucoside and glucose being formed:—

$$C_6H_5CH(CN)O—C_{12}H_{21}O_{10}+H_2O \rightarrow C_6H_5CH(CN)O—C_6H_{11}O_5+C_6H_{12}O_6.$$

The enzyme which effects this decomposition is specific, but being accompanied by *maltase* has been generally supposed to be identical with it. This conclusion, however, appears unwarrantable in view of the evidence recently advanced by the authors that amygdalin is not a derivative of maltose, and in the light of recent work on the specific character of the enzymes (E. F. Armstrong).

Systematic experiments with yeast extracts led to the conclusion that true maltase is without action on amygdalin, for the maltase could be destroyed by heating at 50°, whilst the activity towards amygdalin was unimpaired. Proof was thus obtained of the existence of a specific enzyme not hitherto recognised as a constituent of yeast, which is the active agent in the separation of glucose from amygdalin. This enzyme, "*amygdalase*," is present in larger proportion in top yeasts than in bottom yeasts, and appears to be equally well extracted at all temperatures from 15° to 45°, whereas for the extraction of maltase there is a distinct optimum temperature depending on the variety of yeast.

Although completely freed from maltase by heating at 50°, yeast extract retains not only its power to hydrolyse amygdalin, but also a diminished activity towards methyl-α-glucoside, and unaltered activity towards cane sugar. The inference that methyl-α-glucoside is attacked by the two enzymes maltase and amygdalase cannot well be disputed, particularly as amygdalin is more slowly hydrolysed in presence of methyl-α-glucoside, whereas maltose has no influence. The alternative explanation is that there is yet another *α-glucase* existing side by side with maltase and amygdalase. The enzyme which attacks amygdalin is not identical with *invertase* as Marino and Sericaro have recently declared, for a high temperature (60°) quickly destroys amygdalase, leaving active invertase in solution.

Amygdalase, like maltase and invertase, is present in the yeast in the form of a "*zymogen*" or more complex proteid molecule. This zymogen can be dissolved out at 0°, and its hydrolytic activity developed by heating the solution for a short time at 45°. Unlike maltase, amygdalase is not destroyed during autolysis of yeast, but may be precipitated with the invertase by means of alcohol.

June 20.—"Studies of the Processes operative in Solutions."

(2) The Displacement of Chlorides from Solution by Alcohol and by Hydrogen Chloride. By H. E. **Armstrong**, Dr. J. V. **Eyre**, A. V. **Hussey** and W. P. **Paddison**.

(3) The Sucroclastic Action of Nitric Acid as Influenced by Nitrates. By R. **Whymper**.

(4) The Hydrolysis of Methylic Acetate in Presence of Salts. By H. E. **Armstrong** and J. A. **Watson**.

(5) The Discrimination of Hydrates in Solution. By H. E. **Armstrong** and R. J. **Caldwell**.

(2) The effect of different proportions of the non-electrolyte alcohol and of the electrolyte (in solution) hydrogen chloride in displacing ammonium, sodium and potassium chlorides from their saturated solutions has been determined and the proportion of water calculated which it may be supposed is withdrawn by the precipitant in each case. The results afford an interesting picture of the state of the salts in the various solutions; in particular, they show that sodium and potassium chlorides are present in saturated solutions in an easily precipitable, slightly hydrated form and that they pass into a more soluble and more hydrated form as the amount of precipitant is increased. Except that alcohol has less dehydrating power than hydrogen chloride, no distinction can be drawn between the two as precipitants of chlorides.

(3) The method developed in part i. of these studies by R. J. Caldwell has been applied to nitrates, *i.e.* the average concentrating effect which a number of these salts produce has been determined by hydrolysing cane sugar with nitric acid in their presence and ascertaining the extent to which the solution must be diluted in order to reduce the rate of change to the value which it has when the salt is not present. The average degree of hydration deduced for the various salts is as follows:—

$AgNO_3.5H_2O.$
$NH_4NO_3.7H_2O.$
$KNO_3.8H_2O.$
$NaNO_3.11H_2O.$
$LiNO_3.13H_2O.$
$Sr(NO_3)_2.18H_2O.$

(4) To ascertain whether the method followed in (1) and (3) of these studies can be applied to hydrolytes other than cane sugar, the investigation has been extended to the hydrolysis of methylic acetate by chlorhydric acid in presence of various chlorides. The results arrived at are as follows:—

$NH_4Cl.5H_2O.$
$KCl.8H_2O.$
$NaCl.10H_2.$
$BaCl_2.18H_2O.$
$CaCl_2.20H_2O.$

These values are slightly lower than those deduced with the aid of cane sugar. It is suggested that the chlorides enter to some extent into competition with the acid for the ethereal salt and that, consequently, they partially prevent hydrolysis. Nitrates have a still greater effect in competition with nitric acid, the apparent hydration values being $NH_4NO_3.2H_2O$, $LiNO_3.0H_2O$, $KNO_3.1H_2O$ $NaNO_3.3H_2O$.

(5) The results arrived at in these studies and in those

on enzyme action carried out at the Central Technical College are discussed with reference to the general problem of chemical interchange in solution. It is argued that not only is the ionic dissociation hypothesis irrational and unsupported by chemical evidence which compels its acceptance but that proof is not wanting that it is untenable; that the selective action of enzymes as hydrolysts, the action of salts and other dehydrants in promoting hydrolysis by acids and the similar behaviour of non-electrolytes and electrolytes in precipitating substances from solution are all cases of change which it is easy to explain on the assumption that association takes place, although incompatible with the view that dissolution involves separation into free ions. The importance of the part played by hydrates in solution is considered and the evidence bearing on their composition is analysed—especially that to be derived from the change in the solubility of gases produced by salts, &c. It is contended that the values deduced by the cane-sugar hydrolysis method are rational values. Finally, reference is made to the nature of electrolytes and it is argued that it is incumbent on physicists to reconsider the arguments which lead them to accept the hypothesis of ionic dissociation, in order that they may substitute some more suitable hypothesis.

Royal Microscopical Society, June 19.—Lord Avebury, F.R.S., president, in the chair.—A slide of cow's hair presented by J. E. **Lord**. The hair, which showed a wool-like structure, was taken from the flank of the cow. Hair of this description is used in the manufacture of felt for exportation to a foreign port, where, owing to the prohibitive tariff, it has to be free from wool. The felt was refused admittance, except on a higher scale of tariff, on the ground that it contained wool. This led to an examination of the constituents of the felt, and the wool was traced to the cow. Hair is found on many goats, the llama, and the camel, which is commercially known as wool.—Slides of fluid crystals: Dr. **Hebb**. An intermediate physical state exists between the solid and liquid forms of matter, *i.e.* some substances present themselves as liquids whilst retaining certain characteristics of their solid state. This intermediate state has been found to occur in animal tissues, and it is to Adami and Aschoff that we owe the demonstration of potential fluid crystals in certain organs, *e.g.* the adrenal gland. The slides exhibited were sections cut from the fresh tissue of the adrenal gland. In one illuminated by ordinary light the sphero-crystals were indistinguishable from common fat globules, but in one illuminated by polarised light they evidently possessed the power of double refraction, and exhibited a well-marked black cross.—A slide of a group of six specimens of Stephanoceros, mounted: Mr. **Rousselet**.—Eye-pieces for the microscope: E. M. **Nelson**. The paper had reference to a new eye-piece calculated by Mr. Nelson and described by him in his presidential address in 1900. The author said that in his own work these eye-pieces have quite superseded those of the compensation form. There is no reason why they should not be produced at a price only slightly in excess of that of the ordinary Huyghenian, as they are composed of only two biconvex lenses. In these eye-pieces the refractions are equally divided between the two lenses, and the equation for achromatism given by Coddington and others is also satisfied.—The life-history of the tiger beetle: F. **Enock**.

Royal Meteorological Society, June 19.—Dr. H. R. Mill, president, in the chair.—Weather and crops, 1891–1906: F. C. **Bayard**. An analysis was given of the agricultural and horticultural tables which are included in the annual phenological reports. The author had sorted out the various crops into "good," "average," or "bad" for each district, and against each he had placed the temperature, rain, and sunshine for the four seasons, and whether these statistics were above or below the average. Tables were given showing the general results with regard to wheat, barley, oats, beans, peas, potatoes, turnips, mangolds, hay, clover, apples, pears, plums, raspberries, currants, gooseberries, and strawberries.—The relation of the rainfall to the depth of water in a well: Dr. C. P. **Hooker**. The author gave the weekly measurements of the depth of water in a well 101 feet deep at Further Barton, Cirencester, compared with the weekly rainfall for the years 1903–6. The results included the remarkably wet year 1903, and the droughty summer and autumn 1906.—The "step" anemometer, an instrument designed to obviate the "sheltering" error of the Robinson's cups: W. **Child**.

Royal Anthropological Institute, June 25.—Mr. F. W. Rudler, ex-president, in the chair.—A series of lantern-slides illustrating aboriginal rock paintings discovered by him in Western Australia: F. S. **Brockman**. The subjects depicted consist of human figures, animals, and hands, the former being the more interesting. The figures, which are dressed in a long jacket and trousers, are very crudely drawn and painted in red, black and white pigment. A peculiar feature is that the mouth is not shown. There is some difficulty in determining whom the figures represent, but it is clear that they are not Australians, and it seems most probable that a party of shipwrecked Europeans served as the original model.—A collection of so-called Kanaka skulls from the south of New Caledonia: Dr. David **Waterston**. The skulls were very varied in type, but some showed distinct Polynesian and others Melanesian features, while one was of Australoid and another of negroid character.—Instruments employed to obtain contour tracings of the different aspects of the skull: Prof. **Cunningham**. The instruments included Broca's original stereograph, Lissauer's instrument, Rudolf Martin's Kubuskraniophor, and an American periglyph.

Challenger Society, June 26.—Sir John Murray in the chair.—Dr. **Calman** exhibited and made remarks on some plates of tropical Cumacea, followed by a discussion on the comparative rates of growth of the fauna in warm and cold seas.—The secretary reported on the commencement of the society's "Bibliography of Marine Zoology, 1846–1900," of which Mr. L. A. Borradaile has been appointed editor; the bibliography will enable a worker to find readily the faunistic papers on any area or of any group in which he is interested.

DUBLIN.

Royal Dublin Society, May 21.—Prof. S. Young, F.R.S., in the chair.—Some devices for facilitating the study of spectra: Prof. W. N. **Hartley**. The author described the infusible materials used as supports instead of platinum in high-temperature flames, such as carborundum points and quartz fibres. For solutions, quartz tubes with a capillary orifice were used. The use of the Mecke burner was shown both with and without the air-blast. For the production of chloride spectra, an arrangement was shown by which a bye-pass carried a portion of the gas supply through a bottle containing sponge saturated with chloroform. The Mecke blast burner was shown with the blast produced by a water-blower; the pressure should be 2 kilos. per sq. cm. Photographs were shown of spectra of lime and calcium chloride taken with two hours' exposure.—Note on the spectra of calcium and magnesium: Prof. W. N. **Hartley**. In photographing the spark spectrum of metallic calcium in an atmosphere of hydrogen, and also in a vacuum, without a jar in circuit, it was found always very difficult to obtain precisely the same spectrum with the same exposure. The principal features were the bands in the red, orange, and green, with the line λ 4226; also in one instance there appeared the lines at 3968·6 and 3933·8, but these were very feeble. At pressures less than 5 mm. there was no distinct passage of the spark between the electrodes. They glowed with a violet light; bright stationary spots of white light were seen on the negative electrode, and a great number of scintillations, less bright on the positive electrode, not in one spot, but all over it. At intervals there was a small flame of red light lasting a few seconds, evidently due to the calcium, which apparently passed from the positive electrode; but this ceased after a few seconds. Similar observations were made on magnesium electrodes under the same conditions. The phenomena are believed to be connected with discharge of negative electricity from hot calcium and from lime, described by Dr. F. Horton at the meeting of the Royal Society on January 31.—The free gases contained in monazite: R. J. **Moss**. The gas liberated when Norwegian monazite is ground *in vacuo* consists chiefly of hydrogen and helium, with atmospheric gases. One volume of helium so obtained is associated with about six volumes of hydrogen. It is shown that this evolution of gas is not due to the heat mechanically produced; the gases are probably present in the free state. When the mineral is heated very little hydrogen can be detected in the gas at first evolved, but at a temperature of about 600° C. nearly half the gas evolved is hydrogen. It was found that at temperatures as low as 275° C. some of the oxides present in the mineral were reduced by hydrogen, with the production of water, hence the relatively small quantity of hydrogen in the gas at first evolved in heating the mineral. Hydrogen in other radioactive minerals may escape detection for the same reason.

PARIS.

Academy of Sciences, July 3.—M. Henri Becquerel in the chair.—Some formulæ relating to the number of classes of quadratic forms: G. **Humbert.**—The *rôle* of the spleen in trypanosomatous diseases: A. **Laveran** and M. **Thiroux.** Among animals the spleens of which have been removed, the development of the disease is not sensibly modified.—The direct hydrogenation of the anhydrides of formenic acids: Paul **Sabatier** and A. **Mailhe.** The general method of hydrogenation over finely divided nickel can be systematically applied in this case.—The synthesis of secondary isoamyl alcohol,

$$(CH_3)_2{=}CH{-}CHOH{-}CH_3:$$

Louis **Henry.**—A prehistoric syphilitic skull: L. **Lortet.**—A mineralogical study of the silicated products of the eruption of Vesuvius (April, 1906), and conclusions to be drawn therefrom: A. **Lacroix.**—Finger-prints as a method of identification: M. **Dastre.** The finger-prints of any particular individual, from the youngest age to the most advanced, are invariable, and the concordance of the impressions of the ten digits would constitute practical certainty of identification, the calculable chance of error being less than one part in sixty-four billions.—The evolution of forces: Gustave **Le Bon.**—The integrals of the differential equation $y^1+A_2y^2+A_3y^3=0$: Pierre **Boutroux.**—A mechanism which allows the maintenance of a train of prisms rigorously at minimum deviation: Maurice **Hamy.**—The ionisation of air: L. **Bloch.** A current of air across ordinary or, better, distilled water acquires a negative charge, which is, however, a difference between two unequal charges. The intensity of the ionisation thus implied is greatly augmented with increased pressure.—The electrolysis of very dilute solutions of silver nitrate and oxide: MM. **Leduc** and **Labrouste.** There is little doubt but that silver liberated by electrolysis under a sufficient voltage behaves as an alkaline metal reacting upon water to produce an oxide.—The absolute atomic weight of chlorine: G. D. **Hinrichs.**—The volumetric estimation of phosphorous acid: C. **Marie** and A. **Lucas.**—The action of chlorine and sulphur chloride on some oxides: F. **Bourion.**—The atomic weight of hydrogen: Daniel **Berthelot.** The mean result as deduced from the densities of nitrous oxide, nitric oxide, and nitrogen is calculated to be 14·005.—The specific heat and cryoscopic constants of mercuric iodide: M. **Guinchant.**—Diglycollic acid and its homologues: E. **Jungfleisch** and M. **Godchot.**—Synthesis by means of mixed organometallic derivatives of zinc. Unsaturated $\alpha\beta$-acyclic ketones: E. E. **Blaise** and M. **Maire.**—Some new bromo-derivatives of pyridine: L. **Barthe.**—The action of some γ and δ-bromo-ethers on cyanoacetic, malonic, and methylmalonic ether: G. **Blanc.**—The alkaline rocks of Central Africa: A. **Chudeau.**—A new Myxosporidia parasite in the sardine: L. **Léger** and E. **Hesse.**—The genital organs of the *Taenia nigropunctata*: Pasquale **Mola.**—The action of low temperatures on the eggs of *Paralipsa gularis*, Zeller: J. **de Loverdo.**—Calcification and decalcification in man: P. **Ferrier.** There exists naturally in certain organisms an epoch in life when an elimination of chalk is necessary. This can be brought about by the use of inorganic acids, sodium and magnesium sulphates, sodium phosphate, and alkaline sulphides.—Artificial serums: C. **Fleig.**—A new method of measuring the surface of the human body: M. **Roussy.**

NEW SOUTH WALES.

Linnean Society, May 23.—Mr. A. H. Lucas, president, in the chair.—Special meeting to mark the occasion of the bicentenary of Carl von Linné (1707–1778).

May 30.—Mr. A. H. S. Lucas, president, in the chair.—Studies in Australian entomology, No. xiii., new genera and species of Carabidæ, with some notes on synonymy (Clivinini, Scaritini, Cunipectini, Trigonotomini, and Lebiini): T. G. **Sloane.**—Dimorphism in the females of Australian Agrionidæ (Neuroptera: Odonata): R. J. **Tillyard.** In *Ischnura heterosticta* the male is bronze and blue; of the females, form A (ordinary) is dull black, and form B (dimorph) imitates the male; and the proportion of form B to total number of females is 30 per cent. to 40 per cent. In *I. delicata*, ♂ red and blue; ♀ form A, dull black or olive-green; form B, imitates ♂; 10 per cent. in S.W. Australia. In *Agriocnemis pruinescens*, ♂ black with grey bloom; ♀ form A (wanting); form B, orange; 100 per cent. In *A. splendida*, ♂ bronze and blue; ♀ form A, similar to ♂; form B, red; 40 per cent. In *A. argentea*, ♂ silvery-white (ground colour black); ♀ form A, black; form B (wanting); 0 per cent. In *A. velaris*, ♂ bronze with red tip; ♀ form A (wanting); form B, red; 100 per cent.—The Lake George Senkungsfeld: a study of the evolution of Lakes George and Bathurst, N.S.W.: T. G. **Taylor.** Lake George, situated twenty-five miles south-west of Goulburn, is the largest lake in New South Wales. It is bounded on the west by a *fault scarp* nearly thirty miles long and about 400 feet above the level silt-bed of the lake. The rivers running into the lake originally entered the Yass River, but have been blocked by the fault. The old outlet, 300 feet above the lake, is represented by alluvial boulders up to 2 feet in diameter, which can be traced for three miles across the fault scarp. The second portion of the paper deals with the origin of Lake Bathurst. This is a broad valley probably blocked by the talus and débris carried down by the Mulwaree River.

THURSDAY, JULY 18, 1907.

AN INTRODUCTION TO THE COMPARATIVE ANATOMY OF VERTEBRATES.

Einfuhrung in die Vergleichende Anatomie der Wirbeltiere. By Prof. Robert Wiedersheim. Pp. xxii+471; illustrated. (Jena: Gustav Fischer, 1907.) Price 11 marks.

THE fatalities which may overtake standard text-books are numerous and complex in their action, but on the whole, overgrowth, the result of repeated editions, is one of the commonest causes of extinction. With the incorporation of new material in each edition, the scientific merit of a work may rise, but unfortunately its commercial value will certainly decline; from an examination book with a wide circulation amongst students it becomes a reference book, used only by experts. This is a difficulty which faces every author in the preparation of a new edition of a standard text-book; he may do his duty at the expense of circulation, or he may throw overboard older work to make room for the new, and thus maintain or even increase the circulation, or he may do as Prof. Wiedersheim has done—allow the work to increase with the growth of knowledge, and issue another book altogether, into which are condensed the merits and essentials of the older work.

The volume under review is a condensation of Prof. Wiedersheim's well-known text-book on comparative anatomy. It will be widely used, no doubt, by medical and by science students in Germany, but it will also prove of the greatest service to those who wish to obtain a summary of our modern knowledge of this subject. The author has the incomparable advantage of a first-hand knowledge of the whole length and breadth of vertebrate anatomy; as colleagues and advisers in the University of Freiburg he has Gaupp, Keibel, and E. Fischer, each eminent in his own field of work. He possesses a simple, easy diction, a judicious eye for the selection of his facts, and a very open mind. His attitude perhaps is too cautious, too non-committal; difficult and unsettled problems are simply mentioned or brushed aside.

It is a curious fact that no British anatomist has ever produced a systematic treatise on comparative anatomy of the type so common in Germany—the type best represented by the works of Gegenbaur and Wiedersheim. Huxley's classical work on vertebrate comparative anatomy is arranged on quite different lines; there the anatomical facts are so grouped as to throw light on the relationship of one class of animals to another; clearly, in Huxley's opinion, the chief object of the anatomist is to ascertain the evolutionary history of *the animal*, whereas the German anatomist seeks the evolutionary history of *the organ*. English anatomists set their facts under a zoological classification, whereas, in the book under review, the classification is strictly anatomical. Prof. Wiedersheim may make incidental allusions to the bearing of a fact on the position of one group of animals to another—such as the impossibility of deriving the mammalian lung from the reptilian—but such allusions are few and far between. Clearly he has no immediate object in view saving that of bringing together in an orderly arrangement all that is known of the form and variation of each organ. Strictly speaking, the classification adopted in German works on comparative anatomy is essentially physiological; the structures subserving circulation are dealt with in one chapter, those of respiration in another, and it may be at once admitted that this method of classification has an overwhelming advantage over any other. Yet such a treatise is the last one in the world one would consult for physiological information, because the correlationship between function and form has never appealed very strongly to the German anatomist. As knowledge increases, it becomes more and more certain that the key to comparative anatomy is comparative physiology—a subject yet in its infancy.

This statement, however, is less true of Prof. Wiedersheim than of his compeers; one rejoices to see occasional allusion to function in his work; he rightly describes the functional significance of the air sacs attached to the lungs of birds; his allusion to the function of the accessory sexual organs will probably assist the student to understand their structure and relationship; mention is made of the effects of the substance secreted by the suprarenal body in raising the arterial blood-pressure, although nothing is said of its equally important action on the musculature of the alimentary canal. There is a frank, engaging honesty in the manner with which Prof. Wiedersheim deals with structures of obscure meaning. As regards the descent of the testicle, he says it is a "schwer erklärbare Vorgang"; unlike Metschnikoff, he does not conclude that the hymen at the entrance of the vagina has neither function nor meaning, because in the present state of our ignorance regarding sexual organs generally we have not as yet discovered any function or meaning attached to it. He frankly admits that the significance of the abdominal pores is unknown. On the other hand, he concludes that the lobulation of the lung has no physiological significance—an inference which will not be supported by a closer knowledge of the mechanism of respiration.

There are certain minor blemishes in this work. The index is not nearly full enough. For instance, on taking the book up for the first time, the reviewer wished to ascertain what was taught regarding the fate of the cloaca in higher mammals, but found no reference to that structure in the index. But in the text he discovered, from incidental remarks rather than from any special description, that Prof. Wiedersheim regards the anus of the higher mammals as the cloacal orifice, and that the urogenital aperture is a new opening. The research of Dr. F. Wood Jones leads to a diametrically opposite conclusion, namely, that the urogenital orifice is the cloacal orifice, and that the anus is a new opening, and hence the frequent occurrence of *atresia ani* in children. There are other statements, too, with which English anatomists will not agree, such as those regarding the nature of the sternum, the origin and nature of the temporo-maxillary joint, the origin and nature of the diaphragm, the homology of the muscles of the body wall, and the retrograde nature of the appendix vermiformis. These, however, are all contentious matters, which the author purposely has left undiscussed, preferring evidently to state the older view until the truth of the newer has been more firmly established. A. K.

THE PRINCIPLES AND PRACTICE OF FOOD PRESERVING.

Les Industries de la Conservation des Aliments. By X. Rocques. Pp. xi+506. (Paris: Gauthier-Villars, 1906.) Price 15 francs.

M. ROCQUES'S aim in writing the present work has been to explain, for the benefit of manufacturers and others, the scientific principles upon which the preservation of foodstuffs is based.

At first sight it is somewhat curious that in dealing with the problems of food-preservation no large measure of success should have been met with until comparatively recent times. To retain the fruits of the earth against periods of scarcity must always have been a desirable object. Hence such operations as the garnering of grain and the drying and salting of flesh were practised ages ago; but afterwards there was a gap of many centuries—one might almost say from prehistoric times until yesterday—during which no considerable advance was made in devising means of preventing the progress of decay. It was a question of the infinitely little. Against club or sword of human despoilers a man might match club or sword in defence of his store of foodstuffs, but he was very nearly powerless against the microscopic agents of putrefactive change.

Nevertheless, in a groping, tentative sort of way, some steps were beginning to be made during the eighteenth century. On the theoretical side Van Helmont, Boyle, Becher, Pringle, Macbride, Black, and others studied the allied questions of fermentation and putrefaction, whilst Lavoisier gave the first touches of quantitative exactitude to such inquiries by his experiments upon the alcoholic fermentation of sugar. On the practical side Gaefer and Eisen tested the possibility of preserving vegetables and fruits by desiccation. Then in the early part of last century came Appert, who practised what is essentially the process of sterilisation employed at the present day on an immense scale in the preservation of every sort of comestible. But it was only with the victory of Pasteur in his famous controversy with Liebig that the true nature of fermentative and putrefactive change became clear. It was the micro-organism, and not the air (*per se*), nor spontaneous generation, nor chemical instability, that was responsible for the decay of organic tissues. Henceforward the steps become firm. It is now the aim of all preservative processes to prevent the development of the micro-organism, whether by exclusion of its presence, or by its destruction, or by the inhibition of its growth. Hence it is that either heat or cold may be used for the required purpose: canned peaches are edible because the putrefactive organisms had been destroyed by heating; ice-embedded mastodons, ages after their death, have furnished well-preserved carcasses because the development of micro-organisms has been inhibited by cold.

After touching upon these and other points in an interesting historical sketch, the author deals, shortly but comprehensively, with the phenomena and products of putrefactive change in alimentary substances. He passes then to the consideration of the practical processes employed in preventing these changes. Preservation by means of heat is first described. To give an idea of the general plan of the book we will outline this section. First comes a sketch of the development of the industry, with notes of localities, products, and some statistics of production—not very recent, by the bye—then the general technique is described, including the manufacture of tins and bottles, and the different methods of closing and sterilising these vessels after they are filled. Afterwards the various classes of foods—vegetables, fruits, meat, fish, and milk—are dealt with in detail, the quantity of material, preliminary treatment, and time of sterilisation being given where necessary for each individual article. Numerous illustrations of machinery and operations elucidate the text.

This thorough and practical style of treatment is continued in the remaining sections of the book, dealing respectively with preservation by means of cold, by desiccation, and by the use of antiseptics. M. Rocques laments the fact that France has lagged behind other countries in the use of cold storage, which in the opinion of M. Muntz is the method having the greatest future. In connection with this an interesting parallel may be noted. Just as Lister's antiseptic surgery has been largely replaced by aseptic processes, so in the case of foodstuffs sterilisation by heat is being to a considerable extent obviated by the practical asepsis of refrigeration.

We can cordially endorse the closing words of M. Brouardel's preface: M. Rocques has written a good book and done a good deed at the same time, since in all probability the health of his fellow-men will benefit from using the information he summarises and applying the principles he explains.

C. SIMMONDS.

THE THEORY OF PLANT BREEDING.

Le Transformisme appliqué à l'Agriculture. By Prof. J. Costantin. Pp. 300. (Paris: Alcan, 1906.) Price 6 francs.

BY "transformism" Prof. Costantin understands the passage from one species to another or the creation of new species—Lamarckianism or Darwinism in contradistinction to the older theories of men like Jordan concerning the absolute fixity of species. The book in the main deals with plants, and consists of a general discussion of the meaning of a species and of such phenomena as garden varieties, bud sports, and graft hybrids, the effects of climate and soil on type, together with a summary of the work of de Vries on mutations and of Nilsson and the Svalöf station on the improvement of cereals. It is a difficult and complex country, and as so much of the progress of agriculture must depend on the creation of improved varieties, the importance of a survey of the known and the unknown cannot be exaggerated. For example, if one may judge from the variation in yield among existing varieties of wheat, an increase of 10 to 20 per cent. in the maximum yield is not beyond the reasonable expectation of the raiser of new varieties. This increase involves the cultivator in no extra expense to speak of, whereas if he obtained it by means of fertilisers or more intensive cultivation, the added cost might easily consume all the extra return for the crop.

In the creation of new varieties of horticultural or agricultural plants the guiding principle in the past has been selection. In many cases this has consisted in the skilled observer picking out "mutations," new forms which have arisen *per saltum* and show some essential and transmissible difference from the type. In other cases a process of slow amelioration has gone on through persistently breeding only from the best. For example, the percentage of sugar in the sugar beet has been doubled in about fifty years by selecting for seed purposes only those roots which were richest in sugar, a little core having previously been bored out for analysis. It is necessary, however, to distinguish here; richness in sugar is a congenital condition of the root, transmissible with variations to its descendants, whereas mere size or other temporary factors due to culture cannot be so passed on and do not in consequence form material for selection. Thus it is probable that an immense amount of work that has been done to improve cereals by sowing only the largest or the heaviest grains, or, again, the grains from the longest ears, has been wasted; there is no evidence of the permanent amelioration of any variety by this method. The advances have all been acquired by "pure culture" methods; a desirable type of ear or grain is seen, and a pure strain is created by propagating from that alone.

It is with these questions of mutation and selection that Prof. Costantin's book mainly deals, but though such methods have had the field very largely to themselves in the past, they are not likely to retain their position in the future. Until recently the raiser of new varieties was rather shy of cross-breeding; he obtained thereby such an extraordinary and unstable set of mixtures that it was only by a lucky accident he could select anything tractable from it. Thanks, however, to the Mendelian hypothesis, we are now able to handle with some precision the varied hybrid forms which result from a cross, and the work of the Cambridge school of biologists, of Bateson among sweet-peas, and of Biffen among wheats, has shown what a remarkable practical tool Mendel has placed in the hands of the plant-breeders. Mendel's work has revolutionised the whole point of view, and in consequence Prof. Costantin's book, which, though dated 1906, contains no mention of Mendel and his theories, is hardly of service to the plant-breeder of to-day. Doubtless we may have to come back to a consideration of many of the facts therein, facts which lie outside the scope of Mendel's hypothesis, but just at present the current is setting so strongly the other way that Prof. Costantin's book will not meet with much acceptance.

SCIENCE FOR ARTISTS.

Modern Painters. By John Ruskin. 5 vols.
The Stones of Venice. By John Ruskin. 3 vols.
Unto this Last, and Other Essays on Art and Political Economy. By John Ruskin. Everyman's Library. (London: J. M. Dent and Co., n.d.) Price 1s. net per volume.

A CHEAP edition of Ruskin's works, clearly printed, and with the author's illustrations well reproduced, is a boon which will be keenly appreciated in many directions. The world of art already owes a heavy debt to "The Stones of Venice" and "Modern Painters," but for many years these have been accessible to the young student only through the agency of the public library or some such place. The great critic, whose watchword was "truth," thus failed to see the full fruits of his teaching. Now it is possible for anyone to enjoy the benefit of his writings, and the training of an artist must be regarded as incomplete until he has mastered, at least, the principles of his calling as laid down by Ruskin in "Modern Painters."

It has always, ever since the days of ancient Greece, been fully recognised that no representation of the human form can be even passable unless it is anatomically correct. Every muscle, every sinew, must be in its proper place, and correctly proportioned; even the attitude and expression of each figure must be correctly fitted to the subject, or the result will be unmercifully condemned. But how many a landscape is defaced with impossible clouds, trees which grow nowhere on this earth, and even rocks and mountains such as no eye has ever seen. In truth, nature has an anatomy as real as that of the human body, and the man who knows turns from such parodies with exactly the same feeling of contemptuous disgust as is inspired by a figure with misshapen limbs, or poised in an impossible attitude.

Misrepresentation of nature has been endured by the public from ignorance bred by lack of observation. As Ruskin says, it is not easy to discern the truth. The eye has to be trained to see correctly, and a picture should contain just that amount of fact which would be visible in the circumstances represented, and no more. It is useless for men who would be regarded as scientific Philistines to urge such things upon artists. Only the great ones would listen for a moment, and they are just those who need the advice least of all. They have always known, more or less, how to combine truth of visible detail with those qualities of breath and feeling which are involved in the idea of a "picture." But the rank and file too often palm off on ignorant buyers works which are wrong in drawing, wrong in colour, and ridiculous as representations of nature.

No one can regard Ruskin as a mere man of science, and he should command the attention of all who aspire to be his brother artists. His magnificent chapters on clouds, on plant forms, and on mountain sculpture are admirable alike in conception and execution. They are an excellent beginning. An artist who has studied them with care cannot but go to nature with an opened eye, and a little correct seeing must surely inspire him with the desire to understand, and to know nature as the sculptor knows the human body. The anatomy of scenery can only be fully grasped by industrious study, and every landscape painter should be put, as a prime essential, through properly devised courses of meteorology, botany, and geology, since they are the only clues to the working of the bones and muscles of the world.

OUR BOOK SHELF.

The Hills and Valleys of Torquay: a Study in Valley-Development and an Explanation of Local Scenery. By A. J. Jukes-Browne. Pp. viii+104. (Torquay: Published by the Author, Floriston, Torquay, 1907.) Price 3*s.* 6*d.*

THIS is a pleasantly written but withal scientific explanation of the sculpturing of the land which forms the Torquay promontory. The natural attractions of the region are great, and Torquay itself is said to spread over eight hills. Among these, Lincombe and Warberry Hills, formed of red Devonian grits, rise from 400 to nearly 500 feet; while the coast scenery is diversified by the limestone crags and cliffs of Torquay and Babbacombe, the slates of Ilsham, the dark igneous rock of Black Head, and the red conglomerates, sandstones, and clays of Watcombe and Livermead.

In describing the various stages and processes that have led to the present scenery, the author has endeavoured to make his work as simple as possible, but the reader who has hitherto paid no attention to geology must give earnest application to the introductory geological chapters in order to understand the subject.

The author shows how the present features were gradually developed after the Bovey Beds of Eocene age had been spread over an eroded surface of older rocks. The rivers then took their courses over soft strata, and cut channels through this covering into the Permian and Devonian rocks beneath. In process of time all traces of Bovey Beds have been removed from the area, and there have been revealed the remnants of old rock-platforms like that of Babbacombe, trenched in places by river action, before the present outlines of the coast were shaped.

The work, which will be of special interest to residents and visitors, is illustrated by a number of excellent pictorial views, and by a series of maps, based on those of the Geological Survey. The student may with advantage colour by hand the different geological formations represented on these maps. The author would have done well to mention the Geological Survey memoir on the country around Torquay by Mr. W. A. E. Ussher, a work which must form the basis of future research in the area.

Ammonia and its Compounds. By Dr. J. Grossmann. Pp. x+151. (London and New York: Harper and Bros., 1906.) Price 2*s.* 6*d.* net.

THIS is the first volume of a series of handbooks on chemical technology which, so the preface informs us, are not intended to be highly elaborated treatises, but are rather to afford a general survey of the subject and to serve as guides to the larger standard works. Although the author of the present volume disclaims either originality in the subject-matter or completeness in the compilation of his materials, the careful reader will soon realise that whatever defects the book may possess, it is written by one who is not only familiar with his subject, but combines a full knowledge with the power of clear and concise exposition. A more comprehensive treatise may possess the advantage of a work of reference for specialists, but a small volume like this will no doubt attract a wider circle of readers, and should find its way to the shelves of the student of general chemistry. We can only express a hope that the succeeding volumes may maintain the high standard of excellence attained by the pioneer volume of the series.

But if the publishers are to be congratulated on their new venture, we must candidly express regret that so admirable a little volume should have been printed on such inferior paper. It may be desirable to buy a good book at a low price, but no one would grudge a small additional cost if it enabled him to decipher the lines of the illustrations. We would specially direct attention to the figure on p. 85, in which, owing to the character and surface of the paper, all the fine lines are obliterated, and the drawing rendered quite worthless as an illustration.

J. B. C.

Ventilation, Heating, and Lighting. By W. H. Maxwell. Pp. vi+151. Second edition, revised and enlarged. (London: The Sanitary Publishing Co., 1907.) Price 3*s.* net.

THE simple principles and practice of ventilation, heating, and lighting are described in this volume from the point of view of the sanitary engineer. It would be to the advantage of the community if every architect and sanitary engineer were not only familiar with the physical laws upon which successful ventilation, heating, and lighting depend, but also based their work upon them. Usually, the provision made to ventilate and heat a building is quite inadequate; and when any means are provided they are constructed according to rule-of-thumb methods, with little consideration for the possibly peculiar nature of the building to which they are adapted. A few new devices and systems are described by Mr. Maxwell, and the views of authorities on requirements and efficiency are freely cited. The student and the practical man will find the book easy to understand, and a useful guide to success in examinations or in building construction.

Practical Physiological Chemistry. By Dr. Philip B. Hawk. Pp. xiv+416; illustrated. (London: J. and A. Churchill, 1907.) Price 16*s.* net.

DR. HAWK'S name is well known as an investigator in the subject of physiological chemistry. The present volume testifies to his ability as a teacher of the subject. Although there is nothing strikingly original in his presentation of the subject, the book he has produced is free from error, is clearly written, is practical, and sufficiently full for most purposes. The recent work published by Fischer and his colleagues on the question of protein cleavage products is given with special fulness; the urine, also, is naturally a subject which occupies considerable space; indeed, nearly half the book is devoted to this important secretion. The volume is admirably illustrated and well printed.

W. D. H.

Résistance des Carènes. By M. Fricker. Pp. 170. (Paris: Gauthier-Villars; Masson et Cie., 1907.)

THIS latest addition to the series of little volumes known as "Encyclopédie scientifique des Aide-Mémoire," to which attention has often been directed in these columns, deals with the propagation of waves and questions of resistance of liquids to motion through them, with particular reference to the motions of ships. The problems considered are treated theoretically and experimentally, and the student of naval architecture with some knowledge of the calculus should find the book useful.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Radium Emanation.

IN 1903, it was shown by Mr. Soddy and myself that the spontaneous change of the emanation from radium results in the formation of helium; this observation has been confirmed by Indrikson, by Debierne, by Giesel, by Curie and Dewar, and by Himstedt and G. Meyer. Debierne has shown that actinium chloride and fluoride also develop helium. I have also once detected helium in the gases evolved continuously from a solution of thorium nitrate, and hope soon to confirm this observation.

When the emanation is in contact with, and dissolved in water, the inert gas which is produced by its change consists mainly of neon; only a trace of helium could be detected.

When a saturated solution of copper sulphate is substituted for water, no helium is produced; the main product is argon, possibly containing a trace of neon, for some of the stronger of its lines appeared to be present. The residue, after removal of the copper from this solution, showed the spectra of sodium and of calcium; the red lithium line was also observed, but was very faint. This last observation has been made four times, in two cases with copper sulphate, and in two with copper nitrate; all possible precautions were taken; and similar residues from lead nitrate and from water gave no indication of the presence of lithium; nor was lithium detected in a solution of copper nitrate, similarly treated in every respect except in its not having been in contact with emanation.

These remarkable results appear to indicate the following line of thought:—From its inactivity it is probable that radium emanation belongs to the helium series of elements. During its spontaneous change, it parts with a relatively enormous amount of energy. The direction in which that energy is expended may be modified by circumstances. If the emanation is alone, or in contact with hydrogen and oxygen gases, a portion is "decomposed" or "disintegrated" by the energy given off by the rest. The gaseous substance produced is in this case helium. If, however, the distribution of the energy is modified by the presence of water, that portion of the emanation which is "decomposed" yields neon; if in presence of copper sulphate, argon. Similarly the copper, acted upon by the emanation, is "degraded" to the first member of its group, namely, lithium; it is impossible to prove that sodium or potassium are formed, seeing that they are constituents of the glass vessel in which the solution is contained; but from analogy with the "decomposition-products" of the emanation, they may also be products of the "degradation" of copper.

A full account of this research will shortly be communicated to the Chemical Society. WILLIAM RAMSAY.

July 11.

Effect of Pressure on the Radiation from Radium.

I HAVE, during the last eighteen months, been engaged in an investigation on the effects of pressure on radio-active phenomena. In designing the apparatus necessary for the purpose, it was necessary to consider that if any change in the rate of production of the emanation occurs, through pressure, effects would not be noticeable at once, as a new state of equilibrium would only be reached after several days. Similar considerations hold if any of the slowly decaying products is affected. A special pressure pump was therefore constructed according to the designs of Mr. J. E. Petavel, and this pump allowed me to keep up a pressure of about 2000 atmospheres almost indefinitely without sensible leak. The time of the experiments was not, however, extended beyond four or five days. The results have been entirely negative, and I estimate that a change in the activity of one-third per cent. would have been noticed.

During the course of the investigation several fictitious effects made their appearance, and it was the elimination of these which necessitated a gradual improvement in the methods of observation and took up the greater part of the time occupied in the experimental inquiry.

In addition to the help of Mr. Petavel which has already been mentioned, I have had the assistance of Mr. Makower in the early stages of the work. The final experiments were conducted by my assistant, Dr. Hans Geiger.

ARTHUR SCHUSTER.

Victoria Park, Manchester, July 12.

IN order to ascertain if the rates of disintegration of radium and its successive products (the emanation, A, B, and C) are affected by high pressure, we have placed about 1 gram of barium chloride, containing 1·04 mg. of radium, completely sealed beneath lead, in a thick-walled cylinder of nickel steel, and compressed the radium by a tight-fitting chromium tungsten steel piston 1 cm. in diameter. The greatest pressure applied has been $3{\cdot}2\times10^5$ lb. to the square inch, which is the estimated pressure at a depth of fifty miles beneath the surface of the earth. The penetrating radiation arising from radium C was observed by two large electroscopes placed on either side of the radium, and at a distance of about 30 cm. from it. The γ rays produced a deflection of about twenty-eight divisions a minute in an electroscope, the natural leak of which was 0·4. The pressure on the radium was gradually increased from zero to that at ten, twenty, thirty, forty miles beneath the earth's surface, and was maintained for four days at about the forty-mile value. The pressure was then taken off, and observations were continued for three days more. During all these variations of pressure, no change was detected in the γ radiation, although a variation of 1 per cent. could have been observed without difficulty.

The pressure was then rapidly carried from zero to the fifty-mile value and back, and also maintained at fifty miles for two hours. Again there was no change, certainly not 1 per cent.

It is therefore clear that the transformation from radium to radium C continues in a normal manner at pressures equal to those at forty to fifty miles beneath the earth's surface; and this important conclusion seems inevitably to follow—that *radium generates heat by disintegration equally at the surface of the earth and at pressures which obtain at depths forty to fifty miles beneath the surface.*

The Hon. R. J. Strutt has proved that the quantity of radium in rocks near the earth's surface is greatly in excess of that required to compensate for the loss of heat by conduction and radiation from the earth's surface. Dr. Bronson has proved that the disintegration of radium is unchanged by wide variation of temperature. It appears from our experiments that the transformations take place in the usual manner even under a pressure of 160 tons to the square inch. If radium were distributed throughout the earth in the same amount as at the surface, a higher temperature gradient than that actually found would be expected. A possible explanation of the paradox has been put forward by Strutt and supported by Milne. He supposes that the constituents of the earth some twenty to forty miles beneath the surface are different in character from those near the earth's surface, and that they do not contain radium, or contain it to a smaller extent. This seems to carry with it the conclusion that igneous rocks, which contain considerable quantities of radium, have their origin nearer the surface of the earth than some geologists have supposed.

The Æther and Absolute Motion.

THE particular objection to identifying magnetic force with velocity of the æther, which has been discussed recently in the columns of NATURE by Prof. O. W. Richardson, Sir Oliver Lodge and Prof. W. M. Hicks, Dr. C. V. Burton and Mr. E. Cunningham, must depend on some point of view which is foreign to my ways of thinking. Such a hypothesis involves, of course, that the all-pervading æther shall be at rest under normal conditions; the effect of any local disturbance due to matter must thus be a local effect, and the distant regions of æther will remain unmoved. There can be no question of ascribing a uniform motion to the whole of the æther, extending to the remotest infinity, because there is no conceivable means of producing or altering such a motion. In other words, an infinitely extended æther postulates absolute motion as a fact, in the only real sense of that term, namely, motion relative to the remote quiescent regions of the æther; and once that determination is made, arguments from relativity of motion must lapse.

The interesting point raised by Prof. Richardson, that the steady field of a uniformly moving electron would contain an infinite amount of moment of momentum, requires detailed consideration; but it is not without parallel in more familiar departments of abstract physics. Its scope may be illustrated by the steady motion of a solid sphere in infinitely extended viscous fluid. The sphere, even when in steady motion, experiences resistance, and must be pushed along in order to maintain its motion. This steady push must impart momentum to the fluid, which increases in amount without limit as the time is prolonged; and it is, in fact, well known that the field of flow around the sphere when it has reached its ultimate theoretical steady state contains an infinite amount of linear momentum. But this circumstance does not vitiate the dynamics of fluid resistance. For, in fact, the steady state of motion is very soon set up throughout the neighbourhood of the moving sphere, while the continued supply of momentum simply diffuses away into the distant regions where the velocity is so slight that it does not react sensibly upon the resistance to the sphere. Similar considerations apply to the case of an electron set into steady translatory motion through æther. Here it is rotational momentum that is steadily imparted to the surrounding æther as time goes on, and is carried away into the distant regions by wave-motion. This requires that the æther exerts a torque on the moving electron, the reaction of which on the æther is the source of the angular momentum communicated to that medium. The possibility of permanent adjustment to a torque of this kind is not here anomalous; it is provided for in the fundamental hypothesis of elastic resistance to absolute rotation of the parts of the æther. There is, however, a fundamental difference from the previous illustration of a solid sphere moving through infinite viscous fluid. In that case the force continually does work, leading to continued dissipation of energy into the viscous fluid. But in the electric case the energy in the æther settles down to a steady value, and no further energy is put into it, although a constant stream of angular momentum is put into it so long as the motion of the electron goes on.

The validity of illustrating the nature of magnetic force by velocity of the æther rests on an application of the Principle of Least Action. The power of that principle resides in its allowing dynamical inferences to be drawn without requiring detailed scrutiny of the mechanism through which the forces operate. But the exceptional character of the hypothesis of rotational elasticity, or the possibility of some flaw in the argument, might conceivably have put the application of the principle at fault. It is thus essential, both for verification and for clearness of view, to scrutinise in detail the circumstances of the motion as determined by the Principle of Action, so far as possible. It would appear that, as regards the interesting feature discussed by Dr. Richardson, nothing has gone amiss.

Even in the case of a sphere set in motion in frictionless fluid, it may be said in the same way that when the steady motion has become absolutely established by propagation outward, an infinite amount of momentum has been transferred from front and rear to the sides.

Cambridge, July 8. J. Larmor.

In Nature of July 4, Mr. E. Cunningham discusses my statement of an objection to identifying the magnetic vector with translational velocity of the æther. Mr. Cunningham says:—" If it were definitely stated that the magnetic force in the free æther was proportional to the velocity of the æther relative to the observer the objection would be valid"; and certainly any theory which embodied such a doctrine would stand self-condemned. My argument, however, was not directed against this obviously untenable view.

If, for the free æther, we assume that magnetic force is, within a constant factor, identical with æthereal velocity, then we can determine the velocity of the æther at any point by measuring the magnetic force at that point. For the value of the magnetic force there is a perfectly definite physical criterion, which is independent of any arbitrarily chosen frame of reference, and hence we should have the means of determining *absolutely* the velocity of the æther. Thus, on our assumption, absolute motion attains to a definite physical significance which has no counterpart in the postulates of ordinary dynamics; and, this being so, dynamics must fail to give a true account of electromagnetism.

Accordingly, when we identify the magnetic vector with translational æthereal velocity, and at the same time assume that we are dealing with a dynamical system, we should expect to be led to results inconsistent with known electromagnetic relations. Consider, in fact, the unaccelerated motion of a charged body (or of an electron) through a space where there is no magnetic intensity. Then pass to the case where the space in question is uniformly pervaded by magnetic force in a direction transverse to the motion of the charged body, while at the same time a new component is added to the motion of the body, identical in direction and magnitude with the æther-drift which we assume to constitute our magnetic field. We have thus impressed a uniform velocity on the whole system considered, and if the system is fundamentally a dynamical one, no new acceleration will thus have been introduced: that is, the charged body will move without acceleration across the lines of magnetic force. C. V. Burton.

Cambridge, July 12.

Root Action and Bacteria.

In Nature of June 6 (p. 126), Mr. S. Pickering has a note on "Root Action and Bacteria" in which he concludes that the proper functioning of roots depends on the presence of bacteria.

Experiments I have made here both in the field and in water culture with a large number of varieties of plants do not lead directly to the same conclusion. Water cultures have been made on a fairly large scale, three harvests of ninety plants being taken in a large number of dishes, each containing two litres of water. After the third harvest, the water was allowed to stand and evaporate to half its volume. On attempting to use this water for further water cultures, all the plants sown in it died within two days and some within half an hour, the time varying with the variety of plant that was transplanted into the water, and with the variety that had previously been grown in the water.

Further, boiling this water neither increases nor diminishes its toxicity to plants. It is, moreover, immaterial whether the nutrient solution is such as to become acid or alkaline after use; neutralisation in either case does not make it possible to grow plants in it.

My experiments lead to the conclusion that the roots of all the plants so far tried excrete a substance that is toxic to all plants (including that by which it is excreted), but in different degrees.

Similarly, in the field *Sesanum indicum* will not grow (on stiff black soil) within 2 feet of *Sorghum vulgare*; all the plants tried appear to decrease the yield of neighbouring plants *of the same variety* by about 50 per cent.

The effect of the toxic substance both in the field and in water culture is completely neutralised by tannic and pyrogallic acids, carbon black, and other substances.

It is, of course, possible that bacteria in the soil have a beneficial action by elaborating antitoxins similar to those mentioned.

I have not yet been able to isolate the toxic substance contained in the polluted water of my cultures.

F. Fletcher.

Poona, June 21.

THE NATURAL HISTORY OF THE CEYLON PEARL BANKS.[1]

PROF. HERDMAN is to be congratulated on the completion of his report on the pearl fisheries and marine biology of Ceylon. It fills five large volumes, which, besides containing much information of direct practical importance in regard to pearls and pearl fishing, form a broad and firm basis for further study of the biology of the Ceylonese region of the Indian Ocean. The report speaks volumes as to Prof. Herdman's genius as a collector—we doubt if any single worker ever made such large collections over the whole field of zoology in so short a time; he has also done his share of the descriptive studies, and he, along with Mr. Hornell, is responsible for the parts that deal directly with the pearl oyster itself.

It is very interesting to find that since Prof. Herdman's expedition there have been four successive fat years of pearl fishing—the most profitable, so far as is known, that have ever been. In 1905, eighty-one and a half millions of oysters were fished, and the revenue brought in was upwards of two and a half millions of rupees; in 1906, more than sixty-seven millions of oysters were fished, and the total proceeds amounted to 1,385,000 rupees. This should surely convince the Philistines that there is something in biology after all! Prof. Herdman predicts a moderate fishery for this year, and a good fishery for 1908, adding that "after 1908 the prospects depend upon further careful scientific inspecting, transplanting and culching, upon the lines which have been laid down in successive sections of the report." As is well known, the fisheries have been leased by the Government to a company, and it is a matter for congratulation that Mr. Hornell is retained on the spot, and that, in terms of the lease, the necessity for a scientific treatment of the pearl banks during the next twenty years has been duly recognised and provided for.

Vol. v. begins with an interesting essay on pearl production. The authors (Herdman and Hornell) examine the three main theories—(1) that the pearl is the result of a reaction to a grain-of-sand irritation, (2) that the pearl is a pathological secretion, and (3) that the stimulation caused by the presence of a parasitic worm, which acts as a nucleus, results in the deposition of successive layers of pearly material within an epithelial sac. It seems that the grain-of-sand method is occasionally found operative in the causation of true pearls, and it is possible that some of those that appear to have no nuclei may have been deposited around very minute inorganic particles; some pearls not of the finest quality are probably formed as calculus-like growths independently of known parasites; but most and the best pearls are deposited around the larva of a Platyhelminth. In the Ceylonese pearl oysters (*Margaritifera vulgaris*) it seems likely that the parasite is a larval Tetrarhynchus. Apart from pearly excrescences on the interior of the shell, due to the irritation caused by Clione and other boring animals, the authors distinguish (1) ampullar pearls, where the nucleus and resulting pearl lie between the shell and the body, or in an ampulla of the ectoderm projecting into the mantle; (2) muscle pearls, formed around minute calcareous concretions (calcospherules) near the insertions of the muscles; and (3) cyst pearls, formed around encysted parasites. As to the proposal to secure artificial infection of oysters, the authors think that this is probably quite unnecessary on the Ceylon pearl banks. There seem to be plenty of parasites to go round, and every pearl oyster in the Gulf of Manaar, or, for that matter, around the coast of Ceylon, runs a fair chance of becoming infected. It is to be hoped that further investigation will make our knowledge of the pearl parasite and its life-history more precise.

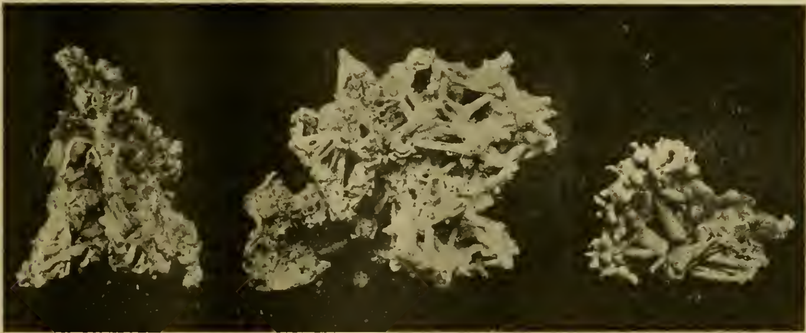

FIG. 1.—*Ramulina herdmani*, Dakin. Natural size.

In their report on Cestodes from Ceylonese fishes, Messrs. A. E. Shipley and J. Hornell have some notes on *Tetrarhynchus unionifactor*, which they described in vol. ii. Some of the larval forms entering the oyster arrive in the mantle and other tissues, acquire an ectodermic sac, and there encyst, finding "a costly grave in the developing pearl." Others reach the alimentary canal, and, after growing there, encyst on the outer surface of the intestine. "They are too big for enclosure in a pearl, and they can wait without anxiety for the advent of their second host (*Rhinoptera javanica*), within whose intestine they rapidly become sexually mature."

The late Prof. M. Stossich made notes on a few Nematodes in the collection, and Dr. Max Lühe describes seven new species of Trematodes from fishes. The first part of the volume ends with a very valuable general summary of practical conclusions and recommendations, which we may hope will find application not only in Ceylon but elsewhere. One cannot but

[1] Report to the Government of Ceylon on the Pearl Oyster Fisheries of the Gulf of Manaar. By W. A. Herdman, D.Sc., F.R.S., P.L.S., with Supplementary Reports on the Marine Biology of Ceylon by Other Naturalists. Part v. Pp. viii+452; 38 plates. (London: Published at the request of the Colonial Government by the Royal Society, 1906.)

admire Prof. Herdman's wide scientific outlook—the true naturalist's point of view—which may be inferred, for instance, from this sentence, "It is impossible, until a careful study has been made of each case, to say which members of the fauna and flora of an oyster bed are of most importance to its prosperity—probably none are wholly without influence for good or evil, so closely interwoven in past history and present function is the web of living nature." If this wise saying were as widely accepted as it is certainly true, biological science would find more generous public support, and we should hear no more of impatient criticisms of scientific investigations which do not yield an increase of rupees so rapidly as Prof. Herdman's study of the Ceylonese oyster beds has done. It is fitting that the practical recommendations should end with a beautiful plate of the life-history of the pearl oyster.

The second half of the volume is occupied with eleven supplementary reports (xxxi–xli). Dr. Nelson Annandale reports on the Cirripedia (11 species); Prof. G. H. Carpenter on a new species of Halobates;

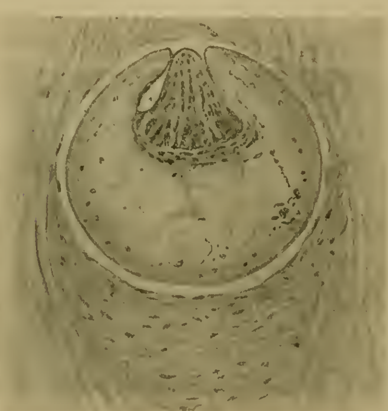

FIG. 2.—Young larval Cestode (Tetrarhynchus, sp.) encysted in connective tissue of pearl oyster.

Mr. W. M. Tattersall on the Leptostraca, Schizopoda, and Stomatopoda; Mr. C. B. Wilson on an interesting series of parasitic Copepods, including two new genera; Mr. T. Southwell on the Anomura (48 species, 2 new); Mr. W. J. Dakin on the Foraminifera (131 species and varieties), which include *Ramulina herdmani*, n.sp., forming masses of calcareous tubules varying in size from a hazel-nut to a small apple; Prof. G. C. Bourne on Jousseaumia, an interesting new genus of Eulamellibranchs commensal with the corals Heterocyathus and Heteropsammia; Messrs. R. Standen and A. Leicester on a large number of Molluscan shells; Prof. Herdman on the Tunicates (64 species); Mr. R. Douglas Laurie on the Brachyura (208 species, 15 new, three of which are referred to new genera).

The volume ends with a general discussion of the faunistic results by Prof. Herdman. His expedition has made known 2615 species of marine animals from the coasts of Ceylon. Of these 575 are described as new to science, and have required the formation of 65 new genera and three new families. About 250 of the Ceylonese species extend into the Malay region and 300 on into the Pacific. At least 240 are known from the Red Sea, and 130 from the Mediterranean. About 280 species extend southwards to the Australian coasts, and a few are found elsewhere in southern latitudes. Finally, 90 Ceylon species are found also in the West Indian region, and may indicate a closer connection by sea in a former period than exists at the present day. Prof. Herdman makes an interesting comparison of his collections with those of the *Investigator*, with those from the Mergui Archipelago and off the coast of Lower Burma, and with those from the Maldive and Laccadive Archipelagoes.

After reviewing his rich collection, Prof. Herdman concludes in the following words:—

"Such are the animate surroundings, including both friends and foes, amid which the pearl oyster habitually lives in the Gulf of Manaar, and seems, if left in comparative peace, able to hold its own in the struggle for existence; but the balance, as we have shown in previous parts of this report, is liable to be seriously disturbed by three all-powerful factors: devastating hordes of voracious fishes which come up from the deeper waters and leave crunched shells and torn byssus in their wake; storms, currents, and overwashes of sand which may sweep away or bury a promising bed; and lastly man, who comes periodically from above on his diving stone and clears the bank of tens of millions of oysters, old and young. The carnivorous fishes and the monsoons cannot be controlled; but to show that much can be done by man to mitigate their influence, and to compensate for the decimation necessarily caused by his own operations, has been the chief object of the present report."

THE DESERT AND THE SOWN.[1]

SOME of the best books of travel nowadays seem to be written by women. We may instance Mrs. Bishop, Miss Durham, and now Miss Lowthian Bell, who, in "The Desert and the Sown," has given us a most delightful description of a wandering undertaken by herself alone with native servants from Jerusalem across Jordan to the Haurân and Jebel Drûz, thence to Damascus and on by Homs, Hama, and Aleppo to Alexandretta. Miss Lowthian Bell's route is, of course, not new. She has seen nothing that has not been seen before, and has contributed nothing new to our archæological knowledge beyond one or two short Arabic inscriptions. But this we do not expect, nor had she any archæological intent in the shaping of her travels beyond the desire to see the famous ruins of Roman Syria. The reason for her journeyings is frankly set forth by her as pure delight in the life of the Near East, and more especially that of the desert. To "travel on where travels above him the Mother of all the clustered stars," deeming "the wild the sweetest of friends," in the words of the Arab poet prefixed by the author to her book ("*yeraya al-wahshaha al'ansha al-anisha, wa yahtadi behayithu ahtadat Umm en-nejumi esh-shawabîkî*"), was her desire, and she has given us a good book describing what she saw in her wandering. As she says at the beginning of the book, "To those bred under an elaborate social order few such moments of exhilaration can come as that which stands at the threshold of wild travel."

Of all wild travel, surely the most exhilarating is that in the Syrian desert. Here the Druze, with his strange religion, descendant of the Old Man of the Mountain and his "Assassins," still reigns in

[1] "The Desert and the Sown." By Gertrude Lowthian Bell. Pp. xv + 347. (London: W. Heiremann, 1907.) Price 16s. net.

his "mountain" and lords it over Moslem and Christian alike, despite the suzerainty of the Turk. Here the wild Arabs, 'Anêzeh, Ghiâth, and Shammar, still live as they did in the days of old, rearing their horses and camels, raiding and stealing those of the neighbours, murdering each other, and praising God and his prophet daily. Here is the desert, whether stony waste or bare waste of volcanic débris and lava like the Safa or Harra,[1] or steppe like the Ruhbe and the greater part of the Hammada, or high desert. The yellow Egyptian desert of limestone and sand is not that of Syria. Except in such districts as the Harra, the Syrian desert is not a desert as the Egyptian is, except for the fact that its inhabitants are nomads and have no fixed home in it. Of this steppe its inhabitants know every inch; as one of Miss Bell's guides said to her: "By God" (Wallâh), "the plain is covered with places wherein I rested." "He had struck the note," she goes on; "I looked out beyond him into the night and saw the desert with his eyes, no longer empty but set thicker with human associations than any city. Every line of it took on significance, every stone was like the ghost of a hearth in which the warmth of Arab life was scarcely cold, though the fire might have been extinguished this hundred years."

FIG. 1.—Kala'at el-Husn, walls of the inner enceinte. From "The Desert and the Sown."

Out of this waste, tenanted now only by the nomad and his flocks, and knowing now no habitation but the tents of goats' hair, rise the ruins of the great cities of the Ghassanides, like Kanawat or Bosra Eski-Sham, in the Haurân, wonderful relics of the civilisation of Syria in the sixth and seventh centuries of our era, in which we see Roman forums with great pillared courts next door to the square towers of the oldest mosques of the Muslim, the last monuments of the "Age of Ignorance" and the oldest of the "Age of Enlightenment" side by side. And apart from the towns we see what are indeed remarkable monuments of Roman civilisation in the Near East, private houses, country-seats of the fifth and sixth centuries, such as the "Sheikh's House at Hayât" (illustrated on p. 103), which is still occupied as a dwelling-house, or the stone houses at el-Bārah and Serjilla (pp. 245, 252), and the "Kaṣr el-Benât" (p. 256), in northern Syria. Miss Bell's photographs of these and other remains of ancient civilisation, including Kala'at el-Beida, Baalbek, Ruwêihâ, the canopied tomb at Dâna (p. 298), are all very good and very interesting.

Miss Bell's route from Jerusalem was taken by way of Jericho and the Jordan ford to es-Salt, in the Belka', where she deliberated as to the way of reaching the Haurân and the Mountain of the Drûz, since the Turkish authorities are by no means friendly to English visitors east of the Jordan, especially to those who wish to visit the Jebel Drûz. However, by avoiding the Turks at 'Ammân and the neighbourhood of the railway, which was crossed north of Mshitta, Miss Bell reached Salkhad in safety. Of Mshitta Miss Bell gives a photograph taken "before the Germans had sliced the carved façade from that wonderful building." It seems regrettable that the "stone lacework" of Mshitta should no longer be seen in its own place under the Syrian sky; now it is cooped up in a dark and low corridor, where it is difficult to see it, in a museum on the banks of the Spree. But with the advent of the railway its removal was perhaps advisable, in view of the possibility of vandalism on the part of some Turkish official.

At the castle of Ṣalkhad the traveller was received with the traditional hospitality of the Drûz, and witnessed an extraordinary scene, very well described on p. 91, a sort of savage war-dance to inaugurate a *ghazu* or raid on the Arabs of the Beni Ṣakhr, as revenge for a previous raid by the latter. This she instances as an "example of the freedom with which the Druzes control their own affairs."

North of Damascus Miss Bell again met with the Drûz, the members of that faith who live in the Lebanon, cheek by jowl with their old enemies the Maronite Christians. And members of the mystical sects of Western Asia, who are half Muslims, half pagans, such as the Nosairis, Meta-

FIG. 2.—Kala'at Sim'ân, the west door. From "The Desert and the Sown."

[1] The vulcanological researches of the late Dr. Alphons Stübel, of Dresden, in the Harra and among the mountains of the Lejâ are well known.

wīlehs, Beha'is, and Ismailis, were also encountered by the way.

In northern Syria two of the most interesting places visited by Miss Bell are the castle of Kala'at el-Husn, near Homs, and the church of Kala'at Sim'ân, between Aleppo and the Bailan Pass. Kala'at el-Ḥusn is the northern Kerak, the "Crac des Chevaliers" of Crusading times, and is one of the finest examples of the military architecture of the Crusaders in existence. Fig. 1, a photograph by Miss Bell, gives an idea of the walls with their French round towers and Saracenic sloping walls. The castle belonged to the Hospitallers, and the Grand Master of the Order lived there, until it was taken by the Egyptian Sultan Malek edh-Dhaher. This, then, was the first stronghold of the Order of St. John, to be succeeded by Rhodes, always associated with the name of de l'Isle Adam, and by Malta, the scene of the heroism of la Valette and the cowardice of Hompesch.

Kala'at Sim'ân (Fig. 2), the scene of the fakir-life of St. Simon Stylites on his pillar, is a fine example of a Byzantine church of the sixth century. Kalb Lōzeh (p. 302) is just such another. Many of these splendid specimens of Syrian stone architecture have been studied by the recent archæological expedition of Princeton University.

At beautiful Antioch and Seleucia Miss Bell's Syrian journey ended.

It is a pity that her map is not better than it is. It is based on Kiepert's map in Oppenheim's "Vom Mittelmeer zum Persischen Golf," with additions and Miss Bell's route marked in red. All the German spellings of Arabic names seem to be retained unaltered, with the result that the British reader is confronted with such words as "Meschetta," "'Ijun," "il-Kreje," "Riat," "Dimaschk Ischscham," and so on, which he will hardly recognise as the "Mshitta," "Ayun," "el-Kreyeh," "Ghiath," and Damascus "Esh-Shām" of Miss Bell's text. This is a bad fault, but one often committed when German maps are copied in England. By the average British reader "Ijun" and "Kreje" will be pronounced "Eyejūn" (Germ. "Eidschan") and "Kreege" (Germ. "Kridsch"). It is too often forgotten that the German pronunciation of consonants and vowels is not yet the world-standard, and that the English pronounce the letters "j," "sch," "ch," quite differently from the Germans. We certainly will not have the German "j" thrust down our throats, at any rate. Miss Bell and her publishers must share the blame for this serious blot on her otherwise admirable book.

H. R. HALL.

HAVE ALL EYES THE POWER OF FORMING IMAGES?[1]

SOME animals, such as the earthworm, have no eyes, and yet they are phototropic either in a positive or negative sense, according as they move towards or away from light. Others, such as planarians, have remarkably simple eyes, consisting of one or several sense elements, behind which is a pigmented cup, composed of one or more cells. Such eyes cannot form an image, and they have been called "direction eyes" because light from only one direction can affect such an eye at a given time. Higher in the scale we find the "compound" or "mosaic" eye, as in insects and other animals. The question arises, To what extent is an image or images formed by such an eye composed of many ocelli? There can be no doubt that the compound eye forms an image or images. Exner has taken a photograph through the eye of a fire-fly, and Parker has shown that the compound eyes of Astacus form a single image. Lastly, we find in vertebrates the "simple" eye, the optical construction of which leads to the formation of an image on the retina. The image of a distant object can readily be seen on the retina of a fresh eye removed after death from an albino rabbit, and if a lighted candle be placed in front of the isolated eye of a frog, a beautiful little inverted image of the flame may be visible on the sclerotic.

Mr. Leon Cole recently investigated the question as to the formation of images by different kinds of eyes by a new and ingenious method. It is obvious that it would be almost impossible to make a direct observation on the formation of an image by certain kinds of eyes, especially mosaic eyes of very small size. Mr. Cole's "aim has been, rather, to treat the formation of images from the point of view of their relation to the animal as a living organism—to determine in what way the ability to form a more or less perfect image affects the responses of the animal to light, and what relation, if any, this result has to the normal habits of the creature, and to its behaviour under experimental conditions" (p. 337).

For phototropic observations, Mr. Cole devised an arrangement by which two sources of illumination were so placed as to cause one or other to illuminate the eyes. The animal was placed with its long axis at right angles to a line joining the two lights. One light was so much larger than the other that the ratio of the two areas illuminated was as 10,000 to 1. The intensity of the light from either source was about 1·25 candle metres. The qualities of the two lights were also compared and tested, and the differences in the spectral components were so slight as to be negligible. The experimenter wished to ascertain "to what extent complexity in the organisation of eyes is correlated with the reactions to luminous areas of different size but of equal total luminosity" (p. 347). The character and relative percentage of phototropic responses as movements to or from lights were used as measures of the reactions. Suppose an animal positive in its reactions to directive light is so placed as to be midway between two luminous areas of the same shape, size, and intensity, the one acting on the right eye and the other on the left. Assume that each luminous area is 1 cm. square, has an intensity of 100 candle-power, and is 2 metres from the animal. The measure of the light falling on each eye would be 25 candle metres. Thus simultaneously stimulated on each side, the animal might go straight ahead without turning, or it might turn at random towards one light more than the other, and as the animal is positively phototropic it would continue to crawl towards this light. But as the chance of random movements in one direction is as great as in the other, in a large number of trials, we should find the number of times that the animal would go towards each light would be practically equal. Enlarge one of the areas to 100 cm. square, but keep the total amount of light the same. The area being 10,000 times as great, the intensity from 1 sq. cm. is now only 0·01 candle-power. The whole amount of light on each side is still the same, 25 candle metres. If the animal had no light-perceiving organs, the reactions would be the same as when the lights were of equal size; the animal would be indifferent. But if it had cells sensory to light distributed in its skin, as there is no apparatus for concentrating the light, the amount of light received at any point of the skin on either side of the animal would be equal to that received by any other. "This is evident from

[1] "An Experimental Study of the Image-forming Powers of Various Types of Eyes." By Leon J. Cole, Zoological Laboratory of the Museum of Comparative Zoology at Harvard College. (Proc. of American Academy of Arts and Sciences, vol. xlii., No. 16, January, 1907.)

the fact that light from every one of the 10,000 areas (each 1 cm. sq.) which make up the large area falls upon each point of the surface of the animal; the intensity of the light from any single square centimetre of the area is only 0·0025 candle metre, but since there are 10,000 such radiating squares the total intensity is 25 candle metres" (pp. 347–8).

In an animal having eyes that form a good image the case is different. The small light, only 1 cm. square, would form on the retina an image having a very small area (x), but the light would have considerable intensity (y). On the retina of the other eye there would be an image covering a larger area (10,000 x), but each area (x) would receive a light intensity of only 1/10,000 y. In all probability the difference between a very weak light and no light at all falling on a visual element would be more stimulating than the same or even a greater difference in the amount of the light at higher intensities. If so, we should expect an animal to react more strongly "to that stimulus which fell upon the larger number of visual elements—that an animal normally positive, for example, would be more strongly positive to the large light than to the small, and similarly that a negative animal would tend more often to move away from the larger than from the luminous area" (p. 349).

A large number of experiments was made on several animals, and the results, when discussed by methods now in use in biometrical work, on the whole bear out the line of reasoning just given. With the earthworm (*Allolobophora foetida*) the results showed that the *intensity* of the light is the controlling factor in its movements to right or left. This animal was negatively phototropic. It has no eyes, but it has cells in the skin sensitive to light. No image could possibly be formed. The largest of the land planarians (*Bipalium kewense*) has small *direction* eyes. Numerous experiments showed that animal has, to a slight extent, the power of appreciating differences of area, as it responded by turning away from the larger luminous area more often than from the smaller. It was negatively phototropic. The larva of the mealworm (*Tenebrio molitor*) has two or three ocelli on each side of the head, but nothing of the nature of lenses. It is negatively phototropic. When two lights, of different areas, acted simultaneously on both eyes, the responses right and left were equal in number, showing that "the ability of the eyes to form distinctive images of objects differing considerably in size is wholly lacking" (p. 371). The sow bug (*Oniscus asellus*), an active isopod, has small eyes consisting of a group of about thirty ocelli on the side of the head at the base of the antero-lateral lobe. It is negatively phototropic. The responses to light were of a less definite character than was observed in the larvæ of the mealworm. It has only unilateral illumination, and yet its eyes have greater efficiency for the formation of images than the larvæ of the meal bug. The cockroach (*Periplaneta americana*) has well-developed compound eyes, and it is very active and keenly sensitive to differences of light and shade. It was difficult to handle, and having more of what may be called a restless intelligence than the other animals already mentioned, the results do not seem quite so trustworthy. It reacts negatively to direct light in an excess of about 50 per cent. of its responses, but although it has relatively large eyes, Mr. Cole does not think the evidence bears out what one would have expected, namely, that the eyes were capable of forming better images than those of the animals already mentioned. The mourning-cloak butterfly (*Vanessa antiopa*) creeps and flies towards a source of light. It is positively phototropic for lights varying in intensity from 2 candle-power at 2 metres distance (0·5 candle metre) to 250 candle-power at 2 metres distance (62·5 candle metres). It can discriminate between lights of different area falling with equal intensity on the animal. Other animals, such as the water-scorpion (*Ranatra fusca*), the Pomace fly (*Drosophila ampelophila*), the European garden snail (*Helix pomatia*), the European garden slug (*Limax maximus*), were also examined. In the case of the garden snail, the inference from the experiments was "that the eyes of the snail do not aid greatly, if at all, in the discrimination of two lights differing in area as the two used" (p. 391).

The results with the cricket frog (*Acris gryllus*) are very instructive. It is, on the whole, positively phototropic. With luminous areas of different sizes but equal intensity, it turns in by far the greater number of trials towards the larger of the two areas. The result was the same when the skin was protected and the eyes alone were left uncovered. After section of the optic nerves, but having the skin exposed to the light, the animal is indifferent to the size of the luminous field. Still, even with the optic nerves severed, the frog is positively phototropic. Here light must be perceived by the skin, a result in keeping with the well-known experiments of Lord Lister made many years ago on the pigment cells in the skin of *Rana temporaria*. Similar results were found with the green frog (*Rana clamata*).

Mr. Cole concludes his paper with an interesting general discussion, showing that there is a correlation between the habits of the animals and the conditions under which they live. For example: "those are creeping forms whose movements towards the light take them in the direction of their food or else that other conditions prevent their phototropism from taking them into unfavourable surroundings" (p. 407). The following is very interesting:—"A query which Romanes found among Darwin's manuscript notes shows careful observation and puts the question very clearly. It is as follows: 'Query. Why do moths and certain gnats fly into candles, and why are they not all on their way to the moon—at least when the moon is on the horizon? I formerly observed that they fly very much less at candles on a moon-light night. Let a cloud pass over and they are again attracted to the candle.' Romanes thinks the answer is that 'the moon is a familiar object, the insects regard it as a matter of course, and so have no desire to examine it.'" Parker and Cole give a more reasonable explanation. The moths and gnats react to larger areas of light than to a point of more intense light. They therefore remain near the ground, on account of the bright patches of moonlight, instead of flying towards the moon; but if they come near a candle, the great intensity of the light at a short distance "overcomes the reactions of the moonlit areas," and the insects fly into the flame. Obscure the moonlight by a cloud so as to take away the patches of moonlit earth, and the insects fly more readily into the flame.

Mr. Cole gives at the close of his admirable and suggestive paper the following classification:—

Type A. Response of eyeless forms.—Usually negative; sometimes positive, and then usually to very weak light. Response to *intensity* only (earthworm).

Type B. Response of forms with "direction" eyes.—Usually negative (Bipalium, Periplaneta, Tenebrio larvæ); sometimes positive (larva of wood-borer). Response wholly to *intensity*.

Type C. Response to size of luminous field.—

Animals usually positive; may be temporarily negative, as in the frog.

Type D. Response to definite objects in the visual field.—Not simple reactions; responses involve psychical phenomena. Respond (1) to moving objects; (2) to stationary objects. This form of response usually inhibits ordinary phototropic reactions.

JOHN G. MCKENDRICK.

SIR W. H. PERKIN, F.R.S.

WITH deep regret the whole scientific world will hear of the death of Sir William Henry Perkin, F.R.S., the founder of the coal-tar colour industry, and one of the most distinguished of British chemists. Sir William Perkin passed away at his residence, Sudbury, on Sunday, July 14, after four days' illness, the cause of death being double pneumonia and appendicitis. Especially affecting will be the news to his London friends, among whom his bodily vigour and mental energy had, even up to the last, been the envy of many a younger man.

Born on March 12, 1838, William Henry Perkin was educated at the City of London School, and at fifteen commenced his studies under A. W. Hofmann at the Royal College of Chemistry. During the Easter vacation in 1856 he discovered mauve, and, supported by his father and brother, immediately began its manufacture under the name of "Tyrian Purple." The importance of this discovery, which has given birth to the extensive industry of coal-tar colours, was fully recognised at the Jubilee celebrations last year, when Dr. Perkin was presented with congratulatory addresses from all the important chemical societies of the world, and also received the honour of knighthood. Messrs. Perkin and Sons not only introduced the first aniline dye into commerce, but soon began to manufacture alizarin, in itself the first member of an important series of dyestuffs which are still to-day classed among the most valuable colouring matters used by dyers and printers. In 1873 the Greenford Green aniline-dye factory was sold, and the business finally transferred to Silvertown, where the manufacture of alizarin is still being carried on with success.

Perkin now devoted himself to laboratory work, and soon discovered the valuable method of synthesis of unsaturated aromatic acids, such as cinnamic acid, which bears his name. He also effected the synthesis of coumarin, the odorous principle of the Tonka bean. Later, he turned his attention to the magneto-optical properties of organic compounds, and enriched chemistry with a series of researches on this subject, of which the last account appeared in the Journal of the Chemical Society for May of the present year. In all he contributed about ninety original papers, published chiefly in the Journal of the Chemical Society.

The value of Perkin's work was not left unrecognised; the Royal Society made him a Fellow in 1866, he was awarded the Royal medal in 1879, the Davy medal in 1889, the Longstaff medal of the Chemical Society in 1888, the Albert medal of the Society of Arts in 1890, and the Birmingham medal of the Gas Institution in 1892. These were followed by the Hofmann medal of the German Chemical Society and the Lavoisier medal of the French Chemical Society in 1906. He held honorary degrees from Würzburg and Heidelberg (Ph.D.), St. Andrews (LL.D.), Manchester and Leeds (D.Sc.), and Munich (Dr.Ing.).

Sir W. Perkin married, in 1859, a daughter of the late Mr. John Lissett, and, some years after this lady's death, the daughter of Mr. Hermann Mollwo. Few fathers can have had the same happiness as he in seeing his three sons distinguish themselves in his favourite science.

Loved by his neighbours at Sudbury for his philanthropic work, respected and admired by his scientific friends the world through, all were instinctively attracted by Sir William Perkin's equable and amiable temperament, and unite in deploring the loss which they and the nation have sustained.

J. C. CAIN.

NOTES.

WE regret to see the announcement of the death of Dr. A. Dupré, F.R.S., on Monday, July 15, at seventy-one years of age.

WE learn with regret of the death, on July 13, of Prof. Heinrich Kreutz, who for many years acted as editor of the *Astronomische Nachrichten*.

THE eleventh International Navigation Congress is to be held at St. Petersburg in May, 1908.

THE American Academy of Arts and Sciences has awarded the Rumford premium to Mr. E. G. Acheson "for the application of heat in the electric furnace to the industrial production of carborundum, graphite and other new and useful substances."

DR. ARTHUR J. EVANS, F.R.S., describes in the *Times* of July 15 some further discoveries made by Dr. Mackenzie and himself, during the past two months, in the great prehistoric Palace of Knossos. The net result of these investigations is to show that an additional area of some three thousand square yards must be added to the palace. At a short distance from the actual "House of Minos," two beehive tombs have been found belonging to a period about 800 B.C., and their contents are of deep interest. If the accurate astronomical orientations have been measured of the structures now revealed, the results will be of great value.

A SMALL exhibition of science apparatus, mostly for chemistry and physics, is being arranged by Mr. R. E. Thwaites, of Wyggeston Grammar School, in connection with the forthcoming meeting of the British Association at Leicester.

THE Recorder of Section I (Physiology) of the British Association informs us that an important change has been made in the provisional programme for the Leicester meeting announced in last week's NATURE. On August 6 there will be no discussion on antitoxins, but instead one on the value of perfusion experiments. This will be opened by Prof. E. A. Schäfer, F.R.S., and will probably be of considerable interest to expert physiologists. To the list of those who will take part in the discussion on the physiological and therapeutical uses of alcohol has now been added the names of Prof. Cushny, and Drs. Dixon, Rivers, and Waller; Prof. Zuntz, Prof. Schäfer, Dr. Reid Hunt, and Prof. Sims Woodhead.

IN connection with the retirement of Prof. G. Lunge from the chair of technical chemistry at Zurich, of which mention was made in last week's issue of NATURE, an interesting farewell meeting was held on July 10 at Zurich Polytechnic. The occasion was the distinguished chemist's last lecture hour, and, in addition to the students, most of his fellow professors and some from the neighbouring university had assembled. On Prof. Lunge's entry into his lecture theatre all rose in silence. After an interval Prof. Treadwell, professor of analytical chemistry, made a short speech in which he eulogised Prof. Lunge's work, and afterwards read an address from the whole of the teaching staff. An address from the students was also read. Prof. Lunge made a suitable reply, and the whole audience showed by its enthusiasm the high regard in which he is held and the regret felt at his retirement.

THE Paris correspondent of the *Times* states that the French Government has just asked Parliament to grant a fresh credit of 12,000*l.* in order to prepare a new French expedition to the Antarctic. Some four or five months ago the Academy of Sciences declared that a new expedition would be of great scientific utility as well as an act of patriotism which would benefit the whole world; and it appointed a commission to draw up a scientific programme of work. The expense is estimated at 30,000*l.*, of which the State is to provide 24,000*l.* The 12,000*l.* now asked for by the Government will be immediately used for the construction of the special ship necessary for the expedition.

A LONG excursion, extending from August 15 to August 24, has been arranged by the Geologists' Association. The district selected is Appleby and its surroundings, and the party will be under the direction of Dr. J. E. Marr, F.R.S. Interesting observational work has been allocated for each day, and the arrangements which have been made for visitors will ensure comfort at a moderate expense. The party will leave Euston at 11.30 a.m. on August 14, and geologists who wish to avail themselves of the opportunity offered should communicate with Mr. A. C. Young, 17 Vicar's Hill, Lewisham, S.E. The association has arranged an excursion also in connection with the centenary celebrations of the Geological Society in September next. The excursion will be to Reading on September 28, and will be conducted by Messrs. H. W. Monckton, O. A. Shrubsole, and H. J. Osborne White.

THE Mackinnon studentship of the Royal Society in physical science has been awarded for a second year to Mr. W. Geoffrey Duffield, for a research on the influence of pressure on spectra, being conducted at the University of Manchester; and the studentship in biology to Dr. H. M. Woodcock, to aid him in working out the life-history of certain hæmatozoa of birds, an investigation which will be carried on at the Lister Institute of Preventive Medicine. The income of the Gunning fund accrued during the past three years has been placed at the disposal of Dr. F. H. Scott for the continuation of his investigations into the metabolic processes in nerve cells. The election to the Joule studentship of the Royal Society will be made at the end of July.

THE Commission appointed by the Presidents of the Board of Agriculture and Fisheries to inquire into the nature of distemper in dogs in Great Britain and the methods of its infection, and to report whether any, and if so what, preventive or remedial measures, exclusive of ordinary medical treatment, can with advantage be taken with respect to it, has now been fully constituted as follows:—The Duke of Beaufort, Lord Middleton, Lord Leconfield, Sir John McFadyean, Mr. E. Barclay, Mr. S. Stockman (chief veterinary officer to the Board of Agriculture and Fisheries), Mr. W. M. Wroughton, and Mr. E. W. Jaquet (secretary of the Kennel Club). The chairman of the commission will be Lord Middleton, and Mr. James Ralph Jackson (veterinary inspector, Board of Agriculture and Fisheries, 4 Whitehall Place, S.W.) will be secretary.

A DISTINGUISHED experimental physicist has been lost by the recent death of M. André Prosper Paul Crova, formerly professor of physics at Montpellier, and since 1886 a correspondant of the Paris Academy of Sciences. M. Crova was born in 1833 at Perpignan, and after receiving his education there became, at the age of twenty, professor of physics in the local Collège. Six years later he filled the same position in the Lycée at Metz. In 1864, M. Crova went to Montpellier, where, first at the Lycée and after 1870 in the Faculty of Science, he occupied a chair of physics. His most important work was devoted to the study of radiant energy, and included a classical determination of the constant of solar radiation. In addition to his well-known researches in this field he occupied himself very largely with optical and electrical problems of a general character, and published a large number of memoirs. As an experimentalist he possessed great skill and practical ingenuity in carrying out researches of very great difficulty, and to his inventive power are due several valuable instruments, including, besides his actinometer, an optical pyrometer and a spectrophotometer.

THE death of Sir William Broadbent, which occurred on July 10 after a long illness, removes a figure well known in the medical world. Those who saw the active interest he took in the meeting of the British Medical Association at Toronto last August little thought that he would soon be laid low, never to rise again. Born in the early part of 1835, he had completed his seventy-second year. He was educated at Huddersfield College, at Owens College, Manchester, and at the Royal School of Medicine at Manchester, graduated as M.B. in the University of London in 1858, taking the M.D. degree two years later. Early in his medical career he became associated with St. Mary's Hospital, of which he was successively assistant physician, physician, and consulting physician. As a clinician he had few rivals, and his teaching was thorough and painstaking. In 1870 he enunciated the hypothesis, since known as "Broadbent's law," on the association of nerve nuclei, by which he sought to explain the immunity of bilaterally associated muscles from paralysis in hemiplegia. He was also much interested in diseases of the heart, on which and on the pulse he wrote standard text-books and published a number of papers on clinical subjects. During the latter years of his life he took an active part in movements associated with the public health and the good of the profession, notably in the crusade against tuberculosis and in cancer research. He was a Fellow of the Royal Society, had bestowed on him many honorary degrees, and was physician-in-ordinary to His Majesty. He received his Baronetcy on the occasion of the marriage of the present Prince of Wales, and was a Knight Commander of the Victorian Order.

THE report of the Birmingham Natural History Society for 1906 records the incorporation with that body of the Midland Malacological Society, which now forms a malacological section. Another important event in the society's career during the period under review was the transference of the offices and library to Avebury House, Newhall Street, where it has been found possible to arrange all the books in one room.

WE have received from the author, Mr. L. M. Lambe, of the Canadian Geological Survey, copies of two papers published in the *Ottawa Naturalist*. One deals with a tooth of a musk-ox from a Canadian Pleistocene deposit, while the other records the occurrence of a supernumerary upper premolar in a dog. As dogs normally possess the full series of four upper molars, the occurrence of an additional one is more noteworthy than would be the case were three the normal number of these teeth.

The wide circulation of "Pokorny's Naturgeschichte der Thierreichs" is indicated by the appearance of the twenty-seventh edition not very long subsequent to the issue of its predecessor. This edition, published by G. Freytag, of Leipzig, is edited by Mr. Max Fischer, and illustrated by twenty-four coloured plates, in addition to the woodcuts. A new feature is an appendix, in which the proper care of the human body and its various parts is briefly described. The proper standard of weight, the amount of sleep and food necessary to be taken, and the care of the eyes are some of the subjects discussed in this appendix, which can scarcely fail to be useful.

Considerable importance attaches to an account of the skull of the Cretaceous pliosaurian genus Brachauchenius given by Mr. S. W. Williston in No. 1540 (vol. xxxii., pp. 477–489) of the Proceedings of the U.S. National Museum. Brachauchenius, which is known from West Kansas, is regarded by its describer as closely related to Pliosaurus, from which it differs in having single-headed cervical ribs. From other plesiosaurians in which the skull is fully known it differs in that the palatines meet each other in the middle, but this is a feature which the author thinks will be met with in Pliosaurus. The assumed relationship of the plesiosaurs to chelonians is disputed. The latter lack, for instance, epiphyses to the humerus, while such resemblance as exists between the shoulder-girdle in the two groups is due to adaptation. Chelonians are without the parietal foramen of plesiosaurs, and retain the hypocentral mode of articulation of the ribs, whereas in plesiosaurs the ribs are attached to the transverse processes. Sauropterygia are, indeed, probably descended from theriodont ancestors, while Chelonia appear derived from a cotylosaurian type, both being widely sundered from ichthyosaurs and rhynchocephalians.

Among fifteen recent issues of the Proceedings of the U.S. National Museum, special reference may be made to three (Nos. 1543, 1547, and 1551) by Mr. A. H. Clark, on new and other crinoids. The most important novelty is *Phrynocrinus nudus*, a new genus and species from Japanese waters, described in No. 1543. In general shape the calyx is acorn-like, and it is further remarkable for the presence of broad spaces between the radial, covered with a leathery skin, showing no external signs of radial plates. In the author's opinion, this crinoid probably indicates a family by itself. The same paper contains the description of a new species of Bathycrinus, also from Japan. *Ptilocrinus pinnatus*, described in No. 1547, is a new genus and species, from the neighbourhood of the Queen Charlotte group, allied to Bathycrinus, but characterised by a peculiar feather-like arrangement of the radials. Japanese crinoids of the genus Eudiocrinus, one of which is regarded as new, form the subject of the third paper (No. 1551). In No. 1548 Mr. P. Bartsch describes a gastropod of the genus Eulima parasitic in the calyx of Ptilocrinus. In three specimens the proboscis was found to be deeply embedded in the calyx of the crinoid; no other Eulima is believed to be parasitic.

Mr. M. J. Nowak communicates to the *Bulletin international de l'Academie des Sciences de Cracovie* (January) a description of fossil plant-leaves found in the Upper Senonian beds at Potylicz, in north Galicia. The leaves are typical of evergreen xerophilous plants, among the genera represented being Gleichenia, Cunninghamia, Quercus, Myrica, Eucalyptus, and Aralia. Mr. W. M. Kudelka presents a paper on the comparative anatomy of the vegetative organs of species of Ribes.

There are many difficulties militating against the successful exploitation of new woods from the colonies and foreign States, but with a little care it should be possible to provide fair, representative specimens for show or report. Mr. H. Stone, who has handled numerous collections in recent years, offers some hints on the subject in the Journal of Economic Biology, vol. iii., part i. He attaches special value to cylindrical samples with a dome-shaped top as showing every variation of grain from the radial to the quarter.

The report of the Midland Reafforesting Association for 1906 announces the formation of three small plantations at Walsall, Bloxwich, and Wolverhampton, the two former on pit waste, the latter on a sand-pit. The three local committees at Old Hill, Walsall, and Wednesbury have been augmented by two new committees for Wolverhampton and Ocker Hill. An arbor-day festival was held in some of the districts to interest the children in the preservation of the trees. The association still lacks the services of a paid secretary owing to insufficiency of funds.

Royal assent was given on July 4 to "The Destructive Insects and Pests Act, 1907," and the Board of Agriculture and Fisheries will now be able, under this new law, to issue an order against the American gooseberry mildew. Mr. E. S. Salmon, mycologist to the South-Eastern Agricultural College, Wye, sends us a letter in which he emphasises the necessity for growers to cooperate with the Board to stamp out this new pest. The disease has been allowed seven years' start in Ireland and two or three years' start in England. Now that the Board of Agriculture has acquired the necessary legislative powers to deal with the disease, it behoves all growers and gardeners generally to cooperate heartily with the Board if they wish to see the American gooseberry mildew stamped out and their gooseberry plantations kept healthy. Up to the present, the outbreaks that have occurred in England are as follows:—Kent, on standard gooseberries only in one nursery (disease believed to be now stamped out); Worcestershire, thirty-one outbreaks in gooseberry plantations; Gloucestershire, one outbreak; Wisbech and district, two outbreaks; Warwickshire, one outbreak.

Brilliant weather has at length set in over the whole of the British Isles, and the failure of summer, which threatened for so long, has fortunately not been realised. The past records of temperature for London fail to show any previous first fortnight of July as cold as that of the present year. The sheltered thermometer did not touch 70° from July 1 to 14, and the observations since 1841 show no corresponding period without that temperature being reached, and in most years a reading of 80° is shown, whilst in some years the thermometer registers 90°. On July 15 the thermometer in London registered 77°, which is the highest temperature since May 11 and 12. The whole type of weather has changed, and the persistent cyclonic disturbances have at last given place to an anticyclone, which during the present week has embraced practically the whole of England.

The volume of rainfall observations (*Nedbøriagttagelser*, vol. xii.) published by the Meteorological Institute of Norway for 1906 is a most important contribution to that branch of meteorological science. The institute, under the able superintendence of Prof. H. Mohn, deals with about 430 rainfall stations for the year in question, and includes means from seventy-seven additional stations at which observations have now been discontinued. Daily observations are given for 200 places, and daily statistics relating to snowfall for some fifty places. The monthly and yearly summaries for the whole 507 stations include means for past years, in some cases going back to 1867. The maps which accompany the volume are very clear, and exhibit the rainfall for the year 1906 by lines showing equal amounts (isohyets); the amounts on the *west coast* between lat. 59° and 62°, the usual track of the Atlantic storms, range from 1200 mm. to 3000 mm. at some few points, while inland the amounts vary from 400 mm. to 800 mm. yearly.

The Director-General of Indian Observatories has issued a memorandum, dated June 8, on the abnormal features of the weather of the past half-year, with a forecast of the probable character of the south-west monsoon rains of 1907. From the various conditions affecting the question, all of which are clearly stated, the outlook for the total rainfall of India during the period June to September does not appear on the whole to be unfavourable; it seems, however, likely that the effect of the heavy and late snowfall will show itself in north-west India in the delay of the establishment of the monsoon, or in diminished rainfall. An interesting fact in connection with the investigation is mentioned by Dr. Walker, viz., that statistical analysis shows that when estimating the amount of monsoon rainfall corresponding to a given pressure distribution and a given frequency of sun-spots, the influence of solar activity upon Indian rainfall is almost exactly that which corresponds to the disturbance in the pressure distribution caused by the solar activity.

In the Journal of the Meteorological Society of Japan for April, Dr. T. Okada gives several interesting instances of the occurrence of Föhn winds at Wonsan, one of the seven observatories of the first order established by the Japanese Government in Corea in 1904. The station lies on the eastern coast, in lat. 39° 9′ N., and is surrounded by high mountain ranges, except on the east side. The phenomenon is almost always associated with westerly winds, and causes abnormally high temperature and excessive dryness of the air as compared with that obtaining at other stations. In another article Dr. Okada discusses the effect of snow upon the diurnal variation of temperature in the lower parts of the atmosphere, based on hourly observations at various depths at Hokkaido in February last. The total daily heat exchange in the snow on the ground was found to be approximately 19 gram-calories per square centimetre; the amount of the exchange on clear days was nearly double that on cloudy days. Other articles (in Japanese) deal with periodicity of earthquakes, and density of snow and evaporation from its surface.

Prof. H. Potonié has issued a fourth edition of his pamphlet on the origin of coal (Berlin: Borntraeger Brothers, 1907). In its present form it covers forty-seven pages, and contains twenty-eight admirably reproduced illustrations. The author's views are well known, and we are pleased to note that he intends shortly to publish an exhaustive work on the subject.

The British standard specification for material used in the construction of railway rolling-stock (Report No. 24 of the Engineering Standards Committee) has been re-published in revised form. Several important alterations have been made. In the specification for steel castings, the number of tensile and bend tests required for waggon-wheel centres has been reduced, as it was considered that the quantity asked for under the existing specification was somewhat in excess of that usually obtaining in general practice. For locomotive-wheel centres cast with heavy balance weights it has been made permissible to reduce the height of the fall in the drop test. In connection with the specification for copper and brass tubes for locomotive boilers, an alternative drifting test has been added to the clause dealing with the bulging test. The principal alterations in the specifications dealing with steel plates for locomotive boilers, locomotive frames, and carriage and waggon frames, are in connection with the new standard iv. diameter test-piece for bars of more than 1 inch diameter. This shorter test-piece has been introduced to reduce the amount of material required for testing and the amount of turning down when such is necessary.

In the Journal of the Franklin Institute (vol. clxiii., No. 6) there is a lengthy paper by Dr. William Campbell on the changes in structure in iron and steel, in which the changes that take place in the iron-carbon series are considered in the light of recent work. He considers that the cementite-martensite series is the unstable one. Absence of silicon and rapid cooling tend to cause white cast iron to be formed. Grey cast irons are the martensite-graphite series, which occur with much silicon and slow cooling. The formation of graphite is due to the decomposition of cementite by re-heating to temperatures of about 1000° C. Most cast irons are a mixture of white and grey, or cementite, martensite, and graphite. The simultaneous occurrence of cementite and graphite in certain specimens of siliconless irons cannot be explained satisfactorily except by assuming that there are two systems, (*a*) ferrite and graphite, and (*b*) ferrite and cementite. This does away with the necessity of assuming a reaction between graphite and martensite to form cementite at about 1000° C. In this paper the term martensite is used in its old meaning, the solid solution of carbon in iron. Now, however, the solid solution is known as austenite, and martensite is regarded as a transition product.

Notwithstanding the much improved statistics recently issued by the Lunacy Commissioners, thoroughly satisfactory materials are still wanting for solving the question whether the prevalence of insanity is or is not increasing. The importance of the problem, especially in its bearing on the persistently urged theory of progressive physical deterioration, imparts special interest to a paper by Mr. Noel A. Humphreys on the alleged increase of insanity, published in the Journal of the Royal Statistical Society (vol. lxx., part ii.). This paper shows in a striking manner the value of scientific statistics in checking crude figures. The author expresses a decided opinion that there is no absolute proof of actual increase of occurring insanity in England and Wales, and that the continued increase in the number and proportion of the registered and certified insane is due to changes in the degree and nature of mental unsoundness for which asylum treatment is considered necessary, and to the marked decline in the rate of discharge (including deaths) from asylums.

In an article entitled "The Measurement of Nerve Force," contributed to the May number of the *Contemporary Review*, Dr. A. T. Schofield describes experiments with an instrument called the "sthenometer," which, it is suggested, provides a means of measuring an unknown "nerve force" emanating from the human organism. The instrument consists essentially of a straw balanced on a needle point and placed under a glass case. When a hand is brought close to the glass, at right angles to the straw and with the tips of the fingers opposite the end of the straw, a motion of the straw toward the hand is obtained. Dr. Schofield concludes from evidence of this kind that the "movement is produced in the sthenometer by some unknown force emanating from the right and left hands that can move a straw over a very considerable arc." It was shown, however, by Messrs. F. J. M. Stratton and P. Phillips in the Journal of the Society for Psychical Research for December, 1906, that heat radiated from the hand is the cause of the motion of the balanced straw of the sthenometer. Hot objects were observed to produce the same effects, and the extent of the motion was found to increase with the heat radiated from the hand as indicated by a thermopile. With the results of these experiments before us, and also a note by Mr. Stratton in the March number of the Journal of the society, it is difficult to understand why the effect described should be supposed to be produced by an unknown force. Much more substantial evidence will be required than that adduced in the article in the *Contemporary Review* before any firm foundation can be secured for the position taken up by Dr. Schofield.

THE three official articles, on the work done at the Physikalisch-Technische Reichsanstalt during the year 1906, which appeared in the April, May, and June numbers of the *Zeitschrift fur Instrumentenkunde*, have now been issued as a separate pamphlet. In addition to statistics showing how the work of the institution is growing, short summaries of the principal conclusions arrived at during the course of the year's work are given, and greatly enhance the interest and value of the publication. As typical examples may be mentioned the paragraphs on the expansion of bodies at very high and at very low temperatures, on the comparison of the various temperature scales at high temperatures, on the self-inductance of lead-covered and other cables, and those on the comparison of the methods of testing magnetic materials. Apart, however, from its scientific value, there is one feature of the report which teaches us an important lesson, that is, the close contact which exists between the institution and the manufacturers of Germany. Almost every official, from the president downwards, has spent some time during the year in visiting the works of clients of the institution, "um persönlich Fühlung mit der Industrie zu nehmen," to quote the words of the report. How long will it take us to learn this lesson?

AN important series of determinations of fundamental atomic weights is described by Prof. T. W. Richards, in conjunction with several of his students, in No. 69 of the Publications of the Carnegie Institution. The atomic weight of potassium was re-determined by ascertaining the ratio of the weight of potassium chloride to that of the silver chloride it produces when precipitated by means of almost exactly the theoretical quantity of silver nitrate. By using a Gooch crucible with a matting of platinum sponge the weight of the silver haloid formed could be determined with a high degree of accuracy, a correction being introduced for the minute quantities of silver chloride retained in the mother liquors. A similar series of determinations was also made with potassium bromide by converting the latter into silver bromide. In both series exactly the same value, 39·114, for the atomic weight of potassium was obtained (Cl=35·473, Br=79·953). Determinations were also made, introducing many new refinements, of the weight of silver nitrate formed from a known weight of silver; the results are of especial interest, inasmuch as they are incompatible with the low value recently advocated for the atomic weight of nitrogen if the atomic weight of silver be taken as 107·93; assuming this value, the atomic weight of nitrogen becomes 14·037. The atomic weight of sulphur was also determined by a new method based on the conversion of silver sulphate in a quartz tube into silver chloride by means of gaseous hydrogen chloride. The change takes place in a manner very favourable to accurate results, and gives a value 32·113 for the atomic weight of sulphur (Ag=107·93), which is considerably higher than that accepted hitherto. An interesting account of the general principles underlying recent determinations of atomic weights was given by Prof. Richards in a lecture delivered before the German Chemical Society, and printed in the current number of the *Berichte*.
