THE EDITORS

SIR DONALD MACKENZIE WALLACE,
K.C.I.E., K.C.V.O.

ARTHUR T. HADLEY, LL.D.,
PRESIDENT OF YALE.

HUGH CHISHOLM, B.A.
(FORMERLY SCHOLAR OF C.C.C. OXFORD)

THE DEPARTMENTAL EDITORS

FOR LAW AND GOVERNMENT:
THE HON. SIR JOHN SCOTT, K.C.M.G., Deputy Judge-Advocate-General.

FOR MILITARY AFFAIRS:
SIR GEORGE SYDENHAM CLARKE, K.C.M.G., F.R.S.

FOR MEDICAL SCIENCE:
D. NOEL PATON, M.D., B.SC., F.R.C.P.ED.

FOR THEOLOGY:
REV. W. E. COLLINS, M.A., Prof. of Ecclesiastical Hist. at King's Coll., Lond.

FOR MINING:
HENRY M. HOWE, A.M., Prof. of Metallurgy at Columbia University.

FOR BOTANY:
D. H. SCOTT, M.A., PH.D., F.R.S., Hon. Keeper, Jodrell Laboratory, Kew.

FOR GEOGRAPHY AND STATISTICS:
J. SCOTT KELTIE, F.S.S., F.S.A.SCOT., LL.D., Sec. Roy. Geog. Soc.

FOR ASTRONOMY:
SIMON NEWCOMB, PH.D., LL.D.

FOR MATHEMATICS:
JOSEPH LARMOR, M.A., D.SC., SEC.R.S., University Lecturer in Mathematics, Cambridge.

FOR ELECTRICITY:
J. A. FLEMING, M.A., D.SC., F.R.S., Prof. of Electrical Engineering, Univ. Coll., London.

FOR ART:
M. H. SPIELMANN, Editor of the *Magazine of Art.*

FOR ZOOLOGY:
G. HERBERT FOWLER, PH.D.

FOR NAVAL AFFAIRS:
JAS. RICHARD THURSFIELD, M.A.

FOR BIOGRAPHY:
RICHARD GARNETT, C.B., LL.D.

FOR LITERATURE:
EDMUND GOSSE, LL.D.

FOR ECONOMICS:
WYNNARD HOOPER, M.A.

FOR RAILWAYS:
MAJOR HENRY G. PROUT, Editor of *Railroad Gazette*, N.Y.

FOR MUSIC:
J. A. FULLER MAITLAND, M.A., F.S.A.

FOR GAMES AND SPORTS:
ALFRED WATSON, Editor of the *Badminton Library.*

THE ASSOCIATE EDITORS

PHILIP A. ASHWORTH, DR. JUR.
H. M. ROSS, B.A.
FRANKLIN H. HOOPER, A.B.
E. H. WILLIAMS, M.D.

THE SUB-EDITORS

JAMES A. MANSON.
G. B. LYNES, A.M.

ENCYCLOPÆDIA BRITANNICA

VOLUME XXVIII (ELECTIONS—GLAMORGAN).

PRINCIPAL CONTENTS.

PREFATORY ESSAY: THE GROWTH OF TOLERATION. Sir LESLIE STEPHEN, K.C.B.

ELECTRICITY. *Electric Conduction*, J. A. FLEMING, D.Sc., F.R.S., Professor of Electrical Engineering, University College, London; *Electrolytic Conduction*, W. C. D. WHETHAM, F.R.S., Fellow of Trinity College, Cambridge; *Electric Current* and *Electric Units*, Professor J. A. FLEMING; *Electric Discharge* and *Electric Waves*, J. J. THOMSON, D.Sc., F.R.S., Cavendish Professor of Experimental Physics, Cambridge University.

ELECTRICITY SUPPLY. *General Principles* and *Lighting*, Professor J. A. FLEMING; *Traction*, LOUIS DUNCAN, Ph.D., formerly President of the American Institute of Electrical Engineers; *Industrial Developments*, EMILE GARCKE, F.S.S., Manager of the Brush Electrical Engineering Company.

ELECTRO-CHEMISTRY and ELECTRO-METALLURGY. W. G. McMILLAN, F.C.S., Secretary to the Institution of Electrical Engineers.

ELECTRO-MAGNETS. Professor J. A. FLEMING.

ELEVATORS. ROBERT H. THURSTON, LL.D., Director of Sibley College and Professor of Mechanical Engineering, Cornell University.

EMBROIDERY. LEWIS F. DAY, Examiner for Art, Board of Education.

EMBRYOLOGY. ADAM SEDGWICK, F.R.S., Fellow of Trinity College, Cambridge, and University Reader in Animal Morphology; *Physiology of Development*, HANS A. E. DRIESCH, Ph.D., Author of "Analytische Theorie der organischen Entwicklung."

EMERSON. Rev. HENRY VAN DYKE, D.D., LL.D., Professor of English Literature, Princeton University, N.J., Author of "The Poetry of Tennyson."

EMPLOYERS' LIABILITY. MAURICE HILL, Barrister-at-Law.

ENAMEL. ALEXANDER FISHER.

ENERGETICS. JOSEPH LARMOR, D.Sc., Sec. R.S., Lecturer in Mathematics, Cambridge University.

ENGINEERS, MILITARY. Colonel R. H. VETCH, C.B.

ENGINES. *Steam*, J. A. EWING, Professor of Mechanism and Applied Mechanics, Cambridge; *Gas and Oil*, DUGALD CLERK, author of "The Theory of the Gas Engine."

ENGLAND, CHURCH OF. The Rev. W. E. COLLINS, M.A., Professor of Ecclesiastical History, King's College, London, and the Rev. FREDERICK BURNSIDE, M.A., Hon. Canon of St Albans.

ENGLAND AND WALES. *Geography*, H. R. MILL, D.Sc., F.R.G.S., Editor of "Symons's Meteorological Magazine"; *Statistics*, I. P. A. RENWICK, M.A., LL.B., Assistant Editor of "The Statesman's Year-Book."

ENGLISH BIBLE. The Rev. H. HENSLEY HENSON, Canon of Westminster.

ENGLISH HISTORY. Sir SPENCER WALPOLE, K.C.B., Author of "History of England from 1815," &c.

ENGLISH LAW. F. W. MAITLAND, LL.D., D.C.L., Professor of English Law, Cambridge University.

ENGLISH LITERATURE. EDMUND GOSSE, LL.D.

ENGRAVING. *Etching*, FREDERICK WEDMORE, Author of "Etching in England," &c.; *Mezzotint*, GERALD P. ROBINSON, President of Society of Mezzotint Engravers; *Lithography*, E. F. STRANGE, National Art Library, South Kensington; *Wood* and *Line*, M. H. SPIELMANN, Editor of "The Magazine of Art."

ENTOMOSTRACA. The Rev. T. R. R. STEBBING, F.R.S., Fellow of King's College, London.

EPIDAURUS. ERNEST GARDNER, Yates Professor of Archæology, University College, London.

ERROR, LAW OF. F. Y. EDGEWORTH, D.C.L., Professor of Political Economy, Oxford University.

ESPARTERO, MARSHAL. A. E. HOUGHTON, L.C.L., Author of "Restoration of the Bourbons in Spain."

ESTABLISHMENT AND DISESTABLISHMENT. The Rev. W. E. COLLINS, M.A., Professor of Ecclesiastical History, King's College, London.

ESTATE DUTY. P. DUNCAN, Treasurer of the Transvaal Colony; *United States*, SIMEON E. BALDWIN, A.M., LL.D., Judge of the Supreme Court of Errors of Connecticut.

ETHICS. J. A. STEWART, LL.D., White's Professor of Moral Philosophy, Oxford University.

EUPHRATES. Major-General Sir C. W. WILSON, K.C.B., LL.D., F.R.S.

EUROPE. *Geography and Statistics*, G. G. CHISHOLM, Editor of "Longman's Gazetteer of the World"; *History*, Sir DONALD MACKENZIE WALLACE, K.C.I.E., K.C.V.O.

EVANGELICAL ALLIANCE. The Rev. W. E. COLLINS.

EVIDENCE. Sir COURTENAY P. ILBERT, K.C.S.I., Clerk of the House of Commons.

EVOLUTION. P. CHALMERS MITCHELL, D.Sc., F.Z.S., Lecturer on Biology at the London Hospital Medical College.

EXCHEQUER. S. E. SPRING-RICE, C.B., Principal Clerk H.M. Treasury.

EXCISE REVENUE. Sir G. H. MURRAY, K.C.B., formerly Chairman of the Board of Inland Revenue.

EXECUTIONS, CIVIL. A. WOOD RENTON, Puisne Judge of Mauritius.

EXHIBITIONS. G. C. LEVEY, C.M.G.

EXPERIMENTS ON ANIMALS. STEPHEN PAGET, M.D., F.R.C.S., Surgeon to the West London Hospital, Author of "Experiments on Animals," &c.

EXTERRITORIALITY. THOMAS BARCLAY, LL.B., Ph.D., sometime Examiner in International Law to the University of Oxford.

EXTRADITION. J. E. P. WALLIS, M.A., Advocate-General of Madras, formerly Editor "State Trials."

FACTORS. LESLIE SCOTT.

FAWCETT. THOMAS SECCOMBE, M.A., Assistant Editor of "The Dictionary of National Biography."

FENS. J. T. BEALBY.

FINANCE. C. F. BASTABLE, LL.D., Professor of Political Economy, Dublin University.

FINLAND. PRINCE KROPOTKIN.

FIRE AND FIRE EXTINCTION. *Britain*, Captain L. DE L. WELLS, R.N., Chief Officer of the Metropolitan Fire Brigade; *United States*, General A. P. ROCKWELL, Boston, Massachusetts.

FISHERIES. WALTER GARSTANG, M.A., F.Z.S., in charge of Fishery Investigations, Marine Biological Association.

FISHERY. G. G. PHILLIMORE, M.A., B.C.L., Barrister-at-Law, London.

FITZGERALD. EDMUND GOSSE, LL.D.

FLAUBERT. EDMUND GOSSE, LL.D.

FLORENCE. ENRICO CORRADINI, formerly Editor of "La Nazione," Florence.

PREFATORY ESSAY.

THE GROWTH OF TOLERATION.

By Sir Leslie Stephen, K.C.B.

AT the opening of the 20th century we might plausibly congratulate ourselves upon the increase of mutual tolerance. A marked change had taken place even within a generation. In the 'sixties there was a period of sharp controversy, which to some of the disputants seemed to herald an intellectual revolution as important as that which took place at the Reformation. Adherents of Darwinism in science, and advocates for the application of critical methods to the Bible, were denounced in a spirit recalling the ancient methods of controversial warfare. In 1902 orthodox divines could regard evolution as an established principle, and were no longer alarmed by the critical results which seemed at first sight so destructive. Whatever the meaning of this change, there is undoubtedly a gain in good temper and calmness of discussion. Perhaps we are a little inclined to exaggerate the real intensity of the previous struggle. The old phrases scarcely covered the old strength of feeling. A recent writer remarks that the Calvinistic dogmatism in which he was educated has vanished "like a nightmare and hideous dream." That may go to prove that it was not really believed even in his youth. It is exceedingly rash to infer men's genuine beliefs from their most sincere avowals. They believe themselves to hold dogmas, the plain meaning of which is neutralized by all manner of tacit reservations and unconscious interpretations. The real utility of the ostensible creed may be sapped long before it is openly abandoned; and when a doctrine vanishes rapidly, the inference is that it had already decayed at the roots. The apparent change may mean merely that men have come to avow clearly the conclusions which were already formed, though latent under various disguises. In any case, however, the general readiness to accept as harmless or obvious opinions which not long ago were regarded as dangerous and offensive is in itself a remarkable change, and may justify a few considerations as to its true nature. To understand it fully we should have to consider how it takes its place in the prolonged process by which a doctrine, universally repudiated three centuries ago, is now as universally accepted, even by some to whom the fundamental position requires a little straining to make room for it.

A remarkable change.

A full acceptance of the duty of toleration is often noticed as the most marked case of the addition of a new article to the code of morality. It seems so obvious to us now that it is necessary to recall the real obstacles by which its acceptance was impeded in order to understand more clearly the later steps in the development of the doctrine. We often look back with simple amazement at the state of mind in which the tyranny of the Inquisition or the atrocious penal laws could be reconciled by any ingenuity to the dictates of the human conscience. Considering the incapacity of the vast mass of mankind for reasoning at all, and the incapacity even of the ablest for establishing a philosophical system solid enough to survive later inquiry; and considering, too, how speedily, as the most confident dogmatists must admit, every speculation places us in front of insoluble mysteries, it seems to be not only atrocious, but grotesque, to punish men for losing their way in the labyrinth. The persecutor virtually admits, by appealing to force, that men cannot attain truth by reasoning. The obvious inference is that error is inevitable, and therefore innocent. When a heretic is punished for an honest error, honestly avowed, he is punished for doing what to him is his obvious duty. His "punishment," then, cannot have a moral quality. It is clearly paradoxical to send a man to hell for the good of his soul. It has to be admitted, in fact, that so far persecution is not moral, though it may be expedient. The heretic is damned to save the soul of his neighbours. The persecutor argues that he is not punishing a criminal, but stamping out a contagion. He is working in the interests of society at large, though inflicting a palpable wrong upon the individual. If religion be regarded as simply a philosophical creed, the absurdity of regarding error as criminal is obvious. Philosophers often hate each other pretty heartily; but they have never, I think, proposed to establish their own opinions by the stake. They have felt bound to admit that error is properly assailed by reason. But a religion is much more than a set of dogmas. It is a complex of intellectual, ethical, and social instincts. It is the bond by which a vast and elaborately organized society is held together. It means devotion to the Church as well as acceptance of certain speculative results. The persecutions of the early Christians were not intended to suppress opinions which the persecutor regarded with simple indifference or contempt, but to put down a system of secret societies, naturally objects of suspicion to the statesmen, because they enforced a discipline of their own, and might come into conflict with the authority of the State. When the empire had become Christian two great societies were fused together, and each had a direct interest in supporting, if also in limiting, the authority of the other. To rupture the unity of belief was to overthrow the authority of the Church, and intellectual dissent meant a revolt against the ties which held the whole social order together. The immediate motive of the persecutions of later days was not the love of men's souls, but the desire to support the great institution against which the heretic was rebelling. From one point of view this makes the persecution the more hideous. It meant, as the unbeliever would say, the spirit of priestcraft, that is, the instinctive hatred of the hierarchy for any one who dared to attack its privileges or dispute its power. The persecutor, however, might be sincerely convinced of the identity between the interests of the Church to all the highest interests of mankind. His motives were no doubt complex. Loyalty to the Church might spring from the purest benevolence, or from political and personal ambition, or even from the love of rich endowments. The really benevolent must always, one fancies, have felt a certain inconsistency between the estimable motive of love for men's souls, and the practical application to the individual sufferer; but presumably persecution in general was a result of the spirit which is developed more or less in all corporate bodies. Their welfare becomes an end in itself apart from the good results by which their existence is supposed to be justified. The mediæval Church was identified in so many ways with a man's whole life, and embodied his beliefs, aspirations, and interests in so many and such complex forms, that loyalty to its interests might become a second nature. The believer would require no further reason for suppressing any rebellion against its authority by the most drastic methods. From that point of view the persecuting impulse is fully intelligible, and it is easy to perceive how difficult it would be to take into account the moral objection. If it were possible to admit that a heretic was a well-meaning person avowing what he believed to be true, he was not the less a rebel against an essential part of the social order, who may be rightly put to death as we should now put to death the most sincere anarchist who applied his principles by assassination.

Obstacles to liberty of conscience.

Such obvious considerations show the difficulty of the transformation of opinion, and may indicate some which are not yet quite surmounted. To make toleration practicable in the early days, men had not only to point out the immorality of persecution, but to show how the political and ecclesiastical constitution could be reorganized. Church and State, and the systems of law which they enforced, interpenetrated each other so thoroughly at the time of the Reformation, that a complete separation of functions was inconceivable. Whether, as various disputants held, the State was properly subordinate to the Church, or the Church to the State, or they were two co-ordinate powers of equal authority, they virtually formed parts of a single organization. Each relied upon the co-operation of the other, and though the spiritual and secular sanctions might be distinct, both were required to the working of a single system. Schism involved rebellion or war. It was not a simple separation of speculative sects, but a disruption of the social structure. The Calvinist changed the ecclesiastical system, but claimed for his Church the old right to the support of the State. The Anglican Church retained the old constitution, and enforced conformity, not the less because obedience was due to the king instead of the bishop of Rome. The breach of continuity no doubt suggested some doubts as to the authority of the new system. Elizabethan statesmen sometimes repudiated the doctrine of religious persecution, and declared that Catholics were punished not as heretics, but as rebels. So long as a priest, as such, was liable to be hanged, drawn, and quartered, it made little difference to him what was the ostensible reason. But, hypocritical as the apology seems, we cannot ignore the real difficulty. The priest was, in point of fact, a drilled and subordinate member of a vast and powerful body representing a main element in the political combination which instigated domestic conspiracies and foreign invasions. Even if his immediate purpose was to administer spiritual consolation to individuals, he was necessarily also an agent of a hostile political power. Undoubtedly measures of political defence took the shape of religious persecution, and it would have been more expedient, as well as more just, to limit expression to the men who were guilty of directly treasonable purpose. The distinction, however, was difficult so long as the religious body used secular weapons. A certain reciprocity is required in international as in all morality. So long as a Catholic was bound by his dogma to be disloyal, the Protestant was strongly tempted to punish Catholicism. Meanwhile, in enforcing conformity, the State was supporting not merely certain dogmas, but the system of moral discipline in which it was essentially interested. Religion was the essence of morality, and to tolerate religious dissent was to demoralize the State. Nobody could be mere tolerant and rational in speculative matters than the excellent Baxter. But he was shocked by the claim of Independents and Quakers to "what they called liberty of conscience." It meant, he explains, liberty not only to think, but to preach and do whatever they pleased; that is, it was the plea for antinomianism and rebellion against all religious order and moral restraint.

The lesson of toleration, therefore, had to be learnt, not by logic alone—by proofs of the immorality of punishing innocent men—but also by the bitter experience won through protracted civil and international warfare. Sects found that they could live side by side when they were forced to combine against a common oppressor. Statesmen, though they had made religious differences a pretext, were most fully alive to material interests, and refused to make political aims subservient to religious bigotry. The greatest were content, like Richelieu, to make things easy for heretics on condition of submission to the secular power. The most effective persuasive to toleration, if not the most logical argument on its behalf, is the simple existence of the heretic. Ocular demonstration shows that he has not horns and hoofs, and it follows that he may be a decent person and a desirable customer. Meanwhile the endless controversies, which, instead of leading to any conclusion, branched out into countless multiplications and subdivisions of opposing theories, had an obvious lesson for the intelligence. The Catholic held that the evil was due to the rejection of the old authority, and that the only hope of restoring unity was to return to the fold. The opposite view was the scepticism which inferred that controversies which led to no result could only be concerned with chimeras. But the natural development of Protestantism was the belief that the differences were superficial, and that a common ground might be discoverable. It should be possible to draw up a list of the fundamental doctrines common to all Christians, or perhaps to all religions whatever. It might still be held that men's salvation depended upon their creed; but the creed might be so simplified and so obviously true, that very few people would have to be damned. The development of this view led to the deism of the 18th century, or to the "Religion of Nature," the truth of which was demonstrable by reason. There was ample room for controversy as to the relation of this religion to the historical religions, which might be regarded either as adding corollaries or as really superfluous. In any case, theory was naturally combined with a doctrine of toleration which is interesting by its limitations as well as its assertions.

Locke was the authorized exponent of the English revolution of 1688; and his treatise upon toleration gives the high-water mark of the advancing doctrine. He is anxious to indicate the widest practicable sphere for free thought; but he has to draw the line at two points. He excludes atheists, that is, those who disbelieve the religion of nature, and who therefore, as he holds, repudiate the only motives which form an efficient sanction of the moral law. He excludes Catholics, because their religion binds them to disloyalty. Rousseau, the apostle of the French revolutionary creed, is still at the same point of view. The citizens of his ideal state must hold the "positive" doctrine that there is a benevolent, all-wise, and omnipotent Providence; and the "negative" doctrine that salvation is not confined to the members of any sect. All who refuse these beliefs must be exiled. Every one, therefore, must be tolerated except the intolerant and those who are anti-social on principle. Now, though we have ceased in theory to make even these exceptions, the ground of exception corresponds to a practical difficulty. If, in fact, we are justified in assuming that men's conduct will be governed by their opinions, or by what we regard as the logical deduction from these opinions, toleration would clearly have to be limited. If an atheist really held that he might kill any one he pleased, we should restrain the application of his principles. "I am an atheist" would not be a sufficient plea in answer to an indictment for murder. So, if Catholicism implied actual disobedience to the constituted authorities, we should not the less put down a rebellion in the interests of Catholicism. As a matter of fact, atheists do not claim a right to murder nor modern Catholics to rebel, and no difficulty arises in regard to their conduct. Some cases may still occur in which a religious practice comes into conflict with secular laws; as when the "peculiar people" refuse to call in medical aid for their children. In practice, there is a general *de facto* agreement to obey the laws; but it must be noticed that such an agreement is a necessary condition of carrying out complete toleration, not only of opinions, but of the corresponding conduct.

The answer, in fact, to the problem which still perplexed Locke and Rousseau implies a distinction which they failed to take into account. Every one would now admit that we must attack philosophical error by reason alone, although we may find it necessary to restrain the corresponding conduct by legal coercion. Toleration of opinions, therefore, must be distinguished from toleration of practices. I may at once deny a man's right to do things and admit his full right to show that the prohibition is unreasonable. The distinction is really fundamental. A certain ambiguity still appears in popular arguments upon the question. Authority is often used in a double sense, as covering both coercion and a rational proof.

The meaning of Authority.

"Authority," as used in scientific or historical questions, means simply one kind of evidence—that kind upon which by far the greatest part of every man's knowledge is necessarily founded. I believe historical facts "on authority" when I have not been an eye-witness, but consider them to be sufficiently proved by appropriate evidence. I believe a scientific doctrine upon authority when I have not followed the reasoning or tried the experiments by which it is proved, but hold it to be established by the consent of experts and verified by the application of tests open to general observation. The discovery of Neptune was a sufficient proof of the value of astronomic theories to those who could not follow a step of the reasoning. The telegraph convinces us that electricians have real knowledge, though we may be utterly ignorant of their investigations. Such belief is, of course, perfectly reasonable; for in this sense authority means an appeal to reason. The enormous growth of scientific knowledge in modern times has made the conception of rational authority familiar. The existence of a vast body of truths, mutually consistent and corroborative, and verified at every moment by whole systems of practical application, proves not only that such belief is reasonable, but that all but an infinitesimal proportion of every individual's knowledge must be taken on trust, that is, upon reasonable authority. It would be manifestly absurd to regard authority in this sense as opposed to reason or capable of being opposed to it. Reason imperatively commands the acceptance of sufficient evidence. The only alternative to believing on authority would be to take your beliefs by chance, which is a very common but not a rational practice.

In philosophical or religious discussions, however, popular writers still oppose reason to authority, as if the words were mutually exclusive. If to believe on authority means to believe because you will be burnt for not believing, the process is clearly irrational. But it is simply rational to attach due weight to the opinions of competent inquirers. When the Protestant claimed the right of private judgment, the claim might be perfectly right or clearly preposterous. It would be right if he meant that he was to be guided by reason in choosing his guides. It would be preposterous if he meant that every ignorant man could settle for himself innumerable questions only to be answered by the combined efforts of profound critics and historical inquirers. But the absurdity would not be that he reasoned, but that he neglected the only kind of evidence which he was competent to appreciate. The argument from incompetence is not properly an argument for abandoning such reasoning power as you possess, but for respecting the opinions of your superiors, and holding your conclusions with due modesty. The two arguments, indeed, are easily confounded. An Irish peasant presumably accepts his creed without asking questions at all. It is to him a primary instinct. But if it should occur to him to inquire, it might be quite reasonable for him to hold that a creed accepted by all the wisest and best men whom he knew, and of whose competence no doubts had ever occurred to him, must have a strong presumption in its favour. If he really accepted it upon that ground, he would be as much a rationalist in principle as the free-thinking artizan who is convinced by Paine's *Age of Reason*. If, on the other hand, he accepted it because he was afraid of consequences, he would be submitting to authority of a radically irrational kind. One claim unquestionably glides very easily into the other. "Accept my creed because I am wiser" is identified with the inconsistent claim, "Accept it because I am stronger." When a man is told to absorb whole systems of dogma in regard to matters which he is totally incapable of understanding, and when his salvation is held to depend upon his accepting the orthodox view, whatever may be the grounds of his acceptance, authority ceases to mean evidence and comes to mean coercion. The superior asserts his right to be believed, and refuses to say why his authority should be accepted. The historian or the man of science may ask us to believe, because, though we cannot follow his argument, he can prove his competence. But the priest who proves the incompetence of the layman from the weakness of the reasoning faculty in general, is proving that the guide is just as incompetent as the traveller. Thus the appeal to authority comes to be essentially sceptical, and involves the assertion that as truth is unattainable, belief may be arbitrary.

To assert authority, then, in its rational or scientific sense is to admit also the obligation of proving its rationality, and, therefore, of renouncing coercion. Every scientific man admits, in theory at least, that he is bound to establish his claims, and therefore to court every kind of investigation. He does not propose to forbid even the fool to reason, but only warns him to remember that he is a fool. Every now and then some ignorant person denies an established truth; he squares the circle or invents perpetual motion. Nobody proposes to punish him except by demonstrating his error. Even his error may be useful, as an illustration of the existing state of mind. A quack remedy in medicine may do as much mischief as a theological heresy; but to suppress whatever was disapproved by the College of Physicians would be to encourage an undesirable faith in the infallibility of that eminent body. If we agree, as we do in such matters, that even incompetence supplies no ground for exercising irrational authority, the doctrine of toleration takes its widest sense. It may then be laid down absolutely that to suppress freedom of discussion is, so far, invariably bad. There is not the least necessity for trying to prevent people from thinking. They are quite ready enough to be stupid or indifferent without external inducements. The huge dead-weight of established prejudices is amply sufficient; and the authority of their defenders more likely to be over than under estimated. We may say that free thinking is not only a right, but a duty. A man, that is, is bound to be as reasonable as he can. The main condition of progress is that the intellectual activity should be stimulated by all legitimate means; not because it destroys, but because it creates a rational authority. The argument that free thought leads to scepticism is suicidal; for a doctrine which can be destroyed by exposure to argument must be a doctrine which it is irrational to believe. The great thinker is one whose mind swarms with hypotheses, and who gradually puzzles out his way through the labyrinth by trying every turn and rejecting those which end in a deadlock. A society in which speculative activity is great must abound in erroneous sects ; but the doctrine of natural selection applies, if it applies anywhere, to the world of ideas. The fittest ideas will survive, and the keener the competition the sooner they will triumph over their rivals. The tendency is not to the destruction of " authority," but to the formation of the only reasonable authority—a consistent body of doctrine which has been raised by systematic unification and is authoritative in the sense of being supported by conclusive evidence.

At this stage, the doctrine thus implies not merely passive, if one may say so, but active toleration; or that it is unconditionally desirable not only to permit but to stimulate intellectual activity. It was reached, and the essential point was stated most cogently in Mill's famous essay upon *Liberty;* and so far as he dealt with liberty of thought little can be added to his argument. He felt, however, certain difficulties when he passed from liberty of speculation to liberty of conduct. As an individual, he endeavoured to limit as much as possible the sphere of State interference ; and yet he could not deny that the State should have social aims, and therefore enforce rules, even while permitting free discussion of their underlying principles. This brings out one essential element of the problem. The accepted view of the Liberal of his time was that there should be a complete separation between Church and State. The sphere of religion was entirely separate from the sphere of political obligation. Macaulay put the case in his usual trenchant fashion in arguing against Gladstone. A State, he said, should have no more religious colouring than a railway company. The individual minister of State was, of course, bound to belong to the Church whose creed he took to be true, and so was the individual railway director. But the ministry or the directors in their corporate capacity had no concern whatever with religious questions. Religion is a matter of purely individual interest. My belief, it was said when it was desired to give a pious turn to the theory, is between myself and my God. No human being has even a right to inquire into it, and to do so is an act of gross impertinence—as Macaulay informed a constituent who had the audacity to ask the question. So long, indeed, as certain beliefs are regarded as in themselves disreputable there is some excuse for reticence. But when the duty of toleration is fully admitted and the inference drawn that a man ought to obey his own reason, I should say that an open avowal of opinion may become a duty. In any case, the theory that a man's religious opinions can have no bearing upon his political action is an assumption of fact. It is not self-evident even in the case of a railway company. If some of the shareholders believed while others denied that Sunday travelling was forbidden by the laws of God, a religious difficulty might arise in the company. Macaulay observes that Marlborough's armies included Catholics and Protestants, who were equally ready to fight, whatever their differences about transubstantiation. That, however, would not have been equally true in the time of Cromwell or Gustavus Adolphus, when Protestants or Catholics had strong motives for betraying leaders of the opposite persuasion. It is a question of fact whether loyalty to a particular Church is or is not compatible with loyalty to a given State. Both spiritual and secular powers aim at enforcing certain rules of conduct, and it is not necessarily nor always true that the two systems of legislation will be consistent. Undoubtedly in the time of Mill and Macaulay the assumption corresponded very closely to the facts. The old Puritanic ideal of a theocratic State which should regard the laws of Moses as part of the laws of England had vanished, or only left some faint traces in the desire to enforce observance of the Sabbath. The Catholic might still hold that the State ought to obey the Church, and even that under some ideal order persecution of heretics would still be right. But, in point of fact, he was as ready as his neighbours to submit to the State and to accept the principle of toleration—so long, at any rate, as he was the person to be tolerated. The question, however, remains, whether or under what conditions this separation of the two powers can be absolutely maintained. The prevalent theory of individualism, which tended to limit the legitimate action of the State to purely material interests, made the problem simple. But every Church holds that its creed embodies the essential motives for morality, whatever may be its precise theory; and unless the laws of the State have nothing to do with morality, or happen in point of fact to be in conformity with the morality approved by the Churches, some conflict must always be possible.

Religion and Politics.

If, therefore, we may develop toleration of opinion and discussion to the farthest point, and agree that intellectual activity should be not only unchecked but stimulated, there must still be a difficulty in regard to the toleration of the corresponding conduct. Coercion by physical force is essential to legal authority; and the very existence of the State implies the forcible suppression of certain modes of conduct. This again presupposes a certain moral agreement. The State does not undertake to suppress immorality as such, and leaves many forms of vice to be discouraged by other agencies. But it is equally true that no conduct should be regarded as criminal which is not also regarded as immoral. If, in the usual and very sound formula, vice cannot be put down by Act of Parliament, still, so far as it goes, the legitimate action of the State must be in harmony with the general moral convictions. Though immorality may not be directly punishable, the laws of marriage will tend to heighten or diminish the general respect for the institution, and have therefore a moral or immoral tendency, according to the doctrine accepted.

The sphere of State action has greatly extended of late years, and the theory that it should be limited to purely material interests has been more and more discredited. The question, therefore, naturally occurs, What has been the bearing of recent political changes upon the principle of toleration? If the State takes to interfere in a greater number of cases, and to interfere with a moral purpose, must not the toleration of conduct become more difficult? If the religious differences which divide sects are compatible with an agreement as to the moral issues involved, they may co-operate in suppressing the same modes of conduct; but it is a question of fact whether there is or is not such an agreement.

The question of disestablishment.

One change of modern times has a bearing upon this question. The early Radicals held that the abolition of a State Church was a simple corollary from the doctrine of toleration. At the time of the first Reform Bill, the disestablishment of the Church and the confiscation of its revenues was regarded on both sides as an inevitable result of parliamentary reform. The prediction has hitherto been falsified. Disestablishment may be still part of the genuine Radical creed; but the demand does not rouse the vehement passions of the previous generation. A State Church may be regarded as an anomaly; but we take anomalies easily, and the hostile sentiment corresponds rather to a pious aspiration for theoretical symmetry than to a deep sense of a pressing injustice. One cause is obvious. In the first quarter of the 19th century the Church was regarded by Radicals as an essential part of the great political combination by which the country was governed. Rich bishops, non-resident clergy, and indolent cathedral chapters were familiar instances of the abuses which favoured corruption, political jobbery, and all the evils of irresponsible class government. The clergy were part of the garrison, which, in alliance with the nobility, the lawyers, and the stock-jobbers, held the position to be stormed by reformers. The removal of the old abuses diminished the strength of the antagonism; and whatever may be said of bishops to-day, they are not idle sinecurists, owing their position to family claims, and trying to earn translation to the best sees by a course of political servility. At the same time the decline of the old jealousy of all Government interference has weakened one presumption in favour of a voluntary system, and favours the growth of another view. It is a disputed question whether disestablishment would really be favourable to toleration. In one way the change would clearly be more congenial to the high churchman than to his opponents. The higher the claims of the priesthood, the greater is the objection to the alliance with the State which ties the hands of the Anglican establishment. The Church, on a sacerdotalist theory, should command instead of obeying, and be able to define and interpret its own dogmas. Had the Church been "free" in the 'sixties, the high and low churchmen would each have tried to expel the other and have combined to expel the broad churchmen. Pusey and Gorham and Maurice and Colenso could hardly have been kept in one fold. The anomalous position which makes a change impossible without the consent of a body representing all other sects has preserved its external unity. If toleration implies disestablishment, it may give greater authority to the intolerant. A free Church might become more exclusive and obscurantist, or split up into separate Churches, each representing an intolerant creed. The liberty of the Church would really mean an increased power of the clergy.

A lover of toleration may prefer the Erastian view. The Church is for him a parliamentary institution, the religious department of the State, which obviously cannot claim any power of deciding what doctrines are true, but which may very well be a good comfortable institution, so regulated as to provide such services and discharge such functions as are in fact acceptable to respectable persons in general. The existence of such a sentiment implies the belief that the laity in general take very little interest in the speculative controversies by which Churches are divided.

Nobody, indeed, can say that sectarian prejudices have died out. That they can be bitter enough is proved by the controversies upon educational questions. The prejudice against State interference has been rather inverted than diminished; everybody accepts State schools in principle; and it is even laid down as self-evident that education is the business of the Government and not of the Church. If the nation were coextensive with the Church, the doctrine would seem to be rather preposterous than obvious. Education must surely be an essential function of the Church, not bare instruction in reading and writing, but inculcation of morality and the beliefs with which, according to every Church, morality is essentially connected. It is surely the most logical position that the class told off to inculcate these beliefs should control education. The acceptance of a State system implies either that religious instruction is not important or that, as a matter of fact, we are all sufficiently agreed. It is presumed that there is such a thing as "unsectarian religion," and the additional dogmas may be added by priests or such teachers as they prefer. Catholics, Anglicans, and Dissenters all accept the rule of three, and the secular teaching may be given in common, while the religious teaching is an extra. A compromise upon these lines is not acceptable to advocates of denominational schools. But even their position implies a concession. They cannot argue on the ground that their distinctive creeds are essential. There is no serious danger that the rising generation will take wrong views of apostolic succession or justification by faith or any of the speculative points upon which the Protestant Churches are divided. They must be abnormally precocious if they have any perception that any such controversies exist. The real argument is, of course, that a child may be brought up to feel a due respect for the parson or for the dissenting minister, and that the Church invested with the function may gain influence in its corporate capacity. The claim may be legitimate, and members of any Church may hold that the secret of its power depends ultimately upon its orthodoxy. But at least it is evident that the argument does not rest upon the importance of absolute purity of doctrine. The opinion that a child ought to be taught to have dogmas, because if it does not hold them it will probably be damned, is probably not held, and certainly cannot be put forward by any body. It is only held that Churches in general are useful; and that people in general believe in the great importance of religion. But, whatever may be the creed of the more devoted, it is plain that the ordinary common-sense looks with very great indifference upon the purely speculative differences even if it is aware of their existence.

Orthodoxy and Education.

Indifference to the critical distinctions is conspicuous in another direction. The controversy between socialists and their antagonists suggests profound moral questions, but it is remarkable that the religious distinctions have so little bearing upon them. Some socialist theories are indeed avowedly based upon materialism and the rejection of all theological creeds. But the most influential individualists in English politics have been also the most thoroughgoing sceptics; and complete "agnosticism" would seem to be equally capable of alliance with either form of social philosophy. On the other side, it cannot be said that the principles of orthodox Christians involve an acceptance of either alternative. The Church of England no doubt was mainly on the conservative side in general; and when "Christian Socialism" made a stir in the middle of the 19th century, its leading advocates were accused of being tacit allies of freethinkers and atheists. But we have changed all that. Perhaps staunch socialists may retain a suspicion that their patrons, if not insincere, have some tacit reservations or want of complete sympathy. But at any rate, the ecclesiastical as well as political parties seem to be anxious to accept as much, rather than as little, as they can of the socialist platform. Conservatives can argue that they are in one respect consistent. They were formerly denounced by the Radical for holding the doctrine of "paternal government." Now that he renounces or modifies individualism, he has to admit that if

Socialism and Individualism.

government should not be "paternal," it ought to be at least "fraternal." The true objection to the old theory was not to its interference, but to the hypocrisy which made a profession of interest in its governed a mere cloak for the selfishness of the ruler. When the Church appeared to the Radical to be essentially identified with a corrupt government, it shared the antipathy routed by the whole ruling class. It was one organ of a caste, and if it had remained in that position, the English Liberal would have agreed with his French contemporary that clericalism was the enemy. If the sentiment is not altogether absent on the English side of the Channel, it is far less bitter and does not connote the uncompromising animosity which instructs to intolerance. The difference might no doubt be explained by the social and intellectual differences; by the absence of the sharp division of classes and the offensive privileges which embittered the French struggle; or by the tendency to compromise which our neighbours consider to be illogical, and which we consider to be a proof of common-sense. Whatever the cause of the English attitude, the result is clearly favourable to toleration. The Church is not in solidarity with a close corporate system; and the lines which divide the orthodox from heretics or unbelievers are not coincident with vital differences upon social questions. The changes of social and political organization have been enormous, and may be described as a victory of democracy. But the democracy has not had to crush a compact and hostile body; it has rather found that the upper classes have been willing to accept its supremacy and carry out its policy. The Church, though an "appendage" of the aristocracy, has not been fitted either by its doctrines or its social position to ally itself unequivocally with the obstructive forces.

Toleration was closely associated with individualism. The most thoroughgoing individualists preached it with the greatest force and made it their most conspicuous doctrine. Yet the doctrine of individualism of the old dogmatic and absolute variety—whatever may be the explanation of that phenomenon—has certainly not led to a doctrine of practical toleration. The implication would seem to be that the individualist sentiment owed much of its strength to the antipathies generated in the prolonged struggle against a privileged class. It was not a simply "centrifugal" force, but a revolt against the claim to an artificial and unjust unity imposed for the comfort of the governing classes. It approved of voluntary associations though it objected to union by coercion. But when the old offensive claims were abandoned and government was controlled by the masses, unity could be reached spontaneously, and the distinction between voluntary and compulsory association became less important. The differences, no longer accentuated by incidental irritants, showed themselves to be less important than they had appeared. When men are brought to co-operate in common aims, whether by voluntary agreement or as members of a State organization, superficial differences show their futility; and toleration may be more acceptable when duties are discharged by public bodies than when they are left to organized sects, each propagating its own creed. Clearly, however, this presupposes a sufficient harmony in point of fact, and a certain underlying agreement between the various parties. The cause of such an agreement, so far as it exists, must be sought mainly in the intellectual development which is the correlative of the political changes.

Religion and Science.

One dominant factor in that development has of course been the vast growth of the natural sciences. The attempt to reach unity by discerning a residuum of belief common to all creeds seemed to be illusory. Atheists repudiated even the "religion of nature," and Christians declared it to be worthless. Meanwhile scientific research was suggesting a more thorough method. It took no dogma whatever for granted. It started from Descartes' principle of unlimited doubt, and accepted unequivocally the Baconian maxim of impartially interrogating nature. Its success in establishing a solid body of truth contrasted with the futility of metaphysical argumentations; and philosophers began to inquire whether the same methods might not be equally fruitful in a different sphere. History, politics, economics, and even philosophy and religion were treated by great thinkers on the precedent of the physical sciences; and, if the full constitution of the "moral sciences" is still indefinitely distant, the spirit of inquiry is at least radically changed. As historical knowledge extends and we become acquainted with the thoughts and institutions of remote races and periods, our theories have to expand. The acceptance of Newtonian astronomy, revealing the infinitesimal importance of our planet, had suggested that the universe was too big for the old-fashioned cosmogonies. The recognition that Christianity was but one of the many forms of belief which had prevailed over vast areas and indefinite periods had a similar effect upon the historical imagination. To study religions in a scientific spirit is to admit that all religions, if not equally good, spring at least from a common source. To a simple-minded missionary the likeness of Buddhism to Christianity suggested an artifice of the devil to distract his dupes by caricaturing the genuine Church. To the rational inquirer the phenomenon is an interesting illustration of his fundamental principles. The spread of investigation goes along with the rapid confrontation of all nations, which make it as impossible for the vulgar as for the scientific inquirer to identify his village with the universe and his creed with the sole revelation of the Deity. The growth of science, in short, suggested the contrast at once between rational and arbitrary authority; between fruitful methods and endless metaphysical logomachies, and between the impartial comparison of systems of belief as products of a common intellectual constitution and the assumption that one must come from God and all others from the devil.

The perception that a religion for philosophers must have some wider basis than a total tradition was of course nothing new. It was the essential contention of the old deists. Pope's "universal prayer" addressed to the "Father of all in every age, in every clime adored," gives the sentiment of the cultivated minds of his time. When Tennyson's phrase about our "little systems" which "have their day and cease to be" became at once proverbial, it implied that the thought was already congenial to far wider circles. Pope scandalized his orthodox contemporaries; Tennyson was taken to be obviously edifying. Huxley has said that Tennyson was the man of letters of his day who had most fully appreciated the tendencies of scientific thought. Anyhow he expressed most clearly a sentiment with which the more educated classes were already saturated in the first half of the century, and which it would be easy to illustrate from all the chief writers of the time. A strong religious sentiment and a belief in a sufficiently vague creed was combined with a conviction that the old dogmatic systems were effete. If the formulæ were still current, and an attempt to challenge them openly exposed an unbeliever to general disapproval, the unreality of the "little systems" was not the less felt; and the distinctions between rival sects could only interest professional divines, who had been somehow sheltered from the wider current of living thought.

The controversies which excited us in the 'sixties illustrated the state of mind. They indicated to the more thoughtful the fact that scientific theories were coming into direct collision with accepted religious creeds, and that, if philosophy was not to be, as materialists held, a simple department of physical science, it must at least conform to the established scientific base. To the ordinary mind, at first sight, it suggested simply an attack upon the first chapter of the book of Genesis. We were invited to substitute a pair of chimpanzees for Adam and Eve—the question upon which Huxley had his famous encounter with Wilberforce. The apologists had gone on arguing upon the old issue, inherited from predecessors by whom the literal truth of the whole Biblical narrative had been taken for granted as a postulate admitted on all hands. They tried for a time to maintain the old ground against Colenso and the Essayists and Reviewers as well as against the Darwinians. But it rapidly became plain that the position was an anachronism. Everything that could be called living thought had long ebbed away from its foundations. The primitive history might still be taught in schools; the old legends and the dogmas connected with them might live on as survivals; but even to ordinary common-sense it was undeniable that it was a monstrous blunder really to stake the truth of religion in general upon the possibility of maintaining the validity of the ancient record. The history or the dogma could not be independently proved; though they might, if properly rationalized, be admissible on some other authority, whether, as Catholics held, the authority were the Church, or as liberal theologians, a philosophy which might be adumbrated by imagery adapted to the prehistoric intellect. The position accordingly changed with singular rapidity. A creed must be defended, not by taking the discredited accrescences as the fulcrum of your argument, but by accepting them as incidental, useful, or perhaps needless accessories of the vital principles really embodied. The process was less one of confuting genuine beliefs than of a general awakening to the fact that many of the ostensible beliefs only lay on the surface of thought or could be abandoned without injury to deeper convictions.

The change, therefore, was clearly prepared by the whole course of speculation. It corresponds to the widening of the intellectual horizon which has made it more and more impossible to damn foreigners, heretics, and the heathen "in the lump," and shown the wickedness of the persecuting sentiment. The orthodox position must be defended, so far as defensible, upon grounds far wider than the old. The divine who now maintains the truth of Christianity no longer holds himself pledged to show the absolute falsity of the other religions which have satisfied the vast majority of the race. He argues that they are imperfect approximations to the ideal which Christianity alone can present in its manifestations of purity and the working of the same divine favour in a distracting medium. The dogmatic system must be correspondingly modified. The old controversies in which Protestants and Catholics wrangled so long and so fiercely have become hopelessly uninteresting. When the assumption that every word of the Bible is literally true disappears, the most superannuated theology can no longer appeal to isolated texts or attempt to explain the relations of man to his Creator from the details of ancient legends. Such argumentations have still a deep historical interest, but only when we come to see that that really represents the attempt to approach great moral problems with a hopelessly imperfect intellectual apparatus. Meanwhile the philosophical basis has changed as much as the historical. The old metaphysical system has been superseded by more fruitful schemes of thought, and if the dogmas are still verbally maintained, we admit that the reasoning by which they were at first elaborated was often more a juggling with words, and implied ignorance of the inevitable limits of human thought. They may be true in some sense; they may, perhaps, be imperfect versions of vitally important truths, but our belief must at least be justified by some different method. They must be regarded as corollaries from the truth of a religious system which is ultimately supported by its position in universal history or as an embodiment of a demonstrable philosophy. The modern apologist argues from the moral beauty of Christianity, not from the internal evidence. He does not base his reasoning upon the miracles, though he is prepared to accept them as congenial incidents. The sceptic might be right in rejecting the supernatural, if an isolated interference with the order of nature were made an ultimate ground of belief. But the supernatural becomes in a sense natural, if we regard it as a manifestation of the divine power which underlies all phenomena. The apologist must appeal to history; not to a particular narrative or to an isolated series of events, but to the whole history of mankind as becoming intelligible when we regard the Christian revelation as the central event to which all other history converges.

Widening of the intellectual horizon.

The agnostic of course holds that the implied concession is fatal to the creed defended. The dogmas have to be interpreted so as to lose all significance; and to accept a genuine historical method is to abandon any really supernatural element. The divine is virtually surrendering when he tries an impossible conciliation. Still a certain approximation is implied as to the method of inquiry and the criterion of truth. The acceptance by divines of evolutionist theories, to which I referred at starting, is no doubt perfectly sincere, and has obvious recommendations. When the first alarm subsided, it became evident that some such theory was congenial to the philosophical needs of the time as well as to scientific tendencies. The order of nature had to be regarded as a continuous process stretching indefinitely backwards and forwards, and every conception of an abrupt beginning or ending had to be banished. The barriers between species were not absolute and impassable gulfs, but implied a common origin, and the slow elaboration by antagonism or association of a consistent order. This change in the natural sciences corresponded to the demands already made in a different sphere by the growth of more philosophical conceptions of the history of mankind. If man himself had to take his place among other living beings, and the impassable gulf to be obliterated, the religious creeds must be regarded as varying products of the instincts common to all men. They could not be simply false, and might contain elements capable of incorporation in superior form of belief. Authority could not be in any single body laying down absolute decrees, but can only be claimed by the creed which submits to the test of the freest discussion, and is elaborated by the gradual convergence of reasonable thought. This, again, is to assert the essential principle of toleration, to which men's minds had been slowly awakening through the whole course of modern speculation. It expressed the ideal of all the more liberal divines who had seen the necessity of basing a tenable creed upon doctrines wide enough to correspond to all the results of inquiry in every department of human knowledge; and the general sentiment even of popular audiences was already on their side. An arbitrary dogmatism, working by threats instead of argument, had grown to be hateful and contemptible, and it had become obvious that the identification of religions with adherence to a particular legend was not a support, but a fatal limitation to its credibility.

The same tendency, we may hope, is apparent in the sphere of politics. Popular orators, no doubt, have still to denounce each other pretty heartily, and to represent Toryism or Liberalism as an emanation from the good or evil principle. Still, some advance has been made in the last century. Democrats used to regard kings and priests as responsible for all the evils that afflict mankind, and aristocrats to denounce revolutionists as directly inspired by the devil. The antagonism is hardly so internecine, and the change, we may hope, is due to a more philosophical mode of thought. A revolution, it has been said, always justifies itself, because it can only be brought about by profound grievances. This is perfectly true in the same sense in which it is true that the resistance to evolution has always some justification. There must have been some cause for the attachment to the old order. The line between good and evil is never precisely identical with the line between parties; and the first condition of sound reasoning on such matters is to attempt to understand your adversary, instead of simply denouncing him. The doctrine applies to those social questions which still arouse the bitterest antipathies. Capitalists and labourers may regard each other as simply children of the devil. Still, so far as newer scientific methods of thought gain acceptance, this pleasing assumption is modified. The old method of settling the question by laying down absolute principles of right is seen to be absurd. In place of it we have to try to understand the mode in which the complex order has been developed, to admit that the fact of its existence implied that it satisfied some general requirements, and that it must be modified tentatively and gradually, so as to approximate to a more widely satisfactory state. A tempting short-cut to the solution of problems was offered by the assumption that justice requires the enforcement of equality, or that it requires that every man should have an absolute right to improve his own position. Each doctrine may be stated plausibly, but when they come into collision we see that neither can be laid down absolutely. We have to consider the conditions by which each is limited, and how far it is applicable. That can only be done by understanding the real nature of the existing system, studying the way in which it has grown, and the functions which have been discharged by its constituent facts. The change which has come over the methods of political economists corresponds to a growing perception of the necessity of this as the only scientific treatment. So far as it is accepted, we are agreed as to the method to be pursued and the criterion which is to be decisive. It supposes not the triumph of one of two contradictory principles, but the gradual elaboration of a comprehensive theory which will do justice to both. The authority to which it appeals is that of impartial and laborious investigation of facts; and that is the kind of authority which rests upon free discussion, and therefore implies toleration in the widest sense.

Political tolerance.

One other conclusion follows. The existence of any creed or institution is a *prima facie* ground of justification. Some, it may be, are simply pernicious. But they must have had some cause; and the longer they have thriven, the greater the presumption that they have had some utility. The scientific spirit, therefore, implies that explanation should precede, and will probably qualify, denunciation. The Darwinian assumes that the survival of a species proves its fitness to its conditions; and for that reason the evolutionist theory has commended itself to the orthodox. Undoubtedly it supplies the strongest argument in their favour. If they cannot safely appeal to any arbitrary authority, or to a purely dialectical proof, they can point to undeniable facts. That religious institutions have played an enormous part in the history of civilization, and that at the present day, in spite of all intellectual revolutions, the religious instinct in some shape represents a

Scientific presumptions in favour of religion.

social force of enormous power, is obviously undeniable. If the particular dogmatic systems have ceased to correspond to genuine beliefs, we must ask to what cause we attribute the enduring vitality of the sects and the loyal devotion which they command. The old explanations are no longer available. We cannot set down religious beliefs as simply the product of priestly imposture. That short and easy method has become obsolete along with the claims to which it was opposed. Nor is it easy to admit the proposition that religious beliefs as a whole represent simply a stupendous misunderstanding generated by the blunders of primitive savages, a set of simply erroneous superstitions, which can be eliminated without difficulty from the general system of thought. Unless they had been more deeply rooted in human nature, they would have died out before the newer lights of intellectual advance. The truth indeed may be that the view which identifies a religion with its avowed creed, and supposes that a man first persuades himself of the truth of certain tenets and then deduces rules for conduct, inverts the true process. A religion in the full sense is a product of the whole social, imaginative, and emotional nature, and the dogmatic system represents a congenial construction which has to use for its materials the prevalent conceptions of the period. When the dogma become incredible to the more intelligent the underlying instincts do not lose strength, but cannot be fully satisfied until some more simple system is worked out. Meanwhile men are often contented with the old scheme of belief, subject to certain tacit reservations instead of open repudiation. The problem of replacing the old synthesis remains, and those who reject the old creeds most completely, and are most convinced of the duty of expressing their dissent, may be most aware of the extreme difficulty of the task.

What institutions, if any, are to take the place of the old churches, and how the emotions which found expression in times of the old belief are to find satisfactory utterance in terms reconcilable to scientific knowledge, is our present problem, which has not been attacked with much success, and must be the work of many generations. The believer who admits, as he is forced to admit, that the old language is obsolete, but that it yet contains a pure essence of truth, has still to define what that truth may be. To me it appears that he will not find the problem of easy solution; but, so far as I am here concerned, I need only note that the tendencies which I have attempted to describe imply a growth of mutual toleration. There is at least an agreement that a simple creed must be tested upon the widest appreciation of the whole process of intellectual development; that the only authority which can permanently demand assent is the gradual convergence of belief under the freest possible play of thought, and that every honest phase of opinion has a right to a fair hearing, and may be of some use even if only by provoking the exposure of its own fallacy.

ENCYCLOPÆDIA BRITANNICA

NEW VOLUMES.

ELECTIONS

Elections.—*United Kingdom.*—Considerable alterations have been made in recent years in the law of Great Britain and Ireland relating to the procedure at parliamentary and municipal elections, and to election petitions. The Local Government Acts have also introduced new classes of voters (county and parochial electors), and have extended to the elections in which they take part the rules applicable to municipal elections.

As regards parliamentary elections, the most important of the amending statutes is the Corrupt and Illegal Practices Act, 1883. This Act, and the Parliamentary Elections Act, 1868, as amended by it, and other enactments dealing with corrupt practices, are temporary Acts requiring annual renewal. As regards municipal elections, the Corrupt Practices (Municipal Elections) Act, 1872, has been repealed by the Municipal Corporations Act, 1882, for England, and by the Local Government (Ireland) Act, 1898, for Ireland. The governing enactments for England are now the Municipal Corporations Act, 1882, part iv., and the Municipal Elections (Corrupt and Illegal Practices) Act, 1884, the latter annually renewable. The provisions of these enactments have been applied with necessary modifications to municipal and other local government elections in Ireland by orders of the Irish Local Government Board made under powers conferred by the Local Government (Ireland) Act, 1898. In Scotland the law regulating municipal and other local government elections is now to be found in the Elections (Scotland) (Corrupt and Illegal Practices) Act, 1890.

The alterations in the law have been in the direction of greater strictness in regard to the conduct of elections, and increased control in the public interest over the proceedings on election petitions. Various acts and payments which were previously lawful in the absence of any corrupt bargain or motive are now altogether forbidden under the name of "illegal practices" as distinguished from "corrupt practices." Failure on the part of a parliamentary candidate or his election agent to comply with the requirements of the law in any particular is sufficient to invalidate the return. Certain relaxations are, however, allowed in consideration of the difficulty of absolutely avoiding all deviation from the strict rules laid down. Thus, where the judges who try an election petition report that there has been treating, undue influence, or any illegal practice by the candidate or his election agent, but that it was trivial, unimportant, and of a limited character, and contrary to the orders and without the sanction or connivance of the candidate or his election agent, and that the candidate and his election agent took all reasonable means for preventing corrupt and illegal practices, and that the election was otherwise free from such practices on their part, the election will not be avoided. The court has also the power to relieve from the consequences of certain innocent contraventions of the law caused by inadvertence or miscalculation.

Election petitions.

The jurisdiction in regard to election petitions formerly exercised by the Court of Common Pleas was on the abolition of that court by the Judicature Act, 1873, transferred to the Common Pleas Division, and again on the abolition of that division was transferred to the King's Bench Division, in whom it is now vested. The rota of judges for the trial of election petitions is also supplied by the King's Bench Division. The trial now takes place before two judges instead of one; and, when necessary, the number of judges on the rota may be increased. Both the judges who try a petition are to sign the certificates to be made to the Speaker. If they differ as to the validity of a return, they are to state such difference in their certificate, and the return is to be held good; if they differ as to a report on any other matter, they are to certify their difference and make no report on such matter. The director of public prosecutions attends the trial personally or by representative. It is his duty to watch the proceedings in the public interest, to issue summonses to witnesses whose evidence is desired by the court, and to prosecute before the Election Court or elsewhere those persons whom he thinks to have been guilty of corrupt or illegal practices at the election in question. If an application is made for leave to withdraw a petition, copies of the affidavits in support are to be delivered to him; and he is entitled to be heard and to call evidence in opposition to such application. Witnesses are not excused from answering criminating questions; but their evidence cannot be used against them in any proceedings except criminal proceedings for perjury in respect of that evidence. If a witness answers truly all questions which he is required by the court to answer, he is entitled to receive a certificate of indemnity, which will save him from all proceedings for any offence under the Corrupt Practices Acts committed by him before the date of the certificate at or in relation to the election, except proceedings to enforce any incapacity incurred by such offence. An application for leave to withdraw a petition must be supported by affidavits from all the parties to the petition and their solicitors, and by the election agents of all of the parties who were candidates at the election. Each of these affidavits is to state that to the best of the deponent's knowledge and belief there has been no agreement and no terms or undertaking made or entered into as to the withdrawal, or, if any agreement has been made, shall state its terms. The applicant and his solicitor are also to state in their affidavits the grounds on which the petition is sought to be withdrawn. If any person makes an agreement for the withdrawal of a petition in consideration of a money payment, or of the promise that the seat shall be vacated or another petition withdrawn, or omits to state in his affidavit that he has made an agreement, lawful or unlawful, for the withdrawal, he is guilty of an indictable misdemeanour. The report of the judges to the Speaker is to contain particulars as to illegal practices similar to those previously required as to corrupt practices; and they are to report further whether any candidate has been guilty by his agents of an illegal practice, and whether certificates of indemnity have been given to persons reported guilty of corrupt or illegal practices.

The Corrupt Practices Acts apply, with necessary variations in details, to parliamentary elections in Scotland and Ireland.

The amendments in the law as to municipal elections are generally similar to those which have been made in parliamentary election law. The procedure on trial of petitions is substantially the same, and wherever no other provision is made by the Acts or rules the procedure on the trial of parliamentary election petitions is to be followed. The commissioner who tries a petition sends to the High Court a certificate of the result, together with reports as to corrupt and illegal practices, &c., similar to those made to the Speaker by the judges who try a parliamentary election petition. The Municipal Elections (Corrupt and Illegal Practices) Act, 1884, applies to school board elections subject to certain variations, and has been extended by the Local Government Act, 1888, to County Council elections, and by the Local Government Act, 1894, to elections by parochial electors. The law in Scotland is on the same lines, and extends to all non-parliamentary elections, and, as has been stated, the English statutes have been applied with adaptations to all municipal and local government elections in Ireland. (L. L. S.)

United States.—Elections are much more frequent in the United States than they are in Great Britain, and they are also more complicated. The terms of elective officers are shorter; and as there are also more offices to be filled, the number of persons to be voted for is necessarily much greater. In the year of a presidential election the citizen may be called upon to vote at one time for all of the following:—(1) National candidates—President and Vice-President (indirectly through the electoral college) and members of the House of Representatives; (2) state candidates—governor, members of the state legislature, attorney-general, treasurer, &c.; (3) county candidates—sheriff, county judges, district attorney, &c.; (4) municipal or town candidates—mayor, aldermen, selectmen, &c. The number of persons actually voted for may therefore be ten or a dozen, or it may be many more. In addition, the citizen is often called upon to vote yea or nay on questions such as amendments to the state constitutions, granting of licences, and approval or disapproval of new municipal undertakings. As there may be, and generally is, more than one candidate for each office, and as all elections are now, and have been for many years, conducted by ballot, the total number of names to appear on the ballot may be one hundred or may be several hundred. These names are arranged in different ways, according to the laws of the different states. Under the Massachusetts law, which is considered the best by reformers, the names of candidates for each office are arranged alphabetically on a "blanket" ballot, as it is called from its size, and the elector places a mark opposite the names of such candidates as he may wish to vote for. Other states, New York for example, have the blanket system, but the names of the candidates are arranged in party columns. Still other states allow the grouping on one ballot of all the candidates of a single party, and there would be therefore as many separate ballots in such states as there were parties in the field.

The qualifications for voting, while varying in the different states in details, are in their main features the same throughout the Union. A residence in the state is required of from three months to two years. Residence is also necessary, but for a shorter period, in the county, city or town, or voting precinct. A few states require the payment of a poll tax. Some require that the voter shall be able to read and understand the Constitution. This latter qualification has been introduced into several of the Southern states as a means of disqualifying the ignorant coloured voters. In all, or practically all, the states idiots, convicts, and the insane are disqualified; in some states paupers; and in some of the Western states the Chinese. In some states women are allowed to vote on certain questions, or for the candidates for certain offices, especially school commissioners; and in a few of the Western states women have the same rights of suffrage as men. The number of those who are qualified to vote, but do not avail themselves of the right, varies greatly in the different states and according to the interest taken in the election. As a general rule, but subject to exceptions, the national elections call out the largest number, the state elections next, and the local elections the smallest number of voters. In an exciting national election between 80 and 90 per cent. of the qualified voters actually vote, a proportion considerably greater than in Great Britain or Germany.

The tendency of recent years has been towards a decrease both in the number and in the frequency of elections. A President and Vice-President are voted for every fourth year, in the years divisible by four, on the first Tuesday following the first Monday of November. Members of the national House of Representatives are chosen for two years on the even-numbered years. State and local elections take place in accordance with state laws, and may or may not be on the same day as the national elections. Originally the rule was for the states to hold annual elections; in fact, so strongly did the feeling prevail of the need in a democratic country for frequent elections, that the maxim "where annual elections end, tyranny begins," became a political proverb. But opinion gradually changed even in the older or Eastern states, and in 1901 Massachusetts and Rhode Island were the only states in the Union holding annual elections for governor and both houses of the state legislature. In the Western states especially state officers are chosen for longer terms—in the case of the governor often for four years—and the number of elections has correspondingly decreased. Another cause of the decrease in the number of elections is the growing practice of holding all the elections of any year on one and the same day. Before the Civil War the state of Pennsylvania, for instance, held its state elections several months before the national elections in November. Similarly, Ohio and Indiana, until within the last few years, held their state elections early in October. The selection of one day in the year for all elections held in that year has resulted in a considerable decrease in the total number.

Another tendency of recent years, but not so pronounced, is to hold local elections in what is known as the "off" year; that is, on the odd-numbered year, when no national election is held. The object of this reform is to encourage independent voting. The average American citizen is only too prone to carry his national political predilections into local elections, and to vote for the local nominees of his party, without regard to the question of fitness of candidates and the fundamental difference of issues involved. This tendency to vote the entire party ticket is the more pronounced because under the system of voting in use in many of the states all the candidates of the party are arranged on one ticket, and it is much easier to vote a straight or unaltered ticket than to change or "scratch" it. Again, the voter, especially the ignorant one, refrains from scratching his ticket, lest in some way he should fail to comply with the technicalities of the law and his vote be lost. On the other hand, if local elections are held on the "off" or odd-year, and there be no national or state candidates, the voter feels much more free to select only those candidates whom he considers best qualified for the various offices.

On the important question of the purity of elections it is difficult to speak with precision. In many of the states, especially those with an enlightened public spirit, such as most of the New England states and many of the North-Western, the elections are fairly conducted, there being no intimidation at all, little or no bribery, and an honest count. It can safely be said that through the Union as a whole the tendency of recent years has been decidedly towards greater honesty of elections. This is owing to a number of causes: (1) The selection of a single day for all elections, and the consequent immense number voting on that day. Some years ago, when for instance the Ohio and Indiana elections were held a few weeks before the general election, each party strained every nerve to carry them, for the sake of prestige and the influence on other states. In fact, presidential elections were often felt to turn on the result in these early voting states, and the party managers were none too scrupulous in the means employed to carry them. Bribery has decreased in such states since the change of election day to that of the rest of the country. (2) The enactment in most of the states (the number in 1901 being 40 out of the 45) of the Australian or secret ballot laws. These have led to the secrecy of the ballot, and hence to a greater or less extent have prevented intimidation and bribery. (3) Educational or other such test, more particularly in the Southern states, the object of which is to exclude the coloured, and especially the ignorant coloured, voters from the polls. In those Southern states in which the coloured vote was large, and still more in those in which it was the majority, it was felt among the whites that intimidation or ballot-box stuffing was justified by the necessity of white supremacy. With the elimination of the coloured vote by educational or other tests the honesty of elections has increased. (4) The enactment of new and more stringent registration laws. Under these laws only those persons are allowed to vote whose names have been placed on the rolls a certain number of days or months before election. These rolls are open to public inspection, and the names may be challenged at the polls, and "colonization" or repeating is therefore almost impossible. (5) The reform of the civil service and the gradual elimination of the vicious principle of "to the victors belong the spoils." With the reform of the civil service elections become less a scramble for office and more a contest of political or economic principle. They bring into the field, therefore, a better class of candidates. (6) The enactment in a number of states of various other laws for the prevention of corrupt practices, for the publication of campaign expenses, and for the prohibition of party workers from coming within a certain specified distance of the polls. In the state of Massachusetts, for instance, an Act passed in 1892, and subsequently amended, provides that political committees shall file a full statement, duly sworn to, of all campaign expenditures made by them. The Act applies to all public elections except that of town officers, and also covers nominations by caucuses and conventions as well. Apart from his personal expenses such as postage, travelling expenses, &c., a candidate is prohibited from spending anything himself to promote either his nomination or his election, but he is allowed to contribute to the treasury of the political committee. The law places no limit on the amount that these committees may spend. The reform sought by the law is through publicity, and not only are details of receipts and expenditures to be published, but the names of contributors and the amount of their contributions. In the state of New York the Act which seeks to prevent corrupt practices, relies in like manner on the efficacy of publicity, but it is less effective than the Massachusetts law in that it provides simply for the filing by the candidates themselves of sworn statements of their own expenses. There is nothing to prevent their contributing to political committees, and the financial methods and the amounts expended by such committees are not made public. But behind all these causes that have led to more honest elections lies the still greater one of a healthier public spirit. In the reaction following the Civil War all reforms halted. In recent years, however, a new and healthier interest has sprung up in things political; and one result of this improved civic spirit is seen in the various laws for purification of elections. It may now be safely affirmed that in the majority of states the elections are honestly conducted; that intimidation, bribery, stuffing of the ballot boxes or other forms of corruption, when they exist, are owing in large measure to temporary or local causes; and that the tendency of recent years has been towards a decrease in all forms of corruption.

The expenses connected with elections, such as the renting and preparing of the polling-places, the payment of the clerks and other officers who conduct the elections and count the vote, are borne by the community. A candidate, therefore, is not, as far as the law is concerned, liable to any expense whatever. As a matter of fact he does commonly contribute to the party treasury, though in the case of certain candidates, particularly those for the presidency and for judicial offices, financial contributions are not general. The amount of a candidate's contribution varies greatly, according to the office sought, the state in which he lives, and his private wealth. On one occasion, in a district in New York, a candidate for Congress is credibly believed to have spent at one election $50,000. On the other hand, in a Congressional election in a certain district in Massachusetts, the only expenditure of one of the candidates was for the two-cent stamp placed on his letter of acceptance. No estimate of the average amount expended can be made. It is, however, the conclusion of Mr Bryce, in his *American Commonwealth*, that as a rule a seat in Congress costs the candidate less than a seat for a county division in the House of Commons. (See also BALLOT.) (F. H. H.)

ELECTRICITY.

UNDER the general heading of ELECTRICITY we place the following articles on electric theory, which are given in the order named :—

I. ELECTRIC CONDUCTION.
II. ELECTROLYTIC CONDUCTION.
III. ELECTRIC CURRENT.
IV. ELECTRIC UNITS.
V. ELECTRIC DISCHARGE THROUGH GASES.
VI. ELECTRIC WAVES.

In addition to these articles, the following, dealing with allied questions, practical and scientific, will be found under separate headings, to which reference must be made :— ACCUMULATORS; ATMOSPHERIC ELECTRICITY; DYNAMO; ELECTRICITY SUPPLY (1. General Principles; 2. Lighting; 3. Traction; 4. Industrial Development); ELECTRO-CHEMISTRY; ELECTROMAGNET; ELECTRO-METALLURGY; MAGNETISM; MAGNETISM, TERRESTRIAL; MAGNETO-OPTICS; MEASURING INSTRUMENTS, ELECTRIC; POWER TRANSMISSION, ELECTRIC; TELEGRAPH; TELEPHONE; THERMO-ELECTRICITY; TRANSFORMERS; WELDING, ELECTRIC.

I. ELECTRIC CONDUCTION.

The *Electric Conductivity* of a substance is that property in virtue of which all its parts come spontaneously to the same electric potential if the substance is kept free from the operation of electric force. Accordingly, the reciprocal quality, *Electric Resistivity*, may be defined as a quality of a substance in virtue of which a difference of potential can exist between different portions of the body when these are in contact with some constant source of electromotive force, in such a manner as to form part of an electric circuit. Deferring more exact quantitative definitions for a moment, we may say that all material substances possess in some degree, large or small, Electric Conductivity, and may for the sake of convenience be broadly divided into five classes in this respect. Between these, however, there is no sharply-marked dividing line, and the classification must therefore be accepted as a more or less arbitrary one. These divisions are: (1) Metallic Conductors, (2) Non-Metallic Conductors, (3) Electrolytic Conductors, (4) Dielectric Conductors, (5) Gaseous Conductors. The first class comprises all metallic substances, and those mixtures or combinations of metallic substances known as alloys. The second includes such non-metallic bodies as carbon, silicon, many of the oxides and peroxides of the metals, and probably also some oxides, sulphides, and selenides. Many of these substances, for instance carbon and silicon, are well known to have the property of existing in several allotropic forms, and in some of these conditions, so far from being fairly good conductors, they may be almost perfect non-conductors. An example of this is seen in the case of carbon in its three allotropic conditions, charcoal, graphite, and diamond. As charcoal it possesses a fairly well-marked but not very high conductivity in comparison with metals; as graphite, a conductivity about one-four-hundredth of that of iron; but as diamond, so little conductivity that the substance is included amongst insulators or non-conductors. The third class, namely, the Electrolytic Conductors, comprises all those substances which undergo chemical decomposition when they form part of an electric circuit traversed by an electric current. The whole subject of Electrolytic Conduction has of late years acquired an immense importance from its bearing on chemical theory, and it is considered separately under the next heading (see II. ELECTROLYTIC CONDUCTION). The fourth class includes those substances which are generally called Insulators or Non-Conductors, but which are better denominated Dielectric Conductors; it comprises such solid substances as mica, ebonite, shellac, indiarubber, gutta-percha, paraffin, and a large number of liquids, chiefly hydrocarbons. These substances differ greatly in insulating power, and according as the conductivity is more or less marked, they are spoken of as bad or good insulators. Amongst the latter many of the liquid gases hold a high position. Thus, liquid oxygen and liquid air have been shown by J. Dewar to be almost perfect non-conductors of electricity, but their absolute resistivity has not yet been numerically determined. The fifth and last class of Conductors includes the Gases. The conditions under which this class of substance becomes possessed of electric conductivity are considered more in detail below (see V. ELECTRIC DISCHARGE). In connexion with metallic conductors, it is a fact of great interest and considerable practical importance, that although the majority of metals when in a finely divided or powdered condition are practically non-conductors, a mass of metallic powder or filings may be made to pass suddenly into a conductive condition by being exposed to the influence of an electric wave. The same is true of the loose contact of two metallic conductors. Thus if a steel point, such as a needle, presses very lightly against a metallic plate, say of aluminium, it is found that this metallic contact, if carefully adjusted, is non-conductive, but that if an electric wave (see VI. ELECTRIC WAVES) is created anywhere in the neighbourhood, this non-conducting contact passes into a conductive state.[1]

Standard Ohm.

Electric conductivity is measured by making a comparison with the conductivity of a known mass of a standard substance taken in a stated form. The practical unit of conductivity is the conductivity of a column of pure mercury at 0° C. having a uniform cross-section, a length of 106·3 centimetres, and a mass of 14·4521 grammes. The practical unit of electric resistance, to which was given legal definition in Great Britain by the authority of the Queen in Council in 1894, is defined to be the "resistance offered to an invariable electric current by a column of mercury at the temperature of melting ice, 14·4521 grammes in mass, of a constant cross-sectional area, and a length 106·3 centimetres." This has been legalized as a standard in Great Britain, France, Germany, and the United States, and is denominated "The International or Standard Ohm." It is intended to represent as nearly as possible a resistance equal to 10^9 absolute C.G.S. units of electric resistance. Convenient multiples and subdivisions of the ohm are the microhm and the megohm, the former being a millionth part of an ohm, and the latter a million ohms. The resistivity of substances is then numerically expressed by stating the resistance of one cubic centimetre of the substance taken between opposed faces, and expressed in ohms, microhms, or megohms, as may be most convenient. The reciprocal of the ohm is called the mho, which is the unit of conductivity, and is defined as the conductivity of a substance whose resistance is one ohm. The absolute unit of conductivity is the conductivity of a substance whose resistivity is one absolute C.G.S. unit, or one-thousandth-millionth part of an ohm. Resistivity is a quality in which material substances differ very widely. The metals and alloys, broadly speaking, are good conductors, and their resistivity is conveniently expressed in microhms per cubic centimetre, or in absolute C.G.S. units. Very small differences in density and in chemical purity make, however, immense differences in electric resistivity; hence the values given by different experimentalists for the resistivity of known metals differ to a considerable extent.

It is found convenient to express the resistivity of metals in two different ways: (1) We may state the resistivity of one cubic centimetre of the material in microhms or absolute units taken between opposed faces. This is called the *Volume-Resistivity*. (2) We may ex-

[1] This fact, investigated and discovered independently by Hughes, Onesti, Branly, Lodge, and others, is applied in the construction of the "Coherer," or sensitive tube employed as a detector or receiver in that form of "wireless telegraphy" chiefly developed by Marconi.

press the resistivity by stating the resistance in ohms offered by a wire of the material of uniform cross-section, one metre in length, and one gramme in weight. This numerical measure of the resistivity is called the *Mass-Resistivity*. The mass-resistivity of a body is connected with its volume-resistivity and the density of the material in the following manner:—The mass-resistivity, expressed in microhms per metre-gramme, divided by 10 times the density is numerically equal to the volume-resistivity per centimetre-cube in absolute C.G.S. units. The mass-resistivity per metre-gramme can always be obtained by measuring the resistance and the mass of any wire of uniform cross-section of which the length is known, and if the density of the substance is then measured, the volume-resistivity can be immediately calculated.

If R is the resistance in ohms of a wire of length l, uniform cross-section s, and density d, then taking ρ for the volume-resistivity we have

$$10^9 R = \rho \frac{l}{s}\text{; but } lsd = M$$

where M is the mass of the wire. Hence

$$10^9 R = \rho d \frac{l^2}{M}.$$

If $l=100$ and $M=1$, then $R=\rho^1=$ resistivity in ohms per metre-gramme and $10^9 \rho^1 = 10{,}000 d\rho$,

or $\rho = 10^5 \rho^1 / d$

and $\rho^1 = 10{,}000 MR/l^2$.

The following rules, therefore, are useful in connexion with these measurements. To obtain the mass-resistivity per metre-gramme of a substance in the form of a uniform metallic wire:—Multiply together 10,000 times the mass in grammes, and the total resistance in ohms, and then divide by the square of the length in centimetres. Again, to obtain the volume-resistivity in C.G.S. units per centimetre-cube, the rule is to multiply the mass-resistivity in ohms by 100,000 and divide by the density. These rules, of course, apply only to wires of uniform cross-section. In the following Tables I., II., and III. are given the mass and volume resistivity of ordinary metals and certain alloys expressed in terms of the Standard Ohm or the absolute C.G.S. unit of resistance, the values being calculated from the experiments of Matthiessen between 1860 and 1865, and from later results obtained by Fleming and Dewar in 1893.

TABLE I. *Electric Mass-Resistivity of Various Metals at* 0° *C., or Resistance per Metre-gramme in Standard Ohms at* 0° *C.* (Matthiessen.)

Metal.	Resistance at 0° C. in Standard Ohms of a Wire 1 Metre long and Weighing 1 Gramme.	Approximate Temperature Coefficient near 20° C.
Silver (annealed)	·1523	0·00377
Silver (hard-drawn)	·1657	
Copper (annealed)	·1421	0·00388
Copper (hard-drawn)	·1449 (Matthiessen's Standard)	
Gold (annealed)	·4025	0·00365
Gold (hard-drawn)	·4094	...
Aluminium (annealed)	·0757	...
Zinc (pressed)	·4013	...
Platinum (annealed)	1·9337	...
Iron (annealed)	·765	...
Nickel (annealed)	1·058 [1]	...
Tin (pressed)	·9618	0·00365
Lead (pressed)	2·2268	0·00387
Antimony (pressed)	2·3787	0·00389
Bismuth (pressed	12·8554 [2]	0·00354
Mercury (liquid)	12·885 [3]	0·00072

[1] and [2] The values for nickel and bismuth given in the table are much higher than more recent values obtained with pure electrolytic nickel and bismuth.

[3] The value here given, namely, 12·885, for the electric mass-resistivity of liquid mercury as determined by Matthiessen is now known to be too high by nearly one per cent. The value at present accepted is 12·789 ohms per metre-gramme at 0° C.

TABLE II. *Electric Volume-Resistivity of Various Metals at* 0° *C., or Resistance per Centimetre-cube in C.G.S. Units at* 0° *C.*

This table is calculated from the results of experiments made by Matthiessen, employing the values given by Fleeming Jenkin in his Cantor Lectures (Soc. of Arts, 1866) for the resistance in B.A. units of a uniform circular-sectioned wire of the metal, one metre long and one millimetre in diameter taken at 0° C. The figures given by Jenkin have been reduced to Standard Ohms and C.G.S. units by multiplying by $\frac{\pi}{4} \times \cdot 9866 \times 10^5 = 77{,}485$.

Metal.	Volume-Resistivity at 0° C. in C.G.S. Units.
Silver (annealed)	1,502
Silver (hard-drawn)	1,629
Copper (annealed)	1,594
Copper (hard-drawn)	1,630 [1]
Gold (annealed)	2,052
Gold (hard-drawn)	2,090
Aluminium (annealed)	3,006
Zinc (pressed)	5,621
Platinum (annealed)	9,035
Iron (annealed)	10,568
Nickel (annealed)	12,429 [2]
Tin (pressed)	13,178
Lead (pressed)	19,580
Antimony (pressed)	35,418
Bismuth (pressed)	130,872
Mercury (liquid)	94,896 [3]

[1] The value (1630) here given for hard-drawn copper is about one-quarter per cent. higher than the value now adopted, namely, 1626. The difference is due to the fact that either Jenkin or Matthiessen did not employ precisely the value at present employed for the density of hard-drawn and annealed copper in calculating the volume-resistivities from the mass-resistivities.

[2] Matthiessen's value for nickel is much greater than that obtained in more recent researches. (See Matthiessen and Vogt, *Phil. Trans. Roy. Soc.*, 1863, and J. A. Fleming, *Proc. Roy. Soc.*, Dec. 1899.)

[3] Matthiessen's value for mercury is nearly one per cent. greater than the value adopted at present as the mean of the best results, namely, 94,070.

TABLE III. *Electric Volume-Resistivity of Various Metals at* 0° *C., or Resistance per Centimetre-cube at* 0° *C. in C.G.S. Units.* (Fleming and Dewar, *Phil. Mag.*, Sept. 1893.)

Metal.	Resistance at 0° C. per Centimetre-cube in C.G.S. Units.	Mean Temperature Coefficient between 0° C. and 100° C.
Silver (electrolytic and well annealed) [1]	1,468	0·00400
Copper (electrolytic and well annealed) [1]	1,561	0·00428
Gold (annealed)	2,197	0·00377
Aluminium (annealed)	2,665	0·00435
Magnesium (pressed)	4,355	0·00381
Zinc	5,751	0·00406
Nickel (electrolytic) [1]	6,935	0·00618
Iron (annealed)	9,065	0·00625
Cadmium	10,023	0·00419
Palladium	10,219	0·00354
Platinum (annealed)	10,917	0·003669
Tin (pressed)	13,048	0·00440
Thallium (pressed)	17,633	0·00398
Lead (pressed)	20,380	0·00411
Bismuth (electrolytic) [2]	110,000	0·00433

[1] The samples of silver, copper, and nickel employed for these tests were prepared electrolytically by Mr J. W. Swan, F.R.S., and were exceedingly pure and soft. The value for volume-resistivity of nickel as given in the above table (from experiments by J. A. Fleming, *Proc. Roy. Soc.*, Dec. 1899) is much less (nearly 40 per cent.) than the value given by Matthiessen's researches.

[2] The electrolytic bismuth here used was prepared by Messrs Hartmann and Braun, and the resistivity taken by J. A. Fleming. The value is nearly 20 per cent. less than that given by Matthiessen.

The volume-resistivity of pure mercury is a very important electric constant, and during the last two decades many of the most competent experimentalists have directed their attention to the determination of its value. The experimental process has usually been to fill a glass tube of known dimensions, having large cup-like extensions at the ends, with pure mercury, and determine the absolute resistance of this column of metal. For the practical details of this method the following references may be consulted:—"The Specific Resistance of Mercury," Lord Rayleigh and Mrs Sidgwick, *Phil. Trans. Roy. Soc.*, 1883, part i. p. 173, and

R. T. Glazebrook, *Phil. Mag.*, October 1885; "On the Specific Resistance of Mercury," R. T. Glazebrook and T. C. Fitzpatrick, *Phil. Trans. Roy. Soc.*, June 1888, or *Proc. Roy. Soc.* vol. xliv. No. 270, or *Electrician*, vol. xxi. p. 538, 1888; "Recent Determinations of the Absolute Resistance of Mercury," R. T. Glazebrook, *Electrician*, vol. xxv. pp. 543, 588, 1890. Also see Professor J. V. Jones, "On the Determination of the Specific Resistance of Mercury in Absolute Measure," *Phil. Trans. Roy. Soc.*, 1891, A, p. 2. The Table IV. below gives the values of the volume-resistivity of mercury as determined by various observers, the constant being expressed (*a*) in terms of the resistance in ohms of a column of mercury one millimetre in cross-section and 100 centimetres in length, taken at 0° C.; and (*b*) in terms of the length in centimetres of a column of mercury one square millimetre in cross-section taken at 0° C. The result of all the most careful determinations has been to show that the resistivity of pure mercury at 0° C. is about 94,070 C.G.S. electromagnetic units of resistance, and that a column of mercury 106·3 centimetres in length having a cross-sectional area of one square millimetre would have a resistance at 0° C. of one Standard Ohm. These values have accordingly been accepted as the official and recognized values for the specific resistance of mercury, and the definition of the ohm. The Table also states the methods which have been adopted by the different observers for obtaining the absolute value of the resistance of a known column of mercury, or of a resistance coil afterwards compared with a known column of mercury. A column of figures is added showing the value in fractions of a Standard Ohm of the British Association Unit (B.A.U.), formerly supposed to represent the true ohm. The real value of the B.A.U. is now taken as ·9866 of a Standard Ohm.

For a critical discussion of the methods which have been adopted in the absolute determination of the resistivity of mercury, and the value of the British Association unit of resistance, the reader may be referred to the *British Association Reports* for 1890 and 1892 (*Report of Electrical Standards Committee*), and to the *Electrician*, vol. xxv. p. 456, and vol. xxix. p. 462. A discussion of the relative value of the results obtained between 1882 and 1890 was given by Mr R. T. Glazebrook in a paper presented to the British Association at Leeds, 1890.

In connexion with electro-technical work the determination of the conductivity or resistivity values of annealed and hard-drawn

Standard for copper.

copper wire at standard temperatures is a very important matter. Matthiessen devoted considerable attention to this subject between the years 1860 and 1864, and since that time much additional work has been carried out. Matthiessen's value, known as *Matthiessen's Standard*, for the mass-resistivity of pure hard-drawn copper wire, expressed in Standard Ohms, is the resistance of a wire of pure hard-drawn copper one metre long and weighing one gramme = ·14493 Standard Ohms at 0° C. For many purposes it is convenient to express temperature in Fahrenheit degrees, and the recommendation of the 1899 Committee on Copper Conductors[1] is as follows:—"Matthiessen's standard for hard-drawn conductivity commercial copper shall be considered to be a wire of pure hard-drawn copper one metre long, weighing one gramme, the resistance of which at 60° F. is ·153858 Standard Ohms." Matthiessen also measured the mass-resistivity of annealed copper, and found that its conductivity is greater than that of hard-drawn copper by about 2·25 per cent. to 2·5 per cent. As annealed copper may vary considerably in its state of annealing, and is always somewhat hardened by bending and winding, it is found in practice that the resistivity of commercial annealed copper is about 1¼ per cent. less than that of hard-drawn copper. The standard now accepted for such copper, on the recommendation of the 1899 Committee, is a wire of pure annealed copper one metre long, weighing one gramme, whose resistance at 0° C. is ·1421 Standard Ohms, or at 60° F., ·150822 Standard Ohms. The specific gravity of copper varies from about 8·89 to 8·95, and the standard value accepted for high conductivity commercial copper is 8·912, corresponding to a weight of 555 lb per cubic foot at 60° F. Hence the volume-resistivity of pure annealed copper at 0° C. is 1·594 microhms per c.c., or 1594 C.G.S. units, and that of pure hard-drawn copper at 0° C. is 1·626 microhms per c.c., or 1626 C.G.S. units. Since Matthiessen's researches, the most careful scientific investigation on the conductivity of copper is that of Mr T. C. Fitzpatrick, carried out in 1890. Mr Fitzpatrick confirmed Matthiessen's chief result, and obtained values for the resistivity of hard-drawn copper which, when corrected for temperature variation, are in entire agreement with those of Matthiessen at the same temperature.

The volume-resistivity of alloys is, generally speaking, much higher than that of pure metals. A Table (V.) is given below showing the volume-resistivity at 0° C. of a number of well-known

TABLE V. *Volume-Resistivity of Alloys of known Composition at 0° C in C.G.S. Units per Centimetre-cube. Mean Temperature Coefficients taken at 15° C.* (Fleming and Dewar.)

Alloys.	Resistivity at 0° C.	Temperature Coefficient at 15° C.	Composition in per cents:
Platinum-silver .	31,582	·000243	Pt 33 %, Ag 66 %
Platinum-iridium .	30,896	·000822	Pt 80 %, Ir 20 %
Platinum-rhodium .	21,142	·00143	Pt 90 %, Rd 10 %
Gold-silver . .	6,280	·00124	Au 90 %, Ag 10 %
Manganese-steel .	67,148	·00127	Mn 12 %, Fe 78 %
Nickel-steel . .	29,452	·00201	Ni 4·35 %, remaining percentage chiefly iron, but uncertain.
German silver . .	29,982	·000273	$Cu_5Zn_3Ni_2$
Platinoid[2] . .	41,731	·00031	
Manganin . .	46,678	0000	Cu 84 %, Mn 12%, Ni 4 %
Aluminium-silver .	4,641	·00238	Al 94 %, Ag 6 %
Aluminium-copper .	2,904	·00381	Al 94 %, Cu 6 %
Copper-aluminium .	8,847	·000897	Cu 97 %, Al 3 %
Copper-nickel-aluminium.	14,912	·000645	Cu 87 %, Ni 6·5 %, Al 6·5 %
Titanium-aluminium	3,887	·00290	

alloys, with their chemical composition. Generally speaking, an alloy having high resistivity has poor mechanical qualities, that is to say, its tensile strength and ductility are small. It is possible to form alloys having a resistivity as high as 100 microhms per cubic centimetre; but, on the other hand, the value of an alloy for electro-technical purposes is judged not merely by its resistivity, but also by the degree to which its resistivity varies with temperature, and by its capability of being easily drawn into fine wire of

[1] In 1899 a Committee was formed of representatives from eight of the leading manufacturers of insulated copper cables, and delegates from the Post Office and Institution of Electrical Engineers, to consider the question of the values to be assigned to the resistivity of hard-drawn and annealed copper. The sittings of the Committee were held in London, the secretary being Mr A. H. Howard. The values given in the above paragraphs are in accordance with the decision of this Committee, and its recommendations have been accepted by the General Post Office and the leading manufacturers of insulated copper wire and cables.

[2] Platinoid is an alloy introduced by Martino, said to be similar in composition to German silver, but with a little tungsten added. It varies a good deal in composition according to manufacture, and the resistivity of different specimens is not identical. Its electric properties were first made known by J. T. Bottomley, in a paper read at the Royal Society, May 5, 1885.

not very small tensile strength. Some pure metals when alloyed with a small proportion of another metal do not suffer much change in resistivity, but in other cases the resultant alloy has a much higher resistivity. Thus an alloy of pure copper with 3 per cent. of aluminium has a resistivity about 5½ times that of copper; but if pure aluminium is alloyed with 6 per. cent. of copper, the resistivity of the product is not more than 20 per cent. greater than that of pure aluminium. The presence of a very small proportion of a non-metallic element in a metallic mass, such as oxygen, sulphur, or phosphorus, has a very great effect in increasing the resistivity. Certain metallic elements also have the same power; thus platinoid has a resistivity 30 per cent. greater than German silver, though it differs from it merely in containing a trace of tungsten.

The resistivity of non-metallic conductors is in all cases higher than that of any pure metal. The resistivity of carbon, for instance, in the forms of charcoal or carbonized organic material and graphite, varies from 600 to 6000 microhms per cubic centimetre, as shown in the following Table VI.:—

TABLE VI. *Electric Volume-Resistivity in Microhms per Centimetre-cube of Various Forms of Carbon at 15° C.*

Substance.	Resistivity.
Arc lamp carbon rod	8000
Jablochkoff candle carbon	4000
Carré carbon	3400
Carbonized bamboo	6000
Carbonized parchmentized thread	4000 to 5000
Ordinary carbon filament from glow-lamp "treated" or flashed	2400 to 2500
Deposited or secondary carbon	600 to 900
Graphite	400 to 500

The resistivity of liquids is, generally speaking, much higher than that of any metals, metallic alloys, or non-metallic conductors. Thus fused plumbic chloride, one of the best conducting liquids, has a resistivity in its fused condition of 0·376 ohm per centimetre-cube, or 376,000 microhms per centimetre-cube, whereas that of metallic alloys only in few cases exceeds 100 microhms per centimetre-cube. The resistivity of solutions of metallic salts also varies very largely with the proportion of the diluent or solvent, and in some instances, as in the aqueous solutions of mineral acids, there is a maximum conductivity corresponding to a certain dilution. The resistivity of many liquids, such as alcohol, ether, benzine, and pure water, is so high, in other words, their conductivity is so small, that they are practically insulators, and the resistivity can only be appropriately expressed in megohms per centimetre-cube.

In Table VII. are given the names of a few of these badly-conducting liquids, with the values of their volume-resistivity in megohms per centimetre-cube:—

TABLE VII. *Electric Volume-Resistivity of Various Badly-Conducting Liquids in Megohms per Centimetre-cube.*

Substance.	Resistivity in Megohms per c.c.	Observer.
Ethylic alcohol	0·5	Pfeiffer.
Ethylic ether	1·175 to 3·760	W. Kohlrausch.
Benzine	4·700	
Absolutely pure water approximates probably to	25·0 at 18° C.	Value estimated by Kohlrausch and Heydweiler.
All very dilute aqueous salt solutions having a concentration of about 0·00001 of an equivalent gramme molecule[1] per litre approximate to	1·00 at 18° C.	From results by F. Kohlrausch and others.

[1] An equivalent gramme molecule is a weight in grammes equal numerically to the chemical equivalent of the salt. For instance, one equivalent gramme molecule of sodic chloride is a mass of 58·5 grammes. NaCl = 58·5.

The resistivity of all those substances which are generally called dielectrics or insulators is also so high that it can only be appropriately expressed in millions of megohms per centimetre-cube, or in megohms per quadrant-cube, the quadrant being a cube the side of which is 10^9 cms. (see Table VIII.).

TABLE VIII. *Electric Volume-Resistivity of Dielectrics reckoned in Millions of Megohms (Mega-megohms) per Centimetre-cube, and in Megohms per Quadrant-cube,* i.e., *a Cube whose Side is* 10 *cms.*

Substance.	Resistivity.		Temperature Cent.
	Mega-megohms per c.c.	Megohms per Quadrant-cube.	
Bohemian glass	61	·061	60°
Mica	84	·084	20°
Gutta-percha	450	·45	24°
Flint glass	1,020	1·02	60°
Glover's vulcanized indiarubber	1,630	1·63	15°
Siemens' ordinary pure vulcanized indiarubber	2,280	2·28	15°
Shellac	9,000	9·0	28°
Indiarubber	10,900	10·9	24°
Siemens' high-insulating fibrous material	11,900	11·9	15°
Siemens' special high-insulating indiarubber	16,170	16·17	15°
Flint glass	20,000	20·0	20°
Ebonite	28,000	28·	46°
Paraffin	34,000	34·	46°

Effects of heat.

Temperature affects in various degrees the resistivity of these different classes of conductors. In all cases, so far as is yet known, the resistivity of pure metal is increased if its temperature is raised, and decreased if the temperature is lowered so that if it could be brought to the absolute zero of temperature (−273° C.) its conductivity would probably become perfect or its resistivity would vanish, or at least arrive at a very small minimum value. With metallic alloys, however, rise of temperature does not always increase resistivity; it sometimes diminishes it, so that many alloys are known which have a maximum resistivity corresponding to a certain temperature, and at or near this point they vary very little in resistance with temperature. Such alloys have, therefore, a negative temperature-variation of resistance at and above fixed temperatures. Prominent amongst these metallic compounds are certain alloys of iron, manganese, nickel, and copper. Some of these were discovered by Mr Weston, in the United States. One well-known alloy of copper, manganese and nickel, now called manganin, which was brought to the notice of electricians by the careful investigations made at the Berlin Physikalisch-Technische Reichsanstalt, is characterized by having a zero temperature coefficient at or about a certain temperature in the neighbourhood of 15° C. Hence within a certain range of temperature on either side of this critical value the resistivity of manganin is hardly affected at all by temperature. Similar alloys can be produced from copper and ferromanganese. An alloy formed of 80 per cent. copper and 20 per cent. manganese in an annealed condition has a nearly zero temperature-variation of resistance between 20° C. and 100° C. In the case of non-metals the action of temperature is generally to diminish the resistivity as temperature rises, though this is not universally so. The interesting observation has been recorded by Mr J. W. Howell, that "treated" carbon filaments, and also graphite, are substances which have a minimum resistance corresponding to a certain temperature approaching red heat (*Electrician*, vol. xxxviii. p. 835). At and beyond this temperature increased heating appears to increase their resistivity; this phenomenon may, however, be accompanied by a molecular change and not be a true temperature variation. In the case of dielectric conductors, and of electrolytes, the action of rising temperature is to reduce resistivity. Many of the so-called insulators, such as mica, ebonite, indiarubber, and the insulating oils, paraffin, &c., decrease in resistivity with great rapidity as the temperature rises. With gutta-percha a rise in temperature from 0° C. to 24° C. is sufficient to reduce the resistivity to one-twentieth part of its value at 0° C., and the resistivity of flint glass at 140° C. is only one-hundredth of what it is at 60° C.

A definition may here be given of the meaning of the term *Temperature Coefficient.* If, in the first place, we suppose that the resistivity (ρ_t) at any temperature ($t°$) is a simple linear function of the resistivity (ρ_0) at 0° C., then we can write

$$\rho_t = \rho_0 (1 + \alpha t),$$

or

$$\alpha = \frac{\rho_t - \rho_0}{\rho_0} \frac{1}{t}.$$

The quantity α is then called the temperature-coefficient, and its reciprocal is the temperature at which the resistivity would become zero. By an extension of this notion we can call the quantity $d\rho/\rho dt$ the temperature coefficient corresponding to any temperature t at which the resistivity is ρ. In all cases the relation between the resistivity of a substance and the temperature is best set out in the form of a curve called a temperature-resistance curve. If a series of such curves are drawn for various pure metals, temperature being taken as abscissa and resistance as ordinate, and if the temperature range extends from the absolute zero of temperature upwards, then it is found that these temperature-resistance lines are curved lines having their convexity either upwards or downwards. In other words, the second differential coefficient of resistance with respect to temperature is either a positive or negative quantity. An extensive series of observations concerning the form of the resistivity curves for various pure metals over a range of temperature extending from −200° C. to +200° C. was carried out in 1892 and 1893 by Fleming and Dewar (*Phil. Mag.*, Oct. 1892 and Sept. 1893). The resistance observations were taken with resistance coils constructed with wires of various metals obtained in a state of great chemical purity. The lengths and mean diameters of the wires were carefully measured, and their resistance was then taken at certain known temperatures obtained by immersing the coils in boiling aniline, boiling water, melting ice, melting carbonic acid in ether, and boiling liquid oxygen, the temperatures thus given being +184°·5 C., +100° C., 0° C., −78°·2 C., and −182°·5 C. The resistivities of the various metals were then calculated and set out in terms of the temperature. From these data a chart was prepared showing the temperature-resistance curves of these metals throughout a range of 400 degrees. The exact form of these curves through the region of temperature lying between −200° C. and −273° C. is not yet known. As shown on the chart, the curves evidently do not converge to precisely the same point. It is, however, much less probable that the resistance of any metal should vanish at a temperature above the absolute zero than at the absolute zero itself, and the precise path of these curves at their lower ends cannot be delineated until means are found for fixing independently the temperature of some regions in which the resistance of metallic wires can be measured.

The resistivity curves of the magnetic metals are also remarkable for the change of curvature they exhibit at the magnetic critical temperature. Thus J. Hopkinson and D. K. Morris (*Phil. Mag.*, September 1897, p. 213) observed the remarkable alteration that takes place in the iron resistance temperature curve in the neighbourhood of 780° C. At that temperature the direction of the curvature of the curve changes so that it becomes convex upwards instead of convex downwards, and in addition the value of the temperature coefficient undergoes a great reduction. The mean temperature coefficient of iron in the neighbourhood of 0° C. is ·0057; at 765° C. it rises to a maximum value ·0204; but at 1000° C. it falls again to a lower value, ·00244. A similar rise to a maximum value and subsequent fall is also noted in the case of the specific heat of iron. The changes in the curvature of the resistivity curves are undoubtedly connected with the molecular changes that occur in the magnetic metals at their critical temperatures.

A fact of considerable interest in connexion with resistivity is the influence exerted by a strong magnetic field in the case of some metals, notably bismuth. It was discovered by Righi and confirmed by Leduc (*Journal de Physique*, vol. v. p. 116, and vol. vi. p. 189), that if a pure bismuth wire is placed in a magnetic field transversely to the direction of the magnetic field, its resistance is considerably increased (see MAGNETISM). This increase is greatly affected by the temperature of the metal (Dewar and Fleming, *Proc. Roy. Soc.* vol. lx. p. 427).

Time effects.

In the case of dielectric conductors, commonly called insulators, such as indiarubber, gutta-percha, glass, and mica, the electric resistivity is not only a function of the temperature but also of the time during which the electromotive force employed to measure it is imposed. Thus if an indiarubber-covered cable is immersed in water and the resistance of the dielectric between the copper conductor and the water measured by ascertaining the current which can be caused to flow through it by an electromotive force, this current is found to vary very rapidly with the time during which the electromotive force is applied. Apart from the small initial effect due to the electrostatic capacity of the cable, the application of an electromotive force to the dielectric produces a current through it which rapidly falls in value, as if the electric resistance of the dielectric were increasing. The current, however, does not fall continuously but tends to a limiting value, and it appears that if the electromotive force is kept applied to the cable for a prolonged time, a small and nearly constant current will ultimately be found flowing through it. It is customary in electro-technical work to consider the resistivity of the dielectric as the value it has after the electromotive force has been applied for one minute, the standard temperature being 75° F. This, however, is a purely conventional proceeding, and the number so obtained does not necessarily represent the true or ohmic resistance of the dielectric. If the electromotive force is increased, in the case of a large number of ordinary dielectrics the apparent resistance at the end of one minute's electrification decreases as the electromotive force increases.

Practical standards.

The practical measurement of resistivity involves many processes and instruments (see MEASURING INSTRUMENTS, ELECTRIC). Broadly speaking, the processes are divided into *Comparison Methods* and *Absolute Methods*. In the former a comparison is effected between the resistance of a material in a known form and some standard resistance. In the *Absolute Methods* the resistivity is determined without reference to any other substance, but with reference only to the fundamental standards of length, mass, and time. Immense labour has been expended during the last twenty years in investigations concerned with the production of a standard of resistance and its evaluation in absolute measure. In some cases the absolute standard is constructed by filling a carefully-calibrated tube of glass with mercury, in order to realise in a material form the official definition of the ohm; in this manner most of the principal national physical laboratories have been provided with standard mercury ohms. (For a full description of the standard mercury ohm of the Berlin Physikalisch-Technische Reichsanstalt, see the *Electrician*, vol. xxxvii. p. 569.) For practical purposes it is more convenient to employ a standard of resistance made of wire.

Opinion is not yet perfectly settled on the question whether a wire made of any alloy can be considered to be a perfectly unalterable standard of resistance, but experience has shown that a platinum-silver alloy (66 per cent. silver, 33 per cent. platinum), and also the alloy called manganin, seem to possess the qualities of permanence essential for a wire-resistance standard. A comparison made in 1892 and 1894 of all the manganin wire copies of the ohm made at the Reichsanstalt in Berlin, showed that these standards had remained constant for two years to within one or two parts in 100,000. It appears, however, that in order that manganin may remain constant in resistivity when used in the manufacture of a resistance coil, it is necessary that the alloy should be *aged* by heating it to a temperature of 140° C. for ten hours; and to prevent subsequent changes in resistivity, solders containing zinc must be avoided, and a silver solder containing 75 per cent. of silver employed in soldering the manganin wire to its connexions.

The authorities of the Berlin Reichsanstalt have devoted considerable attention to the question of the best form for a wire standard of electric resistance. In that now adopted the resistance wire is carefully insulated and wound on a brass cylinder, being doubled on itself to annul inductance as much as possible. In the coil two wires are wound on in parallel, one being much finer than the other, and the final adjustment of the coil to an exact value is made by shortening the finer of the two. A standard of resistance for use in a laboratory now generally consists of a wire of manganin or platinum-silver carefully insulated and enclosed in a brass case. Thick copper rods are connected to the terminals of the wire in the interior of the case, and brought to the outside, being carefully insulated at the same time from one another and from the case. The coil so constructed can be placed under water or paraffin oil, the temperature of which can be exactly observed during the process of taking a resistance measurement. Equalization of the temperature of the surrounding medium is effected by the employment of a stirrer, worked by hand or by a small electric motor. The construction of a standard of electrical resistance consisting of mercury in a glass tube is an operation requiring considerable precautions, and only to be undertaken by those experienced in the matter. Opinions are divided on the question whether greater permanence in resistance can be secured by mercury-in-glass standards of resistance or by wire standards, but the latter are at least more portable and less fragile.

A full description of the construction of a standard wire-resistance coil on the plan adopted by the Berlin Physikalisch-Technische Reichsanstalt is given in the Report of the British Association Committee on Electrical Standards, presented at the Edinburgh Meeting in 1892. For the design and construction of standards of electric resistances adapted for employment in the comparison and measurement of very low or very high resistances, the reader may be referred to standard treatises on electric measurements.

(J. A. F.)

II. Electrolytic Conduction.

Many of the phenomena which accompany the passage of electricity through fused salts and solutions have been described in the articles Electricity and Electrolysis (*Ency. Brit.*, 9th ed.), in which the nomenclature of the subject is defined. But since the date of those articles much additional knowledge has been obtained: the discharge of electricity through gases has been proved to depend largely on electrolytic conduction, and the explanation both of this process and of the passage of a current through liquids has been extended on the lines of the theory of moving particles of matter, called ions, associated with definite electric charges. In this article we are concerned only with liquid electrolytes, the conduction of gases being treated under Electric Discharge (see V., below). The new developments of this section of the subject depend experimentally on the measurement of electrolytic resistance. The fundamental problems underlying such experiments have been considered in the article Electricity (*Ency. Brit.*, 9th ed.).

In determining the electrical resistance of solutions, Kohlrausch's method of eliminating the effects of polarization by the use of alternating currents (see as above) is now universally employed. The currents, usually obtained from a *small* induction coil, or from an alternating current supply reduced by a transformer to a low voltage, are led to a Wheatstone's bridge, in one arm of which is placed the solution to be investigated. Instead of a galvanometer, which cannot indicate alternating currents, a telephone is used. A sound is heard when alternating currents pass through this instrument, and the bridge is adjusted till silence is obtained. A modification of the method, which eliminates several disturbing causes, consists in alternating the current from a galvanic battery by means of a commutator revolving at a uniform speed, which at the same time alternates the connexions of the indicator. The differential current of the bridge thus again becomes direct, and a galvanometer, preferably of the moving coil type (see III. Electric Current, below), can be employed (Whetham, *Phil. Trans. Roy. Soc.*, A, 1900). The solutions are usually placed in glass vessels, the shape of which depends on the order of the resistance to be measured. The platinum electrodes are coated with platinum black, in order to obtain a surface of very large area and thus diminish the effects of polarization. The determination of the conductivity of a liquid in absolute units involves a knowledge of the "cell constant" or "resistance capacity" of the vessel containing it. This can be found if we already know the absolute conductivity of any definite solution. Kohlrausch has compared the specific resistance of many solutions with that of mercury, and from his results a cell constant can be calculated. The following numbers may be used for this purpose: a solution of potassium chloride, containing one-tenth of a gram-equivalent of salt per litre, has at 18° C. a specific resistance of 89·37 ohms per cubic centimetre, or a conductivity of $1{\cdot}119 \times 10^{-13}$ in C.G.S. units.

As in the case of the other properties of solutions, the phenomena are much more simple when the concentration is small than when it is great, and a study of dilute solutions is therefore the best way of getting an insight into the essential principles of the subject. The foundation of our knowledge was laid by Kohlrausch, who expresses his results in terms of "equivalent conductivity," that is, the conductivity (k) of the solution divided by the number (m) of gram-equivalents of electrolyte per litre. He finds that, as the concentration diminishes, the value of k/m approaches a limit, and eventually becomes constant, that is to say, at great dilution the conductivity is proportional to the concentration. Kohlrausch first prepared very pure water by repeated distillation, and found that its resistance continually increased as the process of purification proceeded. The conductivity of the water, and of the slight impurities which must always remain, was subtracted from that of the solution made with it, and the result, divided by m, gave the equivalent conductivity of the substance dissolved. This procedure appears justifiable, for as long as conductivity is proportional to concentration it is evident that each part of the dissolved matter produces its own independent effect, so that the total conductivity is the sum of the conductivities of the parts; when this ceases to hold, the concentration of the solution has in general become so great that the conductivity of the solvent may be neglected. The general result of these experiments can be graphically represented by plotting k/m as ordinates and $m^{\frac{1}{3}}$ as abscissæ, $m^{\frac{1}{3}}$ being a number proportional to the reciprocal of the average distance between the molecules, to which it seems likely that the molecular conductivity may be related. The general types of curve for a neutral salt and for a caustic alkali or acid are shown in Fig. 1. The curve for the neutral salt comes to a limiting value; that for the acid attains a maximum at a certain very small concentration, and falls again when the dilution is carried to an extreme. It has usually been considered that this destruction of conductivity is due to chemical action between the acid and the residual impurities in the water. At such great dilution these impurities are present in quantities comparable with the amount of acid, which they convert into a less highly conducting neutral salt. In the case of acids, then, the maximum must be taken as the limiting value. The decrease in equivalent conductivity at great dilution is, however, so constant that this explanation seems insuffi-

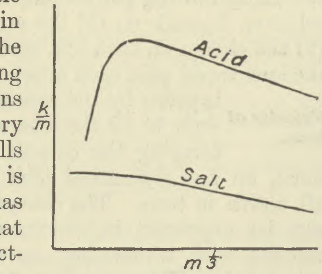

Fig. 1.

cient. The true cause of the phenomenon may perhaps be connected with the fact that the bodies in which it occurs, acids and alkalis, contain the ions, hydrogen in the one case, hydroxyl in the other, which are present in the solvent, water, and have, perhaps because of this relation, velocities higher than those of any other ions. The values of the molecular conductivities of all neutral salts are, at great dilution, of the same order of magnitude, while those of acids at their maxima are about three times as large. The influence of increasing concentration is greater in the case of salts containing divalent ions, and greatest of all in such cases as solutions of ammonia and acetic acid, which are substances of very low conductivity.

Kohlrausch found that, when the polarization at the electrodes was eliminated, the resistance of a solution was constant however determined, and thus established Ohm's Law for electrolytes, which was confirmed in the case of strong currents by Fitzgerald and Trouton (*B. A. Report*, 1886, p. 312). Now, Ohm's Law implies that no work is done by the current in overcoming reversible electromotive forces such as those of polarization. Thus the molecular interchange of ions, which must occur in order that the products may be able to work their way through the liquid and appear at the electrodes, continues throughout the solution whether a current is flowing or not. The influence of the current on the ions is merely directive, and when it flows, streams of electrified ions travel in opposite directions, and, if the applied electromotive force is enough to overcome the local polarization, give up their charges to the electrodes. We may therefore represent the facts by considering the process of electrolysis to be a kind of convection. Faraday's classical experiments proved that when a current flows through an electrolyte the quantity of substance liberated at each electrode is proportional to its chemical equivalent weight, and to the total amount of electricity passed. Accurate determinations have since shown that the mass of an ion deposited by one electromagnetic unit of electricity, *i.e.*, its electrochemical equivalent, is $1{\cdot}036 \times 10^{-4} \times$ its chemical equivalent weight. Thus the amount of electricity associated with one gram-equivalent of any ion is $\frac{10^4}{1{\cdot}036} = 9653$ units. Each monovalent ion must therefore be associated with a certain definite charge, which we may take to be a natural unit of electricity; a divalent ion carries two such units, and so on. A cation, *i.e.*, an ion giving up its charge at the cathode, as the electrode at which the current leaves the solution is called, carries a positive charge of electricity; an anion, travelling in the opposite direction, carries a negative charge. It will now be seen that the quantity of electricity flowing per second, *i.e.*, the current through the solution, depends on (1) the number of the ions concerned, (2) the charge on each ion, and (3) the velocity with which the ions travel past each other. Now, the number of ions is given by the concentration of the solution, for even if all the ions are not actively engaged in carrying the current at the same instant, they must, on any dynamical idea of chemical equilibrium, be all active in turn. The charge on each, as we have seen, can be expressed in absolute units, and therefore the velocity with which they move past each other can be calculated. This was first done by Kohlrausch[1] about 1879.

Theory of ions.

Velocity of ions.

In order to develop Kohlrausch's theory, let us take, as an example, the case of an aqueous solution of potassium chloride, of concentration n gram-equivalents per cubic centimetre. There will then be n gram-equivalents of potassium ions and the same number of chlorine ions in this volume. Let us suppose that on each gram-equivalent of potassium there reside $+e$ units of electricity, and on each gram-equivalent of chlorine ions $-e$ units. If u denotes the average velocity of the potassium ions, the positive charge carried per second across unit area normal to the flow is neu. Similarly, if v be the average velocity of the chlorine ions, the negative charge carried in the opposite direction is nev. But positive electricity moving in one direction is equivalent to negative electricity moving in the other, so that, before changes in concentration sensibly supervene, the total current, C, is $ne(u+v)$. Now let us consider the amounts of potassium and chlorine liberated at the electrodes by this current. At the cathode, if the chlorine ions were at rest, the excess of potassium ions would be simply those arriving in one second, namely, nu. But since the chlorine ions move also, a further separation occurs, and nv potassium ions are left without partners. The total number of gram-equivalents liberated is therefore $n(u+v)$. By Faraday's law, the number of *grams* liberated is equal to the product of the current and the electro-chemical equivalent of the ion; the number of gram-equivalents therefore must be equal to ηC, where η denotes the electro-chemical equivalent of hydrogen in C.G.S. units. Thus we get

$$n(u+v)=\eta C=\eta ne(u+v),$$

and it follows that the charge, e, on 1 gram-equivalent of each kind of ion is equal to $1/\eta$. We know that Ohm's Law holds good for electrolytes, so that the current C is also given by $k \cdot dP/dx$, where k denotes the conductivity of the solution, and dP/dx the potential gradient, *i.e.*, the change in potential per unit length along the lines of current flow. Thus

$$\frac{n}{\eta}(u+v)=k \cdot dP/dx;$$

therefore
$$u+v=\eta\frac{k}{n}\cdot\frac{dP}{dx}$$

Now η is $1{\cdot}036+10^{-4}$, and the concentration of a solution is usually expressed in terms of the number, m, of gram-equivalents per litre instead of per cubic centimetre. Therefore

$$u+v = 1{\cdot}036 \times 10^{-1}\frac{k}{m}\cdot\frac{dP}{dx}.$$

When the potential gradient is one volt (10^8 C.G.S. units) per centimetre this becomes

$$u+v=1{\cdot}036\times 10^{-7}\times k/m.$$

Thus by measuring the value of k/m, which is known as the equivalent conductivity of the solution, we can at once find $u+v$, the velocity of the ions relative to each other. For instance, the equivalent conductivity of a solution of potassium chloride containing one-tenth of a gram-equivalent per litre is 1113×10^{-13} C.G.S. units at 18° C. Therefore

$$u+v=1{\cdot}036\times 10^{7}\times 1113\times 10^{-13}$$
$$=1{\cdot}153\times 10^{-3}=0{\cdot}001153 \text{ cm. per sec.}$$

In order to obtain the absolute velocities u and v, we must find some other relation between them. Let us resolve u into $\frac{1}{2}(u+v)$ in one direction, say to the right, and $\frac{1}{2}(u-v)$ to the left. Similarly, v can be resolved into $\frac{1}{2}(v+u)$ to the left and $\frac{1}{2}(v-u)$ to the right. On pairing these velocities we have a combined movement of the ions to the right, with a speed of $\frac{1}{2}(u-v)$ and a drift right and left, past each other, each ion travelling with a speed of $\frac{1}{2}(u+v)$, constituting the electrolytic separation. If u is greater than v, the combined movement involves a concentration of salt at the cathode, and a corresponding dilution at the anode, and *vice versâ*. The rate at which salt is electrolysed, and thus removed from the solution at each electrode, is $\frac{1}{2}(u+v)$. Thus the total loss of salt at the cathode is $\frac{1}{2}(u+v)-\frac{1}{2}(u-v)$, or v, and at the anode, $\frac{1}{2}(v+u)-\frac{1}{2}(v-u)$, or u. Therefore, by measuring the dilution of the liquid round the electrodes when a current passed, Hittorf[2] deduced the ratio of the two velocities. Many further experiments have been made on the subject.[3]

By combining the results thus obtained with the sum of the velocities, as determined from the conductivities, Kohlrausch calculated the absolute velocities of different ions under stated conditions. Thus, in the case of the solution of potassium chloride considered above, Hittorf's experiments show us that the ratio of the velocity of the anion to that of the cation in this solution is ·51 : ·49. The absolute velocity of the potassium ion under unit potential gradient is therefore 0·000564 cm. per sec., and that of the chlorine ion 0·000589 cm. per sec. Similar calculations can be made for solutions of other concentrations, and of different substances.

The following table shows Kohlrausch's latest values for the ionic velocities of three chlorides of alkali metals at 18° C., calculated for a potential gradient of 1 volt per

cm.; the numbers are in terms of a unit equal to 10^{-6} cm. per sec. :—

TABLE IX.

	KCl			NaCl			LiCl		
m	*u+v*	*u*	*v*	*u+v*	*u*	*v*	*u+v*	*u*	*v*
0	1350	660	690	1140	450	690	1050	360	690
0·0001	1335	654	681	1129	448	681	1037	356	681
·001	1313	643	670	1110	440	670	1013	343	670
·01	1263	619	644	1059	415	644	962	318	644
·03	1218	597	621	1013	390	623	917	298	619
·1	1153	564	589	952	360	592	853	259	594
·3	1088	531	557	876	324	552	774	217	557
1·0	1011	491	520	765	278	487	651	169	482
3·0	911	442	469	582	206	376	463	115	348
5·0				438	153	285	334	80	254
10·0							117	25	92

These numbers clearly show that there is an increase in ionic velocity as the dilution proceeds. Moreover, if we compare the values for the chlorine ion obtained from observations on these three different salts, we see that as the concentrations diminish the velocity of the chlorine ion becomes the same in all of them. A similar relation appears in other cases, and, in general, we may say that at great dilution the velocity of an ion is independent of the nature of the other ion present. This at once introduces the conception of specific ionic velocities, for which some values at 18° C. are given by Kohlrausch in the following table :—

TABLE X.

K	. 66 × 10^{-5} cms. per sec.	Cl	. 69 × 10^{-5} cms. per sec.
Na	. 45 ,, ,,	I	. 69 ,, ,,
Li	. 36 ,, ,,	NO_3	. 64 ,, ,,
NH_4	. 66 ,, ,,	OH	. 162 ,, ,,
H	. 320 ,, ,,	$C_2H_3O_2$	36 ,, ,,
Ag	. 57 ,, ,,	$C_3H_5O_2$	33 ,, ,,

Having obtained these numbers we can deduce the conductivity of the dilute solution of any salt, and the comparison of the calculated with the observed values furnished the first confirmation of Kohlrausch's theory. Some exceptions, however, are known. Thus acetic acid and ammonia give solutions of much lower conductivity than is indicated by the sum of the specific ionic velocities of their ions as determined from other compounds. An attempt to find in Kohlrausch's theory some explanation of this discrepancy shows that it could be due to one of two causes. Either the velocities of the ions must be much less in these solutions than in others, or else only a fractional part of the number of molecules present can be actively concerned in conveying the current. We shall return to this point later.

Friction on the Ions.—It is interesting to calculate the magnitude of the forces required to drive the ions with a certain velocity. If we have a potential gradient of 1 volt per centimetre the electric force is 10^8 in C.G.S. units. The charge of electricity on 1 gram-equivalent of any ion is 1/·0001036 = 9653 units, hence the mechanical force acting on this mass is 9653 × 10^8 dynes. This, let us say, produces a velocity u; then the force required to produce unit velocity is $P_A = \frac{9{\cdot}653 \times 10^{11}}{u}$ dynes $= \frac{9{\cdot}84 \times 10^5}{u}$ kilograms-weight. If the ion have an equivalent weight A, the force producing unit velocity when acting on 1 gram is $P_1 = 9{\cdot}84 \times \frac{10^5}{Au}$ kilograms-weight. Thus the aggregate force required to drive 1 gram of potassium ions with a velocity of 1 centimetre per second through a very dilute solution must be equal to the weight of 38 million kilograms.

TABLE XI.

	Kilograms-weight.			Kilograms-weight.	
	P_A	P_1		P_A	P_1
K .	. 15 × 10^8	38 × 10^6	Cl .	. 14 × 10^8	40 × 10^6
Na .	. 22 ,,	95 ,,	I .	. 14 ,,	11 ,,
Li .	. 27 ,,	390 ,,	NO_3	. 15 ,,	25 ,,
NH_4	. 15 ,,	83 ,,	OH .	. 5·4 ,,	32 ,,
H .	. 3·1 ,,	310 ,,	$C_2H_3O_2$	. 27 ,,	46 ,,
Ag .	. 17 ,,	16 ,,	$C_3H_5O_2$	. 30 ,,	41 ,,

Since the ions move with uniform velocity, the frictional resistances brought into play must be equal and opposite to the driving forces, and therefore these numbers also represent the ionic friction coefficients in very dilute solutions at 18° C.

Direct Measurement of Ionic Velocities.—Oliver Lodge was the first to directly measure the velocity of an ion (*B. A. Report*, 1886, p. 389). In a horizontal glass tube connecting two vessels filled with dilute sulphuric acid he placed a solution of sodium chloride in solid agar-agar jelly. This solid solution was made alkaline with a trace of caustic soda in order to bring out the red colour of a little phenol-phthalein added as indicator. An electric current was then passed from one vessel to the other. The hydrogen ions from the anode vessel of acid were thus carried along the tube, forming hydrochloric acid as they travelled, which decolorized the phenol-phthalein. By this method the velocity of the hydrogen ion through a jelly solution under a known potential gradient was observed to be about 0·0026 cms. per sec., a number of the same order as that required by Kohlrausch's theory. Direct determinations of the velocities of a few other ions have been made by W. C. D. Whetham (*Phil. Trans. Roy. Soc.* vol. clxxxiv., A, p. 337; vol. clxxxvi., A, p. 507; *Phil. Mag.*, October 1894). Two solutions, having one ion in common, of equivalent concentrations, different densities, different colours, and nearly equal specific resistances, were placed one over the other in a vertical glass tube. In one case, for example, decinormal solutions of potassium carbonate and potassium bichromate were used. The colour of the latter is due to the presence of the bichromate group, Cr_2O_7. When a current was passed across the junction, the anions Cl and Cr_2O_7 travelled in the direction opposite to that of the current, and their velocity could be determined by measuring the rate at which the colour boundary moved. Similar experiments were made with alcoholic solutions of cobalt salts, in which the velocities of the ions were found to be much less than in water. The behaviour of agar jelly was then investigated, and the velocity of an ion through a solid jelly was shown to be very little less than in an ordinary liquid solution. The velocities could therefore be measured by tracing the change in colour of an indicator or the formation of a precipitate. Thus decinormal jelly solutions of barium chloride and sodium chloride, the latter containing a trace of sodium sulphate, were placed in contact. Under the influence of an electromotive force the barium ions moved up the tube, disclosing their presence by the trace of insoluble barium sulphate formed. Again, a measurement of the velocity of the hydrogen ion, when travelling through the solution of an acetate, showed that its velocity was then only about the one-fortieth part of that found during its passage through chlorides. From this, as from the measurements on alcohol solutions, it is clear that where the equivalent conductivities are very low the effective velocities of the ions are reduced in the same proportion.

Another series of direct measurements has been made by Orme Masson (*Phil. Trans. Roy. Soc.* vol. cxcii., A, p. 331). He placed the gelatine solution of a salt, potassium chloride, for example, in a horizontal glass tube, and found the rate of migration of the potassium and chlorine ions by observing the speed at which they were replaced when a coloured anion, say, the Cr_2O_7 from a solution of potassium bichromate, entered the tube at one end, and a coloured cation, say, the Cu from copper sulphate, at the other.

Kohlrausch's theory.

All the direct measurements which have been made agree with Kohlrausch's results within the limits of experimental error. His theory therefore probably holds good in every case, whatever be the solvent, if the proper values are given to the ionic velocities, *i.e.*, the values expressing the velocities with which the ions actually move in the solution of the strength taken, and under the conditions of the experiment. If we know the specific velocity of any one ion, we can, from the conductivity of very dilute solutions, at once deduce the velocity of any other ion with which it may be associated, a proceeding which does not involve the difficult task of determining the migration constant of the compound. Thus, taking the specific ionic velocity of hydrogen as 0·00032 cm. per second, we can, by determining the conductivity of dilute solutions of any acid, at once find the specific velocity of the acid radicle involved. Or again, since we know the specific velocity of silver, we can find the velocities of a series of acid radicles at great dilution by measuring the conductivity of their silver salts.

By such methods Ostwald, Bredig, and other observers have found the specific velocities of many ions both of inorganic and organic compounds, and examined the relation between constitution and ionic velocity.[1] The velocity of elementary ions is found to be a periodic function of the atomic weight, similar elements lying on corresponding portions of a curve drawn to express the relation between these two properties. Such a curve much resembles that giving the relation between atomic weight and viscosity in solution. For complex ions the velocity is largely an additive property; to a continuous additive change in the composition of the ion corresponds a continuous but decreasing change in the velocity. The following table gives Ostwald's results for the formic acid series:—

TABLE XII.

		Velocity.	Difference for CH_2.
Formic acid . . .	HCO_2	51·2	...
Acetic ,, . . .	$H_2C_2O_2$	38·3	−12·9
Propionic ,, . . .	$H_5C_3O_2$	34·3	− 4·0
Butyric ,, . . .	$H_7C_4O_2$	30·8	− 3·5
Valeric ,, . . .	$H_9C_5O_2$	28·8	− 2·0
Caprionic ,, . . .	$H_{11}C_6O_2$	27·4	− 1·4

Nature of electrolytes.

We have as yet said nothing about the fundamental cause of electrolytic activity, nor considered why, for example, a solution of potassium chloride is a good conductor, while a solution of sugar allows practically no current to pass All the preceding account of the subject is, then, independent of any view we may take of the nature of electrolytes, and stands on the basis of direct experiment. Nevertheless, the facts considered point to a very definite conclusion. The specific velocity of an ion is independent of the nature of the opposite ion present, and this at once suggests that the ions themselves, while travelling through the liquid, are dissociated from each other. Further evidence, pointing in the same direction, is furnished by the fact that since the conductivity is proportional to the concentration at great dilution, the equivalent-conductivity, and therefore the ionic velocity, is independent of it. The importance of this relation will be seen by considering the alternative to the dissociation hypothesis. If the ions are not permanently free from each other their mobility as parts of the dissolved molecules must be secured by continual interchanges. The velocity with which they work their way through the liquid must then increase as such molecular rearrangements become more frequent, and will therefore depend on the number of solute molecules, *i.e.*, on the concentration. On this supposition the observed constancy of velocity would be impossible. We shall therefore adopt as a working hypothesis the theory, confirmed by other phenomena to be described later, that an electrolyte consists of dissociated ions. It is necessary to point out that the dissociated ions of such a body as potassium chloride are not in the same condition as potassium and chlorine in the free state. The ions are associated with very large electric charges, and, whatever their exact relations with those charges may be, it is certain that the energy of a system in such a state must be different from its energy when unelectrified. It is not unlikely, therefore, that even a compound as stable in the solid form as potassium chloride should be thus dissociated when dissolved. Again, water, the best electrolytic solvent known, is also the body of the highest specific inductive capacity (di-electric constant), and this property, to whatever cause it may be due, will reduce the forces between electric charges in the neighbourhood, and may therefore enable two ions to separate.[2]

Dissociation theory.

This view of the nature of electrolytic solutions, which we owe to Arrhenius,[2] at once explains many well-known phenomena. Other physical properties of these solutions, such as density, colour, optical rotatory power, &c., like the conductivities, are *additive*, *i.e.*, can be calculated by adding together the corresponding properties of the parts. This again suggests that these parts are independent of each other. For instance, the colour of a salt solution is the colour obtained by the superposition of the colours of the ions and the colour of any undissociated salt that may be present. All copper salts in dilute solution are blue, which is therefore the colour of the copper ion. Solid copper chloride is brown or yellow, so that its concentrated solution, which contains both ions and undissociated molecules, is green, but changes to blue as water is added and the ionization becomes complete. A series of equivalent solutions all containing the same coloured ion have absorption spectra which, when photographed, show identical absorption bands of exactly equal intensity.[3] The colour changes shown by many substances which are used as indicators of acids or alkalis can be explained in a similar way. Thus para-nitro-phenol has colourless molecules, but an intensely yellow negative ion. In neutral, and still more in acid solutions, the dissociation of the indicator is practically nothing, and the liquid is colourless. If an alkali is added, however, a highly dissociated salt of para-nitro-phenol is formed, and the yellow colour is at once evident. In other cases, such as that of litmus, both the ion and the undissociated molecule are coloured, but in different ways.

Electrolytes possess the power of coagulating solutions of colloids such as albumen and arsenious sulphide. The mean values of the relative coagulative powers of sulphates of mono-, di-, and trivalent metals have been shown experimentally to be approximately in the ratios 1 : 35 : 1023. The dissociation theory refers this to the action of electric charges carried by the free ions. If a certain minimum charge must be collected in order to start coagulation, it will need the conjunction of $6n$ monovalent, or $3n$ divalent, to equal the effect of $2n$ trivalent ions. The ratios of the coagulative powers can thus be calculated to be $1 : x : x^2$, and putting $x=32$ we get 1 : 32 : 1024, a satisfactory explanation of the facts.[4]

Osmotic pressure.

The dissociation of electrolytes in solution is also suggested by other phenomena. If a solution be separated from a volume of its pure solvent by a membrane permeable to the solvent but not to the solution, the solvent passes through until a definite excess of pressure, called osmotic pressure, exists. By experiments on non-conducting solutions in water and other solvents, it has been found that this osmotic pressure shows the same volume and temperature relations as gaseous pressure, and has the same absolute value. Solutions of electrolytes, however, have abnormally high osmotic pressures, and we are thus led to conclude that, in their case, either the usual laws fail, or else that the number of molecules is greater than the chemical molecular weight and the concentration

[3] Ostwald, *Zeits. physikal. Chemie*, 1892, vol. ix. p. 579; Ewan, *Phil. Mag.* (5), 1892, vol. xxxiii. p. 317; Liveing, *Cambridge Phil. Trans.*, 1900, vol. xviii. p. 298.

[4] See Hardy, *Journal of Physiology*, 1899, vol. xxiv. p. 288; and Whetham, *Phil. Mag.*, November 1899.

of the solution would lead us to expect. Similar relations hold for the lowering of the vapour pressure and the depression of the freezing-point of a solvent caused by dissolving some substance in it. Both these effects are related to the osmotic pressure, and can be calculated from it, and the values of both are abnormally great for electrolytes. We may conclude, then, that the cause of the electrolytic property is also the cause of the increase in the osmotic pressure effects, and the phenomena are at once explained if we assume that the number of effective particles in solution is abnormally great in the case of electrolytes, that is, that electrolytes are partially or completely dissociated into their ions. It will be noticed that such a supposition does not commit us to any definite view as to the nature of solution or the cause of osmotic pressure. If solution be a purely physical process, analogous to evaporation, and the osmotic pressure be due to the impact of the dissolved molecules, the extra pressure of electrolytes is caused by similar impacts of the ions. If solution, on the other hand, be due to chemical action, and osmotic pressure be caused by chemical affinity of solvent for solute, then the same affinity, acting between the ions and the solvent, explains the properties of electrolytes. All that the dissociation theory demands is the freedom of the ions from each other; they may or may not be united with solvent molecules.

Freezing-points are easier to determine than osmotic or vapour pressures, and are therefore more suitable for the experimental investigation of this relation. The connexion between freezing-point and conductivity is well shown by Arrhenius' original table, the following short extract from which will serve our present purpose. The last two columns, headed *i*, give the ratio of the total number of dissolved particles to the number which would exist if all the molecules were undissociated. In column II. the ratio is calculated from Raoult's experiments on the freezing-points, and in column III., from the measurements of Kohlrausch, Ostwald, and others on the electrical conductivities. The first column, showing the ionization (dissociation) coefficients, is also calculated from these latter results.

Freezing-points.

TABLE XIII.

Non-Conductors.		I.	II.	III.
		a	*i*	*i*
Ethyl alcohol	C_2H_5OH	0·00	0·94	1·00
Cane sugar	$C_{12}H_{22}O_{11}$	0·00	1·00	1·00
Acetone	C_3H_6O	0·00	0·92	1·00
Bases, Acids, and Salts.				
Sodium hydroxide	NaOH	0·88	1·96	1·88
Ammonia	NH_3	0·01	1·03	1·01
Hydrochloric acid	HCl	0·90	1·98	1·90
Nitric acid	HNO_3	0·92	1·94	1·92
Sulphuric acid	H_2SO_4	0·60	2·06	2·19
Phosphoric acid	H_3PO_4	0·08	2·32	1·24
Acetic acid	CH_3COOH	0·01	1·03	1·01
Potassium chloride	KCl	0·86	1·82	1·86
Sodium chloride	NaCl	0·82	1·90	1·82
Potassium sulphate	K_2SO_4	0·67	2·11	2·33
Copper sulphate	$CuSO_4$	0·35	0·97	1·35

The remarkable general agreement of these numbers is broken by a few exceptions, such as those seen in the cases of phosphoric acid and copper sulphate. More recent work has not succeeded in finally establishing the strict accuracy of this relation, but its approximate truth seems undoubted. The chief experimental difficulty consists in the precise determination of the very small temperature differences between the freezing-point of the solvent and that of very dilute solutions.

An interesting relation appears when the electrolytic conductivity of solutions is compared with their chemical activity. The readiness and speed with which electrolytes react are in sharp contrast with the difficulty experienced in the case of non-electrolytes. Moreover, a study of the chemical relations of electrolytes indicates that it is always the electrolytic ions that are concerned in their reactions. The tests for a salt, potassium nitrate, for example, are the tests not for KNO_3, but for its ions K and NO_3, and in cases of double decomposition it is always these ions that are exchanged for those of other substances. If an element is present in a compound otherwise than as an ion it is not interchangeable, and cannot be recognized by the usual tests. Thus neither a chlorate, which contains the ion ClO_3, nor monochloracetic acid, shows the reactions of chlorine, though it is, of course, present in both substances; again, the sulphates do not answer to the usual tests which indicate the presence of sulphur as sulphide. The chemical activity of a substance being independent of the reaction in which it is concerned, it is possible to assign to each body a specific coefficient of affinity. Arrhenius has pointed out that the coefficient of affinity of an acid is proportional to its electrolytic ionization.

Chemical activity.

The affinities of acids have been compared in several ways. Ostwald (*Lehrbuch der allg. Chemie*, vol. ii., Leipzig, 1893) investigated the relative affinities of acids for potash, soda, and ammonia, and proved them to be independent of the base used. The method employed was to measure the changes in volume caused by the action. His results are given in column I. of the following table, the affinity of hydrochloric acid being taken as one hundred. Another method is to allow an acid to act on an insoluble salt, and to measure the quantity which goes into solution. Determinations have been made with calcium oxalate, $CaC_2O_4 + H_2O$, which is easily decomposed by acids, oxalic acid and a soluble calcium salt being formed. The affinities of acids relative to that of oxalic acid are thus found, so that the acids can be compared among themselves (column II.). If an aqueous solution of methyl acetate is allowed to stand, a slow decomposition goes on. This is much quickened by the presence of a little dilute acid, though the acid itself remains unchanged. It is found that the influence of different acids on this action is proportional to their specific coefficients of affinity. The results of this method are given in column III. Finally, in column IV. the electrical conductivities of normal solutions of the acids have been tabulated. A better basis of comparison would be the ratio of the actual to the limiting conductivity, but since the conductivity of acids is chiefly due to the mobility of the hydrogen ions, its limiting value is nearly the same for all, and the general result of the comparison would be unchanged.

TABLE XIV.

Acid.	I.	II.	III.	IV.
Hydrochloric	100	100	100	100
Nitric	102	110	92	99·6
Sulphuric	68	67	74	65·1
Formic	4·0	2·5	1·3	1·7
Acetic	1·2	1·0	0·3	0·4
Propionic	1·1	...	0·3	0·3
Monochloracetic	7·2	5·1	4·3	4·9
Dichloracetic	34	18	23·0	25·3
Trichloracetic	82	63	68·2	62·3
Malic	3·0	5·0	1·2	1·3
Tartaric	5·3	6·3	2·3	2·3
Succinic	0·1	0·2	0·5	0·6

It must be remembered that, the solutions not being of quite the same strength, these numbers are not strictly comparable, and that the experimental difficulties involved in the chemical measurements are considerable. Nevertheless, the remarkable general agreement of the numbers in the four columns is quite enough to show the intimate connexion between chemical activity and electrical conductivity. We may take it, then, that only that portion of a body is chemically active which is electrolytically active—that ionization is necessary for chemical activity just as it is necessary for electrolytic conductivity.

The ordinary laws of chemical equilibrium have been applied to the case of the dissociation of a substance into its ions. Let x be the number of molecules which dissociate per second when the number of undissociated molecules in unit volume is unity, then xp is the number when the concentration is p. Recombination can only occur when two ions meet, and since the frequency with which this will happen is proportional to the square of the ionic concentration, we shall get for the number of molecules re-formed in one second yq^2 where q is the number of dissociated molecules in one cubic centimetre. When there is equilibrium, $xp=yq^2$. If μ be the molecular conductivity, and μ_∞ its value at infinite dilution, the fractional number of molecules dissociated is μ/μ_∞, which we may write as α. The number of undissociated molecules is then $1-\alpha$, so that if V is the volume of the solution containing 1 gram-molecule of the dissolved substance, we get

$$q=\frac{1}{V}\alpha \text{ and } p=\frac{1}{V}(1-\alpha),$$

$$\therefore\ \frac{x}{V}(1-\alpha)=\frac{y}{V^2}\alpha^2,$$

$$\therefore\ \frac{\alpha^2}{V(1-\alpha)}=\frac{x}{y}=\text{constant}=k.$$

This constant k gives a numerical value for the chemical affinity, and the equation should represent the effect of dilution on the molecular conductivity of binary electrolytes. Ostwald has confirmed it by observation on an enormous number of weak acids (*Zeits. f. physikal. Chemie*, 1888, ii. p. 278; 1889, iii. pp. 170, 241, 369). Thus in the case of cyanacetic acid, while the volume V changed by doubling from 16 to 1024 litres, the values of k were 0′00(376, 373, 374, 361, 362, 361, 368). The mean values of k for other common acids were — formic, 0·0000214; acetic, 0·0000180; monochloracetic, 0·00155; dichloracetic, 0·051; trichloracetic, 1·21; propionic, 0·0000134. From these numbers we can, by help of the equation, calculate the conductivity of the acids for any dilution. In the case of substances like ammonia and acetic acid, where the dissociation is very small, $1-\alpha$ is nearly equal to unity, and only varies slowly with dilution. The equation then becomes

$$\frac{\alpha^2}{V}=k,$$

or

$$\alpha=\sqrt{Vk}, \qquad . \quad . \quad . \quad (31)$$

so that the molecular conductivity is proportional to the square root of the dilution. The value of k, however, does not keep so satisfactorily constant in the case of highly dissociated substances, and empirical formulæ have been constructed to represent the effect of dilution on them. Thus the values of the expressions $\frac{\alpha^2}{1-\alpha\sqrt{V}}$ (Rudolphi, *Zeits. physikal. Chem.*, 1895, vol. xvii. p. 385) and $\frac{\alpha^3}{(1-\alpha)^2V}$ (Van't Hoff, *ibid.*, 1895, vol. xviii. p. 300) are found to keep constant as V changes. Van't Hoff's formula is equivalent to taking the frequency of dissociation as proportional to the square of the concentration of the molecules, and the frequency of recombination as proportional to the cube of the concentration of the ions. No good explanation of the failure of the usual dilution law in these cases has yet been given.

When the solutions of two substances are mixed, similar considerations to those given above enable us to calculate the resultant changes in dissociation. (See Arrhenius, *loc. cit.*) The simplest and most important case is that of two electrolytes having one ion in common, such as two acids. It is evident that the undissociated part of each acid must eventually be in equilibrium with the free hydrogen ions, and if the concentrations are not such as to secure this condition, readjustment must occur. In order that there should be no change in the states of dissociation on mixing, it is necessary, therefore, that the concentration of the hydrogen ions should be the same in each separate solution. Such solutions were called by Arrhenius, "isohydric." The two solutions, then, will so act on each other when mixed that they become isohydric. Suppose we have one very active acid like hydrochloric, in which dissociation is nearly complete, and another like acetic, in which it is very small. In order that the solutions of these should be isohydric and the concentrations of the hydrogen ions the same, we must have a very large quantity of the feebly dissociated acetic acid, and a very small quantity of the strongly dissociated hydrochloric, and in such proportions alone will equilibrium be possible. This explains the action of a strong acid on the salt of a weak acid. Let us allow dilute sodium acetate to react with dilute hydrochloric acid. Some acetic acid is formed, and this process will go on till the solutions of the two acids are isohydric: that is, till the dissociated hydrogen ions are in equilibrium with both. In order that this should hold, we have seen that a considerable quantity of acetic acid must be present, so that a corresponding amount of the salt will be decomposed, the quantity being greater the less the acid is dissociated. This "replacement" of a "weak" acid by a "strong" one is a matter of common observation in the chemical laboratory. Similar investigations applied to the general case of chemical equilibrium lead to an expression of exactly the same form as that given by Guldberg and Waage, which is universally accepted as an accurate representation of the facts.

The temperature coefficient of conductivity has approximately the same value for most aqueous salt solutions. It decreases both as the temperature is raised and as the concentration is increased, ranging from about 3·5 per cent. per degree for extremely dilute solutions (*i.e.*, practically pure water) at 0° to about 1·5 for concentrated solutions at 18°. For acids its value is usually rather less than for salts at equivalent concentrations. The influence of temperature on the conductivity of solutions depends on (1) the ionization, and (2) the frictional resistance of the liquid to the passage of the ions, the reciprocal of which is called the ionic fluidity. At extreme dilution, when the ionization is complete, a variation in temperature cannot change its amount. The rise of conductivity with temperature, therefore, shows that the fluidity becomes greater when the solution is heated. As the concentration is increased and un-ionized molecules are formed, a change in temperature begins to affect the ionization as well as the fluidity. But the temperature coefficient of conductivity is now generally less than before; thus the effect of temperature on ionization must be of opposite sign to its effect on fluidity. The ionization of a solution, then, is usually diminished by raising the temperature, the rise in conductivity being due to the greater increase in fluidity. Nevertheless, in certain cases, the temperature coefficient of conductivity becomes negative at high temperatures, a solution of phosphoric acid, for example, reaching a maximum conductivity at 75° centigrade.

Thermal phenomena.

The dissociation theory gives an immediate explanation of the fact that, in general, no heat-change occurs when two neutral salt solutions are mixed. Since the salts, both before and after mixture, exist mainly as dissociated ions, it is obvious that large thermal effects can only appear when the state of dissociation of the products is very different from that of the reagents. Let us consider the case of the neutralization of a base by an acid in the light of the dissociation theory. In dilute solution such substances as hydrochloric acid and potash are almost completely dissociated, so that, instead of representing the reaction as

$$HCl + KOH = KCl + H_2O,$$

we must write

$$\overset{+}{H} + \overset{-}{Cl} + \overset{+}{K} + \overset{-}{OH} = \overset{+}{K} + \overset{-}{Cl} + H_2O.$$

The ions K and Cl suffer no change, but the hydrogen of the acid and the hydroxyl (OH) of the potash unite to form water, which is only very slightly dissociated. The heat liberated, then, is almost exclusively that produced by the formation of water from its ions. An exactly similar process occurs when any strongly dissociated acid acts on any strongly dissociated base, so that *in all such cases the heat evolution should be approximately the same.* This is fully borne out by the experiments of Thomsen, who found that the heat of neutralization of one gram-molecule of a strong base by an equivalent quantity of a strong acid was nearly constant, and equal to 13,700 or 13,800 calories. In the case of weaker acids, the dissociation of which is less complete, divergences from this constant value will occur, for some of the molecules have to be separated into their ions. For instance, sulphuric acid, which in the fairly strong solutions used by Thomsen is only about half dissociated, gives a higher value for the heat of neutralization, so that heat must be evolved when it is ionized. The heat of formation of a substance from its ions is, of course, very different from that evolved when it is formed from its elements in the usual way, since the energy associated with an ion is different from that possessed by the atoms of the element in their normal state. We can calculate the heat of formation from its ions for any substance *dissolved in a given liquid*, from a knowledge of the temperature coefficient of ionization, by means of an application of the well-known thermodynamical process, which also gives the latent heat of evaporation of a liquid when the temperature coefficient of its vapour pressure is known. The heats of formation thus obtained may be either positive or negative, and by using them to supplement the heat of formation of water, Arrhenius calculated the total heats of neutralization of soda by different acids, some of them only slightly dissociated, and found values agreeing well with observation (*Zeits. f. physikal. Chemie*, 1889, vol. iv. p. 96; and 1892, vol. ix. p. 339).

Diffusion of Electrolytes.—An application of the theory of ionic velocity due to Nernst[1] and Planck[2] enables us to calculate the diffusion constant of dissolved electrolytes. According to the molecular theory, diffusion is due to the motion of the molecules of the dissolved substance through the liquid. When the dissolved molecules are uniformly distributed, the osmotic pressure will be the same everywhere throughout the solution, but if the concentration varies from point to point the pressure will vary also. There must, then, be a relation between the rate of change of the concentration and the osmotic pressure gradient, and thus we may consider the osmotic pressure gradient as a force driving the solute through a viscous medium. In the case of non-electrolytes and of all non-ionized molecules this analogy completely represents the facts, and the phenomena of diffusion can be deduced from it alone. But the ions of an electrolytic solution can move independently through the liquid, even when no current flows, as the consequences of Ohm's Law indicate. The ions will therefore diffuse independently, and the faster ion will travel quicker into pure water in contact with a solution. The ions carry their charges with them, and, as a matter of fact, it is found that water in contact with a solution takes with respect to it a positive or negative potential, according as the positive or negative ion travels the faster. This process will go on until the simultaneous separation of electric charges produces an electrostatic force strong enough to prevent further separation of ions. We can therefore calculate the rate at which the salt as a whole will diffuse by examining the conditions for a steady transfer, in which the ions diffuse at an equal rate, the faster one being restrained and the slower one urged forward by the electric forces. In this manner the diffusion constant can be calculated in absolute units ($HCl=2\cdot49$, $HNO_3=2\cdot27$, $NaCl=1\cdot12$), the unit of time being the day. By experiments on diffusion this constant has been found by Scheffer, and the numbers observed agree with those calculated ($HCl=2\cdot30$, $HNO_3=2\cdot22$, $NaCl=1\cdot11$).

Contact Difference of Potential.—As we have seen above, when a solution is placed in contact with water the water will take a positive or negative potential with regard to the solution, according as the cation or anion has the greater specific velocity, and therefore the greater initial rate of diffusion. This idea can be developed to explain the difference of potential at the surface of contact of two solutions. If e is the electric charge on each ion, and dP/dx the potential gradient, the electrical force on each ion is $e\,dP/dx$. Again, if dp/dx denote the osmotic pressure gradient, the osmotic force on one of the ions in a small cylindrical space Adx is the force on the whole element shared among the total number of ions, that is, $\frac{Adp}{nAdx}$, or $\frac{1}{n}\cdot\frac{dp}{dx}$ when n is the number of ions in unit volume. We have called u and v the velocities of the cation and anion under unit potential gradient, so that their velocities under unit force will be u/e and v/e. Now, let us write down the velocities under the actual forces, and equate them, as the condition of the final state of steady transfer.

$$\frac{u}{e}\left(\frac{1}{n}\cdot\frac{dp}{dx}+e\frac{dP}{dx}\right)=\frac{v}{e}\left(\frac{1}{n}\frac{dp}{dx}-e\frac{dP}{dx}\right),$$

or

$$\frac{dP}{dx}=\frac{1}{ne}\cdot\frac{v-u}{v+u}\cdot\frac{dp}{dx}.$$

Osmotic pressure, as we have said, shows the same volume and temperature relations as gaseous pressure, and has the same absolute value. We can therefore apply to it the usual equation for a mass M of gas at an absolute temperature T, $p\times\text{volume}=MRT$, where R is a characteristic constant. Putting $M/\text{volume}=\text{density}=mn$, where m is the mass of each ion, we have $dp=mRTdn$, at constant temperature. Then, substituting in our equation, and integrating, we get

$$P_2-P_1=\frac{m}{e}RT\frac{v-u}{v+u}\log\frac{n_2}{n_1}$$

as the difference of potential between two solutions in contact, which differ in concentration, m/e denoting the electro-chemical equivalents. In the case of a galvanic cell, we must also consider the metal-liquid functions. Ions from the zinc plate enter the liquid, but no acid anions enter the zinc; thus at the anode, $v=0$. So also at the cathode, $u=0$, and the equation for the total electromotive force becomes

$$F=\frac{m}{e}RT\left(\log\frac{N_1}{n_1}+\frac{v-u}{v+u}\log\frac{n_2}{n_1}+\log\frac{n_2}{N_2}\right),$$

N_1 and N_2 denoting the concentrations of cations and anions in the substance of the anode and cathode respectively. In common forms of cells, where different metals are used, our ignorance of the meaning of these constants prevents the application of the formula, but galvanic cells can be constructed with two electrodes of the same metal placed in solutions of different substances, or even of the same substance at different concentrations. In these cases, since the unknown contribution from the metal is the same at the opposite electrodes, we can calculate the total electromotive force of the cell, for the equation becomes

$$E=\frac{m}{e}RT\frac{2v}{v+u}\log\frac{n_2}{n_1},$$

where everything is known in absolute measure. The values calculated for such "concentration cells" (usually of the order of 0·05 volt) agree well with observation. As the equation shows, the electromotive force will be greater if the concentration of the ions of the metal in the solution round one electrode is made very small. This can easily be done by placing the electrode in a solution which precipitates the metal. Thus Ostwald found that a cell with silver electrodes, one of which was surrounded by a chloride, had an electromotive force of 0·51 volt, Nernst's formula indicating a theoretical value of 0·52 volt. By placing copper in the solution of a cyanide it can even be made electropositive with regard to zinc, and the cell arranged in accordance with the scheme.

$$Zn/ZnSo_4/K_2So_4/KCN/Cu$$

has a reverse electromotive force, the current outside the cell passing from zinc to copper. Similar ideas have been used to explain the potential difference between a metal and a liquid. Nernst ascribes to each metal a solution pressure with regard to water, which depends on the value of N used above, and tends to drive the metal into solution in the form of positively electrified ions. This process will electrify the liquid positively, and leave the metal negatively charged. Whether this last extension of the theory can be justified or not is still a subject of discussion.[3]

Function of the solvent.

In the early development of the present theory of the subject no attention was paid to the part played by the solvent. It was looked on simply as furnishing a space into which the dissolving solid could diffuse, and, in the case of electrolytes, as providing a screen for separating the ions from one another. The very different power of various solvents, both in dissolving substances and in enabling them to conduct electricity when dissolved, directed attention to the general question of their influence, and measurements of conductivity of the same salt in water and alcohol were made by Fitzpatrick,[4] Völlmer,[5] and others. The problem of the cause of solubility still remains unsettled, but towards the explanation of ionizing power some advance has been made. If the forces holding the ions together in a molecule are electrical in their nature (as is quite possible), it follows that they will be much weakened by immersing the molecule in a medium of high specific

inductive capacity like water. This may explain the differences observed in the molecular conductivities of the same salt dissolved in different solvents, such as water and alcohol, for example, for, other conditions being the same, the effect of solvents in loosening the connexion between two ions, *i.e.*, their relative ionization powers, will depend on their specific inductive capacities. Some experimental evidence which, as far as it goes, confirms this idea has been obtained (Whetham, *Phil. Mag.*, 1894, p. 392; and 1897, p. 1). Kohlrausch's experiments have shown that the conductivity of pure water is exceedingly small, indicating only a slight amount of dissociation. But this is what we should expect, for the concentration is so great and the molecules are so crowded together that no dissociation can be permanent. Nevertheless, there are many indications that even chemically pure water would, if it could be prepared, be slightly dissociated and possess some conducting power (see Kohlrausch and Heydweiler, *Zeits. f. physikal. Chemie*, 1893, p. 492). Allied to this subject is the question of the nature of electrolytic conduction in fused salts. Here, however, the small amount of experimental work makes further consideration premature.

Electrons.

With regard to the fundamental principles of electrolytic conduction, it seems possible that a great step in advance may be made by the application of ideas obtained from the study of electric discharge through gases (*q.v.*). J. J. Thomson has shown (*Phil. Mag.*, 1897, vol. xliv. p. 293, 1898; vol. xlvi. p. 528, 1899; vol. xlviii. p. 547. *Summary in Reports of the Physical Congress at Paris*, 1900, vol. iii. p. 138) that the negative ions in certain cases of discharge are enormously more mobile than the positive ones, and that their mass is only about the one-thousandth part of that of the hydrogen molecule. These negative ions perhaps realize the conception of electrons due to Lorentz and Larmor (*Phil. Trans. Roy. Soc.*, 1895, vol. clxxxvi., A, p. 695, and 1898, vol. cxc., A, p. 205), and may be the ultimate particles of which, in varying number, different atoms are composed. A body containing an excess of these corpuscles is negatively charged, but positively when some of them have been removed. A current consists in the motion of electrons; in the case of gases, the electron particles sometimes travel alone, but in liquid electrolytes they cannot be detached from atoms, and hence their movement involves chemical action. An atom *plus* an electron is a monovalent anion, an atom *minus* an electron, a monovalent cation. In metallic conductors the electrons can pass from one atom to the next, and thus allow a current to flow without chemical decomposition.

Most of the new work on the subject, which does not appear in the general physical and chemical journals, is published in the *Zeitschrift für physikalische Chemie*, Leipzig, the *Zeitschrift für Elektrochemie*, Halle, or the *Journal of Physical Chemistry*, Cornell University, Ithaca, New York State. In these periodicals abstracts of papers published elsewhere will be found. III. ELECTRIC CURRENT.

When a conductor is connected to two other conductors maintained at different electric potentials (see I. ELECTRIC CONDUCTION, above) it immediately exhibits physical qualities which are commonly described by stating that an electric current flows through it. We are in ignorance whether this effect involves any actual flow or circulation of a material or medium in the conductor, and the term is, therefore, to be understood only as a comprehensive and convenient expression for all the physical actions taking place in and near the conductor which determines the locality of the current. These actions are chiefly the production of a magnetic field or of magnetic force in and around the conductor, and the generation of heat in its mass. An electric current considered as a mathematical quantity has direction as well as magnitude, and belongs to that class of quantities called *circuital quantities*, because they can only exist at all when they exist simultaneously everywhere along a completely closed circuit. The path of electric current is, therefore, called an *electric circuit*, and may be made up partly of conductors, metallic or electrolytic, or partly of those substances known as insulators, or better, as dielectric conductors. Energy is associated with every circuit traversed by a current, and the continual dissipation of this energy causes the conducting circuit to become heated. Three qualities of a circuit determine the amount of the electric kinetic energy and potential energy which can be connected with it, and the rate at which it dissipates electric energy; these are its *Inductance* (L), its *Capacity* (C), and its *Resistance* (R). If a portion of the circuit is an electrolyte (see II. ELECTROLYTIC CONDUCTION), chemical decomposition of the electrolyte takes place. A magnetic field or magnetic flux is always associated with the circuit conveying a current, and the lines of this magnetic flux are always closed loops embracing or linked with the electric circuit. The principal facts connected with the electric circuit are: (1) the magnetic force at any point outside a conducting circuit which is traversed by an unvarying electric current is proportional to the chemical decomposition produced per second by the current in an electrolyte forming part of the circuit, provided that no ferromagnetic material is in the neighbourhood of the circuit; (2) the rate of dissipation of energy in any circuit traversed by an electric current is proportional to the square of the current, and varies inversely as the conductivity of the circuit—(this assertion is a statement of Joule's Law, and applies not only to the circuit as a whole but to any part of it); (3) if two points on an electric circuit, not including an active electromotive force, are selected and the difference of their electric potential measured, the current in the circuit is proportional to this difference of potential and to the conductivity of the circuit between these two points.

Measurement.

The magnitude or strength of an electric current may be estimated either by the *electrolytic* or the *magnetic* method. In the first case a standard electrolyte is selected, and a unit current defined as the unvarying current which, when passed through this standard electrolyte, liberates from it on the electrodes a certain mass of ions. It has been agreed that the standard electrolyte for this purpose shall be a neutral solution of nitrate of silver in water, and that the ion which shall be considered is the silver deposited on the cathode. The process of making an electrolytic measurement, therefore, of the strength of an electric current uniform in direction and unvarying in magnitude, consists in passing it through a neutral solution of nitrate of silver contained in a platinum bowl, the anode being a plate of pure silver. The direction of the current is defined to be the direction in which the silver ion moves. For the performance of this experiment the British Board of Trade have issued a particular specification. The practical unit of current is called the *ampere*, which in Great Britain is legally defined as the "unvarying electric current which, when passed through a solution of nitrate of silver made according to a certain specification, deposits silver on the cathode at the rate of ·001118 of a gramme per second." The ampere is intended to reproduce one-tenth of an absolute electromagnetic unit of current. The magnetic method of measuring an electric current is as follows:—Let a thin wire be bent into a circle of unit radius (1 cm.), and let it be supposed to be traversed by a uniform unvarying current; then at the centre of this circular conductor there will be a magnetic force perpendicular to the plane of the circuit. At that point imagine a unit magnetic pole to be placed (see IV. ELECTRIC UNITS), belonging to a thin uniformly magnetized filament of great length; the magnetic field due to this current will then exert a mechanical force on the unit pole. Let the current be adjusted until this mechanical force is $2\pi/10$ dynes. The unvarying current so regulated is one-tenth part of an absolute C.G.S. electromagnetic unit of current. The direction of the current is conventionally defined by the following rule:—Let the circular circuit be supposed to be placed horizontally on the ground, and a watch or clock placed, face upwards, at the centre; then if the magnetic pole is a North-seeking or marked pole, and the force on it tends to raise the pole, the current is said to flow round the circuit in the opposite direction to that in which the hands of the clock or watch move. There are reasons for believing that the practical unit of current as recovered electrolytically by the Board of Trade specification differs from the true ampere as defined electromagnetically by about one part in 1100; that is to say, if the ampere were defined as the unvarying current which would deposit in one second ·001119 of a gramme of silver, it would reconcile the two definitions more completely than at present. The two definitions were originally intended to define one and the same unit current, but as a matter of fact the Board of Trade ampere is probably about one-tenth per cent. smaller than the electromagnetic ampere defined as one-tenth part of the absolute electromagnetic unit in the C.G.S. system.

Periodic currents.

If an electric current is not unvarying, it may be *irregular* or *periodic*. If periodic, it may pass through a cycle of values from a maximum value in one direction to an equal value in the opposite direction, and is in this case also called an *alternating* current. Such a current is measured by the heating effect it produces, and is said to have an effective value of one ampere if it produces the same total heat per unit of time in any given conductor as an unvarying current of one ampere measured electrolytically or magnetically. If a current is periodic or alternating, we have to consider also the law of its variation, and we are concerned first with its *instantaneous* value (i), its *maximum* value (I), its *true mean* value (T.M.), and its *root-mean-square* value (R.M.S.), the two latter quantities being respectively the mean of the instantaneous values taken at numerous equidistant intervals of time during the cycle, and the square root of the mean of the squares of the instantaneous values so taken. Lastly, many of the properties of a periodic current depend upon the manner in which its variations in instantaneous magnitude take place. It is convenient to delineate the mode of variation of a periodic or irregular current by a curve. This may be of such nature that either the ordinates or radii represent the instantaneous values of the periodic current, and it may be therefore either a *wave curve*,—that is, one so drawn that the ordinates represent the instantaneous values and the abscissæ represent the flow of time; or a *polar curve*, in which radii represent instantaneous values, and angles round a point represent time, the complete periodic time of the variable being represented by four right-angles. If a current is periodic, the *frequency* (n) is the number of cycles per second, which is usually denoted by the symbol $\sim$. The periodic time (T) is the duration of one cycle, and the frequency obviously varies inversely as the periodic time. In the case of periodic currents we have to consider also another quantity called the *form factor* (f), which is defined as the ratio between the root-mean-square (R.M.S.) value of the periodic current and its true mean (T.M.) value, or $f=\frac{\text{R.M.S. value}}{\text{T.M. value}}$. Alternating or periodic currents may be also subdivided into *single phase* and *polyphase*, the latter depending upon the union of two or more circuits traversed by currents having certain relative differences of phase. Two periodic currents are said to differ in phase when their zero values do not happen at the same instant. In this case one current is said to *lag* behind the other. We have, therefore, the following classification of electric currents:—

1. Unvarying and uni-directional currents.
2. Irregular currents.
3. Periodic or alternating currents, including
   (*a*) Single phase currents,
   (*b*) Polyphase currents.

The relation between the instantaneous value (i) of the current and the impressed electromotive force (e) acting in the circuit, and the constants of the circuit, namely, the Inductance (L), Resistance (R), and the Capacity (C), is expressed by a *current equation.* Consider first the simplest case, namely, when L and R are constant quantities and C is zero, the electromotive force having a constant value E. Then the current equation is formed by equating the impressed electromotive force to the sum of the effective electromotive forces, which is always the product Ri, and the electromotive force positive or negative which is created by the inductance or capacity of the circuit. In a circuit of constant inductance this electromotive force is a counter electromotive force and is numerically equal to L di/dt. Hence the differential current equation for a circuit of constant inductance and resistance acted upon by a constant electromotive force E is

$$E=Ri+L\frac{di}{dt}. \qquad (1)$$

The solution of this equation is

$$i=\frac{E}{R}\left(1-\epsilon^{-Rt/L}\right) \qquad (2)$$

where ϵ is the base of the Napierian logarithms.

Hence as the time (t), reckoned from the instant when the electromotive force is first applied, increases indefinitely, the value of the current (i) approximates to E/R, or to the value given by Ohm's Law. The ratio L/R which occurs in the equation (2) is of the dimensions of a time, and is called the *time-constant* of the circuit.

Consider next the case when the impressed electromotive force is not constant but periodic, and is a simple sine function having a periodic time T and a frequency n. Let $2\pi n$ be called p. Then the electromotive force at any instant has a value $e=E\sin pt$, where E is the maximum value of e. The current equation for a circuit of constant resistance and inductance is

$$e=E\sin pt=Ri+L\frac{di}{dt}, \qquad (3)$$

and the solution for i is

$$i=\frac{E\sin(pt-\theta)}{\sqrt{R^2+p^2L^2}}+C', \qquad (4)$$

where $\theta=\tan^{-1}Lp/R$, and C′ is an exponential function of t which diminishes to zero as t increases indefinitely. The quantity $\sqrt{R^2+p^2L^2}$ is called the *Impedance* of the circuit.

If we have a condenser of capacity C in series with a conducting circuit possessing an inductance L, and capacity R, then the back electromotive force due to the accumulation of electric charge in the condenser is equal to the quotient of the total electric quantity in the condenser divided by its capacity. Hence if i is the current at any instant flowing into the condenser at the time t, the total electric charge of the condenser is

$C\int_0^t idt$, and the counter electromotive force created by that charge is

$\frac{1}{C}\int_0^t idt$. Hence the differential current equation in the case of a circuit formed of a circuit having impedance, in series with a condenser having capacity, and acted upon by a simple periodic electromotive force $e = \mathrm{E} \sin pt$, is

$$e = \mathrm{R}i + \mathrm{L}\frac{di}{dt} + \frac{1}{\mathrm{C}}\int_0^t idt. \tag{5}$$

The solution of this equation for i is

$$i = \frac{\mathrm{E}}{\sqrt{\mathrm{R}^2 + (\mathrm{L}p - (\mathrm{C}p)^{-1})^2}} \sin (pt - \theta) + \mathrm{C}^1, \tag{6}$$

where θ is a constant phase angle, and C^1 is a function of t which dies out rapidly as the time t continually increases. The equation (2) shows that if a constant unidirectional electromotive force is applied to an inductive circuit, the current does not immediately attain its full strength, but beginning at zero gradually rises up towards a constant value E/R at a rate which depends upon the rate of increase of the quantity $\epsilon^{-\mathrm{R}t/\mathrm{L}}$ towards unity. The larger the value of the inductance L, the slower is the rate of growth. Accordingly, in an inductive circuit it is not possible to make very rapid changes in current strength. If the circuit has a variable inductance, such for instance as the circuit of an electromagnet, in which coils of wire are wrapped round an iron core, the inductance L is a function of the exciting current i, and the differential equations cannot be solved unless the form of the function is known.

In the case of simple periodic currents it is interesting to study the initial effects in a circuit of constant inductance L which take place on first bringing an alternating electromotive force into operation on the circuit. To obtain the complete solution of the differential current equation

$$\mathrm{E} \sin pt = e = \mathrm{R}i + \mathrm{L}\frac{di}{dt}, \tag{7}$$

we differentiate the equation twice to eliminate E sin pt, and arrive at a linear differential equation of the third order, namely,

$$\mathrm{L}\frac{d^3i}{dt^3} + \mathrm{R}\frac{d^2i}{dt^2} + p^2\mathrm{L}\frac{di}{dt} + p^2\mathrm{R}i = 0. \tag{8}$$

The solution of the above equation is

$$i = \mathrm{A}\,\epsilon^{-\mathrm{R}t/\mathrm{L}} + \mathrm{B} \sin pt + \mathrm{B}^1 \cos pt \tag{9}$$

where A, B, and B^1 are constants. This may be written

$$i = \mathrm{A}\,\epsilon^{-\mathrm{R}t/\mathrm{L}} + \mathrm{I} \sin (pt - \phi) \tag{10}$$

where I is the maximum value of the periodic current and ϕ is a constant angle, called the *angle of lag.* To find the value of the constant A we note that at the instant of closing, the circuit i must be zero. Let this closure happen at a time t^1 reckoned from the instant when the electromotive force is zero, then we have

$$i = \mathrm{I} \sin (pt - \phi) + \mathrm{I} \sin (pt^1 - \phi)\,\epsilon^{-\mathrm{R}(t - t^1)/\mathrm{L}}$$

as the complete solution of the above differential current equation. We notice that the solution for i is made up of a simple periodic function added to an exponential function of which the initial value is I sin $(pt^1 - \phi)$. The complete graph of the solution of the current equation is therefore a curve similar to the dotted curve in Fig 2, the ordinates of which are equal to the sum of the ordinates of the (firm line) periodic curve and the (firm line) exponential curve. The initial value of the exponential curve depends upon the phase of the electromotive force when the circuit is closed. We are therefore led to the conclusion that if a simple periodic electromotive force is applied suddenly to an inductive circuit, there may be a short period of time during which the current curve is lop-sided, and more current flows in one direction than in the other. The occurrence of this initial stage depends upon the phase of the electromotive force when the circuit is closed.

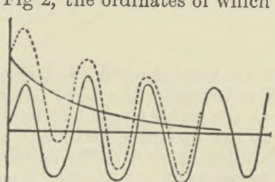

Fig. 2

In the above equations ϕ is the angle by which the current when steady lags behind the electromotive force. Hence $\tan \phi = \mathrm{L}p/\mathrm{R}$. We may in the same manner discuss the initial conditions when a periodic electromotive force is suddenly applied to an inductive circuit having a condenser in series with it, and arrive at a solution of the form

$$i = \mathrm{I} \sin (pt - \theta) + \mathrm{A}\,\epsilon^{-\mathrm{R}t/\mathrm{L}} \sin (pt - \phi)$$

where I is the maximum value of the current during the cycle in the steady state and A and q are constants. The solution shows us that the physical operations which take place when a condenser in series with an inductive circuit suddenly has a simple periodic electromotive force applied to it is as follows :—Before the oscillations of current settle down into a steady periodic state, a second set of oscillations of current is superimposed on the steady set, the latter having possibly a frequency and amplitude different from those which ultimately survive. The simultaneous existence of these oscillations may give rise to variations of electromotive force acting on the condenser which are much greater in amplitude than those which take place in the steady state. The extent to which these superimposed oscillations of current occur, depends upon the phase of the electromotive force when the current is closed.

In dealing with problems connected with electric currents we have to consider the laws which govern the flow of currents in linear conductors (wires), in plane conductors (sheets), and throughout the mass of a material conductor. In the first case consider the collocation of a number of linear conductors, such as rods or wires of metal, joined at their ends to form a *network of conductors.* The network consists of a number of conductors joining certain points and forming meshes. In each conductor a current may exist, and along each conductor there is a fall of potential, or an active electromotive force may be acting in it. Each conductor has a certain resistance. To find the current in each conductor when the individual resistances and electromotive forces are given, proceed as follows :—Consider any one mesh. The sum of all the electromotive forces which exist in the branches bounding that mesh must be equal to the sum of all the products of the resistances into the currents flowing along them, or $\Sigma(\mathrm{E}) = \Sigma(\mathrm{C.R.})$. Hence if we consider each mesh as traversed by imaginary currents all circulating in the same direction, the real currents are the sums or differences of these imaginary cyclic currents in each branch. Hence we may assign to each mesh a cycle symbol x, y, z, &c., and form a cycle equation. Write down the cycle symbol for a mesh and prefix as coefficient the sum of all the resistances which bound that cycle, then subtract the cycle symbols of each adjacent cycle, each multiplied by the value of the bounding or common resistances, and equate this sum to the total electromotive force acting round the cycle. Thus if x y z are the cycle currents, and a b c the resistances bounding the mesh x, and b and c those separating it from the meshes y and z, and E an electromotive force in the branch a, then we have formed the cycle equation $x\,(a + b + c)\,x - by - cz = \mathrm{E}$. For each mesh a similar equation may be formed. Hence we have as many linear equations as there are meshes, and we can obtain the solution for each cycle symbol, and therefore for the current in each branch. The solution giving the current in such branch of the network is therefore always in the form of the quotient of two determinants. The solution of the well-known problem of finding the current in the galvanometer circuit of the arrangement of linear conductors called Wheatstone's Bridge is thus easily obtained. For if we call the cycles (see Fig. 3) $(x+y)$, y and z, and the resistances P, Q, R, S, G, and B, and if E be the electromotive force in the battery circuit, we have the cycle equations

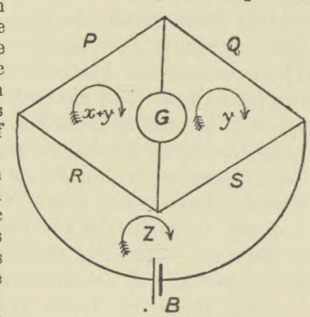

Fig. 3.

$$(\mathrm{P} + \mathrm{G} + \mathrm{R})\,\overline{x + y} - \mathrm{G}y - \mathrm{R}z = 0.$$
$$(\mathrm{Q} + \mathrm{G} + \mathrm{S})\,y - \mathrm{G}\overline{x + y} - \mathrm{S}z = 0.$$
$$(\mathrm{R} + \mathrm{S} + \mathrm{B})\,z - \mathrm{R}\overline{x + y} - \mathrm{S}y = \mathrm{E}.$$

From these we can easily obtain the solution for $\overline{x + y} - y = x$, which is the current through the galvanometer circuit in the form

$$x = \mathrm{E}\delta/\Delta,$$

where δ and Δ are two determinants. (Fleming, "Problems on the Distribution of Electric Currents in Networks of Conductors," *Phil. Mag.*, Sept. 1885.)

In the case of current flow in plane sheets, we have to consider certain points called *sources* at which the current flows into the sheet, and certain points called *sinks* at which it leaves. We may investigate, first, the simple case of one source and one sink in an infinite plane sheet of thickness δ, and conductivity k. Take any point P in the plane at distances R and r from the source and sink respectively. The potential V at P is obviously given by

$$\mathrm{V} = \frac{\mathrm{Q}}{2\pi k\delta} \log \frac{r_1}{r_2},$$

where Q is the quantity of electricity supplied by the source per second. Hence the equation to the equipotential curve is $r_1 r_2 = \mathrm{Const.}$

If we take a point half-way between the sink and the source as the origin of a system of rectangular co-ordinates, and if the distance between sink and source is equal to p, and the line joining them is taken as the axis of x, then the equation to the equipotential line is

$$\frac{y^2 + \overline{x + p}^2}{y^2 + (x - p)^2} = \mathrm{Const.}$$

This is the equation of a family of circles having the axis of y for a common radical axis, one set of circles surrounding the sink and another set of circles surrounding the source. In order to discover the form of the stream of current lines we have to determine the orthogonal trajectories to this family of coaxial circles. It is easy to show that the orthogonal trajectory of the system of circles is another system of circles all passing through the sink and the source, and as a corollary of this fact, that the electric resistance of a circular disc of uniform thickness is the same between any two points taken anywhere on its circumference as sink and source. These equipotential lines may be delineated experimentally by attaching the terminals of a battery or batteries to small wires which touch at various places a sheet of tinfoil. Two wires attached to a galvanometer may then be placed on the tinfoil, and one may be kept stationary and the other may be moved about, so that the galvanometer is not traversed by any current. The moving terminal then traces out an equipotential curve. If there are n sinks and sources in a plane conducting sheet, and if r, r', r'', be the distances of any point from the sinks, and r, r', r'', the distances of the source, then

$$\frac{r\ r'\ r''\ \ldots}{r\ r'\ r''\ \ldots} = \text{a constant},$$

is the equation to the equipotential lines. The orthogonal trajectories or stream lines have the equation[1]

$$\Sigma\,(\theta - \theta') = \text{a constant},$$

where θ and θ' are the angles which the lines drawn from any point in the plane to the sink and corresponding source make with the line joining that sink and source. Generally it may be shown that if there are any number of sinks and sources in an infinite plane-conducting sheet, and if r, θ are the polar co-ordinates of any one, then the equation to the equipotential surfaces is given by the equation

$$\Sigma\,(\text{A} \log r) = \text{a constant},$$

where A is a constant; and the equation to the stream or current lines is

$$\Sigma\,(\theta) = \text{a constant}.$$

In the case of electric flow in three dimensions the electric potential must satisfy Laplace's equation, and a solution is therefore found in the form $\Sigma\left(\frac{\text{A}}{r}\right) = \text{a constant}$, as the equation to an equipotential surface, where r is the distance of any point on that surface from a source or sink.

Practical instruments. The practical measurement of electric current involves the use of instruments which are variously called *galvanoscopes*, *galvanometers*, *amperemeters* or *ampere-balances*. The most frequently-recurring operation in electric work is the determination of the presence or the absence of an electric current in a circuit. For this purpose we may employ galvanoscopes when a mere qualitative determination is required, indicating in a general way the presence of a current, without any reference to its strength. On the other hand, if a current has to be measured in terms of the unit current, then a galvanometer or amperemeter must be made use of. Current measuring instruments may be constructed by taking advantage of any measurable effect due to the presence of a current in a conductor. Hence we may classify them as: 1. *Electromagnetic*; 2. *Electrodynamic*; 3. *Electrothermal*; 3. *Electro-optic*; 5. *Electrochemical*, according as they depend in principle upon the magnetic, electrodynamic, thermal, optical, or chemical effects which are associated with an electric circuit when traversed by a current. The majority of instruments in use depend upon the properties of the magnetic field round a circuit through which a current is flowing, and such instruments may be classified into: (i.) *movable needle and fixed coil instruments*; (ii.) *movable coil and fixed magnet instruments*; (iii.) *movable iron and fixed coil instruments*. In the first class a magnetic needle is suspended in or near a coil which is traversed by the current to be measured. The magnetic field due to this current brings into existence a magnetic torque or couple which causes the needle to tend to set in a certain direction, and this movement is resisted by some opposing couple called the *control*.

Of this type are many forms of galvanometer, such as the simple needle, the mirror galvanometer, the tangent galvanometer in various forms. In the mirror instrument the movement of a single magnetic needle or of an astatic system is detected by attaching to the needle system a light concave mirror on which a ray of light is thrown from a lamp. The mirror reflects the ray upon a scale, where it is made to form the sharp image of the source of light or of an opening through which it passes. The scale is generally placed at a distance of one metre from the mirror. A convenient method for obtaining a sharp image is to focus on the screen the image of a portion of a filament of an incandescent electric lamp. If the scale is semi-transparent, the bright line of light so formed can be read from the other side, and its position determined with great accuracy. The *sensibility* of the galvanometer is expressed by stating the deflection of the spot of light in millimetres on the scale when the mirror is at a distance of one metre from the scale, and when a known fraction of an ampere, say a microampere, is passing through the galvanometer. In the movable coil instruments a current passes through the light suspended coil of wire, the current entering and leaving the coil by a fine suspension wire, generally composed of phosphor-bronze. This coil is placed in the field of a strong permanent magnet, so arranged that the direction of the plane of the coil is parallel to the lines of flux of the field. The coil thus stands in a very intense field; and if a feeble current is passed through it, a couple is brought into operation, tending to twist it round so that its plane becomes inclined to the field. A small movement of the coil can be detected by attaching to it a mirror, and reflecting therefrom a ray of light upon a scale. Of this type are the galvanometers now much used in electrical laboratories. One great advantage possessed by them is that they are not disturbed by the presence of electric currents in neighbouring conductors. By winding the coil on a silver frame the galvanometer can be made very *dead-beat*; that is to say, the galvanometer coil will come to rest very quickly after being disturbed, without executing many oscillations. For many purposes a galvanometer is required which possesses exactly an opposite character, that is to say, as little *dead-beat* as possible. A *ballistic* galvanometer, as such an instrument is termed, is employed for the purpose of measuring, not current, but the time-integral of current. The value of a galvanometer for practical purposes is determined by the degree to which it possesses the following qualities:—(1) The deflection of the coil or needle should be in some constant relation to the current causing it. In mirror instruments it is generally found that, over the limits of scale-length usually employed, the scale deflection is proportional to the current flowing through the instrument. The number by which the scale deflection must be multiplied to obtain the ampere value of the current is called the *galvanometer constant*. (2) The galvanometer should possess a zero-keeping quality; that is to say, when a known current is flowing through it, the galvanometer coil or needle should always take up precisely the same position. (3) For many purposes it is convenient that the value of the galvanometer constant should be capable of being varied by altering the nature of the control. In needle instruments the control generally consists of an external magnet, the proximity of which to the needle determines the magnitude of the control.

A large class of current measuring and detecting instruments depend for their operation on the fact that a mass of ferromagnetic material, say soft iron, if placed in a magnetic field of variable strength, tends to move from places of weak to places of strong magnetic force. If the ferromagnetic material has an elongated shape like a needle, and if it is placed in a uniform field, the direction of the field being inclined to the direction of the longer axis of the needle, then the needle will tend to set its greatest length in the direction of the field. An instrument of this last kind is called a soft-iron needle galvanometer, and it may be made sufficiently sensitive to detect the feeble current through a telephone. A large number of commercial forms of amperemeter are constructed by taking advantage of the same fact. (See MEASURING INSTRUMENTS, ELECTRIC.) Thus if a circular coil of insulated wire of no very great depth is arranged with its plane in a vertical position, and if a small piece of soft iron attached to a pivoted index-needle is so arranged that under the action of gravity the piece of iron occupies a position near the centre of the coil, then when a current is sent through the coil the iron will be displaced to a position nearer the inner surface of the coil. This movement will bring into existence a restoring force due to gravity; hence if the index-needle is made to move over a divided scale, the instrument may be calibrated so as to show directly the value of the current passing through the coil. Another type of current-measuring instrument depends for its action upon the mechanical force discovered by Ampère to exist between conductors which are parallel, or nearly parallel, to each other, and are conveying the same or different electric currents. One of the best-known forms of instrument depending on this principle is the *Electrodynamometer* of Siemens.

Very convenient and accurate instruments based on the

[1] See W. G. Adams, The Bakerian Lecture "On the Forms of Equipotential Curves and Surfaces and Lines of Flow," *Proc. Roy. Soc. London*, 1872; also G. C. Foster and O. J. Lodge, "On the Flow of Electricity in a Uniform Plane-Conducting Circuit," *Phil. Mag.*, May and June 1875.

above principles have been devised by Lord Kelvin, and a large variety of these *ampere balances*, as they are called, suitable for measuring currents from a fraction of an ampere up to many thousands of amperes, have been constructed by that illustrious inventor.

Ampere balances.

The difficulty which has generally presented itself to those who have tried to design instruments on the electrodynamometer principle for use with large currents, has been that of getting the current into and out of the movable conductor, and yet permitting that conductor to remain free to move under very small force. The use of mercury cups is open to many objections on account of the fact that the mercury becomes oxidized, and such instruments are not very convenient for transportation. The great novelty in the ampere balances of Lord Kelvin was a joint or electric coupling, which is at once exceedingly flexible and yet capable of being constructed to carry with safety any desired current. This he achieved by the introduction of a device which is called a metallic ligament. The general principle of its construction is as follows:—Let + A – A

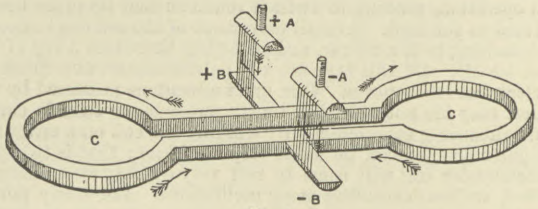

Fig. 4

(Fig. 4) be a pair of semi-cylindrical fixed trunnions which are carried on a supporting frame and held with flat sides downwards. Let + B – B be two smaller trunnions which project out from the sides of the two strips connecting together a pair of rings CC. The rings and the connecting strips constitute the circuit which is to be rendered movable. A current entering by the trunnion + B flows round the two halves of the circuit, as shown by the arrows, and comes out at the trunnion – B. In Fig. 4 the current is shown dividing round the two rings; but in all the balances, except those intended for the largest currents, the current really circulates first round one ring and then round the other. To make the ligament, a very large number of exceedingly fine copper wires laid close together are soldered to the upper surface of the upper trunnion, and also to the end surface of the lower trunnion. The movable circuit CC thus hangs by two ligaments which are formed of very fine copper wires. This mode of suspension enables

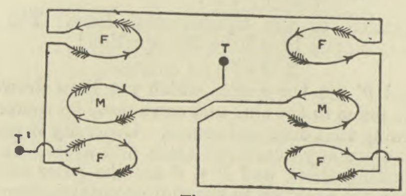

Fig. 5.

the conductor CC to vibrate freely like a balance, but at the same time very large currents can easily be passed through this perfectly flexible joint. Above and below these movable coils, which form as it were the two scale pans of a balance, are fixed other stationary coils, and the connexions of all these six coils (shown in Fig. 5) are such that when a current is passed through the whole of

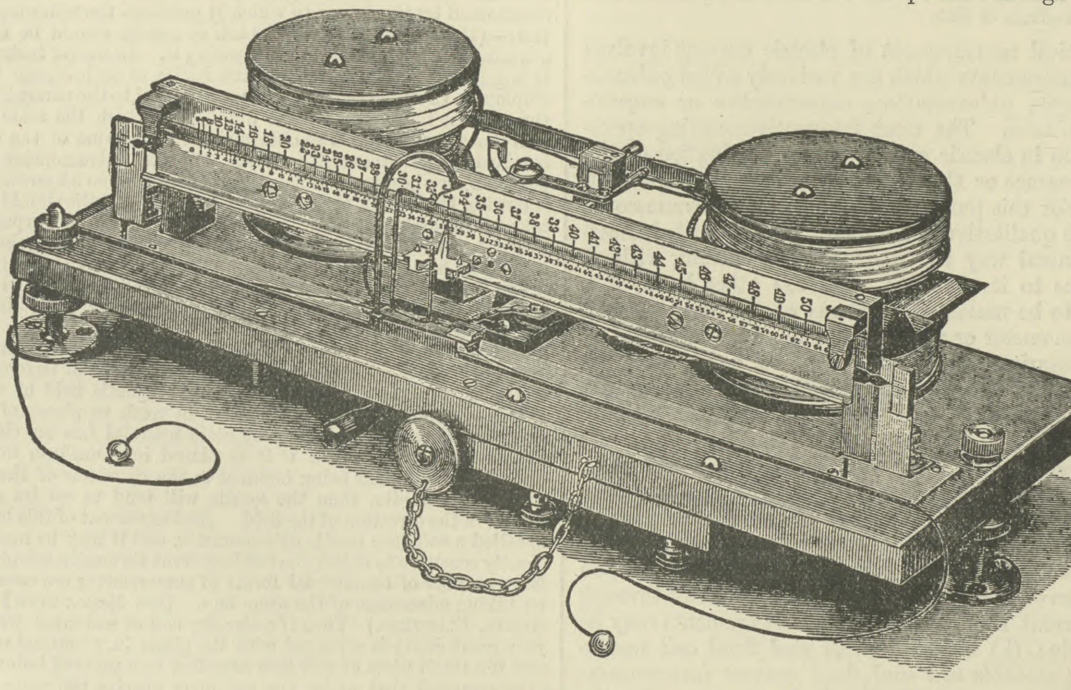

Fig. 6.

the coils in series, forces of attraction and repulsion are brought into existence which tend to force one movable coil upwards and the other movable coil downwards. This tendency is resisted by the weight of a mass of metal, which can be caused to slide along a tray attached to the movable coils. The appearance of the complete instrument is shown by Fig. 6. When a current is passed through the instrument it causes one end of the movable system to tilt downwards, and the other end upwards; the sliding weight is then moved along the tray by means of a silk cord until equilibrium is again established. The value of the current in amperes is then obtained approximately by observing the position of the weight on the scale, or it may be obtained more accurately in the following manner:—The upper edge of the shelf on which the weights slide (see Fig. 7) is graduated into equal divisions, and the weight is provided with a sharp tongue of metal in order that its position on the shelf may be accurately determined. Since the current passing through the balance when equilibrium is obtained with a given weight is proportional to the square root of the couple due to this weight, it follows that the current strength when equilibrium is obtained is

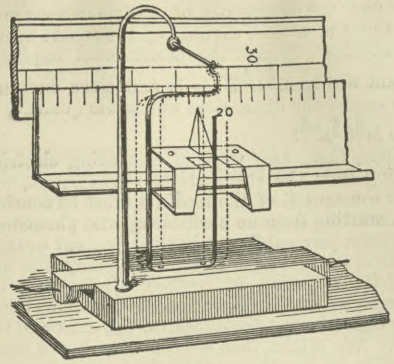

Fig 7.

proportional to the product of the square root of the weight used and the square root of the *displacement* distance of this weight from its zero position. Each instrument is accompanied by a pair of weights and by a square-root table, so that the product of the square root of the number corresponding to the position of the sliding weight, and a certain constant for each weight, gives at once the value of the current in amperes.

These balances are made to cover a certain range of reading, thus:—

The centi-ampere balance ranges from 1 to 100 centi-amperes.
The deci-ampere balance ranges from 1 to 100 deci-amperes.
The ampere balance ranges from 1 to 100 amperes.
The deka-ampere balance ranges from 1 to 100 amperes.
The hecto-ampere balance ranges from 6 to 600 amperes.
The kilo-ampere balance ranges from 100 to 2500 amperes.

They are valuable for the measurement not only of continuous or unvarying, but also of alternating currents. In those intended for alternating currents the main current through the movable coil, whether consisting of one turn or more than one turn, is carried by a wire rope, of which each component strand is insulated by silk covering, to prevent the inductive action from altering the distribution of the current across the transverse section of the conductor. To avoid the creation of induced currents, the coil frames and the base boards are constructed of slate. Kelvin ampere balances are now made in two types—(1) a variable weight type suitable for obtaining the ampere value of any current within their range; and (2) a fixed weight type intended to indicate when a current which can be varied at pleasure has a certain fixed value. An instrument of the latter type of considerable accuracy was designed by Lord Kelvin for the British Board of Trade Electrical Laboratory, and it is there used as the principal standard ampere balance. A fixed weight is placed on one coil and the current is varied gradually until the balance is just in equilibrium. Under these circumstances the current is known to have a fixed value in amperes determined by the weight attached to the instrument. For the measurement of alternating currents, instruments containing soft iron or permanent magnets are not available, and the only forms that can then be employed are those the indications of which do not depend upon the direction of the current, such as the electrodynamometer instruments or ampere balances just described. There are, however, a number of instruments in use for measuring alternating currents in which the heating action of a current is utilized. If a fine wire is traversed by a current either alternating or continuous, heat is generated in it at a rate depending upon the square of the current strength. If the wire is contained in an enclosure which can radiate back to it, the temperature of the wire when it is traversed by a constant current will gradually rise until it reaches a point at which the rate of radiation of heat from the wire is balanced by the rate of generation of heat in it. Under these circumstances the wire expands until it reaches a constant state, and the elongation in its length, being dependent upon its temperature, may be made a measure of the R.M.S. value of the current flowing in the wire. This elongation may be ascertained either by a multiplying arrangement which measures the actual linear elongation, or the two ends of the wire may be fixed, and we may in some way measure the *sag* of the wire as it is heated. Convenient instruments of the latter class have been devised and made by Messrs Hartmann & Braun, and are of considerable use in the laboratory for the measurement of alternating currents. The well-known Cardew voltmeter is an instrument of this type. For the measurement of continuous currents over any range, no instrument is more convenient than that called the Potentiometer.

For further details as to current measurement the reader is referred to the article on MEASURING INSTRUMENTS, ELECTRIC; and for additional information the following treatises may be consulted:—CLERK MAXWELL. *Electricity and Magnetism*, 2 vols. IV. ELECTRIC UNITS.

In order that our acquaintance with any part of Nature may become exact, we must have not merely a qualitative but a quantitative knowledge of facts. Hence the moment that any branch of science emerges from an early stage, attempts are made to measure and evaluate the quantities and effects found to exist. To do this we have to select for each measurable magnitude a *Unit* or standard sample of each quantity, by comparison with which amounts of other like quantities may be numerically defined. There is nothing to prevent us from selecting these standard samples in a perfectly arbitrary and independent manner, and as a matter of fact this is what is generally done in the early stages of every science. The progress of knowledge, however, is greatly assisted if all the measurable quantities are brought into relation with each other by so selecting the units that they are related in the most simple manner, each to the other and to one common set of measurable magnitudes, called the *fundamental quantities.* The progress of this unification of units has been greatly aided by the discovery that forms of physical energy can be converted into one another, and that the conversion is by definite rule and amount. Thus the mechanical energy associated with moving masses can be converted into heat, and the amount of heat required to raise one gramme of water 1° C. in the neighbourhood of 10° C. is equal to forty-two million ergs, the erg being the energy of motion associated with a mass of 2 grammes when moving uniformly without rotation with a velocity of 1 cm. per second. This number is commonly called the mechanical equivalent of heat, but would be more exactly described as the mechanical equivalent of the specific heat of water at 10° C. Again, the fact that the maintenance of an electric current requires energy, and that when produced its energy can be wholly utilized in heating a mass of water, enables us to make a similar statement about the energy required to maintain a current of one ampere through a resistance of one ohm for one second, expressed in its equivalent in the energy of a moving mass. Electric and magnetic units have therefore been selected with the object of establishing simple relations between each of them and the fundamental mechanical units. Electric and magnetic measurements based on such relations are called *Absolute Measurements.* The science of dynamics, as far as that part of it is concerned which deals with the motion and energy of material substances, is based upon certain fundamental definitions concerning the measurable quantities involved. In constructing a system of electric and magnetic units, the first thing to consider is the manner in which we shall connect the system with our dynamical measurements. What, for instance, shall be the unit of electric quantity, and how shall it be determined by simple reference to mechanical units, and, therefore, to units of mass, length, and time? The unit of electric charge may be defined as that charge which if collected on a small conductor repels an equally charged conductor at a unit of distance with the unit of force, and this definition was in fact one of the original starting-points of the Committee of the British Association on Electrical Units. It is well known, however, that the mechanical stress between two electrified bodies depends also upon, and varies inversely as, the Dielectric Constant or Specific Inductive Capacity K of the medium in which they are immersed. Hence unless we take this fact into account, our statement is imperfect; and unless we know the manner in which the mechanical stress is produced and the mechanical details of the operation, we are unable to express the whole of the facts by dynamical statements. The Committee of the British Association evaded this difficulty by omitting all reference to the medium in which the electric operations take place, and thereby they introduced a subsequent difficulty.

If for the moment we neglect all questions of the medium, and regard the mechanical stress between two small electrified conductors merely as a case of action-at-a-distance, then we can obtain the *dimensions* of electrical quantity from the fact discovered by Coulomb, that the mechanical stress between such small bodies varies directly as the product of the electric charge on each, and inversely as the square of their distance (see *Ency. Brit.* vol. vii. p. 241). Hence it follows that if the charges are equal, the dimensions of electrical quantity must be the same as those of a length multiplied by the square root of a force; in other words, they are $M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}$. It has been pointed out, however, by Professor A. W. Rücker (*Phil. Mag.*, February 1889), that we have no right to omit in these dimensional expressions all reference to the qualities of the medium, which are determining factors in the production of the forces; and that in the absence of any exact knowledge as to the true dynamical nature of the operations concerned in electrostatic phenomena, we should treat the Dielectric Constant of the medium in which the operations take place as a fundamental quantity of dimensions as yet unknown, thus introducing into the dimensional equations a quantity K not yet resolved into its equivalent in terms of mass, length, and time. If, then, we take into account this dielectric constant, the dimensions of electric quantity are expressible in terms of length, mass, time, and dielectric constant by the symbol $M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}K^{\frac{1}{2}}$. If a conductor is charged with a certain quantity of electricity represented by Q which is discharged through another conductor n times per second, this in effect constitutes an electric current which would be represented in magnitude by the product nQ. In other words, the strength of a current is measured by quantity per second passing any section of the circuit. It follows, therefore, that on the above system of electrical measurement the dimensions of electric current must be those of electric quantity per second; in other words, must be represented by the dimensional expression $M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-2}K^{\frac{1}{2}}$. There is, however, another way of approaching the subject. If we consider two linear conductors parallel to one another conveying the same electric current, we know there is an attractive force between them which is proportional to the square of the strength of the current, and inversely proportional to the magnetic permeability μ of the medium in which the conductors are placed. From this point of view the dimensions of electric current must be those of the square root of a force divided by the square root of a magnetic permeability. Hence the dimensional expression for an electric current will be $M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}\mu^{-\frac{1}{2}}$, and since electric current is quantity per second the dimensions of electric quantity of measurement will be $M^{\frac{1}{2}}L^{\frac{1}{2}}\mu^{-\frac{1}{2}}$.

We have here, then, two ways of measuring electric quantity; in one, starting from the electrostatic phenomenon, we find that the dielectric constant K of the medium must be considered, while in the other, starting from an electromagnetic phenomenon, we see that the magnetic permeability μ is an important quantity. If we fully understood the structure of the electromagnetic medium, and the mode of its operation in creating electrostatic and electromagnetic effects, we might determine the dynamical nature of its two qualities denominated the dielectric constant and the magnetic permeability. We might then express K and μ in terms of L, M, and T, the units of length, mass, and time, and we should arrive at the same dimensional expressions in both cases; for it is obvious that if the nature of the dynamical machinery involved were thoroughly understood, the dimensions of an electric current or electric quantity would be the same, whatever be the point of view from which we start, or whatever facts we make the basis of our determination of the dimensional expression. As it is, however, being ignorant of the real mechanical nature of the medium, we have two systems of measurement: one called the *electrostatic*, and the other called the *electromagnetic*.

It was formerly the custom to ignore the presence of the quantities K and μ, and to express the dimensions of electric and magnetic quantities on the electrostatic system by assuming that K on the electrostatic system, and μ on the electromagnetic system, was always unity. If, however, we insert the symbols K and μ to stand for the unknown dimensions of the dielectric constant and the magnetic permeability, we can obtain two dimensional expressions for an electric current; and the ratio of the dimensions of electric quantity or electric current on the electrostatic system to the dimensions on the electromagnetic system is that of $LT^{-1}K^{\frac{1}{2}}\mu^{\frac{1}{2}}$; hence $K^{\frac{1}{2}-}\mu^{-\frac{1}{2}}$ must be of the dimensions of a velocity. Accordingly, it appears that although we do not know the dimensions of K and μ independently in terms of length, mass, and time, we do know that their product is of the dimensions of the reciprocal of the square of a velocity.

Turning now to another point, we may consider the dimensions of a magnetic pole strength on the two systems. If two uniformly magnetized filaments of equal strength and great length have their poles brought close to one another, it is known, in accordance with Coulomb's experiments, that the mechanical stress or force between the poles is proportional to the product of their strengths, and varies inversely as the square of the distance between them. It is also known to be inversely proportional to the magnetic permeability of the medium in which the poles are placed. Hence, if the poles are of equal strength, it follows that the dimensions of polar strength on the electromagnetic system of measurement must be $M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}\mu^{-\frac{1}{2}}$ where μ stands for the unknown dimensions of magnetic permeability. If a magnetic pole is carried round a current, it can be shown that the mechanical work done in taking the pole once round the conductor, conveying the current against the direction of the magnetic force due to the current, is $4\pi Cm$. Hence the dimensions of the quantity $4\pi Cm$, where C stands for the total current and m for the strength of the magnetic pole, must be those of energy or work, namely, $ML^{2}T^{-2}$. Accordingly, the dimensions of a magnetic pole strength in electrostatic measure must be those of work divided by those of current in electrostatic measure, or $ML^{2}T^{-2} \div M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-2}K^{\frac{1}{2}} = M^{\frac{1}{2}}L^{\frac{1}{2}}K^{-\frac{1}{2}}$. Hence the ratio of a magnetic pole strength in electrostatic measure to that in electromagnetic measure must be $M^{\frac{1}{2}}L^{\frac{1}{2}}K^{-\frac{1}{2}} \div M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}\mu^{\frac{1}{2}} = L^{-1}TK^{-\frac{1}{2}}\mu^{-\frac{1}{2}}$, and this ratio we see to be that of $K^{\frac{1}{2}}\mu^{\frac{1}{2}}$ to the reciprocal of a velocity, or of $K\mu$ to the reciprocal of the square of a velocity.

Again, we may arrive at two dimensional expressions for electromotive force or difference of potential. Electrostatic difference of potential between two places is measured by the mechanical work required to move a small conductor charged with a unit electric charge from one place to the other against the electric force. Hence if V stands for the difference of potential between the two places, and Q for the charge on the small conductor, the product QV must be of the dimensions of the *work* or *energy*, or of the force × length, or of $ML^{2}T^{-2}$. But Q on the electrostatic system of measurement is of the dimensions $M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}K^{\frac{1}{2}}$; the potential difference V must be therefore of the dimensions $M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}K^{-\frac{1}{2}}$. Again, since by Ohm's Law and Joule's Law electromotive force multiplied by a current is equal to the power expended on a circuit, the dimensions of electromotive force, or, what is the same thing, of potential difference, in the electromagnetic system of measurement must be those of power divided by a current. Since mechanical power means *rate of doing work*, the dimensions of power must be ML^2T^{-3}. We have already seen that on the electromagnetic system the dimensions of a current are $M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}\mu^{-\frac{1}{2}}$; therefore the dimensions of electromotive force or potential on the electromagnetic system must be $M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-2}\mu^{\frac{1}{2}}$. Here again we find that the ratio of the dimensions on the electrostatic system to the dimensions on the electromagnetic system is $L^{-1}TK^{-\frac{1}{2}}\mu^{-\frac{1}{2}}$.

In the same manner we may recover from fundamental facts and relations the dimensions of every electric and magnetic quantity on the two systems, starting in one case from electrostatic phenomena and in the other case from electromagnetic or magnetic. The electrostatic dimensional expression will always involve K, and the electromagnetic dimensional expression will always involve μ, and in every case the dimensions in terms of K are to those in terms of μ for the same quantity in the ratio of a power of $LT^{-1}K^{\frac{1}{2}}\mu^{\frac{1}{2}}$. This therefore confirms the view that whatever may be the true dimensions in terms of fundamental units of μ and K, their product is the inverse square of a velocity.

The following table gives the dimensions of all the principal electric and magnetic quantities on the electrostatic and electromagnetic systems:—

TABLE XV. *Dimensions of Electric Quantities.*

Quantity.	Symbol.	Dimensions on the Electrostatic System E.S.	Dimensions on the Electromagnetic System E.M.	Ratio of E.S. to E.M.
Magnetic Permeability	(μ)	$L^{-2}T^{2}K^{-1}$	μ	$L^{-2}T^{2}K^{-1}\mu^{-1}$
Magnetic Force or Field	(H)	$L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-2}K^{\frac{1}{2}}$	$L^{-\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\mu^{-\frac{1}{2}}$	$L\,T^{-1}K^{\frac{1}{2}}\mu^{\frac{1}{2}}$
Magnetic Flux Density or Induction	(B)	$L^{-\frac{3}{2}}M^{\frac{1}{2}}K^{-\frac{1}{2}}$	$L^{-\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\mu^{\frac{1}{2}}$	$L^{-1}T\,K^{-\frac{1}{2}}\mu^{-\frac{1}{2}}$
Total Magnetic Flux	(Z)	$L^{\frac{1}{2}}M^{\frac{1}{2}}K^{-\frac{1}{2}}$	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}\mu^{\frac{1}{2}}$	$L^{-1}T\,K^{-\frac{1}{2}}\mu^{-\frac{1}{2}}$
Magnetization	(I)	$L^{-\frac{3}{2}}M^{\frac{1}{2}}K^{-\frac{1}{2}}$	$L^{-\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\mu^{\frac{1}{2}}$	$L^{-1}T\,K^{-\frac{1}{2}}\mu^{\frac{1}{2}}$
Magnetic Pole Strength	(m)	$L^{\frac{1}{2}}M^{\frac{1}{2}}K^{-\frac{1}{2}}$	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}\mu^{\frac{1}{2}}$	$L^{-1}T\,K^{-\frac{1}{2}}\mu^{-\frac{1}{2}}$
Magnetic Moment	(M)	$L^{\frac{3}{2}}M^{\frac{1}{2}}K^{-\frac{1}{2}}$	$L^{\frac{5}{2}}M^{\frac{1}{2}}T^{-1}\mu^{\frac{1}{2}}$	$L^{-1}T\,K^{-\frac{1}{2}}\mu^{-\frac{1}{2}}$
Magnetic Potential or Magnetomotive Force	(M.M.F.)	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}K^{\frac{1}{2}}$	$L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\mu^{-\frac{1}{2}}$	$L\,T^{-1}K^{\frac{1}{2}}\mu^{\frac{1}{2}}$
Specific Inductive Capacity	(K)	K	$L^{-2}T^{2}\mu^{-1}$	$L^{2}T^{-2}K\,\mu$
Electric Force	(e)	$L^{-\frac{1}{2}}M^{\frac{1}{2}}T^{-1}K^{-\frac{1}{2}}$	$L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-2}\mu^{\frac{1}{2}}$	$L^{-1}T\,K^{-\frac{1}{2}}\mu^{-\frac{1}{2}}$
Electric Displacement	(D)	$L^{-\frac{1}{2}}M^{\frac{1}{2}}T^{-1}K^{\frac{1}{2}}$	$L^{-\frac{3}{2}}M^{\frac{1}{2}}\mu^{-\frac{1}{2}}$	$L\,T^{-1}K^{\frac{1}{2}}\mu^{\frac{1}{2}}$
Electric Quantity	(Q)	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}K^{\frac{1}{2}}$	$L^{\frac{1}{2}}M^{\frac{1}{2}}\mu^{-\frac{1}{2}}$	$L\,T^{-1}K^{\frac{1}{2}}\mu^{\frac{1}{2}}$
Electric Current	(A)	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}K^{\frac{1}{2}}$	$L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\mu^{-\frac{1}{2}}$	$L\,T^{-1}K^{\frac{1}{2}}\mu^{\frac{1}{2}}$
Electric Potential / Electromotive Force	(V) / (E.M.F.)	$L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}K^{-\frac{1}{2}}$	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}\mu^{\frac{1}{2}}$	$L^{-1}T\,K^{-\frac{1}{2}}\mu^{-\frac{1}{2}}$
Electric Resistance	(R)	$L^{-1}T\,K^{-1}$	$L\,T^{-1}\mu$	$L^{-2}T^{2}K^{-1}\mu^{-1}$
Electric Capacity	(C)	$L\,K$	$L^{-1}T^{2}\mu^{-1}$	$L^{2}T^{-2}K\,\mu$
Self Inductance / Mutual Inductance	(L) / (M)	$L^{-1}T^{2}K^{-1}$	$L\,\mu$	$L^{-2}T^{2}K^{-1}\mu^{-1}$

It will be seen that in every case the ratio of the dimensions on the two systems is a power of $LT^{-1}K^{\frac{1}{2}}\mu^{\frac{1}{2}}$, or of a velocity multiplied by the square root of the product K and μ; in other words, it is the product of a velocity multiplied by the geometric mean of K and μ. This quantity $1/\sqrt{K\mu}$ must therefore be of the dimensions of a velocity, and the questions arise, what is the absolute value of this velocity? and how is it to be determined? The answer is, that the value of the velocity in concrete numbers may be obtained by measuring the magnitude of any electric quantity in two ways, one making use only of electrostatic phenomena, and the other only of electromagnetic. To take one instance:—It is easy to show that the electrostatic capacity of a sphere suspended in air or in vacuo at a great distance from other conductors is given by a number equal to its radius in centimetres. Suppose such a sphere to be charged and discharged rapidly with electricity from any source, such as a battery. It would take electricity from the source at a certain rate, and would in fact act like a resistance in permitting the passage through it or by it of a certain quantity of electricity per unit of time. If K is the capacity and n is the number of discharges per second, then nK is a quantity of the dimensions of an electric conductivity, or of the reciprocal of a resistance. If a conductor, of which the electrostatic capacity can be calculated, and which has associated with it a commutator that charges and discharges it n times per second, is arranged in one branch of a Wheatstone's Bridge, it can be treated and measured as if it were a resistance, and its equivalent resistance calculated in terms of the resistance of all the other branches of the bridge. (See *Phil. Mag.*, Sept. 1885, vol. xx. p. 258.)

Accordingly we have two methods of measuring the capacity of a conductor. One, the electrostatic method, depends only on the measurement of a length, which in the case of a sphere in free space is its radius; the other, the electromagnetic method, determines the capacity in terms of the quotient of a time by a resistance. The ratio of the electrostatic to the electromagnetic value of the same capacity is therefore of the dimensions of a velocity multiplied by a resistance in electromagnetic value, or of the dimensions of a velocity squared. This particular experimental measurement has been carried out carefully by many observers, and the result has been always to show that the velocity v which expresses the ratio is very nearly equal to 30 thousand million centimetres per second; v = nearly 3×10^{10}. The value of this important constant can be determined by experiments made to measure electric quantity, potential, resistance, or capacity, both in electrostatic and in electromagnetic measure. For details of the various methods employed, the reader must be referred to standard treatises on Electricity and Magnetism, where full particulars will be found. (See Maxwell, *Treatise on Electricity and Magnetism*, vol. ii. ch. xix., 2nd ed.; also Mascart and Joubert, *Treatise on Electricity and Magnetism*, vol. ii. ch. viii, Eng. trans. by Atkinson.)

The following table gives a list of most of the determinations of v yet made, with references to the original papers.

TABLE XVI. *Table of Observed Values of 'v' in Centimetres per Second.*

Date.	Name.	Reference.	Electric Quantity Measured.	'v' in Centimetres per Second.
1856	Weber and Kohlrausch	*Electrodynamische Maasbestimmungen* and *Pogg. Ann.* xcix., August 10, 1856	Quantity	$3{\cdot}107 \times 10^{10}$
1867 / 1868	Lord Kelvin and W. F. King	*Report of British Assoc.*, 1869, p. 434; and *Reports on Electrical Standards*, F. Jenkin, p. 186	Potential	$2{\cdot}81 \times 10^{10}$
1868	Clerk Maxwell .	*Phil. Trans. Roy. Soc.*, 1868, p. 643	,,	$2{\cdot}84 \times 10^{10}$
1872	Lord Kelvin and Dugald M'Kichan	*Phil. Trans. Roy. Soc.*, 1873, p. 409	,,	$2{\cdot}89 \times 10^{10}$
1878	Ayrton and Perry	*Journ. Soc. Tel. Eng.* vol. viii. p. 126	Capacity	$2{\cdot}94 \times 10^{10}$
1880	Lord Kelvin and Shida	*Phil. Mag.* vol. x. p. 431, 1880	Potential	$2{\cdot}955 \times 10^{10}$
1881	Stoltow . .	*Soc. Franc. de Phys.*, 1881	Capacity	$2{\cdot}99 \times 10^{10}$
1882	F. Exner .	*Wien. Ber.*, 1882	Potential	$2{\cdot}92 \times 10^{10}$
1883	J. J. Thomson .	*Phil. Trans. Roy. Soc.*, 1883, p. 707	Capacity	$2{\cdot}963 \times 10^{10}$
1884	Klemencic .	*Proc. Soc. of Tel. Eng.*, 1887, p. 162	,,	$3{\cdot}019 \times 10^{10}$
1888	Himstedt .	*Electrician*, Mar. 23, 1888, vol. xx. p. 530	,,	$3{\cdot}007 \times 10^{10}$
1888	Lord Kelvin, Ayrton, and Perry	*British Association*, Bath; and *Electrician*, Sept. 28, 1888	Potential	$2{\cdot}92 \times 10^{10}$
1888	Fison . . .	*Electrician*, vol. xxi. p. 215; and *Proc. Phys. Soc. Lond.*, June 9, 1888	Capacity	$2{\cdot}965 \times 10^{10}$
1889	Lord Kelvin .	*Proc. Roy. Inst.*, 1889	Potential	$3{\cdot}004 \times 10^{10}$
1889	Rowland .	*Phil. Mag.*, 1889	Quantity	$2{\cdot}981 \times 10^{10}$
1889	E. B. Rosa .	*Phil. Mag.*, 1889	Capacity	$3{\cdot}000 \times 10^{10}$
1890	J. J. Thomson and Searle	*Phil. Trans.*, 1890	,,	$2{\cdot}995 \times 10^{10}$
1897	M. E. Maltby .	*Wied. Ann.*, 1897	Alternating currents	$3{\cdot}015 \times 10^{10}$

It will be seen that all the most recent values, especially those in which a comparison of capacity has been made, approximate to 3×10^{10} centimetres per second, a value which is closely in accord with the latest and best determinations of the velocity of light.

We have in the next place to consider the question of practical electric units and the determination and construction of practical standards. The Committee of the British Association charged with the duty of arranging a system of absolute and magnetic units settled also on a system of practical units of convenient magnitude, and gave names to them as follows:—

Practical units.

10^9	Absolute Electromagnetic	Units of Resistance	=	1 Ohm
10^8	,, ,,	Units of Electromotive force	=	1 Volt
$\frac{1}{10}$th of an	,, ,,	Unit of Current	=	1 Ampere
$\frac{1}{10}$th of an	,, ,,	Unit of Quantity	=	1 Coulomb
10^{-9}	,, ,,	Units of Capacity	=	1 Farad
10^{-15}	,, ,,	Units of Capacity	=	1 Microfarad

Since the date when the preceding terms were adopted, other multiples of absolute C.G.S. Units have received practical names, thus:—

10^7	Ergs or Absolute C.G.S. Units of Energy	=	1 Joule
10^7	Ergs per second or C.G.S. Units of Power	=	1 Watt
10^9	Absolute Units of Inductance	=	1 Henry
10^8	Absolute Units of Magnetic Flux	=	1 Weber[1]
1	Absolute Unit of Magnetomotive Force	=	1 Gauss[1]

An Electrical Congress was held in Chicago, U.S.A., in August 1893, to consider the subject of International Practical Electrical Units, and the result of a conference between scientific representatives of Great Britain, the United States, France, Germany, Italy, Mexico, Austria, Switzerland, Sweden, and British North America, after deliberation for six days, was a unanimous agreement to recommend the following resolutions as the definition of Practical International Units. The resolutions have since that date been received and adopted by the Governments above mentioned:—

"*Resolved*, That the several Governments represented by the delegates of this International Congress of Electricians be, and they are hereby, recommended to formally adopt as legal units of electrical measure the following:—

"As a unit of resistance, the *International Ohm*, which is based upon the ohm equal to 10^9 units of resistance of the C.G.S. System of electromagnetic units, and is represented by the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice 14·4521 grammes in mass, of a constant cross-sectional area and of the length of 106·3 cm.

"As a unit of current, the *International Ampere*, which is one-tenth of the unit of current of the C.G.S. System of electromagnetic units, and which is represented sufficiently well for practical use by the unvarying current which, when passed through a solution of nitrate of silver in water, deposits silver at the rate of 0·001118 of a gramme per second.

"As a unit of electromotive force, the *International Volt*, which is the electromotive force that, steadily applied to a conductor whose resistance is one international ohm, will produce a current of one international ampere, and which is represented sufficiently well for practical use by $\frac{1000}{1434}$ of the electromotive force between the poles or electrodes of the voltaic cell known as Clark's Cell, at a temperature of 15° C., and prepared in the manner described in a certain specification.

"As a unit of quantity, the *International Coulomb*, which is the quantity of electricity transferred by a current of one international ampere in one second.

"As the unit of capacity, the *International Farad*, which is the capacity of a condenser charged to a potential of one international volt by one international coulomb of electricity.

"As a unit of work, the *Joule*, which is equal to 10^7 units of work in the C.G.S. System, and which is represented sufficiently well for practical use by the energy expended in one second by an international ampere in an international ohm.

"As a unit of power, the *Watt*, which is equal to 10^7 units of power in the C.G.S. System, and which is represented sufficiently well for practical use by the work done at the rate of one joule per second.

"As the unit of inductance, the *Henry*, which is the induction in a circuit when an electromotive force induced in this circuit is one international volt, while the inducing current varies at the rate of one ampere per second."

It can hardly be said that the present system of practical units is entirely satisfactory in all respects. Great difficulty would of course be experienced in again altering the accepted units, but if at any future time a reformation should be possible, it would be desirable to bear in mind the recommendations made by Mr Oliver Heaviside with regard to their rationalization. The British Association Committee defined the strength of a magnetic pole by reference to the mechanical stress between it and another equal pole: hence the British Association unit magnetic pole is a pole which at a distance of one centimetre attracts or repels another equal pole with a force of one dyne. This, we have seen, is an imperfect definition, because it omits all reference to the permeability of the medium in which the experiment takes place; but it is also unsatisfactory as a starting-point for a system of units for another reason. The important quantity in connexion with polar magnets is not a mechanical stress between the free poles of different magnets, but the magnetic flux emanating from, or associating with, them. From a technical point of view this latter quality is far more important than the mechanical stress between the magnetic poles, because we mostly employ magnets to create induced electromotive force, and the quantity we are then mostly concerned with is the magnetic flux proceeding from the poles. Hence the most natural definition of a unit magnet pole is that pole from which proceeds a total magnetic flux of one unit. The definition of one unit of magnetic flux must then be that flux which, when inserted into or withdrawn from a conducting circuit of one turn having unit area and unit conductivity, creates in it a flow or circulation of one unit of electric quantity. The definition of a unit magnetic pole ought, therefore, to have been approached from the definition of a unit of electric quantity.

Rational units.

On the ordinary or British Association system, if a magnetic filament has a pole strength m,—that is to say, if it has a magnetization I, and a section s, such that Is equals m,—then it can be shown that the total flux emanating from the pole is $4\pi m$. The factor 4π, in consequence of this definition, makes its appearance in many practically important expressions. For instance, in the well-known magnetic equation connecting the vector values of magnetization I, magnetic force H, and magnetic flux density B, where we have the equation

$$B = H + 4\pi I,$$

the appearance of the quantity 4π disguises the real physical meaning of the equation.

The true remedy for this difficulty has been suggested by Heaviside to be the substitution of *rational* for *irrational* formulæ and definitions. He proposes to restate the definition of a unit magnetic pole in such a manner as to remove this constant 4π from the most frequently employed equations. His starting-point is a new definition according to which a unit magnetic pole is said to have a strength of m units if it attracts or repels another equal pole placed at a distance of d centimetres with a force of $\frac{m^2}{4\pi d^2}$ dynes. It follows from this definition that a rational unit magnetic pole is weaker or smaller than the irrational or British Association unit pole in the ratio of $1/\sqrt{4\pi}$ to 1, or ·28205 to 1. The magnetic force due to a rational pole of strength m at a distance of d centimetres being $\frac{m}{4\pi d^2}$ units, if we suppose a magnetic filament having a pole of strength m in rational units to have a smaller sphere of radius r described round its pole, the magnetic force on the surface of this sphere is $m/4\pi r^2$ units, and this is therefore also the numerical value of the flux density. Hence the total magnetic flux through the surface of the sphere is

$$4\pi r^2 \times \frac{m}{4\pi r^2} \text{ units} = m \text{ units};$$

and therefore the number which denotes the total magnetic flux coming out of the pole of strength m in rational units is also m.

[1] Neither the Weber nor the Gauss has received very general adoption, although recommended by the Committee of the British Association on Electrical Units. Many different suggestions have been made as to the meaning to be applied to the word "Gauss." The practical electrical engineer, up to the present, prefers to use *one ampere-turn* as his unit of Magnetomotive Force, and *one line of force* as the unit of Magnetic Flux, equal respectively to $10/4\pi$ times and 1 times the C.G.S. absolute units.

The rational system thus gives us an obvious and natural definition of a unit magnetic pole, namely, that it is a pole through which proceeds the unit of magnetic flux. It follows, therefore, that if the intensity of magnetization of the magnetic filament is I and the section is *s*, the total flux traversing the centre of the magnet is I*s* units; and that if the filament is an endless or poleless iron filament magnetized uniformly by a resultant external magnetic force H, the flux density will be expressed in rational units by the equation $B = I + H$. The physical meaning of this equation is that the flux per square centimetre in the iron is simply obtained by adding together the flux per square centimetre, if the iron is supposed to be removed, and the magnetization of the iron at that place. On the rational system, since the unit pole strength has been decreased in the ratio of I to $1/\sqrt{4\pi}$, or of 3·5441 to 1, when compared with the magnitude of the present irrational unit pole, and since the unit of magnetic flux is the total flux proceeding from a magnetic pole, it follows that Heaviside's unit of magnetic flux is larger than the C.G.S. unit of magnetic flux in the ratio of 3·5441 to 1.

It will be seen, therefore, that the Heaviside rational units are all incommensurable with the practical units. This is a great barrier to their adoption in practice, because it is impossible to discard all the existing resistance coils, ammeters, voltmeters, &c., and equally impossible to recalibrate or readjust them to read in Heaviside Units. Recently, however, a suggestion has been made, in modification of the Heaviside System, which would provide a system of rational practical units not impossible of adoption. It has been pointed out by J. A. Fleming that if in place of the ampere, ohm, watt, joule, farad, and coulomb, we employ the dekampere, dekohm, the dekawatt, the dekajoule, the dekafarad, and the dekacoulomb, we have a system of practical units such that measurements made in these units are equal to measurements made in Heaviside rational units when multiplied by some power of 4π. Moreover, he has shown that this power of 4π, in the case of most units, varies inversely as the power under which μ appears in the complete dimensional expression for the quantity in electromagnetic measurement. Thus a current measured in Heaviside rational units is numerically equal to $(4\pi)^{\frac{1}{2}}$ times the same current measured in dekamperes, and in the electromagnetic dimensional expression for current, namely, $L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\mu^{-\frac{1}{2}}$, μ appears as $\mu^{-\frac{1}{2}}$. If, then, following the suggestion of Fessenden and Fleming, we consider the permeability of the æther to be numerically 4π instead of unity, the measurement of a current in dekamperes will be a number which is the same as that given by reckoning in Heaviside rational units. In this way a system of *Rational Practical Units* (R.P. Units) might be constructed as follows:—

The R.P.	Unit of	Magnetic Force $= 4\pi$	$\times$	the C.G.S.	Unit.
,,	,,	Magnetic Polarity $= 1/4\pi$	$\times$	,,	,,
,,	,,	Magnetic Flux	$=$	1	,,
,,	,,	Magnetomotive Force	$=$	1	,,
,,	,,	Electric Current	$=$	1	,,
,,	,,	Electric Quantity	$=$	1	,,
,,	,,	Electromotive Force	$=$	10^8	,,
,,	,,	Resistance	$=$	10^8	,,
,,	,,	Inductance	$=$	10^8	,,
,,	,,	Power	$=$	10^8	,,
,,	,,	Work	$=$	10^8	,,
,,	,,	Capacity	$=$	10^{-8}	,,

All except the Unit of Magnetic Force and Magnetic Polarity are commeasurable with the corresponding C.G.S. Units, and in multiples which form a convenient practical system.

Turning to the practical recovery of the International Electric Units, as generally accepted by the Chicago Electrical Conference, the most important matter is the realization of the International Ohm, which is intended as nearly as possible to realize in a concrete form 10^9 C.G.S. electromagnetic units of resistance. The old British Association Unit of electrical resistance (denoted by 1 B.A.U.) was found to be too small when compared with the theoretical ohm in the ratio of ·9866 to 1. In creating better standards, it has been decided to express it in terms of the resistance of a column of mercury of a certain length and weight, the reason being that mercury is a homogeneous liquid metal the density of which is very accurately known, and which is without much difficulty obtained in a state of very great chemical purity by distillation in a vacuum. Hence it is an easily recovered material, and observers in different parts of the world can be tolerably certain of obtaining specimens nearly identical in every respect. This is not the case with other solid metals, in the electric resistivity of which great differences may occur, even in chemically pure specimens (see I. ELECTRIC CONDUCTION). Hence the absolute determination of the ohm really resolves itself into a determination of the specific resistance of mercury or the volume resistivity in absolute C.G.S. units.

The full description of the different methods for determining electric quantities, and especially electric resistance, in absolute measure is given in Maxwell's *Treatise on Electricity and Magnetism*, vol. ii. ch. x; also in Mascart and Joubert's *Treatise on Electricity and Magnetism* (English translation by Atkinson), vol. ii. ch. ix. The relative advantages and disadvantages of the various methods which have been proposed for the determination of resistance in absolute measure are very fully discussed in the *Phil. Mag.*, November 1882, p. 329, by Lord Rayleigh, whose researches on this sub eet have been most extensive and profound. On the subject of Electric Units the reader may with advantage consult the following books and original papers for additional information:—

V. ELECTRIC DISCHARGE THROUGH GASES.

A gas in the normal state can conduct very little electricity unless the strength of the electric field to which it is exposed exceeds a certain value, which depends on the kind of gas and its pressure. It is, however, possible to bring by various means a gas into a state in which it conducts electricity under even the feeblest electric forces. As a study of the properties of gases when in this state throws a great deal of light on the processes by which conduction through gases in general is accomplished, we shall begin by considering the properties of a gas and the laws of electric conduction through it when it is in this conducting state.

§ 1. *Properties of a Gas in the Conducting State.*—Gases may be brought into this conducting state in many ways. Thus they conduct when exposed to Röntgen rays,[1] to the radiation from uranium,[2] thorium,[3] or the radio-active substances polonium, radium, and actinium, discovered by Curie, Curie and Bemont, and Debierne;[4] they become conductors by the passage through them of cathode rays,[5] of Lenard rays,[6] or the radiation emitted by electric sparks (E. Wiedemann's *Entladungstrahlen*).[7] They become conductors when in contact with glowing metal or carbon, and when their temperature is raised beyond a certain point. Gases drawn from the neighbourhood of flames and arcs are also good conductors, as are those which have diffused from a region through which an electric discharge is passing.[8] Air becomes a conductor by passing over phosphorus,[9] and retains the property for some little time after it has left the phosphorus. By whatever means the gas may have been made a conductor, when it has reached this state it possesses characteristic properties. In the first place, it does not lose its conductivity immediately after it is removed from the agency which made it a conductor; its conductivity, however, always diminishes, in some cases very rapidly, after the agent is removed, and finally disappears. Thus a gas exposed to Röntgen rays retains its conductivity for some little time after the rays have ceased to pass through it, and flame gases retain their conductivity for a considerable time after their removal from the flame. If, however, the conducting gas is filtered through a plug of tightly-packed glass wool or through water it loses its conductivity;[10] it also loses its conductivity slowly by being passed through metal tubes, and the finer the bore of the tube the more rapidly does the conductivity disappear. The conductivity also may be at once removed by making the gas traverse a strong electric field, and thus sending a current of electricity through it. The effect of filtering and of passage through metal tubes shows that the conductivity is due to something which is mixed with the gas, and that this something is removed from the gas in the one case by filtration, and in the other by diffusion to the sides of the tube. Again, the experiment with the electric field shows that this something is charged, and moves under the field, while since the gas when in the conducting state often shows as a whole no charge, the charges which move in the field must be both positive and negative. We thus regard the conductivity of the gas as due to the presence of electrified particles, some of these particles having positive charges, others negative. These particles we shall call *ions*, but they must not be assumed to be the same as the ions in the electrolysis of solutions. We shall see that in several cases we can determine the charge and masses of these gaseous ions. The process by which the gas is changed into a conductor we shall call the *ionization* of the gas.

In a gas made a conductor by any of the means we have described, the conductivity does not obey Ohm's law, except for very small electromotive forces. The relation between the current passing between two parallel metal plates immersed in such a gas and the potential difference between the plates is represented by a curve such as that shown in Fig. 8, in which the abscissæ represent the potential difference, and the ordinates the current.[11] We see that when the potential difference is small, the curve is straight; in this stage the conduction obeys Ohm's law, but the current soon begins to increase more slowly than the potential difference, until we reach a stage when there is no appreciable increase in the current however great the increase in the potential difference, provided the increase is not sufficient to make the electric field ionize the gas; when this stage is reached the current increases very rapidly with the strength of the field. There is thus, until the electric field ionizes the gas, a limiting value to the current which can be carried by the gas; this maximum value is often called the *saturation current*. The maximum current which can be obtained between two parallel plates of given area depends upon the amount of ionization between the plates; if the ionization is a volume ionization, the greater the distance between the plates the greater the value of the maximum current, so that if we use potential differences large enough to produce saturation, the thicker the layer of gas between the plates the greater the current —a result which would seem paradoxical on the ordinary resistance view of conduction, as here the resistance of a thick layer appears to be less than that of a thin one.

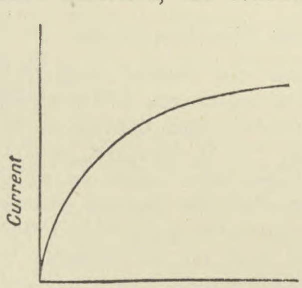

Fig. 8.

The limiting value of the current is very easily explained on the assumption that the conduction is due to ions. For suppose that in the gas between the plates the ionizing agent produces in one second q positive, and q negative ions, if a current c pass between the plates and if e is the charge on an ion, the number of positive ions delivered up at the negative electrode and of negative ions at the positive electrode is in one second c/e. Now when the gas is in a steady state the number of ions taken out of it in a given time cannot be greater than the number of ions produced in the same time; hence c/e cannot be greater than q—that is, the maximum value c is qe. If the ionization takes place uniformly throughout the gas, and if l is the distance between the plates, A the area of the plates, which are supposed to be equal and parallel, and q_0 the number of ions produced in unit volume, then $q=q_0\text{A}l$, so that the maximum value of c is $q_0\text{A}le$, and is thus proportional to the distance between the plates. Excellent examples of this law are afforded by conduction through gas ionized by Röntgen rays.[12] Even if there is no current through the gas to carry off the ions as they are produced, the ions do not increase indefinitely with the time which has elapsed since the gas was exposed to the ionizing agent; their number and the conductivity of the gas very soon acquire a steady value beyond which they do not increase if the rate of ionization remains constant. For the positive and negative ions moving about in the gas sometimes come into collision with each other, and in a certain proportion of these collisions they will remain united, forming a neutral particle, the constituents of which have ceased to be ions. Thus the collisions will cause a certain number of ions to disappear, and the steady state in a gas which is not carrying a current will be reached when the number of ions which disappear in a second from the effect of collisions is equal to the number produced in the same time by the ionizing agent. If q is the number of ions produced in one cubic centimetre of the gas per second by the ionizing agent, and n_1, n_2 the number of positive and negative ions respectively in a cubic centimetre, the number of collisions per second between the positive and negative ions will be proportional to n_1n_2. If we suppose that a certain fraction of the collisions lead to the formation of a neutral particle, then the number of ions which disappear in a second will be equal to αn_1n_2, when α is a quantity which is independent of n_1 and n_2; hence we have

$$\frac{dn_1}{dt}=q-\alpha n_1n_2,$$

$$\frac{dn_2}{dt}=q-\alpha n_1n_2,$$

n_1-n_2 remaining constant, so that if the gas is uncharged to begin with, n_1 always equals n_2. Putting $n_1=n_2$, we get

$$\frac{dn_1}{dt}=q-\alpha n_1^2 \quad . \quad . \quad . \quad . \quad (1).$$

When things have settled into a steady state, $dn_1/dt=0$, and hence by equation (1)

$$n_1=\sqrt{\frac{q}{\alpha}}.$$

Equation (1) may be used to calculate the rate at which the conductivity of the gas decays when the ionizing agent is removed, for putting in that equation $q=0$, we have

$$\frac{dn_1}{dt}=-\alpha n_1^2$$

or,

$$\frac{1}{n_1}-\frac{1}{\text{N}}=\alpha t \quad . \quad . \quad . \quad . \quad (2)$$

or,

$$n_1=\frac{\text{N}}{1+\text{N}\alpha t},$$

where N is the number of ions present when the ionization was stopped, and t the time which has elapsed since the stoppage. This equation has been verified in the case of a gas ionized by the Röntgen rays by Rutherford,[13] and in the case of the gases drawn from flames and arcs by M'Clelland,[14] who measured the quantity of electricity which could be carried by the gas at successive small intervals of time after the ionizing agent had ceased to act. For air, oxygen, carbonic acid, and hydrogen at atmospheric pressure and ionized by Röntgen rays, Townsend[15] found for α the values $3420e$, $3380e$, $3500e$, and $3020e$, where e is the charge on the ion in electrostatic measure; we shall see later that e is about 6×10^{-10}, so that for air, carbonic acid, and oxygen at atmospheric pressure α is about 2×10^{-6}, while for hydrogen it is about 15 per cent. less.

Thus an ion after being formed does not last for ever, nor does it on the other hand disappear instantaneously, but must be regarded as having a certain duration of life, the value of which on the average is seen by equation (2) to be $1/\alpha n$, where n is the number of ions per cubic centimetre of the gas. When the gas between a pair of parallel metal plates is carrying the maximum current, all the ions must reach the plates before they recombine; for this to happen, the velocity of the ions along the lines of electric force must be great enough to make the ion during its life move through a distance equal to the distance between the plates. If V is the velocity of the ion, T its life, and l the distance between the plates, the current will not have its maximum value unless V is greater than l/T; hence the greater the velocity of the ion under a given electromotive force, and the longer its life, the smaller will be the potential difference required to produce the limiting current through the gas. As the ionization produced by an agent like Röntgen rays diminishes as the pressure of the gas diminishes, the life of an ion at low pressure will be longer than at high, since n is smaller; again, the velocity of an ion under a given electromotive force increases as the pressure diminishes (see below). Both these effects tend to diminish the potential difference required to produce the limiting current, so that when the pressure is diminished the potential difference required to produce the maximum current diminishes more rapidly than the pressure. As another illustration of the effect of the life of the ion, let us take the case of a gas where the pressure is kept constant, but the distance between the parallel plates is varied; if we diminish the distance between the plates we increase in the same proportion the potential gradient due to a constant difference of potential. Now the velocity of an ion is proportional to the potential gradient (see below), while when the plates are nearer together the ions have not so far to travel to reach them; taking these effects together, we see that the potential difference required to produce the maximum current between two parallel plates will be proportional to the square of the distance between the plates.

§ 2. *Velocity of the Ions.*—The velocity with which the ions move under given electric forces are quantities of primary importance in the consideration of the passage of electricity through gases. They have been measured by Rutherford [16] and by Zeleny [17] for ions produced by Röntgen rays, by Rutherford [18] for the ions produced by uranium radiation and for the negative ions produced when ultra-violet light is incident on a metal plate; [19] H. A. Wilson [20] has measured the velocity of the ions produced by putting various salts into flames, M'Clelland [21] the velocity of the ions in gases sucked from the neighbourhood of flames and arcs, and Chattock [22] the velocity of the ions produced when electricity escapes from a sharp needle-point into a gas. Several methods have been employed to determine these velocities. The one most frequently employed is to find the electromotive intensity required to force an ion against a stream of gas moving with a known velocity parallel to the lines of electric force. Thus, of two perforated plane electrodes vertically over each other, suppose the lower to be positively, the upper negatively electrified, and suppose that the gas is streaming vertically downwards with the velocity V; then unless the upward velocity of the positive ion is greater than V, no positive electricity will reach the upper plate. If we increase the strength of the field between the plates, and hence the upward velocity of the positive ion, until the positive ions just begin to reach the upper plate, we know that with this strength of field the velocity of the positive ion is equal to V. By this method, which has been used by Rutherford, Zeleny, and H. A. Wilson, the velocity of ions in fields of various strengths has been determined.

The arrangement used by Zeleny is represented in Fig. 9. P and Q are square brass plates. They are bored through their centres, and to the openings the tubes R and S are attached, the space between the plates being covered in so as to form a closed box.

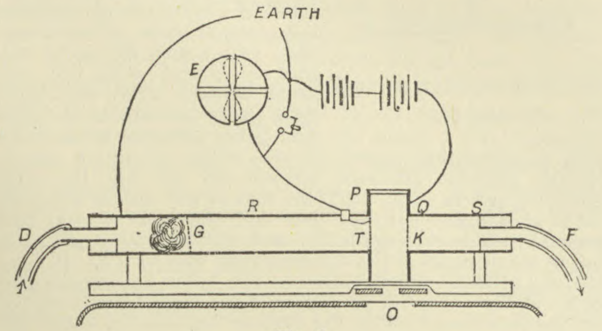

Fig. 9.

K is a piece of wire gauze completely covering the opening in Q; T is an insulated piece of wire gauze nearly but not quite filling the opening in the plate P, and connected with one pair of quadrants of an electrometer E. A plug of glass wool G filters out the dust from a stream of gas which enters the vessel by the tube D and leaves it by F; this plug also makes the velocity of the flow of the gas uniform across the section of the tube. The Röntgen rays to ionize the gas were produced by a bulb at O, the bulb and coil being in a lead-covered box, with an aluminium window through which the rays passed. Q is connected with one pole of a battery of cells, P and the other pole of the battery are put to earth. The changes in the potential of T are due to ions giving up their charges to it. With a given velocity of air-blast the potential of T was found not to change unless the difference of potential between P and Q exceeded a critical value. The field corresponding to this critical value thus made the ions move with the known velocity of the blast.

Another method which has been employed by Rutherford and M'Clelland is based on the action of an electric field in destroying the conductivity of gas streaming through it. Suppose that BAB, DCD (Fig. 10) are a system of parallel plates boxed in so that a stream of gas, after flowing between BB, passes between DD without any loss of gas in the interval. Suppose the plates DD are insulated, and connected with one pair of quadrants of an electrometer, by charging up C to a sufficiently high potential we can drive all the positive ions which enter the system DCD against the plates D; this will cause a deflexion of the electrometer, which in one second will be proportional to the number of positive ions which have entered the system in that time. If we charge A up to a high potential, B being put to earth, we shall find that the deflexion of the electrometer connected with DD is less than it was when A and B were at the same potential, because some of the positive ions in their passage through BAB are driven against the plates B. If u is the velocity along the lines of force in the uniform electric field between A and B, and t the time it takes for the gas to pass through BAB, then all the positive ions within a distance ut of the plates B will be driven up against these plates, and thus if the positive ions are equally distributed through the gas, the number of positive ions which emerge from the system when the electric field is on will bear to the number which emerge when the field is off the ratio of $1 - ut/l$ to unity, where l is the distance between A and B. This ratio is equal to the ratio of the deflexions in one second of the electrometer attached to D, hence the observations of this instrument give $1 - ut/l$. If we know the velocity of the gas and the length of the plates A and B, we can determine t, and since l can be easily measured, we can find u, the velocity of the positive ion in a field of given strength. By charging A and C negatively instead of positively we can arrive at the velocity of the negative ion. In practice it is more convenient to use cylindrical tubes with coaxial wires instead of the systems of parallel plates, though in this case the calculation of the velocity of the ions from the observations is a little more complicated, inasmuch as the electric field is not uniform between the tubes

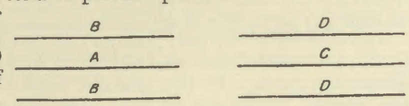

Fig. 10.

A method which gives very accurate results, though it is only applicable in certain cases, is the one used by Rutherford[23] to measure the velocity of the negative ions produced close to a metal plate by the incidence on the plate of ultra-violet light. The principle of the method is as follows:—AB (Fig. 11) is an insulated horizontal plate of well-polished zinc, which can be moved vertically up and down by means of a screw; it is connected with one pair of quadrants of an electrometer, the other pair of quadrants being put to earth. CD is a base-plate with a hole EF in it; this hole is covered with fine wire gauze, through which ultra-violet light passes and falls on the plate AB. The plate CD is connected with an alternating current dynamo, which produces a simply-periodic potential difference between AB and CD, the other pole being put to earth. Suppose that at any instant the plate CD is at a higher potential than AB, then the negative ions from AB will move towards CD, and will continue to do so as long as the potential of CD is higher than that of AB. If, however, the potential difference changes sign before the negative ions reach CD, these ions will go back to AB. Thus AB will not lose any negative charge unless the distance between the plates AB and CD is less than the distance traversed by the negative ion during the time the potential of CD is higher than that of AB. By altering the distance between the plates until CD just begins to lose a negative charge, we find the velocity of the negative ion under unit electromotive intensity. For suppose the difference of potential between AB and CD is equal to $a \sin pt$, then if d is the distance between the plates, the electric intensity is equal to $a \sin pt/d$; if we suppose the velocity of the ion is proportional to the electric intensity, and if u is the velocity for unit electric intensity, the velocity of the negative ion will be $ua \sin pt/d$. Hence if x represent the distance of the ion from AB

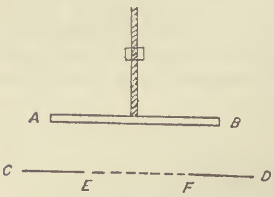

Fig. 11.

$$\frac{dx}{dt}=\frac{ua}{d}\sin pt,$$

$$x=\frac{ua}{pd}(1-\cos pt), \text{ if } x=0 \text{ when } t=0.$$

Thus the greatest distance the ion can get from the plate is equal to $2au/pd$, and if the distance between the plates is gradually reduced to this value the plate AB will begin to lose a negative charge; hence when this happens

$$d=\frac{2au}{pd}, \text{ or } u=\frac{pd^2}{2a},$$

an equation by means of which we can find u.

The velocity of the ions produced by the discharge of electricity from a fine point has been determined by Chattock by an entirely different method. In this case the electric field is so strong and the velocity of the ion so great that the preceding methods are not applicable. Suppose P represents a vertical needle discharging electricity into air, consider the force acting on the ions included between two horizontal planes A, B. If ρ is the density of the electrification, and Z the vertical component of the electric intensity, F the resultant force on the ions between A and B is vertical and equal to

$$\iiint Z\rho dxdydz.$$

Let us suppose that the velocity of the ion is proportional to the electric intensity, so that if w is the vertical velocity of the ions, which are supposed all to be of one sign, $w=RZ$.

Substituting this value of Z, the vertical force on the ions between A and B is equal to

$$\frac{1}{R}\iiint w\rho dxdydz.$$

But $\iint w\rho dxdy=\iota$, where ι is the current streaming from the point. This current, which can be easily measured by putting a galvanometer in series with the discharging point, is independent of z, the vertical distance of a plane between A and B below the charging point. Hence we have

$$F=\frac{\iota}{R}\int dz$$

$$=\frac{\iota}{R}\cdot z.$$

This force must be counterbalanced by the difference of gaseous pressures over the planes A and B; hence if p_B and p_A denote respectively the pressures over B and A, we have

$$p_B-p_A=\frac{\iota}{R}z.$$

Hence by the measurement of these pressures we can determine R, and hence the velocity with which an ion moves under a given electric intensity.

There are other methods of determining the velocities of the ions, but as these depend on the theory of the conduction of electricity through a gas containing charged ions, we shall consider them in our discussion of that theory.

§ 3. *Results of Measurements.*—The results of experiments made by the preceding methods on the velocity of ions produced by Röntgen rays, by uranium rays, by the incidence of ultra-violet light on metals, and by the discharge of electricity from points, show that, whether the ions are produced in one or other of these ways, their velocities in a given gas are as nearly equal, considering the great difficulties of these experiments, as we could expect, on the supposition that the ions are identical. We may therefore conclude that the ions produced by these agents depend only on the gas, and not on the agent. It has been proved by direct experiment that in the case of the first three agents the velocity of an ion is proportional to the electric intensity acting upon it. In the case of the ions produced by ultra-violet light Rutherford (*loc. cit.*) has shown that, at any rate down to pressures as low as 34 mm. of mercury, the velocity of the ion under a given electric intensity is inversely proportional to the pressure. He has also shown that the velocity of the ion remains unaltered however the metal on which the light falls is changed, provided that the gas in which the metals are immersed remains the same. Zeleny made the very interesting discovery that the velocity of the negative ions was always greater than that of the positive in the case of ions produced by Röntgen rays. Rutherford showed that this was true for the ions produced by uranium radiation, and Chattock (*loc. cit.*) that it held also for those produced by the discharge of electricity from points. Townsend,[24] by measuring the rates of diffusion of ions, has shown that the ratio of the velocity of the negative ion to that of the positive is considerably greater in a dry gas than in a wet one. The presence of moisture produces a very appreciable diminution in the velocity of the negative, while its effect on the positive ion is comparatively small, and generally in the opposite direction; *i.e.*, the positive ions seem to move a trifle faster in a damp gas than they do in a dry one. Rutherford's results for the velocity of the ions in different gases produced by different agents are given in the following table. The velocities given are those due to a potential gradient of 1 volt per centimetre.

Gas.	Mean Velocity of Positive and Negative Ions in Röntgen Ray Conduction.	Velocity of Negative Ions in Ultra-Violet Light Conduction.
Air	1·6 cm./sec.	1·4 cm./sec.
Hydrogen	5·2 ,,	3·9 ,,
Carbonic acid	1·07 ,,	·78 ,,

Rutherford also compared the velocities of the ions produced by uranium radiation with those produced by Röntgen rays, and found them equal within the limits of error of the experiments. For the ions produced by the escape of electrification from a point Chattock (*loc. cit.*) found 1·38 cm./sec. as the velocity of the positive ion, and 1·8 cm./sec. as that of the negative. For the ratio of the velocity of the negative ion to that of the positive Zeleny found the following values. The gases were not specially dried.

Gas.	Velocity of Negative Ion divided by Velocity of Positive Ion.	Gas.	Velocity of Negative Ion divided by Velocity of Positive Ion.
Air	1·24	Carbonic acid	1·
Oxygen	1·24	Ammonia	1·045
Nitrogen	1·23	Acetylene	·985
Hydrogen	1·14	Nitrogen monoxide	1·105
Coal gas	1·15		

The effect of moisture on the ratio of the velocities of the ions is shown by the results given by Townsend in the following table. The quantity K determined by Townsend is not the velocity of the ion, but the coefficient of diffusion of the ion through the gas. K is, however, proportional to that velocity.

Coefficients of Diffusion of Ions produced by Röntgen Rays in Dry Gases.

Gas.	K for + ion.	K for − ion.	Mean Values of K.	Ratio of Values of K.
Air . . .	·028	·043	·0347	1·54
Oxygen . .	·025	·0396	·0323	1·58
Carbonic Acid .	·023	·026	·0245	1·13
Hydrogen .	·123	·190	·156	1·54
Coefficients of Diffusion in Moist Gases.				
Air . . .	·032	·035	·0335	1·09
Oxygen . .	·0288	·0358	·0323	1·24
Carbonic Acid .	·0245	·0255	·025	1·04
Hydrogen .	·128	·142	·135	1·11

We can derive some information as to the constitution of the ions by calculating the velocity with which a molecule of the gas would move in the electric field if it carried the same charge as the ion. From the theory of the diffusion of gases, as developed by Maxwell (see DIFFUSION, *Ency. Brit.* vol. vii.), we know that if the particles of a gas A are surrounded by a gas B, then, if the partial pressure of A is small, the velocity u with which its particles will move when acted upon by a force Xe is given by the equation

$$u=\frac{Xe}{(p_1/N_1)}D,$$

where D represents the coefficient of inter-diffusion of A into B, and N_1 the number of particles of A per cubic centimetre when the pressure due to A is p_1. Let us calculate by this equation the velocity with which a molecule of hydrogen would move through hydrogen if it carried the charge carried by an ion, which we shall prove shortly to be equal to the charge carried by an atom of hydrogen in the electrolysis of solutions. Since p_1/N_1 is independent of the pressure, it is equal to π/N, where π is the atmospheric pressure and N the number of molecules in a cubic centimetre of gas at atmospheric pressure. Now $Ne=1{\cdot}22\times10^{10}$, if e is measured in electrostatic units; $\pi=10^6$, and D in this case is the coefficient of diffusion of hydrogen into itself, and is equal to 1·7. Substituting these values we find

$$u=1{\cdot}97\times10^4X.$$

If the potential gradient is 1 volt per centimetre, $X=1/300$. Substituting this value for X, we find $u=66$ cm./sec., for the velocity of a hydrogen molecule. We have seen that the velocity of the ion in hydrogen is only about 5 cm./sec., so that the ion moves more slowly than it would if it were a single molecule. The most obvious inference would seem to be that the ion is bigger than the molecule, and is in fact an aggregation of molecules, the charged ion acting as a nucleus around which molecules collect like dust round a charged body. This view is supported by the effect produced by moisture in diminishing the velocity of the negative ion, for, as C. T. R. Wilson[25] has shown, moisture tends to collect round the ions, and condenses more easily on the negative than on the positive ion. In connexion with the velocities of ions in the gases drawn from flames, we shall find other instances which suggest that condensation takes place round the ions. An increase in the size of the system is not, however, the only way by which the velocity might fall below that calculated for the hydrogen molecule, for we must remember that the hydrogen molecule, whose coefficient of diffusion is 1·7, is not charged, while the ion is. The forces exerted by the ion on the other molecules of hydrogen are not the same as those which would be exerted by a molecule of hydrogen, and as the coefficient of diffusion depends on the forces between the molecules, the coefficient of diffusion of a charged molecule into hydrogen might be very different from that of an uncharged one.

§ 4. *Velocity of Ions in Gases from Flames and Arcs.*—The velocities of the ions in gases drawn from Bunsen flames and arcs are very much smaller than those of the ions previously considered. They were found by M'Clelland[26] to depend upon the distance the gases had travelled from the flame. Thus with a Bunsen flame the velocity of the ion at a distance of 5·5 cm. from the flame, where the temperature was 230° C., with a potential gradient of 1 volt per cm., was ·23 cm./sec.; at a distance of 10 cm. from the flame, where the temperature was 160° C., it was ·21 cm./sec.; while at a distance of 14·5 cm. from the flame, where the temperature was 105° C., it was only ·04 cm./sec. If the temperature of the gas at a distance from the flame was raised by external means the velocity of the ions increased. Similar results were obtained with a CO flame. These results suggest a rapid condensation on the ions as they get into cooler regions. With these ions, as with those previously considered, the velocity of the negative ion is always greater than that of the positive, the difference amounting to about 15 per cent. M'Clelland also found that, with the ions from flames, arcs, and the neighbourhood of incandescent wires, the velocity diminishes as the temperature of the flame, arc, or wire increases, the other circumstances remaining the same. The velocities of the ions produced by putting salts into flames have been measured by H. A. Wilson.[27] The salts used were Na_2CO_3, K_2CO_3, Li_2CO_3, Cs_2CO_3, Rb_2CO_3, KCl, NaCl, KF, KI, KBr. They were sprayed by a Gouy sprayer into a flame whose temperature was estimated at about 2000° C. It was found that in all cases the velocity of the positive ion under a potential gradient of 1 volt per centimetre was about 62 cm./sec., while the velocity of the negative ion under the same potential gradient was about 1030 cm./sec. The velocity of the negative ions is thus independent of the nature of the salt from which they are derived. The velocities of these ions are much greater than those of the ions produced by Röntgen rays, and very much greater than those in the comparatively cold gases sucked from flames. The ratio of the velocity of the negative ion to that of the positive is also very much greater. Experiments were also made by Wilson on the velocities of the ions when the salts were volatilized by a stream of hot air at a temperature of about 1000° C. The salts tried were Na_2CO_3, NaOH, NaCl, K_2CO_3, KOH, KCl, KBr, KI, KF, LiCl, Li_2CO_3, RbCl, Rb_2CO_3, CsCl, Cs_2CO_3, $CaCl_2$, $BaCl_2$, $SrCl_2$, $Ba(NO_3)_2$. The velocities of the ions under a potential gradient of 1 volt per centimetre are: for (1) negative ions of all the salts, 26 cm./sec.; for (2) positive ions of salts Li, Na, K, Rb, and Cs, 7·2 cm./sec.; and for (3) positive ions of salts of Ba, Sr, and Ca, 3·8 cm./sec. These numbers, on account of the difficulties of the experiment, are only to be considered as approximately true. The velocities in the hot air are very much smaller than those in the flame. They show, however, the same peculiarities, the velocities of all the negative ions being the same, as well as those of the positive ions from the alkali metals. It will be noticed that the fall in temperature from 2000° C. in the flame to 1000° C. in the hot air has had a much greater effect on the velocity of the negative ion than on that of the positive. The reduction in the velocity which follows the fall in temperature is analogous to that observed by M'Clelland in the case of the gases drawn from flames.

§ 5. *Determination of the Electric Charge carried by an Ion.*—The charge on the ions was first measured by the present writer,[28] using a method founded on C. T. R. Wilson's[29] discovery that when Röntgen rays are passed through dust-free air a cloud is produced by an expansion of the gas, which is too small to produce cloudy condensation when the gas is not exposed to these rays. When the gas is exposed to the rays the ions produced by them seem to act as nuclei around which the water condenses. It has been shown (J. J. Thomson, *Applications of Dynamics to Physics and Chemistry*, p. 164) that for a charged sphere of less than a certain radius the effect of the charge in promoting condensation more than counterbalances the effect of surface tension in preventing it. Thus a charged ion will produce a very small drop of water, which may act as a nucleus for larger drops. That the drops constituting the cloud are formed round the ions is proved by the fact that the cloud is not formed when the gas is exposed to a strong electric field while the rays are passing through it, the electric field removing the ions from the gas as fast as they are formed. The experiment also shows that the drops are only formed round the ions. Suppose now we wish to count the number of ions in a cubic centimetre of air, we cool the air by sudden expansion until the supersaturation produced by the cooling is sufficient to cause a cloud to be formed round the ions. The problem of finding the number of ions per cubic centimetre of the gas is thus reduced to finding the number of drops per cubic centimetre in the cloud. Knowing the amount of the expansion, we can calculate the amount of water deposited per cubic centimetre of the cloud. The water is deposited as drops, and if the drops are of equal size the number per cubic centimetre will be equal to the volume of the water deposited per cubic centimetre divided by the volume of one of the drops. Hence we can calculate the number of the drops if we know their size, and this can be determined by measuring v, the velocity with which they fell under gravity through the air. From the theory of the motion of a sphere through a viscous fluid,

$$v=\frac{2}{9}\frac{ga^2}{\mu},$$

where a is the radius of the drop, g the value of gravity, and μ the coefficient of viscosity of the gas through which the drop falls. From this equation we can determine a, and hence deduce n, the number of ions per cubic centimetre. If we place two parallel metal plates in the gas, and establish between them a known potential difference, we shall get a current of electricity through the gas which we can measure by means of an electrometer. If e is the charge on an ion, and u the mean velocity of the positive and negative ions in the electric field between the plates, the current across a square centimetre is neu; hence, by the electrical measurements we determine the product neu. We know n by the experiments on the clouds, and u by the determinations which have been made of the velocities of the ions. We can therefore deduce the value of e, the charge on the ion. For the details of the experiment see papers by J. J. Thomson, *Phil. Mag.* xlvi. p. 528; xlviii. p. 547. The result of measurements made by this method is that the charge on the ion is the same whether the ionization is produced by Röntgen rays or by the incidence of ultra-violet light on a metal plate. It is also the same whether the gas ionized is hydrogen, air, or CO_2, and thus is presumably independent of the nature of the gas. The value of the ionic charge in electrostatic units is about $6\cdot5\times10^{-10}$ c.g.s. units.

The ratio of the ionic charge to the charge carried by an atom of hydrogen in the electrolysis of solutions has been determined by Townsend by a method depending upon the measurement of the rate of diffusion of the ions into the surrounding gas (*Phil. Trans.* cxciii. p. 129). If we have a quantity of positive and negative ions in a gas contained in a vessel with metal walls, their number will diminish in two ways: (1) some of the positive and negative ions will unite and form a neutral system, and (2) the ions will diffuse to the walls of the vessel, and coming in contact with the metal, cease to behave like ions, so that the metal sides can be regarded as absorbing all the ions which come in contact with it. The number absorbed in a given time depends upon the coefficient of diffusion of the ions through the gas in the vessel, and if we arrange the experiment so that the first cause of the decrease in the number of ions produces effects small compared with those produced by the second, a measurement of the rate at which the ions disappear will give the coefficient of diffusion of the gas. The theory of the connexion between these quantities may be illustrated by the consideration of a very simple case.

Suppose that initially the distribution of ions between two parallel metal plates is uniform, and that the ions are left to diminish by diffusion to the plates. Then if D is the coefficient of diffusion of the ions into the gas, we have by the theory of gaseous diffusion (see DIFFUSION, *Ency. Brit.* 9th edition), if n is the number of ions per cubic centimetre of the gas,

$$\frac{dn}{dt}=\mathrm{D}\left(\frac{d^2n}{dx^2}+\frac{d^2n}{dy^2}+\frac{d^2n}{dz^2}\right).$$

Let us take the axis of x normal to the metal plate; then if the distribution of ions was initially uniform, n will be independent of y and z, and the equation becomes

$$\frac{dn}{dt}=\mathrm{D}\frac{d^2n}{dx^2}.$$

If a is the distance between the plates, the boundary conditions are that $n=0$ when $x=0$, or when $x=a$ for all values of t, and that when $t=0$ n is constant for all values of x between 0 and a, and equal to n_0. The solution of the differential equations with these boundary conditions is

$$n=\frac{4n_0}{\pi}\sum_{n=1}^{n=\infty}\frac{e^{-\frac{(2n-1)^2\pi^2\mathrm{D}t}{a^2}}}{2n-1}\sin(2n-1)\frac{\pi x}{a}.$$

If N is the number of ions between the plates at the time t, N_0 the number when $t=0$,

$$\frac{\mathrm{N}}{\mathrm{N}_0}=\frac{\int_0^a ndx}{n_0a}=\frac{8}{\pi^2}\sum_{n=1}^{n=\infty}\frac{e^{-\frac{(2n-1)^2\pi^2\mathrm{D}t}{a^2}}}{(2n-1)^2}\quad . \quad . \quad . \quad (1).$$

Now N/N_0 can easily be determined, as it is equal to the ratio of the quantities of electricity which can be sent across the plates by a strong electromotive force at the time t and at the time $t=0$. These quantities can readily be measured by an electrometer. Knowing N/N_0, we can then, by means of equation (1), calculate D. In practice it was found more convenient to use cylindrical tubes instead of parallel plates, and though the calculation of the connexion between N/N_0 and D is in this case a little more troublesome, the principles involved are the same. We have seen (see § 3) that if u is the velocity of the ion under an electric intensity X, e the charge on the ion,

$$u=\frac{\mathrm{X}e}{(p_1/\mathrm{N}_1)}\mathrm{D},$$

where N_1 is the number of ions per cubic centimetre of the gas required to produce a partial pressure of the ions equal to p_1, but

$$\frac{p_1}{\mathrm{N}_1}=\frac{\pi}{\mathrm{N}},$$

where N is the number of molecules in a cubic centimetre of any gas at the atmospheric pressure, π. Putting $\pi=10^6$, $\mathrm{X}=1/300$ (this corresponds to a potential gradient of 1 volt per centimetre), u_1 the velocity of the ion under this potential gradient, we have

$$u_1=\frac{1}{300\times10^6}\mathrm{N}e\,.\,\mathrm{D},$$

or

$$\mathrm{N}e=3\times10^{10}\frac{u_1}{\mathrm{D}}.$$

Now u_1 is known from the experiments on the velocity of the ions, and D is known by Townsend's experiments. In this way Townsend found that if e_A, e_O, e_C, e_H, denote the charges on the ions produced by Röntgen rays in air, oxygen, carbonic acid, and hydrogen respectively, we have $\mathrm{N}e_A=1\cdot35\times10^{10}$; $\mathrm{N}e_O=1\cdot25\times10^{10}$; $\mathrm{N}e_C=1\cdot30\times10^{10}$; $\mathrm{N}e_H=1\cdot15\times10^{10}$; while if E is the charge carried by the atom of hydrogen in the electrolysis of solutions, we know $\mathrm{NE}=1\cdot22\times10^{10}$.

It follows from these results that the charges on the ions produced by Röntgen rays in the gases named are all equal to each other and to the electrolytic charge on the hydrogen atom. Thus these results confirm that obtained by the method of clouds, viz., that the charge on the ion is independent of the nature of the gas from which it is produced. If we substitute for E the value obtained by the cloud method, viz., $6\cdot5\times10^{-10}$, we obtain for N the value $1\cdot9\times10^{19}$. This value, obtained by direct experiment, thus agrees very closely with the value $2\cdot1\times10^{19}$ obtained by Maxwell for the number of particles in a cubic centimetre of air by the application of the kinetic theory of gases. Townsend has applied his method to the calculation of the charges on the ions produced by the incidence of ultra-violet light on metals, by radio-active substances, and by the discharge of electricity from points, as well as those produced by Röntgen rays, and has found that in all these cases the charges are the same. Thus the charge on the ion seems to be independent of the agent by which it is produced as well as of the gas from which it originates.

§ 6. *Calculation of the Mass of the Ions at Low Pressures.*—Although at ordinary pressures the ion seems to have a very complex structure and to be the aggregate of many molecules, yet we have evidence that at very low pressures the structure of the ion, and especially of the negative one, becomes very much simpler. This evidence is afforded by determination of the mass of the atom. We can measure the ratio of the mass of an ion to the charge on the ion by observing the deflexion produced by a given magnetic force on a moving ion. If an ion carrying a charge e is moving with a velocity v, at a point where the magnetic force is H, a mechanical force acts on the ion, whose direction is at right angles both to the direction of motion of the ion and to the magnetic force, and whose magnitude is $ev\mathrm{H}\sin\theta$, where θ is the angle between v and H. Suppose then that we have an ion moving through a gas whose pressure is so low that the free path of the ion is long compared with the distance through which it moves whilst we are experimenting upon it; in this case the motion of the ion will be free, and will not be affected by the presence of the gas.

Let the mass of the ion be m, its charge e, and let it move in a field where the electric and magnetic forces are both uniform, the electric force X being parallel to the axis of x, and the magnetic force Z parallel to the axis of z, then if x, y, are the co-ordinates of the ion at the time t, the equations of motion of the ion are—

$$m\frac{d^2x}{dt^2}=\mathrm{X}e-\mathrm{H}e\frac{dy}{dt},$$

$$m\frac{d^2y}{dt^2}=\mathrm{H}e\frac{dx}{dt}.$$

The solution of these equations, if x, y, dx/dt, dy/dt all vanish when $t=0$, is

$$x=\frac{\mathrm{X}m}{e\mathrm{H}^2}\left\{1-\cos\left(\frac{e}{m}\mathrm{H}t\right)\right\}$$

$$y=\frac{\mathrm{X}m}{e\mathrm{H}^2}\left\{\frac{e}{m}\mathrm{H}t-\sin\left(\frac{e}{m}\mathrm{H}t\right)\right\}.$$

These equations show that the path of the ion is a cycloid, the generating circle of which has a diameter equal to $2\mathrm{X}m/e\mathrm{H}^2$, and rolls on the line $x=0$.

Suppose now that we have a number of ions starting from the plane $x=0$, and moving towards the plane $x=a$. The particles starting from $x=0$ describe cycloids, and the greatest distance they can get from the plane is equal to the diameter of the generating circle of the cycloid, *i.e.*, to $2\mathrm{X}m/e\mathrm{H}^2$. (After reaching this distance they begin to approach the plane.) Hence if a is less than the diameter of the generating circle, all the particles starting from $x=0$ will reach the plane $x=a$, if this is unlimited in extent; while if a is greater than the diameter of the generating circle none of the particles which start from $x=0$ will reach the plane $x=a$. Thus, if $x=0$ is a plane illuminated by ultra-violet light, and consequently the seat of a supply of negative ions, and $x=a$ a plane connected with an electrometer, then if a definite electric intensity is established between the planes, *i.e.*, if X be fixed, so that the rate of emission of negative ions from the illuminated plate is given, and if a is less than $2\mathrm{X}m/e\mathrm{H}^2$, all the ions which start from $x=0$ will reach $x=a$. That is, the rate at which this plane receives an electric charge will be the same whether there is a magnetic field between the plate or not, but if a is greater than $2\mathrm{X}m/e\mathrm{H}^2$, then no particle which starts from the plate $x=0$ will reach the plate $x=a$, and this plate will receive no charge. Thus the supply of electricity to the plate has been entirely stopped by the magnetic field. Thus, on this theory, if the distance between the plates is less than a certain value, the magnetic force should produce no effect on the rate at which the electrometer plate receives a charge, while if the distance is greater than this value the magnetic force would completely stop the supply of electricity to the plate. The actual phenomena are not so abrupt as this theory indicates. We find that when the plates are very near together the magnetic force produces a very slight effect, and this an *increase* in the rate of charging of the plate. On increasing the distance we come to a stage where the magnetic force produces a great diminution in the rate of charging. It does not, however, stop it abruptly, there being a considerable range of distance, in which the magnetic force diminishes but does not destroy the current. At still greater distances the current to the plate under the magnetic force is quite inappreciable compared with that when there is no magnetic force. We should get this gradual instead of abrupt decay of the current if the particles, instead of all starting from the actual surface of the plate $x=0$, started from a layer of finite thickness t; in that case the first particles stopped would be those which started from the surface of the plate. This would be when $a=2\mathrm{X}m/e\mathrm{H}^2$, but particles would continue to reach the plate until $a=t+2\mathrm{X}m/e\mathrm{H}^2$. Thus if we measure the value of a when the magnetic force first begins to affect the leak to the electrometer we determine $2\mathrm{X}m/e\mathrm{H}^2$, and as we can easily measure X and H, we can deduce the value of m/e.

By this method the writer determined the value of m/e for the negative ions produced when ultra-violet light falls on a metal plate, as well as for the negative ions produced by an incandescent carbon filament in an atmosphere of hydrogen (*Phil. Mag.* xlviii. p. 547). For the ions produced by ultra-violet light the value e/m was found to be $7{\cdot}3\times10^6$, and for those produced by the incandescent carbon filament, $8{\cdot}7\times10^6$ (e is measured in electro-magnetic units). The difference between these values is not greater than the error of experiment. When we consider the properties of the cathode rays we shall see that for the negatively electrified particles which constitute those rays the value of e/m is the same as that just found, and is independent of the nature of the gas from which the rays originate; in fact, in all cases in which the value of e/m has been determined for gases at low pressures, the result has been to show that it is a constant quantity independent both of the nature of the gas from which the ions are produced and of that of the agent used to produce them. Townsend's experiments (*loc. cit.*) show that the value of e, the charge on the ion, is equal to the charge carried by an atom of hydrogen in the electrolysis of solutions. But if M is the mass of an atom of hydrogen, e/M is equal to 10^4, and M is equal to about $1000m$. Thus the mass of the negative ion is exceedingly small compared with that of the mass of the atom of hydrogen, the smallest mass recognized in chemistry. The production of negative ions thus involves the splitting up of the atom, as from a collection of ions something is detached whose mass is less than that of a single atom. It is important to notice in connexion with this subject that an entirely different line of argument, based on what is known as the Zeeman effect (see MAGNETO-OPTICS), leads to the recognition of negatively electrified particles, for which e/m is of the same order as that just deduced from the consideration of purely electrical phenomena.

When we determine e/m for the positive ions we find an entirely different set of laws from those which hold for the negative ions. The value of e/m for the positive ions is not constant, nor has it the exceedingly large value which is characteristic of the negative ions. The writer has determined the value of e/m for the positive ions produced near an incandescent platinum wire in an atmosphere of oxygen or carbonic acid gas at a very low pressure, using the method already described for the determination of the corresponding quantity for the negative ions, *i.e.*, by measuring the distance between two parallel plates when a magnetic field begins to affect the current passing between them. To get any result with positive ions, it is necessary to use exceedingly strong magnetic fields, for while a magnetic force of about 150 was found a convenient one for the experiment with the negative ions, it had no appreciable effect on the positive ions, and for these it was necessary to use a magnetic force of about 8000. Using this magnetic force, the value of e/m for the positive ions in oxygen was found to be about $10^4/40$, while for carbonic acid gas it was slightly less. If the charge on the positive ion had been carried by a molecule of oxygen, the value of e/m would have been $10^4/32$, so that the carrier of the positive charge is probably a molecule of oxygen. Experiments, which we shall have to consider later in connexion with another part of the subject, made by W. Wien[30] and Ewers[31] on the value of e/m for the positively charged particles in what are called the *Kanal-strahlen*, are entirely consistent with the view that the mass of the carrier of the positive charge in this case is that of a molecule of some substance present in the vessel in which the ions are produced and varying as these substances are changed. Thus the carriers of negative electricity at a low pressure have a constant mass very small compared with that of the atom of any known substance, while the carriers of positive electricity have a variable mass which is comparable with that of the molecule of the chemical elements.

§ 7. *Distribution of Potential between two Parallel Plates in a Conducting Gas.*—Zeleny[32] and Child[33] have shown that when a current of electricity is passing between two parallel plates immersed in a gas exposed to Röntgen rays, the electric intensity in the space between the plates is not constant, but is greater in the immediate neighbourhood of the plates than it is in the rest of the gas, where it has a nearly constant value. The general character of the distribution of electric potential between the plates is shown in Fig. 12, where the ordinates represent the potential. We can readily see why the electric intensity should be greater near the plates than in the rest of the gas, for from the layer of gas next the positive plate the positive ions will be driven out, so that there will be an excess of negative ions in this layer. Similarly, in the layer of gas next the negative plate there will be an excess of positive ions, and this free electrification will increase the slope of potential in the neighbourhood of the plates. The distribution of electric intensity between the plates can be deduced by the following considerations :—

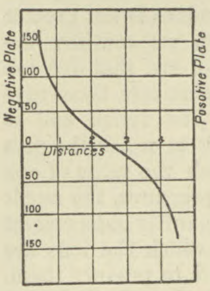

Fig. 12.

Let the two plates be at right angles to the axis of x; then we may suppose that between the plates the electric intensity X is everywhere parallel to the axis of x. The velocities of both the positive and negative ions are assumed to be proportional to X. Let R_1X, R_2X represent these velocities respectively ; let n_1, n_2 be respectively the number of positive and negative ions per unit volume at a point fixed by the co-ordinate x; let q be the number of positive or negative ions produced in unit time per unit volume at this point ; and let the number of ions which recombine in unit volume in unit time be an_1n_2 ; then if e is the charge on the ion, the volume density of the electrification is $(n_1 - n_2)e$, hence

$$\frac{dX}{dx} = 4\pi(n_1 - n_2)e \quad . \quad . \quad . \quad . \quad (1).$$

If I is the current through unit area of the gas and if we neglect any diffusion except that caused by the electric field,

$$n_1eR_1X + n_2eR_2X = I \quad . \quad . \quad . \quad . \quad (2).$$

From equations (1) and (2) we have

$$n_1e = \frac{1}{R_1 + R_2}\left(\frac{I}{X} + \frac{R_2}{4\pi}\frac{dX}{dx}\right) \quad . \quad . \quad . \quad (3),$$

$$n_2e = \frac{1}{R_1 + R_2}\left(\frac{I}{X} - \frac{R_1}{4\pi}\frac{dX}{dx}\right) \quad . \quad . \quad . \quad (4),$$

and from these equations we can, if we know the distribution of electric intensity between the plates, calculate the number of positive and negative ions.

In a steady state the number of positive and negative ions in unit volume at a given place remains constant, hence

$$\frac{d}{dx}(Rn_1X) = q - an_1n_2 \quad . \quad . \quad . \quad . \quad (5)$$

$$-\frac{d}{dx}(R_2n_2X) = q - an_1n_2 \quad . \quad . \quad . \quad . \quad (6).$$

If R_1 and R_2 are constant, we have from (1), (5), and (6)

$$\frac{d^2X^2}{dx^2} = 8\pi e(q - an_1n_2)\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \quad . \quad . \quad . \quad (7),$$

an equation which is very useful, because it enables us, if we know the distribution of X^2, to find whether at any point in the gas the ionization is greater or less than the recombination of the ions. We see that $q - an_1n_2$, which is the excess of ionization over recombination, is proportional to d^2X^2/dx^2. Thus when the ionization exceeds the recombination, *i.e.*, when $q - an_1n_2$ is positive, the curve for X^2 is convex to the axis of x, while when the recombination exceeds the ionization the curve for X^2 will be concave to the axis of x. Thus, for example, Fig. 13 represents the

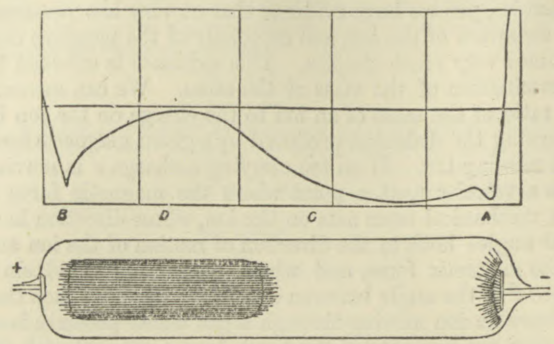

Fig. 13.

curve for X^2 observed by Graham (*Wied. Ann.* lxiv. p. 49) in a tube through which a steady current is passing. Interpreting it by equation (7), we infer that ionization was much in excess of recombination at A and B, slightly so along C, while along D the recombination exceeded the ionization. Substituting in equation (7) the values of n_1 n_2 given in (3), we get

$$\frac{d^2X^2}{dx^2} = 8\pi e\left[q - \frac{a}{e^2X^2(R_1 + R_2)^2}\left(I + \frac{R_2}{8\pi}\frac{dX^2}{dx}\right)\left(I - \frac{R_1}{8\pi}\frac{dX^2}{dx}\right)\right]\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \quad (8).$$

This equation can be solved (see Thomson, *Phil. Mag.* xlvii. p. 253), when q is constant and $R_1 = R_2$. From the solution it appears that if X_1 be the value of x close to one of the plates, and X_0 the value midway between them,

$$\frac{X_1}{X_0} = \frac{1}{\beta^{2-2/\beta}}$$

where $\beta = \frac{8\pi ek_1}{a}$.

Since $e = 6{\cdot}5 \times 10^{-10}$, $a = 2 \times 10^{-6}$, and R_1 for air at atmospheric pressure $= 450$, β is about 3·8 for air at atmospheric pressure and it becomes much greater at lower pressures.

Thus X_1/X_0 is always greater than unity, and the value of the ratio increases from unity to infinity as β increases from zero to infinity. As β does not involve either q or I, the ratio of X_1 to X_0 is independent of the strength of the current and of the intensity of the ionization.

No general solution of equation (8) has been found when R_1 is not equal to R_2, but we can get an approximation to the solution when q is constant. The equations (1), (2), (3), (4) are satisfied by the values—

$$n_1 = n_2 = (q/a)^{\frac{1}{2}},$$

$$R_1n_1Xe = \frac{R_1}{R_1 + R_2}I,$$

$$R_2n_2Xe = \frac{R_2}{R_1 + R_2}I,$$

$$X = \left(\frac{a}{q}\right)^{\frac{1}{2}}\frac{I}{e(R_1 + R_2)}.$$

These solutions cannot, however, hold right up to the surface of the plates, for across each unit of area, at a point P, $R_1I/(R_1 + R_2)e$ positive ions pass in unit time, and these must all come from the region between P and the positive plate. If λ is the distance of P from this plate, this region cannot furnish more than $q\lambda$ positive ions, and only this number if there are no recombinations. Hence the solution cannot hold when $q\lambda$ is less than $R_1I/(R_1 + R_2)e$, or where λ is less than $R_1I/(R_1 + R_2)qe$.

Similarly the solution cannot hold nearer to the negative plate than the distance $R_2I/(R_1 + R_2)qe$.

We can arrive at the same value of λ in another way. The force cannot by equation (7) be constant unless as many ions recombine as are produced by the ionizing agent. Now the ions travel a certain distance before they recombine, this distance being the product of the velocity of the ion and the duration of its life. Now the life of the positive ion is $1/\alpha n_2$, and its velocity is R_1X; hence the distance an ion will travel before it recombines is equal to average $R_1X/\alpha n_2$.

If we suppose X and n_2 to have the values they have in the region where X is constant, we find, substituting the values for X and n_2, that this distance is equal to $\frac{R_1}{R_1+R_2}\frac{I}{qe}$, the value we found before for the thickness of the layer within which X was variable; hence in this region we may assume that there is no recombination going on. We shall suppose that the electric intensity is uniform, except in a layer of thickness $R_1I/(R_1+R_2)qe$ next the positive electrode, and in one of thickness $R_2I/(R_1+R_2)qe$ next the negative electrode, and that within these layers there is no recombination of the ions. On these suppositions, it can readily be proved that if X_1, X_2, X are respectively the values of the electric intensity next the positive electrode, next the negative electrode, and between the layers.

$$X_1 = X\{1+\beta_1\}^{\frac{1}{2}},$$
$$X_2 = X(1+\beta_2)^{\frac{1}{2}},$$

where $\beta_1 = \frac{4\pi e}{\alpha}\frac{R_1}{R_2}(R_1+R_2)$, $\beta_2 = \frac{4\pi e}{\alpha}\frac{R_2}{R_1}(R_1+R_2)$.

Thus X_1 and X_2 are always greater than X, and if the velocity of the negative ion is greater than that of the positive, β_2 is greater than β_1; hence the electric intensity at the negative electrode is greater than that of the positive, and the thickness of the layer of inconstant X is greater at the negative than at the positive electrode. The curve representing the distribution of electric intensity between the plates when R_2/R_1 is large is shown in Fig. 14.

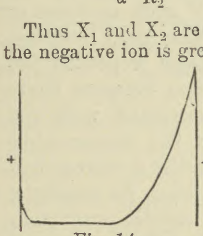

Fig. 14.

When β_1 and β_2 are large, as they are for hydrogen up to the atmospheric pressure and for air at somewhat lower pressures, the potential difference on crossing the layers next the positive and negative electrodes may easily be shown to be respectively

$$\tfrac{1}{2}(1+\beta_1)^{\frac{1}{2}}\frac{\alpha^{\frac{1}{2}}}{q^{\frac{3}{2}}}\frac{I^2}{e^2}\frac{R_1}{(R_1+R_2)^2},$$
$$\tfrac{1}{2}(1+\beta_2)^{\frac{1}{2}}\frac{\alpha^{\frac{1}{2}}}{q^{\frac{3}{2}}}\frac{I^2}{e^2}\frac{R_2}{(R_1+R_2)^2}.$$

Thus if R_2 is greater than R_1 the fall of potential at the negative electrode is greater than that at the positive; both are proportional to the square of the current. If V is the potential difference between the plates, and l the distance between them, it follows from these expressions that

$$V = \left(\frac{\alpha}{q}\right)^{\frac{1}{2}}\frac{I}{e(R_1+R_2)}\left\{\tfrac{1}{2}(1+\beta_1)^{\frac{1}{2}}\frac{R_1}{R_1+R_2}\frac{I}{qe} + \tfrac{1}{2}(1+\beta_2)^{\frac{1}{2}}\frac{R_2}{R_1+R_2}\frac{I}{qe} - \frac{I}{qe} + l\right\}$$

This relation between the current and potential difference between the plates is of the form

$$V = AI + BI^2.$$

If I is small, so that we may neglect I^2,

$$V = \left(\frac{\alpha}{q}\right)^{\frac{1}{2}}\frac{Il}{e(R_1+R_2)}.$$

This solution has been applied by Rutherford (*Phil. Mag.* xliv. p. 422) to find (R_1+R_2). Since $(q/\alpha)^{\frac{1}{2}}$ is the number of positive and negative ions per unit volume, if we stop the ionizing agent at the instant it is cut off, $l(q/\alpha)^{\frac{1}{2}}e$ is the quantity of positive electricity between the plates. By applying a very large potential difference between the plates we can drive this positive electricity to one of the plates before it has time to recombine with the negative ions. Hence Q, the positive charge received by the plate, is equal to $l(q/\alpha)^{\frac{1}{2}}e$, and

$$V = Il^2/Q(R_1+R_2);$$

and as we can measure V, I, and Q, we can determine (R_1+R_2). The measurements of the velocities of the ions by this method agree well with those made by the direct methods already described.

The solution given above only holds as long as the layers of variable force next the positive and negative plates do not meet. As the current increases the layers expand, until, when the saturating current is reached, they touch. After this there is no space between the plates where the electric intensity is uniform. The electric intensity at a place at a distance x from the positive plate is given by the equation

$$X^2 = 8\pi qe\left\{\frac{x^2}{2}\left(\frac{1}{R_1}+\frac{1}{R_2}\right) - \frac{Ix}{R_2}\right\} + X_1^2,$$

where X_1 is the electric intensity at the positive plate. We see again that, if the velocity of the negative ion is greater than that of the positive, the electric intensity is greater at the negative electrode than it is at the positive.

§ 8. *Path of a Moving Ion in a Magnetic Field.*—For the explanation of some of the effects of a magnet on the electric discharge we require to know the path of an ion in a magnetic field. We have already investigated one case of this problem (see § 6); there are, however, two other important cases which it is necessary to consider.

The first case is that of a charged ion moving in a uniform field of magnetic force, and free from the action of any electric force, the pressure of the gas being so low that it does not retard the motion of the particle. Then if v is the velocity of the particle, m its mass, and e its charge, H the magnetic force and δ the angle between v and H, the mechanical force acting on the particle is at right angles both to v and H, and equal to evH sin θ. Since the force on the particle is at right angles to its direction of motion, the velocity of the particle will be constant, and since the force is at right angles to the magnetic force, the components of the velocity parallel to the magnetic force will be constant, *i.e.*, $v\cos\theta$ is constant, so that as v is constant, θ is also constant. If ρ is the radius of curvature of the path of the particle $mv^2/\rho = Hev\sin\theta$, so that as v and θ are constant ρ is constant. Thus the path of the particle is a curve whose tangent makes a constant angle θ with the direction of the magnetic force, and whose radius of curvature is $mv/He\sin\theta$. The path of the particle is therefore a helix wound on a circular cylinder whose axis is parallel to the magnetic force, and whose radius is $\rho\sin\theta$ or $mv\sin\theta/He$.

The other case we shall consider is when the pressure of the gas through which the particle moves is considerable, so that the viscosity of the gas makes the velocity of the particle proportional to the force acting upon it. In this case there must be an electric field acting on the particles, otherwise the viscosity of the gas will reduce them to rest. Let X, Y, Z be the x, y, z components of the electric intensity, α, β, γ those of the magnetic force, and u, v, w the components of the velocity of the particle. The components of the force on the particle are

$$Xe + e(\beta w - \gamma v),\quad Ye + e(\gamma u - \alpha w),\quad Ze + e(\alpha v - \beta u).$$

If the velocity of the particle is R/e times the force acting on it, we have

$$u = R(X + \beta w - \gamma v),$$
$$v = R(Y + \gamma u - \alpha w),$$
$$w = R(Z + \alpha v - \beta u).$$

Solving these equations, we have

$$u = \frac{RX + R^2(\gamma Y - \beta Z) + R^3\alpha(\alpha X + \beta Y + \gamma Z)}{1 + R^2(\alpha^2 + \beta^2 + \gamma^2)},$$
$$v = \frac{RY + R^2(\alpha Z - \gamma X) + R^3\beta(\alpha X + \beta Y + \gamma Z)}{1 + R^2(\alpha^2 + \beta^2 + \gamma^2)},$$
$$w = \frac{RZ + R^2(\beta X - \alpha V) + R^3\gamma(\alpha X + \beta Y + \gamma Z)}{1 + R^2(\alpha^2 + \beta^2 + \gamma^2)}.$$

We see at once from these equations that when R times the magnetic force is small compared with unity, u, v, w are proportional to X, Y, Z; that is, the particle follows a line of electric force. But on the other hand, when R times the magnetic force is large, u, v, w are proportional to α, β, γ; that is, the path of the particle is a line of magnetic force. In the general case, if H is the magnetic, F the electric force, and θ the angle between them, the velocity has a component along the electric force proportional to RF, another component along the magnetic force proportional to $R^3H^2F\cos\theta$, and a third component at right angles to both the electric and magnetic forces, and proportional to $R^2HF\sin\theta$. In this case the path is along the lines of neither electric nor magnetic force, but is a spiral. The quicker the particle moves under a given force the more likely it is to follow the lines of magnetic force. Thus the negative particles are more likely to do this than the positive. If the particle moves with a velocity of n cm./sec. under a potential gradient of 1 volt per centimetre through the gas when at a pressure of one atmosphere, then at the pressure of $1/m$ atmosphere R is equal to $nm10^{-8}$. Thus from what we know of the velocities of the ions it is only at very low pressures that RH can be large for practicable values of H.

§ 9. *Difference of Potential between Metals immersed in a Conducting Gas.*—If plates of different metals immersed in a conducting gas are connected with the quadrants of an electrometer, they will show the same potential difference as if they had been immersed in an electrolyte. This has been proved when the conductivity is due to gases from flames by Maclean and Goto,[34] when due to ultra-violet light by Stoletow,[35] Righi,[36] Hallwachs,[37] Arrhenius,[38] when due to Röntgen rays by Erskine Murray,[39] and when due to rays from uranium by Lord Kelvin.[40]

We shall now leave the consideration of conducting gases in general and proceed to discuss the phenomena accompanying the discharge of electricity through them in special cases.

§ 10. *Conduction through Gases when in a Normal State.*—Even in its normal state a gas possesses a small amount of conductivity, which, however, is so small that it is only quite recently that the existence of a leak from a charged body through the air and independent of dust in the air has been unmistakably proved. The experiments of Matteucci, Warburg, Boys, Linss, Elster and Geitel, and C. T. R. Wilson[41] have proved that there is a very slight leak from a charged body through the surrounding gas, that this leak takes place in the dark as well as in daylight, in caves as well as above ground, and that the rate of leak is approximately proportional to the pressure of the gas. Matteucci could detect no difference between the rate of leak through hydrogen and that through air or carbonic acid. Warburg, however, found, on the other hand, that the rate of leak through hydrogen was only about one-half of that through the other two gases.

§ 11. *Conduction of Electricity through Hot Gases, &c.*—Gases become conductors when raised to a temperature at which metals become luminous. Thus Becquerel[42] found that air at a white heat would allow electricity to pass through it, even though the potential difference was only a few volts. This result was confirmed by Blondlot,[43] who observed that air at a bright red heat allowed a current to pass through it under a potential difference of $\frac{1}{1000}$ of a volt. The writer[44] observed that gases which are dissociated by heat, such as iodine, chlorine, bromine, and their compounds, conduct much better at the same temperature than gases such as air, hydrogen, nitrogen, which are not dissociated. The vapours of many metals are good conductors, mercury, however, being an exception. It is probable that a large part of the conductivity is produced at the surface of contact of the gas with the glowing electrodes or other solids which may be immersed in it, as H. A. Wilson[45] has shown that when salts are put into a flame there is great ionization where the salt-bearing flame comes into contact with glowing metals, and comparatively little anywhere else. We shall see later on that there is always a production of ions at the surface of a glowing metal. The view that the greater part of the ions are produced next the surface of the glowing electrodes explains a curious phenomenon observed by the writer, who found that when a current of electricity was passing between two glowing electrodes in a hot gas the interposition of a cold piece of thin metal stopped the current as completely as the interposition of a non-conductor, but that as soon as the metal began to glow the current was re-established. If the ions came from the glowing electrodes, then the negative ion, which travels to the positive electrode, started from the negative electrode; thus an interposed piece of metal, so long as no ions are produced at its surface, will stop the negative ions from reaching the positive electrode and the positive ions from reaching the negative electrode. The current will, however, begin again as soon as the plate begins to glow, for then ions are produced at the plate, furnishing a supply of positive ions for the negative electrode and of negative ions for the positive. The same view will explain the fact discovered by Blondlot (*loc. cit*), and also by Pringsheim,[46] that for the conduction of electricity through hot gases under small potential differences the current increases faster than the potential difference. If the ions are produced at the surface of the electrodes, the number torn from the electrode and sent into the gas will depend upon the potential difference. But the velocity with which these ions move is proportional to the potential difference, and as the current is proportional to the product of the number of ions into the velocity of an ion, it will increase more rapidly than the potential difference. Pringsheim has succeeded in observing a polarization analogous to electrolytic polarization in the conduction through hot gases.

The gases coming from flames are conductors of electricity, and retain this property for some time after leaving the flame. In one case observed by Giese[47] the conductivity lasted for fifteen minutes after the gases had left the flame. The conductivity of flame gases is more persistent than that of gases which have been exposed to Röntgen rays, and can survive bubbling through a considerable column of conducting liquid,[48] such as water or mercury, without total destruction. The gas, however, loses its conductivity when forced through a porous pot of unglazed earthenware. This difference between flame gases and other conducting gases is connected with the very slow speed with which the ions in the former move in the electric field (see § 4). This implies a correspondingly slow rate of diffusion, so that in going, for example, through a long metal tube a very much smaller proportion of the ions will diffuse to the walls of the tube than would be the case with the more rapidly moving ions from a gas exposed to Röntgen rays. We owe a large portion of our knowledge of the laws of conduction through flames to Giese, whose researches on flames led him to the view, which he was the first to suggest, that electricity is carried through them by oppositely charged particles. Thus Giese showed that the conductivity can be removed from the gas by making the gas traverse an electric field, and that the current in the great majority of cases does not increase so rapidly as the potential difference. Certain exceptions which he found to this rule can be explained in the same way as the analogous cases in the conduction through hot gases. A more extensive investigation of the relation between current and potential difference for flame gases has been made by M'Clelland,[49] who finds that the relation between current and potential difference is represented by a curve like Fig. 8. The current through the flame exhibits polar properties, for if the electrodes are of different sizes the current is much greater when the larger electrode is negative than when it is positive. We can easily see that this result is a direct consequence of the greater part of the ionization taking place next the glowing electrode, and of the velocity of the negative ion greatly exceeding that of the positive, for in consequence of this difference in velocity the current will be chiefly carried by the negative ions, and if the ionization takes place at the surface of the glowing electrodes, there will be a much larger quantity of negative ions available for carrying the current when the larger electrode is negative than when it is positive. The same considerations will explain why if the electrodes are of equal size, but placed in parts of the flame where the temperatures are different, the current will be greater when the hotter electrode is negative than when it is positive. If the electrodes are connected with a galvanometer without any battery there is a small current from the colder to the hotter electrode through the flame, for the negative ions diffuse faster than the positive, so that there will be an excess of positive ions at the electrodes. This excess will be greater at the hotter electrode than at the colder, because there are more ions formed at the hotter electrode, which will therefore be continually receiving a charge of positive electricity. Arrhenius[50] has shown that when solutions of salts of the alkali metals are thrown into a flame by a spray-producer, the conductivity of the flame is greatly increased, and that the conductivity of salt vapours in flames is closely analogous to the conductivity of an aqueous solution of the salt, being proportional to the square root of the concentration of the salt vapour in the flame. He concluded that the salt vapour is partly ionized at the high temperature of the flame. H. A. Wilson (*loc. cit.*) has shown, however, that the greater part of the ionization takes place, not in the general body of the flame, but at the surface of the glowing electrodes. He gives several independent proofs of this; perhaps the simplest is one where the salt was introduced as a bead between two glowing electrodes immersed in the flame. If the bead was placed between the electrodes, so that the salt vapour did not come into contact with the glowing metal, the current was not increased at all; if it came into contact with the negative electrode the current was very greatly increased; while if it only came in contact with the positive electrode the current was but slightly increased. The difference between the effects at the positive and negative electrodes is due to the velocity of the negative ion being much greater than that of the positive. Hittorf[51] long ago showed that the current is greater when the bead of salt is placed near the negative electrode than when it is placed near the positive. The distribution of potential between two electrodes immersed in a flame sprayed with salt solution is not by any means uniform, as is obvious from the curves in Fig. 15, which are taken

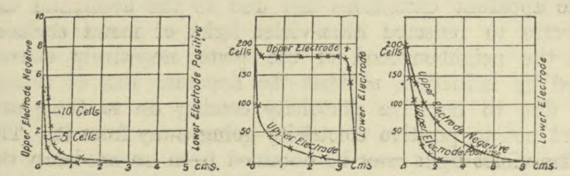

Fig. 15.

from the paper by H. A. Wilson (*loc. cit.*). The electrodes were horizontal strips of metallic gauze. The first curve represents the distribution of potential when both the electrodes are red-hot; near each electrode there is a rapid fall of potential, which is greatest at the negative one, while between the electrodes there is an approximately uniform small potential gradient. The general distribution of potential is analogous to that observed in electric discharge through gases at low pressures. In the second curve the electrodes are so far apart that the upper one is appreciably colder than the lower, and in the third the tendency of the fall of potential to be greatest at the negative electrode is very well marked. The current sent by a given potential difference through a flame depends upon the material of which the electrodes are made. Thus Petinelli[52] found that, *ceteris paribus*, the current between two carbon electrodes was about 500 times that between two iron electrodes. If one electrode was carbon and the other iron, the current when the carbon was negative and the iron positive was more than a hundred times greater than when the electrodes were reversed. A charged body placed near a flame will lose its charge even although it is placed below or to one side of the flame, so as to be out of the way of the flame gas. The electric field due to the charged body drags out of the flame the ions of opposite sign to the charge on the body. These ions move up to the body and gradually discharge it.

§ 12. *Ionization produced by Glowing Metals.*—It will thus be seen that in conduction through flames ionization in the neighbourhood of glowing metals plays a large part. The electrical properties of glowing metals have been studied with great care by Elster and Geitel,[53] to whom we owe most of our knowledge of this subject. They found that when a platinum wire is heated to luminosity in air, the air in the neighbourhood of the wire is charged with positive electricity, while the wire itself receives a negative charge. The close coincidence between the appearance of luminosity in the wire and positive electrification in the air is very remarkable. So far as we know, we do not get one without the other. At first the amount of positive electrification in the air is small, but this very rapidly increases as the temperature increases. Though at a dull red heat only positive electrification appears in the air round the wire, yet as the temperature increases some negative electricity begins to come off, until at a white heat there are as many negative as positive ions in the gas round the wire. When the pressure of the gas is very low there are always more negative than positive ions round the wire when it is white hot. This is in accordance with the experiments of Guthrie,[54] who was the first to make observations on the electrical effects near glowing bodies. He found that if a heated iron sphere was connected with the earth and held near a charged body, then when it was white hot the body soon lost its charge, whether this was positive or negative; but when it became colder the body was discharged when negatively, but not when positively, electrified. Elster and Geitel tried the effect of heating the wire in various gases, such as air, hydrogen, oxygen, carbonic acid, water vapour, and vapours of sulphur, phosphorus, and mercury. In the last they got no sign of electrification; in hydrogen at a red heat the electrification in the gas was negative; and in all the other gases and vapours the electrification at a red heat was positive. When carbon filaments were heated the electrification in the gas was always negative; these filaments, however, give off so much gas that the conditions of the experiment are somewhat indefinite. Branly[55] observed that the effects at a dull red heat depended on the nature of the glowing body; thus, when this was a lamp shade covered with oxides of lead or bismuth a positively electrified body in the neighbourhood was discharged, whilst a negatively electrified one was not. This is a reversal of the effect observed with surfaces of clean metal. Stanton[56] found that a hot surface of clean copper discharges a positively electrified conductor in its neighbourhood, but ceases to do so as soon as the copper gets coated with a layer of oxide. When, however, the hot oxidized copper and a positively electrified body are placed in an atmosphere of hydrogen, the electrified body loses its charge as long as the oxide is being reduced, but ceases to do so as soon as the reduction is complete. M'Clelland has found that by sending a strong blast against a red-hot wire both positive and negative ions are blown off, though there are more positive than negative ones. It would thus appear that by the incandescence of the metal the gas was ionized, and both positive and negative ions produced, but that then at a red heat more of one kind of ion than of the opposite went to the wire. In this case chemical forces probably exert a very large effect. For example, if we have oxidation going on we should expect the electropositive metal to combine with a negative ion and have an excess of positive ions in the surrounding gas, while if reduction is going on we should expect the oxide to combine with a positive ion, and so leave an excess of negative ions in the gas. This accords with the observations. The different rates at which the positive and negative ions diffuse would also have an influence on the sign of the charge in the gas, as in consequence of the more rapid diffusion of the negative ions more negative than positive ions would come in contact with the metal, and this would tend to make the charge in the gas positive. M'Clelland[57] has found that the velocity of the ions coming from the neighbourhood of the wire depends upon the temperature of the wire; the higher this temperature the smaller the velocity. When a wire is heated occluded gas is driven out, and this has an effect upon the electrical phenomena. The writer observed that the behaviour of a wire in a high vacuum did not become regular until it had been raised to a white heat repeatedly at intervals for more than a week, the irregularities being probably due to occluded gases, which are only got out with great difficulty. Elster and Geitel[58] showed that in gases at very low pressures the discharge of a positively electrified conductor near an incandescent wire in hydrogen, where the gas in the neighbourhood of the wire is negatively electrified, is retarded by a magnetic field when the lines of magnetic force are transverse to those of electric force. When the incandescent wire is in oxygen, where the electrification in the gas is positive, they found a very much smaller effect, and in the opposite direction. The writer has found, however, that in very intense magnetic fields the discharge of a negatively electrified body is retarded according to the same laws as that of a positively electrified body in hydrogen in much weaker fields. The theory of this effect, given in § 6, shows that the greater sensitiveness of the discharge in hydrogen to the magnetic force is due to the smallness of the mass of the negative ion at low pressures, as compared with that of the positive ion.

§ 13. *Conducting Gas produced by Arcs.*—The effect of an arc on the gas in its neighbourhood is very similar to that of an incandescent wire. Thus in the neighbourhood of the arc, in air or oxygen, there is positive electrification, while near the arc, between platinum terminals in hydrogen, there is, at atmospheric pressure, a slight negative electrification.[59] The gases sucked from the neighbourhood of the arc retain their conductivity for some time, and, like those from flames, can be bubbled through conducting liquids, or passed through several layers of wire gauze, without losing it. The conduction through these gases, which has been studied by M'Clelland,[60] and Merritt and Stewart,[61] exhibits the ordinary characteristics of discharge through ionized gas. M'Clelland has measured the velocity of the ions in an electric field, and finds it to be of the same order as for ions from flames. The velocity of the negative ion is greater than that of the positive, and the brighter the arc the slower the velocity. The electrification in the neighbourhood of the arc depends upon the nature of the terminals. Thus if an arc be sent through hydrogen, between well-oxidized copper terminals, the oxide gets reduced, and while reduction is going on there is negative electrification in the hydrogen near the arc; when, however, the oxide has been reduced and the terminals are bright, there is positive electrification near the arc. This shows the influence exerted by chemical effects on the sign of the electrification. The considerations advanced to explain the analogous effects with incandescent metals will apply to this case.

Conducting gas seems to be produced not only by the arc discharge, but also to a greater or less degree by every form of electric discharge. Thus Hittorf[62] showed that a few galvanic cells can send a current through a gas which is conveying a discharge at right angles to the current. Schuster[63] made an experiment which showed this effect in a very clear way. A large discharge-tube containing air at a low pressure was divided into two compartments by a metal plate with openings round the perimeter, these openings allowing the gas in one compartment to flow into the other, while the metal screened off one compartment from any electrical action occurring in the other. When a vigorous discharge passed through one compartment a potential difference of about one-quarter of a volt was sufficient to send a current through the gas in the other compartment. Again, if a blast of air be blown across the terminals of an electrical machine in action upon the disc of an electroscope, charged with either positive or negative electricity, the electroscope is rapidly discharged.[64] A charged body placed near a place where sparks are passing, whether from an induction coil or an electrical machine, will soon lose its charge.

§ 14. *Conductivity produced by Ultra-Violet Light.*—The discovery by Hertz,[65] in 1887, that the incidence of ultra-violet light on a spark gap facilitates the passage of a spark, led to a series of investigations by Hallwachs,[66] Hoor,[67] Righi,[68] and Stoletow[69] on the effect of ultra-violet light on electrified bodies. These researches have shown that a freshly cleaned metal surface, charged with negative electricity, rapidly loses its charge, however small, when exposed to ultra-violet light, and that if the surface is insulated and without charge initially, it acquires a positive charge under the influence of the light. The magnitude of this positive charge may be very much increased by directing a blast of air on the plate. This, as Zeleny[70] has shown, has the effect of blowing from the neighbourhood of the plate negatively electrified gas, which has similar properties to the charged gas obtained by the separation of ions from a gas exposed to Röntgen rays or uranium radiation. If the metal plate is positively electrified, there is no loss of electrification caused by ultra-violet light. This has been questioned, but a very careful examination of the question by Elster and Geitel[71] has shown that the apparent exceptions are due to the accidental exposure to reflected ultra-violet light of metal surfaces in the neighbourhood of the plate negatively electrified by induction, so that the apparent loss of charge is due to negative electricity coming up to the plate, and not to positive electricity going away from it. The ultra-violet light may be obtained from an arc-lamp, the effectiveness of which is increased if one of the terminals is made of zinc or aluminium, the light from these substances being very rich in ultra-violet rays; it may also be got very conveniently by sparking with an induction coil between zinc or cadmium terminals. Sunlight is not rich in ultra-violet light, and does not produce anything like so great an effect as the arc light. Elster and Geitel,[72] who have investigated with great success the effects of light on electrified bodies, have shown that the more electro-positive metals lose negative charges when exposed to ordinary light, and do not need the presence of the ultra-violet rays. Thus they found that amalgams of sodium or potassium enclosed in a glass vessel lose a negative charge when exposed to daylight, though the glass stops the small amount of ultra-violet light left in sunlight after its passage through the atmosphere. If sodium or potassium be employed, or, what is more convenient, the mercury-like liquid obtained by mixing sodium and potassium in the proportion of their combining weights, they found that negative electricity was discharged by an ordinary petroleum lamp. If the still more electro-positive metal rubidium is used, the discharge can be produced by the light from a glass rod just heated to redness; but there is no discharge till the glass is luminous. Elster and Geitel arrange the metals in the following order for the facility with which negative electrification is discharged by light:—rubidium, potassium, alloy of sodium and potassium, sodium, lithium, magnesium, thallium, zinc. With copper, platinum, lead, iron, cadmium, carbon, and mercury the effects with ordinary light are too small to be appreciable. The order is the same as that in Volta's electro-chemical series. With ultra-violet light the different metals show much smaller differences in their power of discharging negative electricity than they do with ordinary light. Elster and Geitel found that the ratio of the photo-electric effects of two metals exposed to approximately monochromatic light depended upon the wave-length of the light, different metals showing a maximum sensitiveness in different parts of the spectrum. This is shown by the following table for the alkaline metals. The numbers in the table are the rates of emission of negative electricity under similar circumstances. The rate of emission under the light from a petroleum lamp was taken as unity:—

	Blue.	Yellow.	Orange.	Red.
Rb . . .	·16	·64	·33	·039
Na . . .	·37	·36	·14	·009
K . . .	·57	·07	·04	·002

The table shows that the absorption of light by the metal has great influence on the photo-electric effect, for while K is more sensitive in blue light than Na, the strong absorption of yellow light by Na makes it more than five times more sensitive to this light than K. Stoletow, at an early period, called attention to the connexion between strong absorption and photo-electric effects. He showed that water, which does not absorb to any great extent either the ultra-violet or visible rays, does not show any photo-electric effect, while strongly coloured solutions, and especially solutions of fluorescent substances such as methyl green or violet, do so to a very considerable extent; indeed, a solution of methyl green is more sensitive than zinc. Hallwachs[73] has proved that in liquids showing photo-electric effects there is always strong absorption; we may, however, have absorption without these effects. Phosphorescent substances, such as sulphide of calcium, show this effect, as also do various specimens of fluor-spar. As phosphorescence and fluorescence are probably accompanied by a very intense absorption by the surface layers, the evidence is strong that to get the photo-electric effects we must have strong absorption of some kind of light, either visible or ultra-violet.

The connexion between the potential gradient and the rate of escape of negative electricity from the plate has been investigated by Stoletow,[74] Righi,[75] and Elster and Geitel.[76] The method adopted by Stoletow was as follows:—Light from an arc-lamp A, Fig. 16, passed through a hole in a metal screen; it then fell on the metal plates C, connected up with a battery and galvanometer. The plate nearest the light was perforated, and the light passed through the perforations on to the sensitive plate connected with the negative pole of the battery. The current passing round the circuit was measured by a galvanometer. The results of Stoletow's investigations are shown in the curves of Fig. 17, where the ordinates represent the current, the abscissæ the potential difference between the plates, and the numbers on the curves the distance between the plates in millimetres. X is a small unknown distance. The conduction does not obey Ohm's law, the current not increasing so fast as the potential difference. There seem, however, indications of a stage when the current increases more rapidly than the potential difference, probably due to a greater number of ions being pulled away by the greater potential gradient. For large

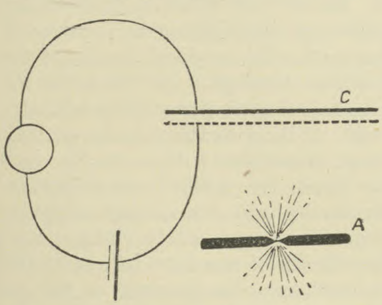

Fig. 16.

potential differences the curves seem to approximate to straight lines inclined to the axis along which potential differences are measured. In the corresponding curves for conduction through a gas exposed to Röntgen rays or uranium radiation the curves ultimately become straight lines parallel to this axis. Stoletow has shown, however, that at low pressures the curves for ultra-violet light become parallel to the axis, so that the current gets "saturated," just as it does in other cases of discharge through conducting gases. At atmospheric pressures Stoletow has shown that the current for a given gas depends only on the potential gradient, so that it is not altered if the potential difference and the distance between the plates are increased in the same proportion. The nature of the gas between the plates has a considerable effect upon the current through the gas. Elster and Geitel[77] measured the current when the illuminated plate was immersed in air, carbonic acid, oxygen, and hydrogen, and found that it was much greater through carbonic acid than through any of the other gases. Stoletow[78] and Righi[79] have investigated the effect of the pressure of the gas on the current passing through it, and find that the current increases as the pressure diminishes, until a certain pressure is reached, below which further diminution causes a diminution in the current, though the change in the current is small compared with the change in the pressure. The stage at which the change of current with pressure is most rapid is at a pressure a little greater than that at which the current is a maximum. The amount of change in the current with the pressure may be illustrated by the following measurements given by Stoletow. The potential difference was equal to that of 65 Clark's cells, and the distance between the plates was 3·71 mm.; p stands for the pressure in millimetres of mercury, and c for the corresponding current.

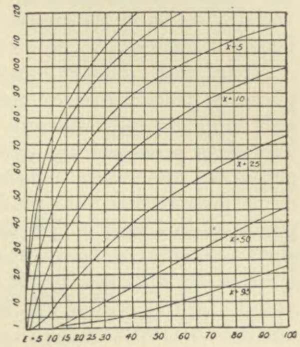

Fig. 17.

p=754, 152, 21, 8·8, 3·3, 2·48, 1·01, ·64, ·52, ·275, ·105, ·014, ·0047, ·0031

c=8·46, 13·6, 26·4, 32·2, 48·9, 74·7, 106·8, 108·2, 102·4, 82·6, 65·8 53·8, 50·7, 49·5

If p_m is the pressure at which the current is a maximum, Stoletow has shown that p_m is proportional to the potential gradient; he has also shown that at very low pressures the current is not, as it is at atmospheric pressures, fixed by the potential gradient, but that with the same potential gradient the current increases with the distance between the plates. This seems to indicate that at these low pressures the ionization is not confined to the surface of the plate, but extends throughout a layer of finite thickness, so that when the plates are brought nearer together than the thickness of this layer the supply of ions is curtailed and the current consequently reduced. Stoletow found that at exceedingly low pressures the current was independent of the pressure. This would seem to indicate that in these cases the current was carried either by mercury vapour from the pump or more probably by corpuscles from the metal surface at these very low pressures the current is very easily saturated and thus becomes independent both of the electric field and of the pressure. The fact that Rutherford found the velocity of the ions at higher pressures to be the same whatever metal was used, indicates that at higher pressure little, if any, of the current is carried by molecules torn from the metal plate. Stoletow (*loc. cit.*) made a series of experiments to see if the discharge from a negatively electrified plate lasted an appreciable time after the light was cut off. He was not able to obtain any evidence that the cessation of the leak was not contemporaneous with the cessation of the light, and was able to show that there was no leak after the light had been cut off for $\frac{1}{1000}$ of a second.

Elster and Geitel[80] found that the orientation of the plane of polarization of the incident light had considerable influence upon the amount of the photo-electric effect. The effect produced by light polarized in a plane at right angles to the plane of incidence is at oblique incidence much greater than that produced by light polarized in the plane of incidence. To show this effect the reflecting surface ought to be very smooth; a suitable surface is most easily obtained by using the liquid alloy of sodium and potassium, which has the further advantage of being sensitive to ordinary light. In light polarized in a plane at right angles to that of incidence, the periodic electric intensity which, on the electro-magnetic theory of light, exists in the incident light-wave has a component at right angles to the reflecting surface, and produces a periodic effect on the electrification of the surface. When the light is polarized in the plane of incidence the electric intensity is parallel to the reflecting surface, and does not produce a periodic variation in the electrification over this surface. The periodic electric intensity at right angles to the surface seems to facilitate the escape of negative electricity from the surface. Another circumstance which may be connected with the effect produced by the position of the plane of polarization, is the fact discovered by Quincke,[81] that light polarized at right angles to the plane of incidence penetrates more deeply into metal than light polarized in that plane. At normal incidence the electric intensity in the incident light has no component at right angles to the reflecting surface, whatever the plane of polarization. Elster and Geitel have shown that when the surfaces are smooth there is little photo-electric effect at normal incidence.

The question whether ultra-violet light produces any ionization when it passes through a gas without falling on a metallic surface has been investigated by Buisson[82] in the case of air, and by Henry[83] for the vapours of iodine and methyl iodide, two gases which are very much ionized when Röntgen rays pass through them; neither of these observers could detect any trace of ionization. Quite recently, however, Lenard[84] has shown that ionization is produced in certain cases by the passage through a gas of ultra-violet light; the kind of light which produces this effect is, however, absorbed so rapidly by the gas that the ionization can only be observed within a few centimetres of the source of light which in Lenard's case was a spark between aluminium terminals. C. T. R. Wilson[85] has shown that when ultra-violet light passes through dust-free damp air it produces cloudy condensation along its path; he could, however, detect no sign of electrification on the drops, so that this is not evidence of ionization. Elster and Geitel[86] found that at very low pressures the rate of escape of negative electrification is very much diminished by a magnetic force parallel to the reflecting surface. We have already considered the theory of this effect in § 6. Lenard and Wolff[87] found that a steam jet in the neighbourhood of a negatively electrified surface illuminated by ultra-violet light showed by its change of colour that the steam in it had been condensed. They attributed this condensation to metallic dust coming from the electrified surface, the metallic dust, in accordance with Aitken's[88] experiments, producing condensation by forming nuclei around which the water-drops collect. The indications of a steam jet are, however, very ambiguous, as condensation is produced not only by dust, but also by chemical action and by the presence of ions. We have already seen reasons for thinking that little, if any, of the current from the negatively electrified surface is carried by metallic particles.

The phenomena connected with the discharge of negative electricity by ultra-violet light admit of explanation by the theory that the incidence of ultra-violet light on a metal causes a discharge of negatively electrified corpuscles from the metal; when the metal is surrounded by a gas at a very low pressure we have seen that the existence of this stream of corpuscles from the metal can be detected by direct experiment. Those rapidly-moving corpuscles coming from the metal will ionize the gas through which they pass; but if the gas is at a pressure comparable with the atmospheric pressure, they will only be able to penetrate a short distance into the gas; the metal will thus be surrounded by a thin layer of ionized gas. If the metal is positively electrified the electrostatic attraction will prevent the escape of the negatively electrified corpuscles, so that in this case there will not be any layer of ionized gas round the metal. When this ionized layer exists, and is acted on by an electric field, the positive ions in the layer will move in towards the metal plate, while the negative ones will move away from it. These positive and negative ions, however, tend to recombine and form a neutral molecule, so that the only ions which are available for carrying a current of electricity through the gas are those which are torn from the ionized layer before they have time to recombine. Thus the stronger the field the greater the number of negative ions liberated from the layer, and therefore the greater the current. As the strength of the electric field is increased, the strength of the current will increase until all the negative ions are torn from the layer before they have time to combine with the positive ions; when this occurs the current will be saturated, and will not increase with the electric field, until the latter gets so strong that it imparts so great a velocity to the ions already in the field that they are able to produce fresh ions. Let us now consider what on this theory would be the effect of diminishing the pressure of the gas surrounding the metal. The corpuscles coming from the metal will travel farther through a gas the lower the pressure, while the number of ions per cubic centimetre produced by the passage of the ions through the gas will diminish as the pressure diminishes: thus, as the ions are a greater distance apart, the rate of recombination will be slower, as each ion has to move through a greater distance before meeting with an oppositely charged ion; in addition to this the velocity of the ions in an electric field of given strength increases as the pressure of the gas diminishes. Thus the negative ions will be more easily torn from the ionized layer when the pressure is low than when it is high, and thus the current will increase when the pressure of the gas is diminished. This increase will go on until the layer through which the ionization extends fills the space between the electrodes between which the current is passing; when this stage is reached any further diminution in the pressure will diminish the number of ions produced between the electrodes, and hence the number available for carrying the current. The saturation value of the current will therefore diminish; thus there will be a certain pressure, at which, with a given electric field, the current through the gas is a maximum. When the pressure of the gas is exceedingly low, the corpuscles coming from the metal will make very few collisions before reaching the other electrode. Thus there will be very little ionization between the electrodes, and there will be very little recombination, as there are so few positive ions for the negative ones to combine with. Thus the current will be very easily saturated, and will become independent both of the electric field and of the pressure, becoming equal to that carried by the negative corpuscles discharged from the surface of the metal by the action of the ultra-violet light. Thus this theory gives a simple explanation of the most conspicuous photo-electric effect. When the pressure of the gas is low and the potential gradient large the negative ions will be moving through the gas with very great velocities; for, as we have seen, the velocity varies inversely as the pressure, and at atmospheric pressure in air the velocity is about 1·5 cm./sec. for a potential gradient of 1 volt per centimetre. Now, in the case of the cathode and Lenard rays (see § 19) we have also negatively electrified particles moving with great velocities, and we know that in these cases the gas is ionized by the passage through it of the particles. We should expect then at low pressure, in the case of the discharge by ultra-violet rays, to get a secondary volume ionization due to the motion of the negative ions. The fact that the saturation current through a thick layer of gas is greater than that through a thin layer, indicates that there is some such volume ionization.

§ 15. *Conductivity in Gases produced by Röntgen Rays.*—Röntgen rays passing through a gas turn it into a conductor, and the gas retains its conductivity for some little time after the rays have ceased. The gas through which the rays have passed shows all the characteristics mentioned in § 1; the conductivity is discharged when the gas is sucked through a plug of cotton-wool or bubbled through water, or subjected to a strong current of electricity. If the gas is sent through a metal tube or allowed to stand in a metal vessel it acquires a positive charge, because the negative ions, diffusing more rapidly than the positive, reach the walls in greater numbers, and so leave an excess of positive ions in the gas. The ease with which the negative ions give up their charges to the metal seems to depend to some extent on the nature of the metal, for Rutherford [89] found that the excess of positive ions was greater when the Röntgenized gas had passed through zinc tubes than when it had passed through copper. If the tubes through which the Röntgenized gas is blown are made of insulating material the ions cling to the walls of the tube for a considerable time, and a blast of air sent through them will dislodge ions hours after the Röntgenized air has passed. Minchin [90] has shown that metal plates previously uncharged get, when exposed to Röntgen rays, charges of electricity, positive in some cases, negative in others. The potentials to which these metals are raised by the charges are not large, being, except in the case of sodium or sodium amalgam, much less than 1 volt. The effects are due to the Röntgenized gas acting, as far as the contact difference of potentials of metals immersed in them go, like a bath of an electrolyte (see § 9), so that two different metals connected with the quadrants of an electrometer will show the same potential difference as they would if immersed in an electrolyte.

We can measure q, the number of ions produced per second by the rays in a cubic centimetre of the gas, by measuring I, the saturation current through the gas, for (see § 7) $I = qle$, where l is the distance between the parallel plates which act as electrodes, and e is the charge on the ion. If we use this method to determine the ionization of the gas by the rays we must be careful, for a reason which will be explained later, not to let the rays strike against the electrodes. From experiments made by Perrin,[91] Rutherford,[92] and the writer,[93] the results of which are given in the following table, it will be seen that the amount of ionization of gas at the same pressure varies very much with the nature of the gas. It is least for hydrogen and greatest for mercury vapour, but is not proportional to the density of the gas, for the ionization is much greater for HCl than it is for CO_2.

Value of q (Air = 1).

Gas.	Rutherford.	Perrin.	J. J. Thomson.
H_2	·5	·026	·33
N_2	·9	...	·89
O_2	1·2	...	1·1
CO_2	1·2	1·34	1·4
CO			
NO	...	...	1·08
N_2O	...	1·3	1·47
C_2N_2	...	...	1·05
C_2H_2	...	...	1
H_2S	6	...	6
SO_2	4	6	6·4
HCl	11	8?	8·9
Cl_2	18	...	17·4
NH_3	...	·1?	1?
Coal Gas	·8		

[For helium Strutt (*Phil. Mag.*, March 1900) found the value ·44]. The values of q for the vapours of mercury and iodine are greater than any of those given in the preceding table, but the difficulties in the way of getting accurate numerical values are very great. The numbers given above show that, with the exception of CN, the coefficients of ionization of the gases obey, approximately at any rate, the addition law, *i.e.*, if 2[A], 2[B] represent the coefficients of ionization for the elementary gases A_2, B_2 respectively, the ionization of the compound gas, A_pB_q will be equal to $p[A]+p[B]$. It is only when the current is saturated that it is proportional to the coefficient of ionization. With very small potential differences the current through hydrogen is greater than that through air, though the coefficient of ionization is very much less. We have by § 7—

$$\iota = e(R_1 + R_2)\sqrt{\frac{q}{a}}$$

if the current is small; hence this current is proportional to $R_1 + R_2$, the mean velocity of the ions under a given electric intensity. Now, the velocity of the ions in hydrogen is about three times that in air, and this greater velocity is more than sufficient to counterbalance the effect of the smaller ionization. The very large ionization of mercury vapour is interesting, as this is a monatomic gas; the process of ionization must, therefore, involve much finer subdivision than the splitting of a molecule into atoms. The number of ions produced by the rays is very small compared with the number of molecules, the proportion between the two depending, of course, upon the intensity of the radiation. It may, however, give some idea of the order of this quantity to state that in some experiments made by the writer, using the rays from a bulb of the kind ordinarily used for taking Röntgen photographs, the proportion of the number of ions to the number of the molecules of the gas was as 1 to 10^{12}. Perrin (*loc. cit.*) has shown that the number of ions produced in a cubic centimetre of a gas is proportional to the pressure of the gas, and independent of the temperature. This statement is equivalent to saying that the number of ions produced from a given number of molecules of the gas is independent of the pressure and directly proportional to the absolute temperature of the gas.

§ 16. *Absorption of Rays by the Gas.*—The rays gradually get absorbed by the gas. The intensity of a parallel beam of rays after travelling through a distance d in the gas may be represented by $\epsilon^{-\lambda d}$, the intensity when the beam entered the gas being taken as unity. λ may be called the co-efficient of absorption of the gas; it depends upon the kind of rays travelling through the gas, being small for rays emitted from a very highly exhausted bulb —Röntgen's "hard rays"—and larger for the rays emitted by a bulb at a higher pressure. As we have no way of specifying the kind of ray we are using, the determinations of λ are indefinite. We can, however, by using the same bulb in the same condition, compare the values of λ for different gases for the same kind of radiation. Rutherford found that while the intensity of the radiation after passing through 10 cm. of air, oxygen, or coal gas was only diminished by about 1 per cent., it was diminished by about 4 per cent. after passing through 10 cm. of sulphuretted hydrogen, by 20 per cent after passing through 20 cm. of chlorine, by 50 per cent. after passing through 7 cm. of mercury vapour at atmospheric pressure, and by 60 per cent. after passing through 13 cm. of the vapour of methyl iodide. The order of the absorbing power of the gases was the same as that of the amount of ionization, and in many cases the coefficient λ seemed to be roughly proportional to the ionization. If more accurate determinations of λ should confirm this result, which seems to be true for uranium radiation, and if the energy absorbed is spent in ionizing the gas, then since the amount of energy absorbed is proportional to the number of ions formed, whatever the gas from which the ions are derived, it follows that the work required to produce a given number of ions is the same for all gases.

§ 17. *Ionization near a Metal Plate exposed to Röntgen Rays.*—Perrin (*loc. cit.*) found that the ionization close to a metal plate struck by Röntgen rays was greater than in the gas at some distance from the rays. This may be shown by the following experiment due to Perrin :—

AA^1 (Fig. 18) is a condenser with a guard ring. A beam of Röntgen rays, indicated by the arrows, passes between its plates without touching them, and enters a second condenser BB^1 at right angles to the plates, through a window KL covered with thin aluminium. The distance between the plates of the condenser BB^1 is equal to $\alpha\beta$. The plates B and $\alpha\beta$ are connected with the needle of an electrometer, and put to earth, and the plates B^1 and A^1 are connected with the terminals of a battery containing a large number of cells, the middle of this battery being put to earth. Thus B^1 and A^1 are at equal and opposite potentials. The connexion between the needle and the earth is then broken, and the rays sent through the condensers. If there is no secondary effect due to the impact of the rays on the metal, since rays of the same intensity pass through the same volume of gas in the two condensers, the ionization between the plates of the condenser ought to be the same, and so under strong electric fields the charge received by B would be equal and opposite to that received by $\alpha\beta$. Hence the needle of the electrometer would remain uncharged. It is found, however, that the needle does receive a charge if the metal plates of the condenser BB^1 are dry, the amount of the charge depending upon the material of which the plates are made. The sign of the charge is such as to show there is more ionization in BB^1 than in AA^1. If the plates are wet with water, alcohol, or petroleum, the needle of the electrometer remains uncharged. There is thus an increased ionization produced when Röntgen rays strike directly against metal. The interposition of a film of water between the metals and the rays seems to destroy, or at any rate greatly reduce, this effect, which was called by Perrin the metal effect.

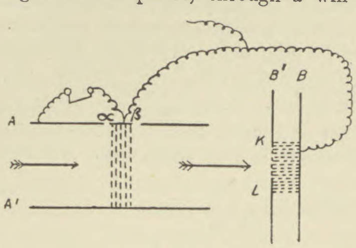

Fig. 18.

The method of studying this effect adopted by Langevin and Townsend [94] was to measure the saturation currents between two parallel metal plates. A considerable portion of one of these plates was made of aluminium, and its inner surface wetted, so as to get rid of the metal effect. The Röntgen rays, passing through this plate at right angles, fell on the other. Apart from the metal effect, the total amount of ionization between the plates is proportional to the distance between them; hence increasing this distance from d to $d+x$ should increase the amount of ionization and therefore the saturation current by an amount independent of d. It was found, however, that the amount by which the saturation current is increased for a given value of x is much greater when d is small than when it is large, and although it attains a constant value when the plates are a considerable distance apart, it does not do so before, in a gas at atmospheric pressure, d amounts to several millimetres. Thus the abnormal ionization extends from the surface through a layer of gas several millimetres thick. By making a series of determinations of the saturation current for a consecutive series of values of d, we can determine the amount of ionization in the various layers of the gas. In this way Townsend has shown that the ionization in a layer near the surface of the metal is sometimes more than twenty times that in a layer of equal thickness some distance away from the metal. The effect depends greatly on the particular metal of which the plate is made. If it is a heavy one, the ionization near the metal is very great, but the thickness of the layer through which the ionization is abnormal is comparatively small; but if the metal is a light one, the ionization near the surface is not so great, though the thickness of the layer through which the influence of the metal is felt is much greater. The results of Townsend's experiments are represented in Fig. 19, where the ordinates represent the total ionization due to the secondary rays within a distance from the surface represented by the abscissæ. Curves are given when the reflecting surfaces are copper, zinc, and aluminium. The line P represents the ionization due to the direct rays. Perrin seemed to think that the metal effect might be due to the greater ease with which a gas is ionized when brought near to a conductor; we had an example of this in the case of conduction through flames. The thickness of the layer through which the ionization is anomalous seems to imply that some other cause must be at work. It would seem most probable that this ionization is the result of the secondary radiation which is produced when Röntgen rays pass through matter. Röntgen [95] showed that when the rays pass through air, the air gives off secondary radiations having all the properties of Röntgen rays, but of less penetrating power. Sagnac [96] showed that metals on which Röntgen rays fall give out secondary rays; these are not the primary rays irregularly reflected, but are different in character, not being nearly so penetrating. The lighter the metal struck by the primary rays, the more penetrating are the secondary rays, although when the metal is light the rays are not so numerous as when it is heavy. He showed that when the secondary rays strike against a metal, tertiary rays are given out which are still less penetrating than the secondary. As these secondary and tertiary rays ionize a gas when they pass through, it is clear that until we are so far away from the metal that they are absorbed by the gas before reaching us, the ionization in the gas is greater than that due to the primary rays. The secondary rays observed by Sagnac could traverse several centimetres of air before being absorbed. The fact that the greater part of the metal effect takes place within a few millimetres of the surface of the metal shows that the rays producing this ionization are absorbed by a few millimetres of air; they are probably tertiary rays produced by the passage through the surface layers of the metal of secondary rays starting from a little behind them.

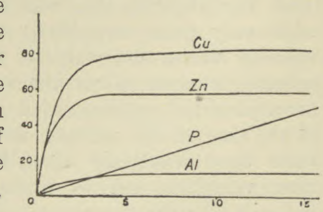

Fig. 19.

§ 18. *Conduction produced by the Radiation from Uranium, Thorium, &c.*—Becquerel [97] showed that a gas surrounding a piece of uranium or one of its salts becomes a conductor of electricity, and Schmidt [98] found that the same is true of thorium. Subsequently M. and Mme. Curie [99] found that this property was possessed to a very much greater extent by two new substances, radium and polonium, which they obtained from pitch-blende. Polonium appears to emit a kind of radiation very similar to the Röntgen rays, inasmuch as, besides rendering gases conductive, it produces phosphorescent effects on a potassium platinocyanide screen, and affects a photographic plate even when protected by a screen opaque to ordinary light. Like the Röntgen radiation, it can be neither refracted nor polarized;

it is not, however, nearly so penetrating as the ordinary primary Röntgen radiation, resembling, in this respect, the secondary Röntgen radiation. Radium emits radiation of at least two types—one, easily absorbed, resembles Röntgen, the other, more penetrating, resembles cathode rays, being deflected by a magnet, and carrying a charge of negative electricity. The properties of gas rendered conducting by uranium or thorium radiation have been investigated by Becquerel (*loc. cit.*), Rutherford,[100] Owens,[101] De Smolan and Beattie.[102] These properties are the same as when the gas is made a conductor by Röntgen radiation; the velocities of the ions are the same, as are also the laws connecting the current and the potential difference. The uranium radiation being much more quickly absorbed than Röntgen radiation, the phenomena due to the former are liable to be complicated by absorption effects. Rutherford has shown that uranium salts emit at least two kinds of radiation—one is absorbed in a few millimetres of air at atmospheric pressure, while the other can traverse many centimetres before being extinguished. The ionization in thin layers of air close to the surface of the uranium is chiefly due to the more easily absorbed radiation, and as this is wholly absorbed by a few millimetres of the gas, we can by altering the gas over the uranium compare the total amount of ionization in different gases when all this radiation is absorbed. Rutherford found that this was the same for air, hydrogen, oxygen, carbonic acid, coal gas, hydrochloric acid, and ammonia, and that though in hydrogen the ionization close to the uranium was not so great as in a heavier gas, yet the greater thickness of the layer through which it extended just compensated for the deficiency in intensity. If we could be sure that all the energy of the rays is spent in ionizing the gas, and none in raising the temperature, this would indicate that the work required to produce a definite number of ions is independent of the gas from which they are produced, a result suggested also by the experiments on conduction due to Röntgen radiation. Rutherford's experiments on compounds of thorium indicate that, besides emitting radiation, these emit something which is itself radio-active. The activity of this emanation gradually disappears, but lasts long enough to be appreciable for some minutes after it has left the thorium. It is not destroyed by being passed through plugs of cotton-wool or being bubbled through water or sulphuric acid, processes which, as we have seen, would be fatal to the existence of ions. The emanation can pass through very thin plates of metal and through several sheets of paper. It is blown about by the slightest draught, even when acted upon by a strong electric field—in fact, an electric field seems to have no effect upon it, a fact which suggests that it is not permanently charged with electricity. This deduction is confirmed by the circumstance that on blowing a quantity of it into an inductor no evidence of any charge can be detected. Rutherford has also shown that if the air between two plates is made conducting by thorium radiation, and a current of electricity sent between them, the metal against which the positive ions discharged becomes radio-active, and retains, though with gradually diminishing intensity, this power long after the current has ceased. The radiation it emits is not identical in character with that emitted by the thorium, there being great differences in the proportion of the two radiations stopped by an aluminium plate of given thickness. A plate rendered radio-active in this way can be washed with water, caustic potash, or nitric acid without losing its activity, which is, however, considerably diminished by warm sulphuric acid. M. and Mme. Curie (*Comptes Rendus*, Nov. 1899) have shown that substances exposed to the radiation from radium become themselves radio-active for a time; the radiation from polonium produces a similar effect, but to a much smaller extent. Debierne (*Comptes Rendus*, July 1900) has shown that the radiation from actinium produces very intense induced radio-activity.

Elster and Geitel[103] have shown that the current through a gas at a very low pressure made a conductor by the radiation from radium is much diminished by a strong magnetic field, when the lines of magnetic force are at right angles to the current.

§ 19. *Conductivity due to Passage of Cathode and Lenard Rays through a Gas.*—The passage through a gas of the small particles carrying negative charges which constitute cathode and Lenard rays makes it a conductor in which both positive and negative ions are present. This has been proved for cathode rays by the writer,[104] and by Lenard[105] for the rays which bear his name. The conduction through gas ionized in this way follows the same laws as in the cases hitherto considered, the current increasing less rapidly than the potential difference, and reaching a saturation value at which it remains constant even though the potential difference is greatly increased. The number of ions produced by the passage of these negative charges through a gas is many times the number of these charged particles. The amount of ionization produced by Lenard rays in different gases has been investigated by M'Lennan,[106] who found that, for all the gases he tried (air, oxygen, nitrogen, carbonic acid, hydrogen, and nitrous oxide), the amount of ionization produced in one second by Lenard rays of given intensity in 1 cubic centimetre was proportional to the density of the gas, and independent of its chemical composition. Thus the ionization in 1 cc. of oxygen at 47 mm. pressure is the same as in 1 cc. of hydrogen at 16×47 mm. pressure. Lenard[107] has shown that the absorption of his rays depends only on the density and not on the chemical composition, so that in this case, as in the case of uranium and probably of Röntgen radiation, equal absorption gives equal ionization, whatever the nature of the gas.

§ 20. *Spark Discharge through Gases.*—Hitherto we have only considered cases when conductivity was conferred on the gas by agents independent of the electric field used to drive the current through it, and for the conducting gases hitherto considered the weakest electric field was sufficient to cause some current to flow through the gas. We shall now proceed to consider cases where the conductivity of the gas is due to the electric field itself. Here there is neither appreciable conductivity nor current unless the electric field is strong. Let us suppose that we have two parallel plates of metal placed close together, and that one plate is connected through a large resistance to one pole of a large battery of cells, while the other plate is connected with the other pole; no appreciable current will pass round this circuit unless the electromotive force of the battery exceeds a definite value, but when it does exceed this value a current will pass, accompanied by luminosity between the plates, the potential difference between which will be found to be little if at all affected by the number of cells in the circuit. This potential difference, which is frequently called the statical spark potential, we will call the spark potential difference; its value depends on the distance between the plates, and on the nature and pressure of the gas in which they are immersed. It must not be supposed, however, that whenever it is applied to the plates we always get a spark to pass. If it is only maintained for a short time, it may be that no spark passes; indeed, it is possible under certain circumstances to apply to the plates a much greater potential difference without getting a spark. Faraday[108] long ago showed that it takes a greater potential difference to start the first spark than is required to keep up the sparks, and that the effect of one spark in facilitating the passage of a second does not die away until the gas has rested for several minutes. The writer[109] found that if the gas between the electrodes was dried with extreme care, it was possible to get the gas to stand without discharge a potential difference between the electrodes three or four times as great as that which was sufficient to produce a discharge in less perfectly dried gas; the gas, however, seemed to be in an unstable state as far as its electrical behaviour was concerned, for when once a spark had been forced through it, the potential difference between the plates at once fell to the value it had before the gas was dried, and the gas was not again able to withstand a potential difference any greater than this without discharge until it had had a rest for several minutes. The very great potential difference withstood in this case without discharge seems to suggest that if we had a perfectly pure dry gas it might be able to withstand almost any potential difference without discharge. It would, however, be in an unstable state, and might be compared to a supersaturated solution, into which a foreign body has to be introduced to start the crystallization, though the process, when once started, goes on until the solution ceases to be supersaturated; another analogy would be gas supersaturated with aqueous vapour, where for condensation to take place we require the presence of nuclei round which the drops may collect. Various influences may prevent the gas getting into the unstable electric state, such as the presence of moisture, the fall of ultra-violet light on the cathode or of Röntgen rays on the spark gap, the presence of gases from flames, sparks, or arcs—in short, the presence of any ion seems fatal to the continuance of this unstable state. The influence of several of these agents has been investigated by Warburg,[110] whose method consisted in measuring the interval which elapses between the application of a potential difference greater than the spark potential difference and the passage of the spark. This *lag* of the spark, as we may call it, is a very important quantity in the phenomena attending the passage of the spark, for if it is great, and the spark terminals are connected with an induction coil or some other source of electricity furnishing a potential difference which changes quickly, the terminals may support for the short time during which it lasts a potential difference which would cause a spark to pass if the lag were much shorter. Thus an agent may make sparks pass when the potentials of the terminals are inconstant by diminishing the time of lag, even though it has no effect on the steady potential difference required to produce a spark. A notable illustration of this is afforded by the action of ultra-violet light on sparks passing between the terminals of an induction coil. Hertz[111] showed that when the spark gap was exposed to such light, sparks passed much more easily than when the light was screened off; then E. Wiedemann and Ebert[112] showed that it was only when the cathode was exposed to the light that any effect was produced (it is only in this case that any ions are sent into the spark gap); finally, Warburg (*loc. cit.*) showed that the effect of the ultra-violet light was to diminish very greatly the lag, without producing much effect on the statical spark potential. Swyngedauw[113] also showed that ultra-violet light had a much greater effect on the sparking potential when this was rapidly changing than it had on the statical spark potential.

The effect of ultra-violet light on the lag is strikingly shown by the following table taken from Warburg's paper. The fractions in the columns have for their numerator the number of times a spark passed when the potential difference at the top of the column was applied to the electrodes for a time ·0012 seconds: the denominator of the fraction is the number of times the potential difference was applied; thus the fraction $\frac{0}{10}$ indicates that the spark never passed, the fraction $\frac{10}{10}$ that it always did so. Hydrogen at a pressure of 11 millimetres of mercury was employed. The statical spark potential was 960 volts in daylight, 1260 in the light from an arc lamp which had passed through glass, and 1080 in the direct light from the lamps:—

Potential Difference in Volts.	960.	1440.	1500.	1920.	2040.	2940.	3000.	3960.	5040.	8940.
In the dark .	...	...	...	...	...	...	$\frac{0}{10}$	$\frac{1}{10}$	$\frac{1}{10}$	$\frac{8}{10}$
In daylight .	...	...	$\frac{1}{10}$	...	$\frac{3}{10}$	$\frac{8}{10}$				
In the arc light through glass	...	$\frac{0}{10}$	...	$\frac{10}{10}$						
In the arc light	$\frac{0}{10}$	$\frac{10}{10}$								

It will be seen from this table that we may apply in the dark for ·0012 sec. a potential difference nine times that required to produce a spark with a steady potential difference without always producing a spark, and also that daylight has a distinct effect in diminishing the lag of the spark. It was also shown by Warburg that the chief effect of a small quantity of water vapour was to make the lag very much less than for a perfectly dry gas.

The significance of this lag seems first to have been pointed out by Jaumann,[114] who showed that it was much diminished if very rapid changes took place in the potential of the electrodes. During the lag some process is going on by which the gas between the electrodes is being changed from an insulator into a conductor. Experiments were made by Jaumann and Warburg[115] to see whether this process was accompanied by a dark discharge of electricity through the gas—no luminous effects can be observed in the darkest room,—but they could get no indication by means of electroscopes of the existence of such a discharge, though Warburg obtained some indirect evidence which led him to the conclusion that such a discharge takes place. This evidence is based upon the action of a magnet upon the discharge of electricity through a gas at low pressure. If the magnetic force is transverse to the current of electricity through the gas, the discharge is hindered by the magnetic field, owing to the deflexion of the conducting gas. Now Warburg found that not only was the luminous discharge at low pressures hampered by the magnetic field, but that the lag was much increased by the magnetic field. He concluded from this that during the lag there is a current of electricity through the gas too feeble to affect an electroscope, and without luminosity. Walter[116] and Boys,[117] by taking photographs of sparks on rapidly-moving plates, have shown that the bright spark is preceded by faintly luminous brush discharges. It seems to the writer probable that the process by which the gas is changed from an insulator to a conductor is analogous to the ionization of a gas by cathode or Lenard rays. In these cases the rapid motion of an ion through the gas ionizes the gas surrounding the moving ion. Suppose then that in some way or another we had some ions in the gas between the electrodes, these would be acted on by the electric field and set in motion, and if they had sufficient energy given them during their life by the electric field for each to give rise to more than one ion, the number of ions would go on increasing, the gas become a conductor, and a spark would pass. If, however, the energy given by the electric field to the ion were not sufficient to enable each ion to provide more than one successor, the number would not grow, and the gas would remain an insulator. Thus for the electric field to turn a gas into a conductor would on this view require a field of sufficient intensity to give the requisite energy to an ion already in the field. This is in accordance with the phenomena. It is also necessary that some ions (a very small number would suffice) should be present to start the spark, and the very great values to which the potential difference may attain under certain conditions without any discharge passing seem to lend support to this view.

§ 21. *Connexion between Length of Spark and Potential Difference.*—The relation between the spark potential and the length of the spark has been investigated by Baille,[118] Paschen,[119] and Liebig.[120] Their researches have shown that when the electrodes are planes, or spheres whose radii are large compared with the length of the spark, the relation between the potential difference V and the length of spark l, when l for gases at atmospheric pressure is greater than 2 millimetres, can be expressed by the linear relation $V = \alpha + \beta l$. For air at atmospheric pressure $\alpha = 4{\cdot}997$, $\beta = 99{\cdot}593$, in electrostatic measure. Thus the curve representing the relation between spark length and potential difference is a straight line which does not pass through the origin. For sparks at atmospheric pressures whose length is less than 2 millimetres the curve ceases to be a straight line, and for slightly shorter sparks becomes concave to the axis along which the spark length is measured. There is some evidence that for still shorter sparks the curve has a point of inflexion, so that the potential required to produce very short sparks increases as the length of the spark diminishes. An illustration of this is that sparks passing between a plane and a slightly curved surface, when these are very near together, do not pass between the points which are nearest together, but prefer a longer route. There is a certain minimum potential required for the production of a spark, and no spark can pass if the potential falls below this value. This minimum is independent of the pressure of the gas; for air it is 341 volts, for hydrogen 302 volts, for nitrogen 251 volts, and for helium 261 volts.[121] The fact that the potential difference required to produce a spark can be represented by an equation of the form $V = \alpha + \beta l$ shows that the electric intensity between the plates V/l is greater for short sparks than it is for long. Baille found that to spark across a layer of air ·0015 cm. thick required an electric intensity about nine times that required to spark across a layer 1 cm. thick. The fact that a greater electric intensity is required to spark across a thin layer of gas than a thick one was discovered by Lord Kelvin[122] in 1860.

Baille,[123] Paschen,[124] and Freyberg[125] have made some very interesting experiments on the potential difference required to spark between two equal spheres of small enough radius to make the variations in electric intensity in different parts of the field considerable. These experiments show that for a given length of spark passing between two equal spheres, one charged and insulated and the other put to earth, the potential difference varies with the diameter of the sphere. Starting from plane electrodes, the potential difference at first increases with the curvature, and attains a maximum when the spheres have a certain diameter, depending upon the spark length and increasing with it. When the spheres are smaller than this, the potential difference falls off quickly, so that a much smaller difference of potential is required to produce a spark between very small spheres than between parallel planes. When the spark passes between pointed electrodes the potential difference is still smaller. Schuster[126] has calculated from Baille and Paschen's experiments the maximum electric intensity in the field when the spark is passing, and has shown that, keeping the spark length constant, the maximum intensity increases as the diameter of the spheres diminishes. Thus with a spark length of 1 cm. the maximum electric intensity between plane electrodes was 106, and between spheres 1 cm. in diameter 733. If the diameter of the electrodes is kept constant and the length of the spark increased, Schuster found that, starting with very short sparks, an increase in the length of the spark at first diminished the maximum electric intensity in the field, but that this attained a minimum, after which any further increase in the spark length increased the maximum electric intensity. The smaller the spheres the shorter the spark corresponding to the minimum electric intensity. When the sparks pass between spherical electrodes of different diameter, Faraday[127] and, later, De la Rue and Müller[128] found different values for the spark potential according as the smaller electrode was positive or negative. According to Wesendonck,[129] this difference only occurs when a brush discharge accompanies the spark; when nothing but a spark passes between the balls he finds that the potential difference remains the same when the signs of the electrodes are reversed. Photographs of long sparks, such as those in Fig. 20, show distinct

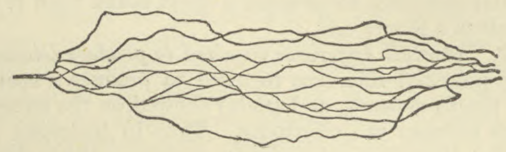

Fig. 20.

differences between the appearances at the positive and negative electrodes; thus there is a straight piece of considerable length at the positive electrode which is wanting at the negative, and when the spark branches as in Fig. 20, the branches point to the negative electrode. Experiments made by Righi,[130] Peace,[131] and others show that the material of which the electrodes are made has little if any effect on the potential difference required to produce a spark. It is just possible that this result might be modified if a large quantity of electricity were allowed to pass with each spark.

§ 22. *Connexion between Spark Potential and Pressure of Gas.*—As the pressure of the gas diminishes, the potential difference required to produce a spark of given length also diminishes, until the pressure reaches a critical value, which depends mainly upon the length of the spark and the nature of the gas. At this pressure, the potential difference being a minimum, any further diminution in the pressure leads to its increase. The critical pressure is higher the shorter the spark. The following values for the critical pressures corresponding to different spark lengths are due to Peace.[132]

Spark Length.	Critical Pressure.	Spark Length.	Critical Pressure.
·001 cm.	250 mm.	·01016 cm.	55 mm.
·0025 cm.	150 mm.	·02032 cm.	35 mm.
·00508 cm.	110 mm.		

The connexion between spark potential and pressures at pressures much greater than the critical pressure has been investigated by Baille,[133] Macfarlane,[134] and Paschen,[135] who have found that this relation can be represented by a very slightly curved portion of a hyperbola. Paschen showed that as long as the product of the density of the gas and the spark length is constant, the sparking potential is also constant over a wide range of pressure for the same gas. His results can be approximately represented by an equation of the form $V = a + b\frac{l}{\lambda}$, where V is the potential difference, l the spark length, λ the mean free path of a molecule of the gas, and a and b constants. The relation between the spark potential and the pressure, for pressures in the neighbourhood of the

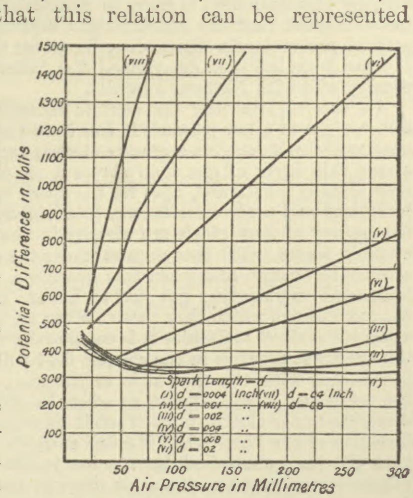

Fig. 21.

critical pressure, has been investigated by Peace (*loc. cit.*); the results of some of his experiments are shown by the curves in Fig. 21, where the ordinates represent the potential and the abscissæ the pressure. The small changes in the potential over a considerable range of pressure in the case of the shorter sparks is very well marked; the curves corresponding to different spark lengths cut one another, indicating that at low pressures it requires a greater potential difference to produce a short spark than it does to produce a longer one.

§ 23. *Potential Difference required to produce Discharge.*—The potential difference required to produce a spark of given length depends, as Faraday showed, on the nature of the gas between the electrodes. Thus in hydrogen it is much less than in air at the same pressure. Measurements have been made by Faraday,[136] Baille,[137] Liebig,[138] Paschen,[139] Wolf,[140] Röntgen,[141] and Natterer.[142] The following table gives the ratio of the potential difference required to produce sparks in hydrogen and carbonic acid to that required to produce a spark of the same length in air, the pressure in all cases being 750 mm.

Spark Length in Centimetres.	Hydrogen.			Carbonic Acid.		
	Baille.	Liebig.	Paschen.	Baille.	Liebig.	Paschen.
·1 . .	·49	·873	·639	1·67	1·20	1·05
·2 . .	·49	·787	·578	1·24	1·16	·988
·3 . .	·50	·753	·560	·94	1·07	·962
·4 . .	·50	·704	·553	·76	1·03	·930
·5 . .	·50	·670	·548	...	·994	·910
·6 . .	...	·656	·555	...	·974	·910

Wolf found that the electric intensity required to produce a spark 1 mm. in length between electrodes 5 cm. in radius, when the pressure was x atmospheres, was—for hydrogen, $65{\cdot}09\,x+62$; for oxygen, $96{\cdot}0\,x+44$; for air, $107\,x+39$; for nitrogen, $120{\cdot}8x+50$; for carbonic acid, $102{\cdot}2\,x+72$. Röntgen came to the conclusion that the potential difference required to produce a spark of given length from a pointed electrode in different gases is inversely proportional to the mean free path of the molecules of the gas. Ebert[143] found that if a vessel containing two electrodes was pumped until the pressure was reached when the discharge went with the minimum potential difference, then the pressures for different gases were such as to make the free path of the molecules of the different gases the same at the critical pressure. Natterer, as the result of a series of experiments on the lengths of spark given by a small induction coil, came to the conclusion that for gases with the same number of atoms in the molecule the spark length diminished as the molecular weight of the gas increased. The measurements made by this method are hardly definite enough to enable us to say whether this statement is more in accordance with the facts than the statement that the spark length diminishes as the mean free path of the molecule diminishes, for as far as the mean free path of these gases has been determined the latter view seems to accord equally well with Natterer's results.

We can explain why the electric intensity required to spark across a gas at a low pressure is less than that required at a high one, and why it requires a greater electric intensity to spark across a very thin layer of gas than across a thick one, if we take the view already mentioned, that for the spark to pass, the gas has to be ionized and made a conductor, this ionization being effected by the agency of ions which are already in the gas before the spark actually passes. The ions acquire under the electric field a certain amount of energy, and when this exceeds a certain value the ions ionize the surrounding gas just as Lenard or cathode rays ionize the gas through which they pass. When an ion is moving through a gas with whose molecules it is continually coming into collision, the energy it acquires in the electric field will not go on increasing indefinitely with the time it is in the gas; for in consequence of the collisions it will almost as often be moving in the opposite direction to the electric force (when it loses energy) as it does in the direction of the force (when it gains energy). It follows, therefore, that the energy acquired by the ion in the electric field will be approximately equal to the work done by the field on the ion as it moves through the average distance it traverses before its direction of motion is reversed. This distance will be proportional to λ, the mean free path of the ion; let it equal $c\lambda$. Then if F is the electric intensity and e the charge on the ion, the energy acquired by the ion is $Fec\lambda$. If the ion is to ionize the gas and so allow the spark to pass, this energy must exceed a certain value q, hence the limiting value of F for a spark is given by the equation $Fec\lambda=q$, or $F\lambda$ is constant. Thus F is inversely proportional to λ, or directly proportional to the pressure of the gas, so that a smaller electric intensity is required to spark at a low pressure than at a high one. Next suppose that d, the distance between the electrodes, is less than $c\lambda$, then the greatest distance the ion can move in the direction of the force is d, so that to get ionization $Fed=q$; hence F will be greater than before. This is on the supposition that the chances in favour of the moving ion ionizing the surrounding gas are as great as they were in the other case; it would seem, however, that, if this ionization is due to collisions between the ions and the gas, the chances are not so great, because the ion is delivered up against an electrode before it has completed its collisions. This would tend still further to increase F, the intensity required to produce a spark.

The spark itself at atmospheric pressures is not in general affected by the magnetic field, but the kind of aureole or glory of luminous gas with which it is surrounded spreads out in strong magnetic fields into a wide band. Precht[144] has observed that if the discharge passes between a point as the positive electrode and the rounded end of a wire as the negative electrode, it can be charged from a brush to a spark discharge by a strong magnetic field even at atmospheric pressures. Schuster and Hemsalech[145] have made some very interesting researches on the constitutions of sparks following rapidly one after another, such as are produced by the oscillatory discharge of a Leyden jar. These were photographed on a rapidly moving film mounted on the rim of a wheel making about thirty rotations per second; the motion of the film was at right angles to the direction of the spark, so that the line traced on the film by any luminous matter moving with finite velocity along the spark length would be inclined to the direction of the spark, and the inclination would, if the velocity of the film were known, determine the velocity of the luminous matter. By sending the light of the spark through a spectroscope before reaching the film, the velocity corresponding to any line in the spectrum could be determined. The conclusion arrived at by the authors was that the first spark passed through air, but that if the sparks followed each other very quickly, and the spark was not too long, the succeeding ones passed through metal vaporized by the heat produced by the first spark. The measurement of the velocity of diffusion of the metallic vapours in the flame gave some very interesting results, since different lines of one and the same metal indicated different velocities. Thus in bismuth some of the lines indicated a velocity of diffusion of 1420 metre/sec., others a velocity of about 300 metre/sec., and others a still smaller velocity.

§ 24. *Discharge from a Point.*—A very interesting case of electric discharge is that between a sharply pointed electrode, such as a needle, and a metal surface of considerable area. At atmospheric pressures the luminosity is confined to the immediate neighbourhood of the point. If the sign of the potential of the point does not change, the discharge is carried by ions of one sign—that of the charge on the pointed electrode. The velocity of these ions under a given potential gradient has been measured by Chattock,[146] and found to agree with that of the ions produced by Röntgen or uranium radiation, while Townsend[147] has shown that the charge on these ions is the same as that on the ions streaming from the point. If the pointed electrode be placed at right angles to a metal plane serving as the other electrode, the discharge takes place when, for a given distance of the point from the plane, the potential difference between the electrodes exceeds a definite value depending upon the pressure and nature of the gas through which the discharge passes; its value also depends upon whether, beginning with a small potential difference, we gradually increase it until discharge commences, or, beginning with a large potential difference, we decrease it until the discharge stops. The value found by the latter method is less than that by the former. According to Chattock's measurements the potential difference V for discharge between the point and the plate is given by the linear relation $V=a+bl$, where l is the distance of the point from the plate and a and b are constants. From v. Obermayer's[148] experiments, in which the distance l was greater than in Chattock's, it would seem that the potential for larger distances does not increase quite so rapidly with l as is indicated by Chattock's relation. The potential required to produce this discharge is much less than that required to produce a spark of length l between parallel plates; thus from Chattock's experiments to produce the point discharge when $l=\cdot5$ cm. in air at atmospheric pressure requires a potential difference of about 3800 volts when the pointed electrode is positive, while to produce a spark at the same distance between plane electrodes would require a potential difference of about 15,000 volts. Chattock showed that with the same pointed electrode the value of the electric intensity at the point was the same whatever the distance of the point from the plane. The value of the electric intensity depended upon the sharpness of the point. When the end of the pointed electrode is a hemisphere of radius a, Chattock showed that for the same gas at the same pressure the electric intensity f when discharge takes place is roughly proportioned to $a^{-\cdot 8}$. The value of the electric intensity at the pointed electrode is much greater than its value at a plane electrode for long sparks; but we must remember that at a distance from a pointed electrode equal to a small multiple of the radius of curvature of its extremity the electric intensity falls very far below that required to produce discharge in a uniform field, so that the discharge from a pointed electrode ought to be compared with a spark whose length is comparable with the radius of curvature of the point. For such short sparks the electric intensity is very high. The electric intensity required to produce the discharge from a gas diminishes as the pressure of the gas diminishes, but not nearly so rapidly as the electric intensity for long sparks. Here again the discharge from a point is comparable with short sparks, which, as we have seen, are much less sensitive to pressure changes than longer ones. The minimum potential at which the electricity streams from the point does not depend upon the material of which the point is made; it varies, however, considerably with the nature of the gas. The following are the results of some experiments on this point. Those in the first two columns are due to Röntgen,[149] those in the third and fourth to Precht [150]:—

Gas.	Discharge Potential. Point +.		Pressure 760.	
	Pressure 205.	Pressure 110.	Point +.	Point −
	Volts.	Volts.	Volts.	Volts.
H_2	1296	1174	2125	1550
O_2	2402	1975	2800	2350
CO	2634	2100		
CH_4	2777	2317		
NO	3183	2543		
CO_2	3287	2655	3475	2100
N_2	...	...	2600	2000
Air	...	...	2750	2050

We see from this table that in the case of the discharge from a positively electrified point the greater the molecular weight of the gas the greater the potential required for discharge. Röntgen concluded from his experiments that the discharging potential from a positive point in different gases at the same pressure varies inversely as the mean free path of the molecules of the gas. In the same gas, however, at different pressures the discharging potential does not vary so quickly with the pressure as does the mean free path. In Precht's experiments, in which different gases were used, the variations in the discharging potential are not so great as the variations in the mean free path of the gases.

The current of electrified air flowing from the point when the electricity is escaping—the well-known "electrical wind"—is accompanied by a reaction on the point which tends to drive it backwards. This reaction has been measured by Arrhenius,[151] who finds that when positive electricity is escaping from a point in air the reaction on the point for a given current varies inversely as the pressure of the gas, and for different gases (air, hydrogen, and carbonic acid) inversely as the square root of the molecular weight of the gas. The reaction when negative electricity is escaping is much less. The proportion between the reactions for positive and negative currents depends on the pressure of the gas. Thus for equal positive and negative currents in air at a pressure of 70 cm. the reaction for a positive point was 1·9 times that of a negative one, at 40 cm. pressure 2·6 times, at 20 cm. pressure 3·2 times, at 10·3 cm. pressure 7 times, and at 5·1 cm. pressure 15 times the reaction for the negative point. An investigation similar to that in § 2 shows that the reaction should be proportional to the quotient of the current by the velocity acquired by an ion under unit potential gradient. Now this velocity is inversely proportional to the pressure, so that the reaction should on this view be directly proportional to the pressure. This agrees with Arrhenius' results when the point is positive. Again, the velocities of an ion in hydrogen, air, and carbonic acid at the same pressure are approximately inversely proportional to the square roots of their molecular weights, so that the reaction should be directly proportional to this quantity. This also agrees with Arrhenius' results for the discharge from a positive point. The velocity of the negative ion is greater than that of a positive one under the same potential gradient, so that the reaction for the negative point should be less than that for a positive one, but the excess of the positive reaction over the negative is much greater than that of the velocity of the negative ion over the velocity of the positive. There is, however, reason to believe that a considerable condensation takes place around the negative ion as a nucleus after it is formed, so that the velocity of the negative ion under a given potential gradient will be greater immediately after the ion is formed than when it has existed for some time. The measurements which have been made of the velocities of the ions relate to those which have been some time in existence, but a large part of the reaction will be due to the newly-formed ions moving with a greater velocity, and thus giving a smaller reaction than that calculated from the observed velocity.

With a given potential difference between the point and the neighbouring conductor the current issuing from the point is greater when the point is negative than when it is positive, except in oxygen, when it is less. Warburg[152] has shown that the addition of a small quantity of oxygen to nitrogen produces a great diminution in the current from a negative point, but has very little effect on the discharge from a positive point. Thus the removal of a trace of oxygen made a leak from a negative point 50 times what it was before. Experiments with hydrogen and helium showed that impurities had a great effect in these gases on the current when the point was negative, and but little when it was positive. This suggests that the impurities, by condensing round the negative ions as nuclei, seriously diminish their velocity. If a point is charged up to a high and rapidly alternating potential, such as can be produced by the electric oscillations started when a Leyden jar is discharged, then in hydrogen, nitrogen, ammonia, and carbonic acid gas a conductor placed in the neighbourhood of the point gets a negative charge, while in air and oxygen it gets a positive one.[153] There are two considerations which are of importance in connexion with this effect. The first is the velocity of the ions in the electric field, and the second the ease with which the ions can give up their charges to the metal point. The greater velocity of the negative ions would, if the potential were rapidly alternating, cause an excess of negative ions to be left in the surrounding gas. This is the case in hydrogen. If, however, the metal had a much greater tendency to unite with negative than with positive ions, such as we should expect to be the case in oxygen, this would act in the opposite direction, and tend to leave an excess of positive ions in the gas. In oxygen and air the second effect seems to overpower the first. Precht (*loc. cit.*) has observed the changes which take place in the pointed electrodes after the discharge has been running for some time. He finds that the metal is torn from the positive point, which sometimes gets hollowed out into a kind of crater, but that there is no change in a negative point.

§ 25. *The Arc Discharge.*—The discharges we have hitherto considered have been characterized by large potential differences and small currents. In the arc discharge we get very large currents with comparatively small potential differences. We may get the arc discharge by taking a battery of cells large enough to give a potential difference of 60 to 80 volts, and connecting the cells with two carbon terminals, which are put in contact, so that a current of electricity flows round the circuit. If the terminals, while the current is on, are drawn apart, a bright discharge, which may carry a current of many amperes, passes from one to the other. This arc discharge, as it is called, is characterized by intense heat and by the brilliant luminosity of the terminals. This makes it a powerful source of light. The temperature of the positive terminal is much higher than that of the negative. According to Violle,[154] the temperature of the tip of the former is about 3500° C., and that of the latter 2700° C. The temperature of the arc itself he found to be higher than that of either of its terminals. As the arc passes, the positive terminal gets hollowed out into a crater-like shape, but the negative terminal remains pointed. Both terminals lose weight.

The appearance of the terminals is shown in Fig. 22, given by Mrs Ayrton;[155] *a*, *b* represent the terminals when the arc is quiet, and *c* when it is accompanied by a hissing sound. The intrinsic

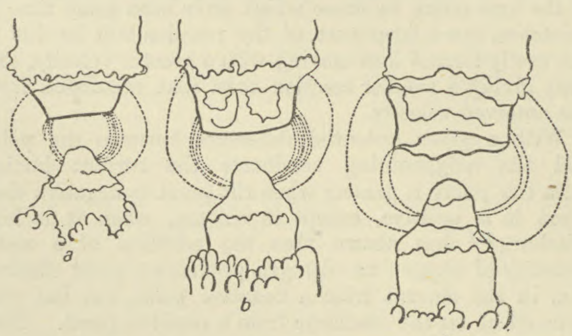

Fig. 22.

brightness of the positive crater does not increase with an increase in the current; an increased current produces an increase in the area of the luminous crater, but the amount of light given out by each unit of area of luminous surface is unaltered. This indicates that the temperature of the crater is constant; it is probably that at which carbon volatilizes. W. E. Wilson[156] has shown that at pressures of several atmospheres the intrinsic brightness of the crater is considerably diminished.

The connexion between V, the potential difference between the terminals, and l, the length of the arc, is somewhat analogous to that which holds for the spark discharge. Fröhlich[157] gives for this connexion the relation $V=m+nl$, where m and n are constants. Mrs Ayrton finds that both m and n depend upon the current passing between the terminals, and gives as the relation between V and l, $V=\alpha+\frac{\beta}{I}+\left(\gamma+\frac{\delta}{I}\right)l$, where α, β, γ, δ are constants and I the current. The relation between current and potential difference was made the subject of a series of experiments by Ayrton,[158] some of whose results are represented in Fig. 23. For a quiet arc an increase in current is accompanied by a fall in potential difference, while for the hissing arc the potential difference is independent of the current. The quantities m and n which occur in Fröhlich's equation have been determined by several experimenters. For carbon electrodes in air at atmospheric pressure m is about 39 volts, varying somewhat with the size and purity of the carbons; it is diminished by soaking the terminals in salt solution. The value of n given by different observers varies considerably, ranging from ·76 to 2 volts when l is measured in millimetres; it depends upon the current, diminishing as the current increases. When metallic terminals are used instead of carbons, the value of m depends upon the nature of the metal, m in general being larger the higher the temperature at which the metal volatilizes. Thus

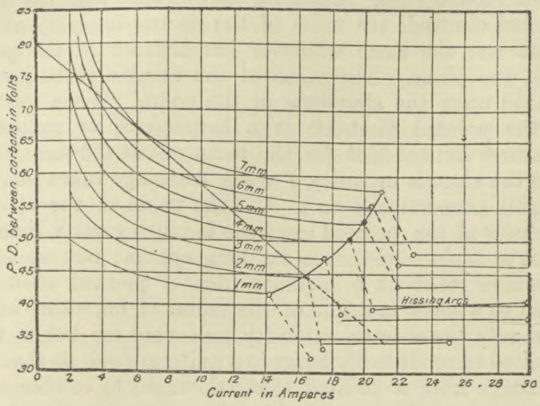

Fig. 23.

v. Lang[159] found the following values for m in air at atmospheric pressure:—C=35; Pt=27·4; Fe=25; Ni=26·18; Cu=23·86; Ag=15·23; Zn=19·86; Cd=10·28. Lecher[160] gives Pt=28, Fe=20, Ag=8, while Arons[161] found for Hg the value 12·8; in this case the fall of potential along the arc itself was abnormally small. In comparing these values it is important to remember that Lecher (*loc. cit.*) has shown that with Fe or Pt terminals the arc discharge is intermittent. Arons has shown that this is also the case with Hg terminals, but no intermittence has been detected with terminals of C, Ag, or Cu. The preceding measurements refer to mean potentials, and no conclusions as to the actual potential differences at any time can be drawn when the discharge is discontinuous, unless we know the law of discontinuity. The ease with which an arc is sustained depends greatly on the nature of the electrodes; when they are brass, zinc, cadmium, or magnesium it is exceedingly difficult to get the arc.

The potential difference between the terminals is affected by the pressure of the gas. The most extensive series of experiments on this point is that made by Duncan, Rowland, and Tod,[163] whose results are represented in Fig. 24. We see from these curves that for very short arcs the potential difference increases continuously with the pressure, but for longer ones there is a critical pressure at which the potential difference is a minimum, and that this critical pressure seems to increase with the length of arc. The nature of the gas also affects the potential difference. The magnitude of this effect may be gathered from the following values given by Arons[164] for the potential difference required to produce an arc 1·5 mm. long, carrying a current of 4·5 ampères, between terminals of different metals in air and pure nitrogen.

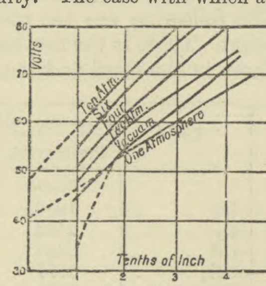

Fig. 24.

Terminal.	Air.	Nitrogen.	Terminal.	Air.	Nitrogen.
Ag . .	21	?	Pt . .	36	30
Zn . .	23	21	Al . .	39	27
Cd . .	25	21	Pb . .	...	18
Cu . .	27	30	Mg . .	..	22
Fe . .	29	20			

Thus, with the discharge for an arc of given length and current, the nature of the terminals is the most important factor in determining the potential difference. The effects produced by the pressure and nature of the surrounding gas, although quite appreciable, are not of so much importance, while in the spark discharge the nature of the terminals is of no importance, everything depending upon the nature and pressure of the gas.

The potential gradient in the arc is very far from being uniform. With carbon terminals Luggin[165] found that, with a current of 15 amperes, there was a fall of potential of 33·7 close to the anode, and one of 8·7 close to the cathode, so that the curve representing the distribution of potential between the terminals would be somewhat like that shown in Fig. 25. We have seen that a somewhat analogous distribution of potential holds in the case of conduction through flames (see § 11), though in that case the greatest drop of potential is in general at the cathode and not at the anode. The difference between the changes of potential at the anode and cathode are not so large with Fe and Cu terminals as with carbon ones; with mercury terminals, Arons[166] found the anode fall to be 7·4 volts, the cathode fall 5·4 volts.

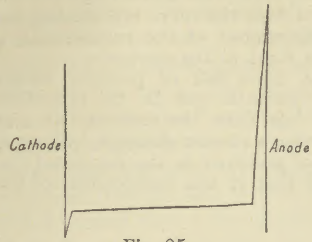

Fig. 25.

If we take the view that the conduction in the arc is effected by means of charged ions, the experiments on conduction through flames would lead us to believe that the larger part of the current would be carried by the negative ions. In a flame at a temperature of about 2000° C. the velocity of the negative ion is about 17 times that of the positive, while at a temperature of 1000° C. it is only about four times that of the positive. If the ratio of the velocity of the negative goes on increasing with the temperature, we should expect that at the high temperature of the arc it would reach a very large value, so that the ability of the negative ions to carry the current would be very much greater than that of the positive. If the current is carried by the negative ions we can see why the electric field close to the positive electrode must be very strong, for in consequence of the volatilization of the electrodes there is a wind of metallic vapour issuing from the electrodes. The experiments of Schuster and Hemsalech on the spark discharge indicate that the velocity of this wind would be several hundred metres per second. Thus in order to bring the negative ions up to the positive electrode it is necessary to have an electric field strong enough to drive them against this very rapid wind. Fleming[167] has given reasons for thinking that the discharge in the arc proceeds from the negative to the positive terminal. Placing in the arc a carbon electrode whose temperature was much lower than that of either terminal, he found that when this was connected with the negative electrode of the arc through a galvanometer and a battery of a few cells, a current could be sent by the cells through the circuit in the direction of the current through the arc, but not in the opposite one. He advances the view that the particles of metal torn from the cathode are the carriers of the current; it seems to the writer more probable that the main portion of the current is carried by the negative ions of very small mass, which we meet with in so many cases of the discharge of electricity through gases. There is in the arc a transport of matter from one terminal to the other; thus, if one terminal is made of copper and the other of iron, after the arc has passed for some time, copper will be found on the iron terminal and iron on the copper one. Experiments have been made by Groves,[168] Matteucci,[169] and Herwig[170] to see whether there is any connexion between the quantity of metal so transferred and the amount of the same metal that would have been deposited in the ordinary electrolysis of solutions by the same current, but no definite relations have been established. The vaporization of the terminals and the subsequent condensation of the metallic vapours would make this relation, if it existed, very difficult to detect. It is, however, worthy of notice that the amount of metal lost by the terminals is in many cases much less than the product of the quantity of electricity which has passed through the arc and the electro-chemical equivalent of the metal, showing that the bulk of the electricity must be carried by something different from positively charged atoms of the metal.

The fact that the potential difference required to produce a spark of length l is of the form $m+nl$ shows that no electricity can be carried across an arc, however short, without the expenditure of a finite amount of work. The nature of the physical process which this work has to do has not been settled. According to the theory of S. P. Thompson,[171] this work is that required to vaporize the terminals, but though this is doubtless a part of the work the current has to do, it cannot be the whole, as a calculation of the work required to vaporize the amount of mercury that would carry one unit of electricity shows that it corresponds to a potential difference of less than a volt, while the actual potential difference is about 12 volts. On the view that the discharge in the arc is carried by ions, part at least of the work must be spent in producing the ions, part in getting the small ions from the negative terminals. That chemical processes play an important part is shown by the fact, discovered by Mrs Ayrton, that access of oxygen to the positive crater lowers the potential difference by about 10 volts, and also by the difference between the potential differences in air and pure nitrogen.

Hissing Arcs.—When the current is increased beyond a certain value the discharge becomes noisy, and is accompanied by a hissing sound, while the potential difference between the electrodes falls considerably, and no longer varies with the current (see Fig. 23). The hissing of the arc has been studied by Mrs Ayrton, who has shown that it is caused by the crater extending beyond the tip of the terminal, and being no longer completely protected by the carbon vapour from oxidation by the air. She has proved that if the arc passes in a closed vessel no hissing takes place on an increase in the current after the oxygen has been burnt up, but that it at once recurs when fresh oxygen is blown into the vessel. Trotter[172] has shown that the arc is in rapid rotation in the unstable stage through which it passes just before hissing.

Magnetic Deflexion of the Arc.—The arc is deflected by a magnetic in much the same way as a flexible current between its terminals. As the arc lengthens when deflected by a magnet the potential difference between the terminals is increased by the magnetic field, and by using very strong magnetic fields it can be blown out.

A very interesting example of the arc discharge is when by means of transformers we produce a great difference of potential between the terminals, and transmit a considerable current. The discharge rises from the electrodes in two columns, sometimes some feet long, which unite at the top, where striations are often seen. These columns flicker slowly about and are very easily blown out, a slight puff of air being sufficient to extinguish them. The air-blast apparently breaks the belt of ionized gas along which the current passes, and the current is stopped just as a current through a wire would be stopped if the wire were cut. This arc differs from the arc hitherto considered in that it passes through the air, and not through the metallic vapours from the terminals.

§ 26. *Discharge through Gases at Low Pressures.*—As the pressure of a gas through which a spark is passing is gradually reduced, the luminous discharge broadens out, and pronounced differences begin to appear between the brightness and colour of various parts of the discharge, until at a pressure of about ·5 mm. of mercury the discharge presents an appearance similar to that shown in Fig. 26.

A velvety glow spreads, often in irregular patches, over the surface of the negative electrode k, and a body placed in the glow casts a shadow on the electrode.[173] Next to this there is a comparatively dark region, called the first dark space, or Crookes dark space; its length depends on the pressure of the gas, increasing as the pressure diminishes. Schuster has shown that an increase in the current produces a slight increase in the thickness of the dark space, the luminous boundary of which is approximately the locus of the extremities of normals of constant length drawn from the negative electrode. According to Hittorf,[174] this dark space disappears when the negative electrode is raised to a temperature at which it is incandescent. Adjoining it is a luminous column called the negative glow, the length of which is very variable, even when the pressure is constant. It is independent of the position of the positive electrode, its development is checked when the space round the negative electrode is too much restricted by the walls of the tube, and its size increases with the current. Thus if the cathode is a straight wire, it may, with a very small current, only just cover the tip of the wire, but as the current is increased it will cover more and more of the wire until it reaches the glass through which the wire passes. Next after the negative glow comes a second comparatively non-luminous space, ph (Fig. 26), called by some writers the "second negative dark space," and by others the "Faraday dark space"; it is of very variable length, and is sometimes entirely absent. Next after this we have a luminous column reaching right up to the positive electrode, called the positive column. When the pressure is within certain limits its luminosity often exhibits remarkable periodic alterations in intensity, such as those shown in Fig. 26; these are called *striations*. The bright parts of the striations are slightly concave to the positive electrode, and the distance between them increases as the pressure of the gas diminishes. If the discharge takes place in a tube which is wider at some places than others, they are nearer together in the narrow parts than they are in the wide. They are much influenced by the strength of the current, disappearing when it is increased beyond a certain value, and they are especially noticeable when the gas contains traces of the vapour of some organic compounds, *e.g.*, ether. The positive column behaves very differently from the negative glow and the Crookes dark space, for while the latter do not depend on the position of the positive electrode, and are not increased when the length of the tube is increased, the positive column takes the shortest route from the positive to the negative electrode, and by the use of sufficiently long tubes can be made of almost any length. The writer has had tubes with positive columns 50 feet long. The colours of the various parts of the discharge are very different, depending

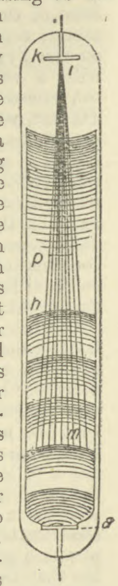

Fig. 26.

on the nature of the gas; thus, in nitrogen the positive column is somewhat the colour of chamois leather, while the negative glow is bluish. There are also very interesting differences in the spectra[175] of different parts of the discharge. Besides the difference in luminosity and colour there are also great variations in other quantities, such as the electric force at various points in the discharge and the mean temperature of the gas.

The distribution of electric force was measured by Hittorf,[176] and recently by Graham,[177] A. Herz,[178] Skinner,[179] and H. A. Wilson.[180] Fig. 27 is a curve given by Wilson, showing the distribution in a tube filled with hydrogen at a pressure of 2·25 mm. of mercury, and carrying a current of ·568 milli-amperes; the luminous parts of the discharge are indicated by the dotted lines. The electric

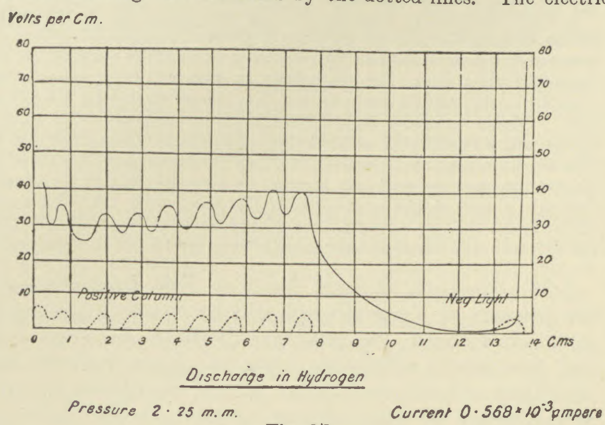

Fig. 27.

force is a minimum just outside the Crookes dark space, and increases with great rapidity inside that space. In the Faraday dark space the potential gradient indicates an excess of negative electrification. In the positive column there is a periodic variation in the potential gradient corresponding to the striation, while in front of the anode the electric force is again a minimum, and increases rapidly right up against the anode. In § 7 we saw that on the hypothesis that the discharge is carried by ions moving with a velocity proportional to the force acting upon them, the excess of ionization over recombination is proportional to d^2X/dx^2, when X is the electric force; hence the ionization will exceed the recombination when the curve for X^2 is convex to the axis of x, and be less than the recombination when the curve is concave to the axis of x. Applying this to the curve in Fig. 27, we see that there is strong ionization near each of the electrodes, and that the ionization exceeds the recombination in the Faraday dark space, while in the luminous parts of the discharge the recombination exceeds the ionization. In the striated discharge we see from Fig. 13 that recombination is greater than ionization in the bright parts, and less in the dark parts.

Cathode Fall of Potential.—The electric field in the neighbourhood of the electrodes, and especially of the cathode, has been made the subject of many researches. Hittorf showed that the potential difference between the cathode and a point in the negative glow was independent of the current, unless the current was so large that the negative glow covered the whole of the cathode. When that stage was reached an increase in the current increased the fall of potential. Warburg[181] showed that this fall of potential was independent of the pressure of the gas, and that if the terminals were made of aluminium or magnesium the fall of potential was considerably less than when they were made of other metals, all of which gave approximately the same potential fall. He showed too that the potential fall was very much influenced by impurities in the gas. Thus the potential fall in nitrogen containing traces of moisture and oxygen was 260 volts, but after the gas was carefully dried the potential rose to 343, while on the removal of the oxygen it fell again to 243 volts. Measurements of the cathode fall of potential have been made by Capstick[182] and Strutt,[183] whose results are shown in the following table. The cathode fall of potential seems to agree very nearly with the minimum potential difference required to produce a spark :—

Gas.	Cathode Fall with Pt Electrodes.			Minimum Potential Difference required to produce a Spark (Strutt).
	Warburg.	Capstick.	Strutt.	
Air . .	340–350 volts.	..	..	341
H_2 . .	About 300 volts.	298	..	302–303
O_2 . .	..	369		
N_2 . .	230 if free from O.	232	..	251
Hg. vapour	340			
Helium .	..	..	226	261–326
H_2O . .	..	469		

Schuster found that the potential difference V in the dark space at a distance x from the cathode was represented by the formula $V = V_0(1 - \epsilon^{Rx})$. Graham (*loc. cit.*) found that this formula did not hold right up to the cathode, but that the curve representing the electric intensity in the neighbourhood of the cathode had a minimum value immediately in front of the electrode.

Anode Fall of Potential.—A finite fall of potential occurs between the anode and the luminous gas in its immediate neighbourhood; this is much less than the cathode fall, and it seems to take place within even a shorter distance. Skinner, who investigated the anode fall of potential in the unstriated discharge through nitrogen, found that it was independent of the current through the gas, increased slowly with the pressure of the gas, and depended upon the material and state of surface of the electrodes. For Al and Mg, the metals for which the cathode fall is least, the anode fall is greatest. The anode fall for different metals and for different gaseous pressures is represented in Fig. 28. Both Skinner and H. A. Wilson found the potential gradient in the gas just in front of the anode beyond the region of the anode fall was exceedingly small, not amounting to a volt per centimetre. A. Herz showed that the potential gradient in the unstriated positive column diminished as the current increased, in such a way that if X is the electric intensity when the current is ι, X_0 when it is ι_0, then $X - X_0 = -b(\iota - \iota_0)$, where b is a constant.

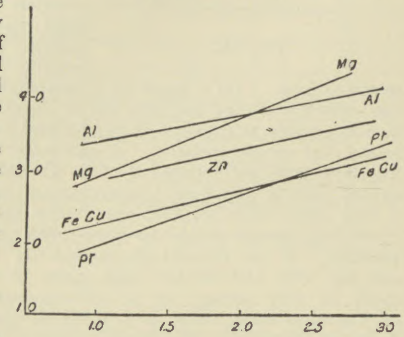

Fig. 28.

Heat produced by the Discharge.—The average temperature of a gas at low pressure conveying a luminous discharge is by no means high. E. Wiedemann[184] proved that the average temperature of the gas in a tube containing air at a pressure of 3 mm. of mercury is less than 100° C, though the discharge is luminous. These measurements refer to the average temperature of all the molecules in a considerable space, and the low average temperature does not of course preclude the possibility of a small number of molecules having velocities very much greater than the mean velocity corresponding to the temperature indicated by the thermometer. Hittorf,[185] measuring the mean temperature at three points in the discharge, one in the positive column, the second in the negative glow, and the third in the Crookes dark space, found that the temperature was highest in the darkest space, and lowest in the positive column. E. Wiedemann[186] showed that the distribution of temperature along the discharge depended on the pressure, and that while at low pressures the temperature at the cathode was higher than at the anode, the reverse was true when the pressure exceeded 26 mm. A very complete investigation of the distribution of temperature along the discharge has been made by Wood,[187] who observed that in the unstriated discharge the temperature is constant in the positive column, diminishes in the Faraday dark space, reaches a minimum at a point in this space a little in front of the negative glow, and rapidly increases in the dark space next the cathode. In the striated discharge the temperature is a maximum in the bright parts of the striations and a minimum in the dark parts; in no part of the discharge did Wood find the mean temperature to exceed 100° C. The distribution of temperature thus follows the same course as the distribution of electric force in the tube. The rate of work done by the current at any point of the path is proportional to the product of the current and the electric force, or since the current is constant all along the tube, to the electric force. If this work were entirely converted into heat, the temperature curves would be the same as the curves for the electric force, and from the investigations of Wood and Graham this would seem to be very approximately the case. We conclude that in tubes at moderate pressures the greater part of the electrical work done appears as heat in the gas at a place not very distant from where the work was done.

§ 27. *Cathode Rays.*—When the gas in the discharge tube is at a very low pressure some remarkable phenomena occur in the neighbourhood of the cathode. These seem to have been first observed by Plücker,[188] who noticed on the walls of the glass tube near the cathode a greenish phosphorescence, which he regarded as due to rays proceeding from the cathode, striking against the sides of the tube, and then travelling back to the cathode. He found that the action of a magnet on these rays was not the same as the action on the part of the discharge near the positive electrode. Hittorf[189] showed that the agent producing the phosphorescence was intercepted by a solid, whether conductor or insulator, placed between the cathode and the sides of the tube. He regarded the phosphorescence as caused by a motion starting from the cathode and travelling in straight lines through the gas. Goldstein[190] confirmed this discovery of Hittorf's, and further showed that a distinct, though not very sharp, shadow is cast by a small object placed near a large plane cathode. This is a proof that the rays producing the phosphorescence must be emitted almost normally from the cathode, and not, like the rays of light from a luminous surface, in all directions, for such rays would not produce a perceptible shadow if a small body were placed near the plane. Goldstein regarded the phosphorescence as due to waves in the ether, for whose propagation the gas was not necessary. Crookes,[191] who made many remarkable researches in this subject, took a different view. He regarded the rays as streams of negatively electrified particles projected normally from the cathode with great velocity, and, when the pressure is sufficiently low, reaching the sides of the tube, and by their impact producing phosphorescence and heat. The rays on this view are deflected by a magnet, because a magnet exerts a force on a charged moving body.

These rays striking against glass make it phosphorescent. The colour of the phosphorescence depends on the kind of glass; thus the light from soda glass is a yellowish green, and that from lead glass blue. Many other bodies phosphoresce when exposed to these rays, and in particular the phosphorescence of some gems, such as rubies and diamonds, is exceedingly vivid. The spectrum of the phosphorescent light is generally continuous, but Crookes has shown that the phosphorescence of some of the rare earths, such as yttrium, gives a spectrum of bright bands, and he has founded on this fact a spectroscopic method of great importance. Goldstein[192] discovered that the haloid salts of the alkali metals change colour under the rays, sodium chloride, for example, becoming violet. The coloration is a surface one, and has been traced by E. Wiedemann and Schmidt[193] to the formation of a sub-chloride. Chlorides of tin, mercury, and lead also change colour in the same way. E. Wiedemann[194] discovered another remarkable effect, which he called thermo-luminescence; he found that many bodies after being exposed to the cathode rays possess for some time the power of becoming luminous when their temperature is raised to a point far below that at which they become luminous in the normal state. Substances belonging to the class called by van't Hoff[195] solid solutions exhibit this property of thermo-luminescence to a remarkable extent. They are formed when two salts, one greatly in excess of the other, are simultaneously precipitated from a solution. A trace of $MnSO_4$ in $CaSO_4$ shows very brilliant thermo-luminescence. The impact of cathode rays produces after a time perceptible changes in the glass. Crookes[196] found that after glass has been phosphorescing for some time under the cathode rays it seems to get tired, and the phosphorescence is not so bright as it was initially. Thus, for example, when the shadow of a Maltese cross is thrown on the walls of the tube as in Fig. 29, if after the discharge has been going on for some time the cross is shaken down or a new cathode used whose line of fire does not cut the cross, the pattern of the cross will still be seen on the glass, but it will now be brighter instead of darker than the surrounding portion. The portions shielded by the cross, not being tired by being made to phosphoresce for a long time, respond more vigorously to the stimulus than those portions which have not been protected. Skinner[197] and the writer found on the glass which had been exposed to the rays gelatinous filaments, apparently silica, resulting from the reduction of the glass. A reducing action was also noticed by Villard[198] and Wehnelt.[199] It can be well shown by letting the rays fall on a plate of oxidized copper, when the part struck by the rays will become bright. The rays heat bodies on which they fall, and if they are concentrated by using as a cathode a portion of a spherical surface, the heat at the centre becomes so great that a piece of platinum wire can be melted or a diamond charred. Measurements of the heating effects of the rays have been made by the writer and Cady. Crookes[200] has shown that a vane mounted as in a radiometer is set in rotation by the rays, the direction of the rotation being the same as would be produced by a stream of particles proceeding from the cathode. Riecke[201] made a series of measurements of the pressure produced on the vanes.

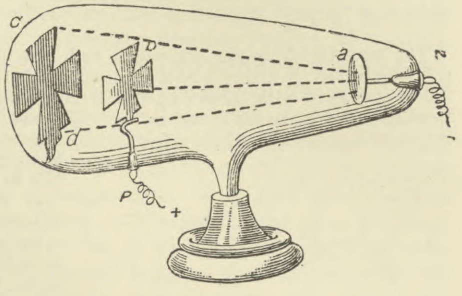

Fig. 29.

§ 28. *Effect of a Magnet.*—The rays are deflected by a magnet, so that the distribution of phosphorescence over the glass and the shape and position of the shadows cast by bodies in the tube are altered by the proximity of a magnet. The laws of magnetic deflexion of these rays have been investigated by Plücker,[202] Hittorf,[203] Crookes,[204] and Schuster.[205] The deflexion is the same as that of negatively electrified particles travelling along the path of the rays. Such particles would in a magnetic field be acted on by a force at right angles to the direction of motion of the particle and also to the magnetic force, the magnitude of the force being proportional to the product of the velocity of the particle, the magnetic force, and the sine of the angle between these vectors. In this case we have seen (§ 8) that if the particle is not acted on by an electrostatic field, the path in a uniform magnetic field is a spiral, which, if the magnetic force is at right angles to the direction of projection of the particle, becomes a circle in the plane at right angles to the magnetic force, the radius being mv/He, where m, v, e are respectively the mass, velocity, and charge on the particle, and H is the magnetic force. The smaller the difference of potential between the electrodes of the discharge tube the greater the deflexion produced by a magnetic field of given strength, and as the difference of potential rapidly increases with diminution of pressure, after a certain pressure has been passed, the higher the exhaustion of the tube the less the magnetic deflexion of the rays. Birkeland[206] has shown that when the discharge is from an induction coil the cathode rays produced in the tube at any one time are not equally deflected by a magnet, but that a narrow patch of phosphorescence when deflected by a magnet is split up into several distinct patches, giving rise to what Birkeland calls the magnetic spectrum. Strutt[207] has shown that this magnetic spectrum does not occur if the discharge of a large number of cells is employed instead of the coil. The writer[208] has shown that if the potential difference between the electrodes is kept the same the magnetic deflexion is independent of the nature of the gas filling the discharge tube; this was tested with gases so different as air, hydrogen, carbonic acid, and methyl iodide.

§ 29. *Charge of Negative Electricity carried by the Rays.*—We have seen that the rays are deflected by a magnet, as if they were particles charged with negative electricity. Perrin[209] showed by direct experiment that a stream of negative electricity is associated with the rays. A modification made by the writer of Perrin's experiment is sketched in Fig. 30.[210]

The rays start from the cathode A, and pass through a slit in a solid brass rod B fitting tightly into the neck of the tube. This rod is connected with earth and used as the anode. The rays after passing through the slit travel through the vessel C. D and E are two insulated metal cylinders insulated from each other, and each having a slit cut in its face so as to enable the rays to pass into the inside of the inner cylinder, which is connected with an electrometer, the outer cylinder being connected with the earth. The two cylinders are placed on the far side of the vessel, but out of the direct line of fire of the rays. When the rays go straight through the slit there is only a very small negative charge communicated to the inner cylinder, but when they are deflected by a magnet so that the phosphorescent patch falls on the slit in the outer cylinder the inner cylinder receives a very large negative charge, the increase coinciding very sharply with the appearance of the phosphorescent patch on the slit. When the patch is so much deflected by the magnet that it falls below the slit, the negative charge in the cylinder again disappears. This experiment shows that the cathode rays are accompanied by a stream of negative electrification. The same apparatus can be used to show that the passage of cathode rays through a gas makes it a conductor of electricity. For if the induction coil is kept running and a stream of the rays kept steadily going into the inner cylinder, the potential of the inner cylinder reaches a definite negative value below which it does not fall, however long the rays may be kept going. The cylinder reaches a steady state in which the gain of negative electricity from the cathode rays is equal to the loss by leakage through the conducting gas, the conductivity being produced by the passage of the rays through it. If the inner cylinder is charged up initially with a greater negative charge than corresponds to the steady state, on turning the rays on to the cylinder the negative charge will decrease and not increase until it reaches the steady state. The conductivity produced by the passage of cathode rays through a gas diminishes rapidly with the pressure. When rays pass through a gas at a low pressure, they are deflected by an electric field; when the pressure of the gas is higher the conductivity it acquires when the cathode rays pass through it is so large that the potential gradient cannot reach a sufficiently high value to produce an appreciable deflexion. In proving the existence of this deflexion the writer[211] used the apparatus represented in Fig. 31. The rays from the cathode C pass through a slit in the anode A, which is a metal plug fitting tightly into the tube and connected with the earth. After passing through a second slit in another earth-connected metal plug B, they travel between two aluminium plates D and E, and then fall on the end of the tube, where they produce a narrow, well-defined phosphorescent patch. At high exhaustions the rays were deflected when the aluminium plates were connected with the terminals of a battery of storage cells, the direction of the deflexion being such as would occur if the rays were negatively electrified particles.

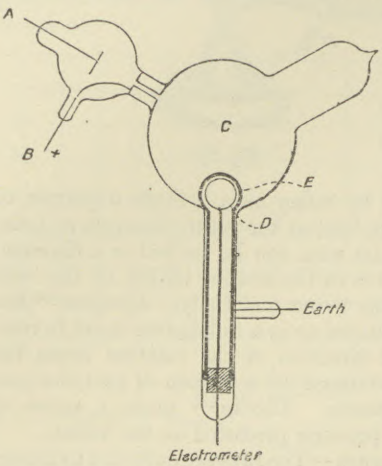

Fig. 30.

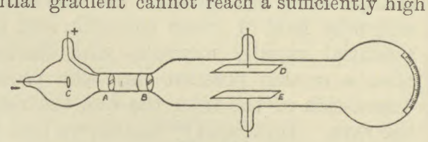

Fig. 31.

Thus the cathode rays carry a charge of negative electricity, they are deflected by an electric field as if they were negatively electrified, and are acted on by a magnetic force in just the way this force would act on a negatively electrified body moving along the path of the rays. There is therefore every reason for believing that they are charges of negative electricity in rapid motion, and by measuring the deflexion produced by magnetic and electric fields we can determine the velocity with which these particles move and the ratio of the mass of the particle to the charge carried by it.

If the rays travel through a space l in a uniform electric field acting at right angles to the direction of motion of the rays, and if the electric force is equal to F, the acceleration at right angles to the path is Fe/m, where e is the charge on the particle and m its mass. Hence, if θ is the angle through which the direction of motion is twisted, $\theta = Fel/mv^2$, where v is the velocity of the particle. Again, if the particle moves through a distance l in a uniform magnetic field of strength H at right angles to its direction of motion, the acceleration at right angles to the path is Hev/m. Hence if ϕ is the angle through which the direction of motion is twisted, $\phi = Hevl/mv^2 = Hel/mv$. Hence if we measure θ and ϕ we can determine the values of v and m/e. The easiest way of determining v is to make the electrostatic and magnetic forces act in opposite directions on the particle, and adjust the magnetic force until it just neutralizes the electric; then if H is the magnetic and F the electric force, $F = Hv$. From experiments made in this way at very low pressures by the writer[212] the value of m/e for the mean of seven determinations was $1 \cdot 3 \times 10^{-7}$, and was the same whatever the nature of the gas, the gases tried being air, hydrogen, and carbonic acid. The velocity v depends upon the pressure of the gas, increasing as the pressure decreases. The velocities observed in these experiments ranged between $2 \cdot 2 \times 10^9$ cm./sec. to $3 \cdot 6 \times 10^9$ cm./sec. Another method used by the writer to measure v and m/e was to allow a bundle of rays to enter a metal cylinder and measure the charge of negative electricity carried in by them. In the cylinder a thermo-electric junction was arranged, and the impact of the rays against this raised its temperature by an amount which could be measured by the current sent round the thermo-electric circuit. Thus with a knowledge of the thermal capacity of the junction it was possible to determine the mechanical equivalent of the heat given up by the rays to the surface on which they impinged. Let N be the number of charged particles entering the cylinder, and Q the negative charge it receives; then $Ne = Q$. If E is the mechanical equivalent of the heat produced by the impact, then assuming that the particles give up all their energy on collision, we have $\frac{1}{2}Nmv^2 = E$; hence $\frac{1}{2}mv^2e = 2E/Q$. Thus measurements of E and Q combined with measurements of the magnetic deflexion which gives mv/e will enable us to determine m/e and v. Measurements made by this method gave for m/e the value $\cdot 9 \times 10^{-7}$ with velocities ranging from $2 \cdot 4 \times 10^9$ cm./sec. to $3 \cdot 2 \times 10^9$ cm./sec. Kauffmann,[213] who has made an extensive series of measurements of the value of m/e and v, uses a somewhat different process. One of the quantities measured by him is the magnetic deflexion, and the other is the difference in potential between the cathode and anode. If V is this difference, and if we assume that the energy of the moving particle is due to passing between two places differing in potential by V, we have $mv^2 = 2Ve$. If V is measured this equation, combined with the equation for the magnetic deflexion, enables us to find m/e and v. In this way Kauffmann found $m/e = \cdot 54 \times 10^{-7}$. He confirms the result that this value is independent of the nature of the gas and of the electrodes. This method assumes that the potential at the commencement of the path of a particle is the same as the potential of the cathode. Now the potential close to the cathode changes with great rapidity, so that if the cathode particle started from a place close to but not absolutely in contact with the cathode a considerable correction would be necessary. The effect of this correction would be to increase the value of m/e. By measuring directly the value of v Wiechert[214] has deduced the value of m/e. He determined v by making the cathode rays pass through two equal spirals at a considerable distance from each other, the spirals being traversed by a very rapidly alternating current produced by discharging condensers. If the velocity of the cathode rays was infinite the currents in the two circuits would be in the same phase when the rays passed through them, and the magnetic deflexion would be the same. If, however, the rays took a time equal to half the time of oscillation of the current to pass from one spiral to another, the deflexions would be opposite. Therefore, by comparing the deflexions in the two spirals the velocity of the rays can be determined. The result was that any value of e/m between $1 \cdot 01 \times 10^7$ and $1 \cdot 55 \times 10^7$ was quite probable, but that it was unlikely that e/m was greater than $1 \cdot 84 \times 10^7$ or less than $\cdot 87 \times 10^7$.

We may conclude from these experiments that the value of m/e for the particles constituting the cathode rays is of the order 10^{-7}, and we have seen that m/e has the same value in all the other cases of negative ions in a gas at low pressure for which it has been measured—viz., for the ions produced when ultra-violet light falls on a metal plate, or when an incandescent carbon filament is surrounded by a gas at a low pressure. We have also seen that the value of the charge on the gaseous ion, in all cases in which it has been measured—viz., the ions produced by Röntgen and uranium radiation, by ultra-violet light, and by the discharge of electrification from a point—is the same in magnitude as the charge carried by the hydrogen atom in the electrolysis of solutions. The mass of the hydrogen alone is, however, 10^{-4} times this charge, while the mass of the carriers of negative electrification is only 10^{-7} times the charge; hence the mass of the carriers of the negative electrification is only $\frac{1}{1000}$ of the mass of the hydrogen atom. We are thus, by the study of the electric discharge, forced to recognize the existence of masses very much smaller than the smallest mass hitherto recognized in chemistry.

Direct determinations of the velocity of the cathode rays have been made by the writer[215] by measuring the interval between the appearance of phosphorescence on two pieces of glass placed at a known distance apart, and by Maiorana[216] and Battelli and Stefanini,[217] who measured the interval between the arrival of the negative charge carried by the rays at two places separated by a known distance. The values of the velocity got in this way are much smaller than the values got by the indirect methods previously described: thus the writer at a fairly high pressure found the velocity to be 2×10^7 cm./sec. Maiorana found values ranging between 10^7 and 6×10^7 cm./sec., and Battelli and Stefanini values ranging from 6×10^6 to $1{\cdot}2\times10^7$. In these methods it is very difficult to eliminate the effect of the interval which elapses between the arrival of the rays and the attainment by the means of detection, such as the phosphorescence of the glass or the deflexion of the electrometer, of sufficient intensity to affect the senses.

§ 30. *Transmission of Cathode Rays through Solids—Lenard Rays.*—It was for a long time believed that all solids were absolutely opaque to these rays, as Crookes and Goldstein had proved that very thin glass, and even a film of collodion, cast intensely black shadows. Hertz,[218] however, showed that behind a piece of gold-leaf or aluminium foil an appreciable amount of phosphorescence occurred on the glass, and that the phosphorescence moved when a magnet was brought near. A most important advance was next made by Lenard,[219] who got the cathode rays to pass from the inside of a discharge tube to the air outside. For this purpose he used a tube like that shown in Fig. 32. The cathode K is an aluminium disc 1·2 cm. in diameter fastened to a stiff wire, which is surrounded by a glass tube. The anode A is a brass strip partly surrounding the cathode. The end of the tube in front of the cathode is closed by a strong metal cap, fastened in with marine glue, in the middle of which a hole 1·7 mm. in diameter is bored, and covered with a piece of very thin aluminium foil about ·0026 mm. in thickness. The aluminium window is in metallic contact with the cap, and this and the anode are connected with the earth. The tube is then exhausted until the cathode rays strike against the window. Diffuse light spreads from the window into the air outside the tube, and can be traced in a dark room for a distance of several centimetres. From the window too proceed rays which, like the cathode rays, can produce phosphorescence, for certain bodies phosphoresce when placed in the neighbourhood of the window. This effect is conveniently observed by the platino-cyanide screens used to detect Röntgen radiation. The properties of the rays outside the tube resemble in all respects those of cathode rays; they are deflected by a magnet and by an electric field, they ionize the gas through which they pass and make it a conductor of electricity, and they affect a photographic plate and change the colour of the haloid salts of the alkali metals. As, however, it is convenient to distinguish between cathode rays outside and inside the tube, we shall call the former Lenard rays. In air at atmospheric pressure the Lenard rays spread out very diffusely. If the aluminium window, instead of opening into the air, opens into another tube which can be exhausted, it is found that the lower the pressure of the gas in this tube the farther the rays travel and the less diffuse they are. By filling the tube with different gases Lenard showed that the greater the density of the gas the greater is the absorption of these rays. Thus they travel farther in hydrogen than in any other gas at the same pressure. Lenard showed, too, that if he adjusted the pressure so that the density of the gas in this tube was the same—if, for example, the pressure when the tube was filled with oxygen was $\frac{1}{16}$ of the pressure when it was filled with hydrogen—the absorption was constant whatever the nature of the gas. The distance to which the Lenard rays penetrate into this tube depends upon the pressure in the discharge tube; if the exhaustion in the latter is very high, so that there is a large potential difference between the cathode and the anode, and therefore a high velocity for the cathode rays, the Lenard rays will penetrate farther than when the pressure in the discharge tube is higher and the velocity of the cathode rays smaller. Lenard showed that the greater the penetrating power of his rays the smaller was their magnetic deflexion, and therefore the greater their velocity; thus the greater the velocity of the cathode rays the greater is the velocity of the Lenard rays to which they give rise. Lenard[220] has studied the passage of his rays through solids as well as through gases, and has arrived at the very interesting result that the absorption of a substance depends only upon its density, and not upon its chemical composition or physical state; in other words, the amount of absorption of the rays when they traverse a given distance depends only on the quantity of matter they cut through in the distance. By measuring the magnetic and electric deflexion of these rays Lenard[221] determined the value of e/m and also v, m being the mass of the particle, e its charge, and v its velocity. He found $e/m = 6{\cdot}4\times10^6$, which agrees well with the value found for the cathode rays, and v in his experiments reached the value 8×10^9 cm./sec. for penetrating rays. M'Clelland[222] showed that the rays carry a charge of negative electricity, and M'Lennan measured the amount of ionization rays of given intensity produced in different gases, finding that if the pressure is adjusted so that the density of the different gases is the same the number of ions per cubic centimetre is also the same. In this case, as Lenard has shown, the absorption is the same, so that with the Lenard rays, as with uranium and probably with Röntgen rays, equal absorption corresponds to equal ionization. A convenient method for producing Lenard rays of great intensity has been described by Des Coudres.[223]

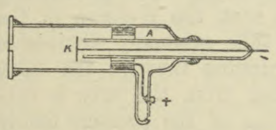

Fig. 32.

Diffuse Reflexion of Cathode Rays.—When cathode rays fall upon a surface, whether of an insulator or a conductor, cathode rays start from the surface in all directions. This phenomenon, which was discovered by Goldstein,[224] has been investigated by Starke,[225] Campbell-Swinton,[226] and Merrit; it is often regarded as analogous to the diffuse reflexion of light from such a surface as gypsum, and is spoken of as the diffuse reflexion of the cathode rays. According to Merritt the deviation in a magnetic field of these reflected rays is the same as that of the incident rays. The experiments, however, were confined to rays reflected so that the angle of reflexion was nearly equal to that of incidence. According to Campbell-Swinton the diffuse "reflexion" is accompanied by a certain amount of specular reflexion.

Repulsion of two Cathode Streams.—Goldstein[227] discovered that if in a tube there are two cathodes connected together, the cathodic rays from one cathode are deflected when they pass near the other. Experiments bearing on this subject have been made by Crookes[228] and Wiedemann and Ebert.[229] The phenomena may be described by saying that the repulsion of the rays from a cathode A by a cathode B is only appreciable when the rays from A pass through the Crookes dark space round B. This is what we should expect if we remember that the electric field in the dark space is far stronger than in the rest of the discharge, and that the gas in the other parts of the tube is rendered a conductor by the passage through it of the cathode rays, and therefore incapable of transmitting electrostatic repulsion.

§ 31. *Positive Rays or "Kanal-strahlen."*—Goldstein [230] found that with a perforated cathode certain rays occurred behind the cathode which were not appreciably deflected by a magnet; these he called *Kanal-strahlen*, but we shall, for reasons which will appear later, call them "positive rays."

Their appearance is well shown in Fig. 33, taken from a paper by Wehnelt,[231] in which they are represented at B. Goldstein found that their colour depends on the gas in which they are formed, being gold-colour in air and nitrogen, rose-colour in hydrogen, yellowish rose in oxygen, and greenish gray in carbonic acid. W. Wien [232] showed that by using very intense magnetic fields they can be deflected (although the deflexion is very small compared with that of the cathode rays) in a direction corresponding to that of positive ions moving away from the cathode. He proved directly that the rays carry a charge of positive electricity—a fact which was confirmed by Ewers.[233] Villard,[234] on the other hand, was unable to detect any positive charge until the rays had been started some time; then he observed a positive charge, which he ascribed to the diffusion of ions from the other part of the discharge tube. Wien also showed that the rays are deflected by an electric field, and by measuring the magnetic and electric deflexions he was able to determine m/e and v. For the former he found with iron electrodes the value $3{\cdot}2 \times 10^{-3}$, and for v $3{\cdot}6 \times 10^{7}$ cm./sec. The value of m/e contrasts very markedly with the value of the same quantity 10^{-7} for the cathode rays, for Wien's value is of the same order as the mass of a molecule divided by its charge, and suggests that the carriers of the positive electricity are chemical atoms or molecules. According to Ewers (*loc. cit.*) the value of m/e depends upon the nature of the electrodes, and he regards the metallic ions from the electrode as being the carriers of the positive electricity in the positive rays. The researches of Schuster,[235] Villard (*loc. cit.*), and Wehnelt have established that in the Crookes dark space there is a flow of positive electricity up to the cathode; according to Schuster a body placed in the dark space throws a shadow on the cathode. An example of these shadows is shown in Fig. 33. The flow of positive electricity to the cathode and of negative away from the cathode are mutually dependent; it is only from those parts of the cathode struck by the positive flow that cathode rays start, and it is only those parts of the gas which are struck by the cathode rays that furnish the stream of positive electricity. The positive rays seem to be the continuation of this positive stream through the perforations in the cathode.

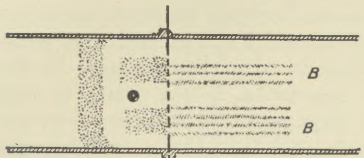

Fig. 33.

§ 32. *Röntgen Rays.*—Röntgen [236] discovered in 1895 a very remarkable effect arising from the cathode rays. He found that, in the neighbourhood of a discharge tube exhausted so highly that the cathode rays produced a vivid green phosphorescence on the glass, a plate covered with a phosphorescent substance such as potassium platinocyanide began to glow. He found that if a thick piece of metal were placed between the bulb and the phosphorescent screen, a sharp shadow of the metal was cast upon the screen, but that other substances, such as wood and thin pieces of aluminium, cast but slight shadows, showing that the agent which produced the phosphorescence could traverse with considerable freedom bodies which are opaque to ordinary light. He found that as a general rule the greater the density of the substance the greater its opacity to this agent. Thus while the effect produced by the phosphorescence could pass through the flesh, it was stopped by the bones of the hand, so that if a hand were held between the discharge tube and the phosphorescent screen the outline of the bones was distinctly visible as a shadow cast on the screen, or if a purse containing coins were placed between the tube and the screen the purse itself threw but little shadow, while the coins cast a dark one. Röntgen showed that the cause of the phosphorescence—now called Röntgen rays—was propagated in straight lines, and was not bent on passing from one medium to another, there thus being no refraction. Again, no deflexion by a magnet can be detected; Röntgen could discover none with the strongest magnetic fields at his disposal, and the writer has sent the rays through a magnetic field of about 8000 lines of force per sq. cm. for a distance of about a centimetre without producing any appreciable effect. Many attempts have been made to detect signs of polarization by measuring their absorption by two thin plates of tourmaline placed first with their axes parallel and then with their axes crossed, but no sensible difference has been detected in the two cases; the absorption of ordinary light would have been very much greater in the second case than in the first. The rays affect a photographic plate as well as a phosphorescent screen, and shadow photographs can be readily taken. The time of exposure depends on the intensity of the rays, and this depends on the discharge through the tube and on the substances traversed by the rays in their journey to the plate. In some cases an exposure of a few seconds is sufficient, in others hours may be required. The rays coming from different discharge tubes have very different penetrating power. If the pressure in the tube is fairly high, so that the potential difference between its electrodes is small and the velocity of the cathode rays low, the Röntgen rays will be very readily absorbed. Such rays are called "soft rays." If the exhaustion of the bulb is carried further, so that there is a considerable increase in the potential difference between the cathode and anode and therefore in the velocity of the cathode rays, the Röntgen rays have much greater penetrating power and are often called "hard rays." With a highly exhausted tube and a large induction coil it is possible to get appreciable effects from rays which have passed through sheets of iron or brass several millimetres thick. The penetrating power of the rays thus varies with the pressure in the tube; as the pressure in the tube gradually diminishes when the discharge is kept running through the tube, the type of discharge proceeding from the tube is continually changing. This lowering of the pressure finally leads to such a high degree of exhaustion that the discharge has great difficulty in passing, and the emission of the rays becomes very irregular. Heating the tube causes some gas to come off the sides, and by thus increasing the pressure causes a temporary improvement. Tubes are sometimes provided with pieces of carbon or caustic potash, which when heated give up gas and so tend to restore the original pressure. The lowering of pressure by the discharge is not confined to the very low pressures which occur in the tubes used to generate Röntgen rays, but is found also at pressures greater than 1 mm. of mercury. An appreciable amount of gas can be made to disappear in this way when introduced gradually into the tube; the writer in a small tube used up a quantity which would occupy a volume of 5 c.c. at atmospheric pressure. The gas seems to be absorbed by the glass rather than by the electrode, as the absorption goes on when a ring discharge is sent through a bulb without electrodes. Not only do different bulbs emit different kinds of rays, but the same bulb may emit at the same time rays of different kinds. The property by which it is most convenient to identify a ray is the absorption it suffers when it passes through a certain thickness of aluminium and tin-foil. In some experiments made by M'Clelland and the writer [237] on the absorption of the rays produced by sheets of tin-foil, it was found that the absorption by the first sheets of tin-foil traversed by the rays was much greater than that by the same number of sheets when the rays had already passed through several sheets of tin-foil. This effect is just what would occur if some of the rays were readily absorbed by tin-foil, whilst others passed through with greater facility; thus the first few layers would stop all the readily absorbable rays, while those left would get through. M'Clelland showed that if he took thicknesses of two different substances such as to give equal absorptions with the rays from one bulb, they would not necessarily give equal absorptions with the rays from another, again proving the variety which exists in these rays. The fact that the rays when they pass through a gas ionize it and make it a conductor of electricity (see § 15) provides one of the best means of investigating their intensity, as the measurement of the amount of conductivity they confer on a gas is both more exact and more convenient than measurements of photographic or phosphorescent effects.

When Röntgen rays impinge on a surface there is a diffuse return of rays. The absence of refraction would lead us to expect that there would be no regular reflexion, but the experiments of Rood,[238] Joly,[239] and Lord Blythswood [240] seem to prove that it does exist to a small extent. By far the larger part, however, of the effect produced when the rays strike a surface is the emission of secondary Röntgen radiation, which possesses the characteristic properties of primary Röntgen radiation, but differs in being far less penetrating. The effects produced when Röntgen rays fall upon the surfaces of solids or liquids have been investigated by Perrin,[241] Sagnac,[242] and Townsend.[243] The results obtained by these observers have already been discussed (§ 17).

§ 33. *Nature of Röntgen Rays.*—Whether Röntgen rays are a form of light, that is, are some form of electro-magnetic disturbance propagated through the ether, is a question on which at present the evidence is not quite decisive. They resemble light in their rectilinear propagation. They affect a photographic plate, and, as Brandes and Dorn [245] have shown, they produce an effect, though a small one, on the retina, giving rise to a very faint illumination of the whole field of view. They resemble light in not being deflected by either electric or magnetic forces, while the secondary rays, of small penetrating power, produced by the incidence of the more penetrating primary rays, may be compared with the fluorescent visible light given out by certain substances when illuminated with ultra-violet light. The absence of refraction is not an argument against the rays being a kind of light, for all theories of refraction make this property depend upon the relation between the period of vibration, T, of the refracting substance, and the period t of the light vibrations, the refraction vanishing when T/t is very small. Thus there would be no refraction for light of very small period, and this would also be true if instead of regular periodic undulations we have a pulse of electro-magnetic disturbance, provided the time taken by light to travel over the thickness of the pulse be small compared with the periods of vibration of the molecules of the refracting substance. The absence of polarization in Röntgen rays after passing through tourmaline is again not decisive; the structure of tourmaline may be too coarse to produce polarization by absorption in waves of such small wave-length, or of such thin pulses as we must, if we accept this view, regard as forming Röntgen rays. The difficulties of experiments on the diffraction of these rays are very great, apart from those which would be caused by the smallness of the wave-length or the thinness of the pulse. The secondary radiation produced when the rays strike against the photographic plate or pass through air might give rise to what might easily be mistaken for diffraction effects. Röntgen [246] has never succeeded in observing effects which prove the existence of diffraction. Fomm [247] observed, in the photograph of a narrow slit, light and dark bands which look like diffraction bands, but observations with slits of different sizes showed that they were not of this nature, and Haga and Wind [248] have explained them as contrast effects. The last two observers, however, noticed with a very narrow wedge-shaped slit a broadening of the image of the narrow part which they are satisfied could not be explained by the causes previously mentioned, and which they regard as conclusive proof of diffraction. Other observations on this point have been made by Maier.[249] We may sum up our present state of knowledge by saying that while there is nothing in the properties of these waves inconsistent with their being a form of light, the direct experimental proof of this result is not very strong. Sir George Stokes [250] has put forward the view that the disturbances which constitute them are not regular periodic undulations, but very thin pulses. The writer [251] has shown that when charged particles are suddenly stopped, pulses of very intense electric and magnetic disturbance are started; as the cathode rays consist of negatively electrified particles, the impact of these on a solid would give rise to these intense pulses. Electromagnetic theory thus shows that effects resembling light in being electro-magnetic disturbances propagated through the ether must be produced when the cathode rays strike against an obstacle. Since under these circumstances Röntgen rays are produced, it seems natural, unless direct evidence to the contrary is obtained, to connect the Röntgen rays with these pulses.

Absorption of Röntgen Rays.—Though as a rule dense bodies absorb Röntgen rays more powerfully than light ones, there does not appear to be that simple connexion between density and absorption which Lenard has shown to exist in the case of the Lenard rays. For the latter the absorption by slabs of different substances is the same, independent of the nature and physical condition of the substance, if the thickness of the slab is inversely proportional to the density of the substance. For the Röntgen rays Benoist [252] gives the following numbers for the absorption by slabs whose thicknesses are inversely proportional to their densities:—

Pt.	Pd.	Ag.	Cu.	Sn.	Mica.	Glass.	Al.	P.	Air. SO_2. CH_3Cl.
·81	·83	·75	·60	·74	·13	·26	·09	.1	·14

We do not know yet whether the proportion between the absorption of different substances is the same for the more penetrating rays as for those easily absorbed, and it is quite possible that the numbers in the preceding table only hold for one particular kind of ray. Gladstone and Hibbert,[253] Humphreys,[254] Novak and Sale,[255] have shown that the absorption of a compound is equal to the sum of the absorptions due to its components.

Apparatus for producing Röntgen Rays.—The tube now used most frequently for producing Röntgen rays is of the kind introduced by Porter,[256] and known as a focus tube (Fig. 34). The cathode is a portion of a hollow sphere, and the cathode rays come to a point on or near a metal plate A, connected with the anode; this plate is the source of the rays. The walls of the tube get strongly electrified. This electrification affects the working of the tube, and the production of rays can often be improved by having an earth-connected piece of tin-foil on the outside of the bulb, and moving it about until the best position is attained. To produce the discharge an induction coil is generally employed. Recently an interrupter called Wehnelt's [257] interrupter (though it was used by Spottiswoode many years ago) has been much used. One of its forms is shown in Fig. 35. A pointed platinum terminal forms the cathode, while the anode consists of a large lead plate. These are placed in a vessel containing dilute sulphuric acid, and an electromotive force of about 50 volts is applied to the terminals. In consequence there is a vigorous development of gas at the cathode, and the bubbles, interrupting the continuity of the circuit from the electrode to the electrolyte, render the current

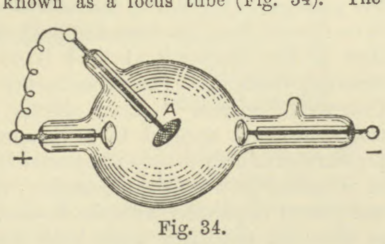

Fig. 34.

intermittent. With this device a very rapid rate of intermission can be obtained with large currents, but its use is apt to curtail the life of the bulb; there is also considerable waste of platinum in the interrupter, which is dissipated as fine powder from the cathode, and remains suspended in the electrolyte.

Phosphorescent Screens.—Screens which become fluorescent under the influence of the Röntgen rays are generally made of platino-cyanides; that of potassium is very efficacious, but others can be used. Scheelite prepared in a particular way is sometimes employed. Though bodies which fluoresce under the Röntgen rays generally do so under Lenard rays, yet according to Precht,[258] there are substances which fluoresce brightly under the latter which only do so to a very slight extent under the former.

§ 34. *Scattering of the Negative Electrodes.*—In addition to the cathode rays, portions of metal start normally from the cathode and form a metallic deposit on the walls of the tube. The amount of this deposit varies very much with the metal. Crookes[259] found that the quantities of metal torn from electrodes of the same size, in equal times, by the same current, are in the order Pd, Au, Ag, Pb, Sn, Pt, Cu, Cd, Ni, In, Fe. . . . In air there is very little deposit from an Al cathode, but it is abundant in tubes filled with the monatomic gases, mercury vapour, argon, or helium.[260] The scattering increases as the density of the gas diminishes. The particles of metal are at low pressures deflected by a magnet, though not nearly to the same extent as the cathode rays. According to Grandquist,[261] the loss of weight of the cathode in a given time is proportional to the square of the current; it is therefore not, like the loss of the cathode in ordinary electrolysis, proportional to the quantity of current which passes through it.

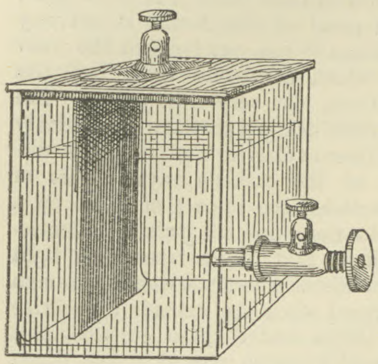

Fig. 35.

§ 35. *Action of a Magnet on the Discharge.*—The older observations on this point are described in the article ELECTRICITY, *Ency. Brit.* vol. viii. p. 74. More recent experiments have furnished some interesting results. The writer[262] found that with a ring discharge at low pressures a transverse magnetic field stopped the discharge, while a longitudinal one facilitated it. This can be explained by the fact that the ions left behind by one discharge facilitate the passage of the next; the action of the transverse field is to remove the ions from the path of the discharge, while that of the longitudinal field is to restrain them from straying from it. The experiments of Birkeland[263] and Campbell-Swinton[264] have shown that a longitudinal magnetic force applied to a vacuum tube at a very low pressure diminishes to a remarkable degree the difference of potential between the electrodes; thus when a spark gap was placed in parallel with the discharge tube, and adjusted so that the discharge went both across the air gap and through the tube, the length of the air gap when the magnetic field was present could be reduced to a small fraction of the value when the field was absent. Birkeland showed that the great diminution occurred suddenly when the magnetic force at the cathode reached a definite value, depending on the pressure of the gas. Warburg[265] discovered an effect of a magnetic field on the discharge from a small electrode in the neighbourhood of a large one, which was subsequently re-observed by Phillips.[266] When the small electrode is positively electrified and raised to a potential of a few hundred volts, the electricity escaped from it readily when a strong magnetic field was applied, although it insulated well when there was no field; when the small electrode was negatively electrified there was no such effect. This may be due to the velocity of the negative ion being greater than that of the positive, whereby the discharge is carried mainly by the negative ions. When the small electrode is negative, these ions will be shot off from places of strong electric force, and acquiring a high velocity, will consequently be but little affected by a magnet; when the small electrode is positive the negative ions starting from the weak parts of the field, having only a small velocity, will consequently be greatly affected by the magnetic field, and may by it be so concentrated that they form a conducting path and so cause the discharge. Phillips observed that if a discharge is first sent through a tube, then stopped and a strong magnetic field started, a luminous ring discharge appears, which rotates around a line of magnetic force as axis.

(J. J. T.)

VI. Electric Waves.

§ 1. Maxwell proved that on his theory electromagnetic disturbances are propagated as a wave motion through the dielectric, while Lord Kelvin[1] had in 1853 proved from electromagnetic theory that the discharge of a condenser is oscillatory, a result which Feddersen[2] verified by a beautiful series of experiments. The oscillating discharge of a condenser had been inferred by Henry as long ago as 1842 from his experiments on the magnetization produced in needles by the discharge of a condenser. From these two results it follows that electric waves must be passing through the dielectric surrounding a condenser in the act of discharging, but it was not until 1887 that the existence of such waves was demonstrated by direct experiment. This great step was made by Hertz,[3] whose experiments on this subject form one of the greatest contributions ever made to experimental physics. The difficulty which had stood in the way of the observations of these waves was the absence of any method of detecting electrical and magnetic forces, reversed some millions of times per second, and only lasting for an exceedingly short time. This was removed by Hertz, who showed that such forces would produce small sparks between pieces of metal very nearly in contact, and that these sparks were sufficiently regular to be used to detect electric waves and to investigate their properties. Other and more delicate methods have subsequently been discovered, but the results obtained by Hertz with his detector were of such signal importance, that we shall begin our account of experiments on these waves by a description of some of Hertz's more fundamental experiments. To produce the waves he used two forms of vibrator. The first is represented in Fig. 36. A and B are two zinc plates about

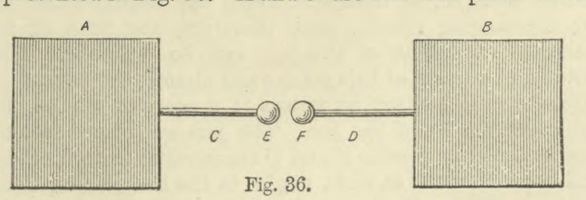

Fig. 36.

40 cm. square; to these brass rods, C,D, each about 30 cm. long, are soldered, terminating in brass balls E and F. To get good results it is necessary that these balls should be very brightly polished, and as they get roughened by the sparks which pass between them it is necessary to repolish them at short intervals; they should be shaded from light and from sparks, or other source of ultra-violet light. In order to excite the waves, C and D are connected to the two poles of an induction coil; sparks cross the air-gap which becomes a conductor, and the charges on the plates oscillate backwards and forwards like the charges on the coatings of a Leyden jar when it is short circuited. The object of polishing the balls and screening off light is to get a sudden and sharp discharge: if the balls are rough there will be sharp points from which the

charge will gradually leak, and the discharge will not be abrupt enough to start electrical vibrations, as these have an exceedingly short period. From the open form of this vibrator we should expect the radiation to be very large and the rate of decay of the amplitude very rapid. Bjerknes[4] found that the amplitude fell to $1/e$ of the original value, after a time 4T where T was the period of the electrical vibrations. Thus after a few vibrations the amplitude becomes inappreciable. To detect the waves produced by this vibrator Hertz used a piece of copper-wire bent into a circle, the ends being furnished with two balls, or a ball and a point connected by a screw, so that the distance between them admitted of very fine adjustment. The radius of the circle for use with the vibrator just described was 35 cm., and was so chosen that the free period of the detector might be the same as that of the vibrator, and the effects in it increased by resonance. It is evident, however, that with a primary system as greatly damped as the vibrator used by Hertz, we could not expect very marked resonance effects, and as a matter of fact the accurate timing of vibrator and detector in this case is not very important. With electrical vibrators which can maintain a large number of vibrations, resonance effects are very striking, as is beautifully shown by the following experiment due to Lodge,[5] whose researches have greatly advanced our knowledge of electric waves. A and C (Fig. 37)

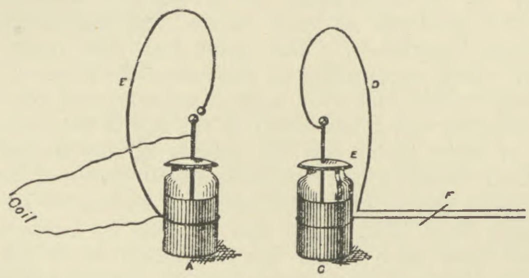

Fig. 37.

are two Leyden jars, whose inner and outer coatings are connected by wires, B and D, bent so as to include a considerable area. There is an air-break in the circuit connecting the inside and outside of one of the jars, A, and electrical oscillations are started in A by joining the inside and outside with the terminals of a coil or electrical machine. The circuit in the jar C is provided with a sliding piece, F, by means of which the self-induction of the discharging circuit, and, therefore, the time of an electrical oscillation of the jar, can be adjusted. The inside and outside of this jar are put almost, but not quite, into electrical contact by means of a piece of tin-foil, E, bent over the lip of the jar. The jars are placed face to face so that the circuits B and D are parallel to each other, and approximately at right angles to the line joining their centres. When the electrical machine is in action sparks pass across the air-break in the circuit in A, and by moving the slider F it is possible to find one position for it in which sparks pass from the inside to the outside of C across the tin-foil, while when the slider is moved a short distance on either side of this position the sparks cease.

Hertz found that when he held his detector in the neighbourhood of the vibrator minute sparks passed between the balls. These sparks were not stopped when a large plate of non-conducting substance, such as the wall of a room, was interposed between the vibrator and detector, but a large plate of very thin metal stopped them completely.

To illustrate the analogy between electric waves and waves of light Hertz found another form of apparatus more convenient. The vibrator consisted of two equal brass cylinders, 12 cm. long and 3 cm. in diameter, placed with their axes coincident, and in the focal line of a large zinc parabolic mirror about 2 metres high, with a focal length of 12·5 cm. The ends of the cylinders nearest each other, between which the sparks passed, were carefully polished. The detector, which was placed in the focal line of an equal parabolic mirror, consisted of two lengths of wire, each having a straight piece about 50 cm. long and a curved piece about 15 cm. long bent round at right angles so as to pass through the back of the mirror. The ends which came through the mirror were connected with a spark micrometer, the sparks being observed from behind the mirror. The mirrors are shown in Fig. 38.

§ 2. *Reflexion and Refraction.*—To show the reflexion of the waves Hertz placed the mirrors side by side, so that their openings looked in the same direction, and their axes

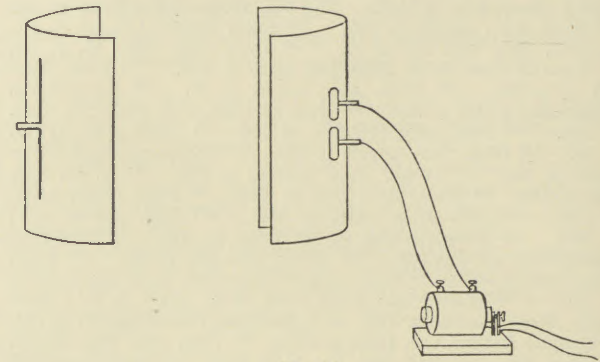

Fig. 38.

converged at a point about 3 m. from the mirrors. No sparks were then observed in the detector when the vibrator was in action. When, however, a large zinc plate about 2 m. square was placed at right angles to the line bisecting the angle between the axes of the mirrors sparks became visible, but disappeared again when the metal plate was twisted through an angle of about 15° to either side. This experiment showed that electric waves are reflected, and that, approximately at any rate, the angle of incidence is equal to the angle of reflexion. To show refraction Hertz used a large prism made of hard pitch, about 1·5 m. high, with a slant side of 1·2 m. and an angle of 30°. When the waves from the vibrator passed through this the sparks in the detector were not excited when the axes of the two mirrors were parallel, but appeared when the axis of the mirror containing the detector made a certain angle with the axis of that containing the vibrator. When the system was adjusted for minimum deviation the sparks were most vigorous, when the angle between the axes of the mirrors was 22°. This corresponds to an index of refraction of 1·69.

§ 3. *Analogy to a Plate of Tourmaline.*—If a screen be made by winding wire round a large rectangular framework, so that the turns of the wire are parallel to one pair of sides of the frame, and if this screen be interposed between the parabolic mirrors when placed so as to face each other, there will be no sparks in the detector when the turns of the wire are parallel to the focal lines of the mirror; but if the frame is turned through a right angle so that the wires are perpendicular to the focal lines of the mirror the sparks will recommence. If the framework is substituted for the metal plate in the experiment on the reflexion of electric waves, sparks will appear in the detector when the wires are parallel to the focal lines of the mirrors, and will disappear when the wires are at right angles to these lines. Thus the framework reflects but does not transmit the waves when the electric force in them is parallel to the wires, while it transmits but does not reflect waves in which the electric force is at right angles to the wires.

The wire framework behaves towards the electric waves exactly as a plate of tourmaline does to waves of light. Du Bois and Rubens,[6] by using a framework wound with very fine wire placed very close together, have succeeded in polarizing waves of radiant heat, whose wave length, although longer than that of ordinary light, is very small compared with that of electric waves.

§ 4. *Angle of Polarization.*—When light polarized at right angles to the plane of incidence falls on a refracting substance at an angle $\tan^{-1}\mu$, where μ is the refractive index of the substance, all the light is refracted and none reflected; whereas when light is polarized in the plane of incidence some of the light is always reflected whatever the angle of incidence. Trouton[7] has shown that similar effects take place with electric waves. From a paraffin wall 3 feet thick, reflexion always took place when the electric force in the incident wave was at right angles to the plane of incidence, whereas at a certain angle of incidence there was no reflexion when the vibrator was turned, so that the electric force was in the plane of incidence. This shows that on the electromagnetic theory of light the electric force is at right angles to the plane of polarization.

§ 5. *Stationary Electrical Vibrations.*—Hertz[8] made his experiments on these in a large room about 15 m. long. The vibrator, which was of the type first described, was placed at one end of the room, its plates being parallel to the wall, at the other end a piece of sheet zinc about 4 m. by 2 m. was placed vertically against the wall. The detector—the circular ring previously described—was held so that its plane was parallel to the metal plates of the vibrator, its centre on the line at right angles to the metal plate, bisecting at right angles the spark gap of the vibrator, and with the spark gap of the detector parallel to that of the vibrator. The following effects were observed when the detector was moved about. When it was close up to the zinc plate there were no sparks, but they began to pass feebly as soon as it was moved forward a little way from the plate, and increased rapidly in brightness until it was about 1·8 m. from the plate when they attained their maximum. When its distance was still further increased they diminished in brightness, and vanished again at a distance of about 4 m. from the plate. When the distance was still further increased they reappeared, attained another maximum, and so on. They thus exhibited a remarkable periodicity similar to that which occurs when stationary vibrations are produced by the interference of direct waves with those reflected from a surface placed at right angles to the direction of propagation. Similar periodic alterations in the spark were observed by Hertz when the waves, instead of passing freely through the air and being reflected by a metal plate at the end of the room, were led along wires, as in the arrangement shown in Fig. 39. L and K are metal plates placed parallel to the plates of the vibrator, long parallel wires being attached to act as guides to the waves which were reflected from the isolated end. (Hertz only used one plate and one wire, but the double set of plates and wires introduced by Sarasin and De la Rive make the results more definite.) In this case the detector is best placed so that its plane is at right angles to the wires, while the air space is parallel to the plane containing the wires. The sparks instead of vanishing when the detector is at the far end of the wire are a maximum in this position, but wax and wane periodically as the detector is moved along the wires. The most obvious interpretation of these experiments was the one given by Hertz—that there was interference between the direct waves given out by the vibrator and those reflected either from the plate or from the ends of the wire, this interference giving rise to stationary waves. The places where the electric force was a maxima were the places where the sparks were brightest, and the places where the electric force was zero were the places where the sparks vanished. On this explanation the distance between two consecutive places where the sparks vanished would be half the wave length of the waves given out by the vibrator. Some very interesting experiments made by Sarasin and De la Rive[9] showed that this explanation could not be the true one, since by using detectors of different sizes they found that the distance between two consecutive places where the sparks vanished depended mainly upon the size of the detector, and very little upon that of the vibrator. With small detectors they found the distance small, with large detectors, large; in fact it is directly proportional to the diameter of the detector. We can see that this result is a consequence of the large damping of the oscillations of the vibrator and the very small damping of those of the detector. Bjerknes showed that the time taken for the amplitude of the vibrations of the vibrator to sink to $1/e$ of their original value was only 4T, while for the detector it was 500T′, when T and T′ are respectively the times of vibration of the vibrator and the detector. The rapid decay of the oscillations of the vibrator will stifle the interference between the direct and the reflected wave, as the amplitude of the direct wave will, since it is emitted later, be much smaller than that of the reflected one, and not able to annul its effects completely; while the well-maintained vibrations of the detector will interfere and produce the effects observed by Sarasin and De la Rive. To see this let us consider the extreme case in which the oscillations of the vibrator are absolutely dead-beat. Here an impulse, starting from the vibrator on its way to the reflector, strikes against the detector and sets it in vibration; it then travels up to the plate and is reflected, the electric force in the impulse being reversed by reflexion. After reflexion the impulse again strikes the detector, which is still vibrating from the effects of the first impact; if the phase of this vibration is such that the reflected impulse tends to produce a current round the detector in the same direction as that which is circulating from the effects of the first impact, the sparks will be increased, but if the reflected impulse tends to produce a current in the opposite direction the sparks will be diminished. Since the electric force is reversed by reflexion, the greatest increase in the sparks will take place when the impulse finds, on its return, the detector in the opposite phase to that in which it left it; that is, if the time which has elapsed between the departure and return of the impulse is equal to an odd multiple of half the time of vibration of the detector. If d is the distance of the detector from the reflector when the sparks are brightest, and V the velocity of propagation of electromagnetic disturbance, then $2d/V = (2n+1)(T'/2)$; where n is an integer and T′ the time of vibration of the detector, the distance between two spark maxima will be VT′/2, and the places where the sparks are a minimum will be midway between the maxima. Sarasin and De la Rive found that when the same detector was used the distance between two spark maxima was the same with the waves through air reflected from a metal plate and with those guided by wires and reflected from the free ends of the wire, the inference being that the velocity of waves along wires is the same as that through the air. This result, which as we shall see follows from Maxwell's theory, when the wires are not

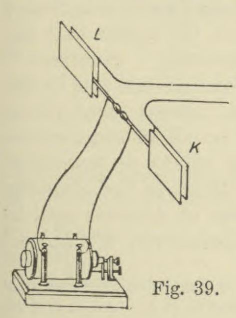

Fig. 39.

too fine, had been questioned by Hertz on account of some of his experiments on wires.

§ 6. *Detectors.*—The use of a detector with a period of vibration of its own thus tends to make the experiments more complicated, and many other forms of detector have been employed by subsequent experimenters. For example, in place of the sparks in air the luminous discharge through a rarefied gas has been used by Dragoumis,[10] Lecher [11] (who used tubes without electrodes laid across the wires in an arrangement resembling that shown in Fig. 42); and Arons.[12] Zehnder [13] used an exhausted tube to which an external electromotive force almost but not quite sufficient of itself to produce a discharge was applied; here the additional electromotive force due to the waves was sufficient to start the discharge. Detectors depending on the heat produced by the rapidly alternating currents have been used by Paalzow and Rubens,[14] Rubens and Ritter,[15] and Klemencic.[16] Rubens measured the heat produced by a bolometer arrangement, and Klemencic used a thermo-electric method for the same purpose. Boltzmann [17] used an electroscope as a detector. The spark gap consisted of a ball and a point, the ball being connected with the electroscope and the point with a battery of 200 dry cells. When the spark passed the cells charged up the electroscope. Ritter [18] utilized the contraction of a frog's leg as a detector, Lucas and Garrett [19] the explosion produced by the sparks in an explosive mixture of hydrogen and oxygen; while Bjerknes [20] and Franke [21] used the mechanical attraction between oppositely charged conductors. If the two sides of the spark gap are connected with the two pairs of quadrants of a very delicate electrometer, the needle of which is connected with one pair of quadrants, there will be a deflexion of the electrometer when the detector is struck by electric waves. A very efficient detector, indeed by far the simplest and best for metrical work, is that invented by Rutherford [22]; it consists of a bundle of fine iron wires magnetized to saturation and placed inside a small magnetizing coil, through which the electric waves cause rapidly alternating currents to pass which demagnetize the soft iron. If the instrument is used to detect waves in air, long straight wires are attached to the ends of the demagnetizing coil to collect the energy from the field; to investigate waves in wires it is sufficient to make a loop or two in the wire and place the magnetized piece of iron inside it. The amount of demagnetization, which can be observed by the change in the deflexion of a magnetometer placed near the iron, measures the intensity of the electric waves, and very accurate determinations can be made with ease with this apparatus. It is also very delicate, though in this respect it does not equal the detector to be next described, the coherer; Rutherford got indications in 1895 when the vibrator was $\frac{3}{4}$ of a mile away from the detector, and where the waves had to traverse a thickly populated part of Cambridge. It can also be used to measure the coefficient of damping of the electric waves, for since the wire is initially magnetized to saturation, if the direction of the current when it first begins to flow in the magnetizing coil is such as to tend to increase the magnetization of the wire, it will produce no effect, and it will not be until the current is reversed that the wire will lose some of its magnetization. The effect then gives the measure of the intensity half a period after the commencement of the waves. If the wire is put in the coil the opposite way, *i.e.*, so that the magnetic force due to the current begins at once to demagnetize the wire, the demagnetization gives a measure of the initial intensity of the wave. Comparing this result with that obtained when the wires were reversed, we get the coefficient of damping.

§ 7. *Coherers.* — The most sensitive detector of electric waves is the "coherer," although for metrical work it is not so suitable as that just described. It depends upon the fact discovered by Branly,[23] that the resistance between loose metallic contacts, such as a pile of iron turnings, diminishes when they are struck by an electric wave. One of the forms made by Lodge [24] on this principle consists simply of a glass tube containing iron turnings, in contact with which are wires led into opposite ends of the tube. The arrangement is placed in series with a galvanometer (one of the simplest kind will do) and a battery; when the iron turnings are struck by electric waves their resistance is diminished and the deflexion of the galvanometer is increased. Thus the deflexion of the galvanometer can be used to indicate the arrival of electric waves. The tube must be tapped between each experiment, and the deflexion of the galvanometer brought back to about its original value. This detector is marvellously delicate, but not metrical, the change produced in the resistance depending upon so many things besides the intensity of the waves, that the magnitude of the galvanometer deflexion is to some extent a matter of chance. Instead of the iron turnings we may use two iron wires, one resting on the other; the resistance of this contact will be altered by the incidence of the waves. To get greater regularity Bose [25] uses instead of the iron turnings spiral springs, which are pushed against each other by means of a screw until the most sensitive state is attained. The sensitiveness of the coherer depends on the electromotive force put in the galvanometer circuit. Very sensitive ones can be made by using springs of very fine silver wire coated electrolytically with nickel. Though the impact of electric waves generally produces a diminution of resistance with these loose contacts, yet there are exceptions to the rule. Thus Branly [26] showed that with lead oxide, PbO_2, there is an increase in resistance. Aschkinass [27] proved the same to be true with copper sulphide, CuS; and Bose [28] has shown that with potassium there is an increase of resistance and great power of self-recovery of the original resistance after the waves have ceased. Several theories of this action have been proposed. Branly (*loc. cit.*) thought that the small sparks which certainly pass between adjacent portions of metal cleared away layers of oxide or some other kind of non-conducting film, and in this way improved the contact. It would seem that if this theory is true the films must be of a much more refined kind than layers of oxide or dirt, for the coherer effect has been observed with clean non-oxidizable metals. Lodge (*loc. cit.*) explains the effect by supposing that the heat produced by the sparks fuses adjacent portions of metal into contact and hence diminishes the resistance; it is from this view of the action that the name coherer is applied to the detector. Auerbeck [29] thought that the effect was a mechanical one due to the electrostatic attractions between the various small pieces of metal. It is probable that some or all of these causes are at work in some cases, but the effects of potassium make us hesitate to accept any of them as the complete explanation. The coherer is the form of detector used in telegraphy without wires. (See TELEGRAPHY, WIRELESS.)

Bose [30] has designed an instrument which generates electric waves with a length of not more than a centimetre or so, and therefore allows their properties to be demonstrated with apparatus of moderate dimensions. The waves are excited by sparking between two platinum beads carried by jointed electrodes; a platinum sphere is placed between the beads, and the distance between the beads and the sphere can be adjusted by bending the electrodes. The diameter of the sphere is 8 mm., and the wave length of the shortest electrical waves generated is said to be about 6 mm. The beads are connected with the terminals of a small induction coil, which, with the battery to work it and the sparking arrangement, are enclosed in a metal box, the radiation passing out through a metal tube opposite to the spark gap. The ordinary vibrating break of the coil is not used, a single spark made by making and breaking the circuit by means of a button outside the box being employed instead. The detector is one of the spiral spring coherers previously described; it is shielded from external disturbance by

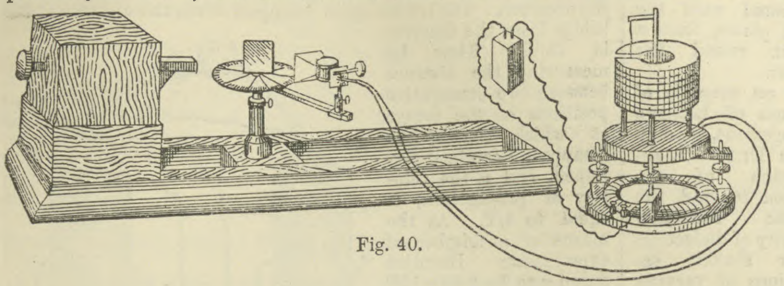

Fig. 40.

being enclosed in a metal box provided with a funnel-shaped opening to admit the radiation. The wires leading from the coherers to the galvanometer are also surrounded by metal tubes to protect them from stray radiation. The radiating apparatus and the receiver are mounted on stands sliding in an optical bench. If a parallel beam of radiation is required, a cylindrical lens of ebonite or sulphur is mounted in a tube fitting on to the radiator tube and stopped by a guide when the spark is at the principal focal line of the lens. For experiments requiring angular measurements a spectrometer circle is mounted on one of the sliding stands, the receiver being carried on a radial arm and pointing to the centre of the circle. The arrangement is represented in Fig. 40.

With this apparatus the laws of reflexion, refraction, and polarization can readily be verified, and also the double refraction of crystals, and of bodies possessing a fibrous or laminated structure such as jute or books. (The double refraction of electric waves seems first to have been observed by Righi,[31] and other researches on this subject have been made by Garbasso[32] and Mack.[33]) Bose[34] showed the rotation of the plane of polarization by means of pieces of twisted jute rope; if the pieces were arranged so that their twists were all in one direction and placed in the path of the radiation, they rotated the plane of polarization in a direction depending upon the direction of twist; if they were mixed so that there were as many twisted in one direction as the other, there was no rotation.

A series of experiments showing the complete analogy between electric and light waves is described by Righi in his book *L'Ottica delle Oscillazioni Elettriches.* Righi's exciter, which is especially

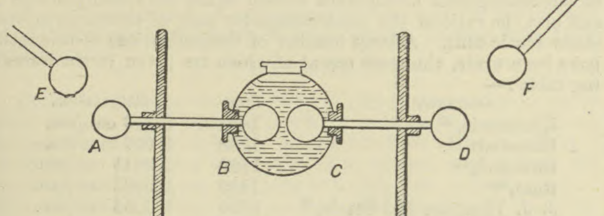

Fig. 41.

convenient when large statical electric machines are used instead of induction coils, is shown in Fig. 41. E and F are balls con-

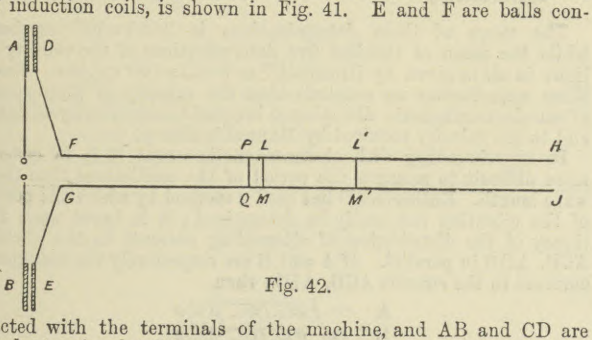

Fig. 42.

nected with the terminals of the machine, and AB and CD are conductors insulated from each other, the ends B, C, between which the sparks pass, being immersed in vaseline oil. The period of the vibrations given out by the system is adjusted by means of metal plates M and N attached to AB and CD.

§ 8. *Waves in Wires.*—Many problems on electric waves along wires can readily be investigated by a method due to Lecher,[35] and known as Lecher's bridge, which furnishes us with a means of dealing with waves of a definite and determinable wave-length. In this arrangement (Fig. 42) two large plates A and B are, as in Hertz's exciter, connected with the terminals of an induction coil; opposite these and insulated from them are two smaller plates D, E, to which ·ng parallel wires DFH, EGJ are attached. These wires are bridged across by a wire LM, and their farther ends H, J, may be insulated, or connected together, or with the plates of a condenser. To detect the waves in the circuit beyond the bridge, Lecher used an exhausted tube placed across the wires, and Rubens a bolometer, but Rutherford's detector is the most convenient and accurate. If this detector is placed in a fixed position at the end of the circuit, it is found that the deflexions of this detector depend greatly upon the position of the bridge

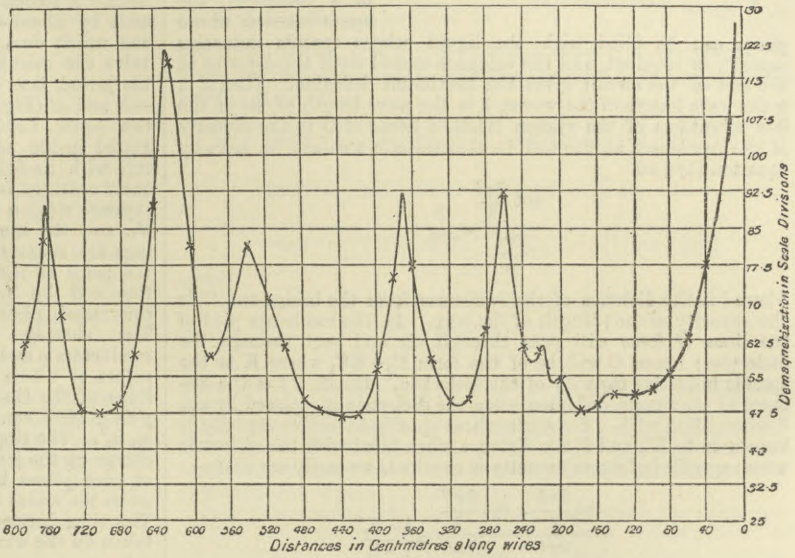

Fig. 43.

LM, rising rapidly to a maximum for some positions, and falling rapidly away when the bridge is displaced. As the bridge is moved from the coil end towards the detector the deflexions show periodic variations, such as are represented in Fig. 43 when the ordinates represent the deflexions of the detector and the abscissæ the distance of the bridge from the ends D, E. The maximum deflexions of the detector correspond to the positions in which the two circuits DFLMGE, HLMJ (in which the vibrations are but slightly damped), are in resonance. For since the self-induction and resistance of the bridge LM is very small compared with that of the circuit beyond, it follows from the theory of circuits in parallel that only a small part of the current will in general flow round the longer circuit; it is only when the two circuits DFLMGE, HLMJ are in resonance that a considerable current will flow round the latter. Hence when we get a maximum effect in the detector we know that the waves we are dealing with are those corresponding to the free periods of the system HLMJ, so that if we know the free periods of this circuit we know the wave length of the electric waves under consideration. Thus if the ends of the wires H, J are free and have no capacity, the current along them must vanish at H and J, which must be in opposite electric condition. Hence half the wave length must be an odd submultiple of the length of the circuit HLMJ. If H and J are connected together the wave length must be a submultiple of the length of this circuit. When the capacity at the ends is appreciable the wave length of the circuit is determined by a somewhat complex expression (see § 30). To facilitate the determination of the wave length in such cases, Lecher introduced a second bridge L'M', and moved this about until the deflexion of the detector was a maximum; when this occurs the wave length is one of those corresponding to the closed circuit LMM'L', and must therefore be a submultiple of the length of the circuit. Lecher showed that if instead of using a single wire LM to form the bridge, he used two parallel wires PQ, LM, placed close together, the currents in the further circuit were hardly appreciably diminished when the main wires were cut between PL and QM. Blondlot[36] used a modification of this apparatus better suited for the production of short waves. In his form (Fig. 44) the exciter consists of two semicircular arms connected with the terminals of an induction coil, and the long wires, instead of being connected with the small plates, form a circuit round the exciter.

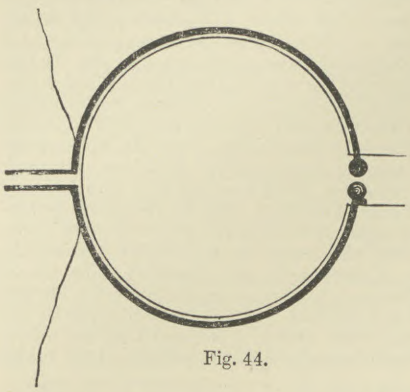

Fig. 44.

As an example of the use of Lecher's arrangement, we may quote Drude's[37] application of the method to find the specific induction capacity of dielectrics under electric oscillations of varying frequency. In this application the ends of the wire are connected to the plates of a condenser, the space between whose plates can be filled with the liquid whose specific inductive capacity is required, and the bridge is moved until the detector at the end of the circuit gives the maximum deflexion. Then if λ is the wave length of the waves, λ is the wave length of one of the free vibrations of the system HLMJ; hence if C is the capacity of the condenser at the end in electrostatic measure we have by equation (1) § 30

$$\frac{\cot\frac{2\pi l}{\lambda}}{\frac{2\pi l}{\lambda}} = \frac{C}{C'l}$$

where l is the distance of the condenser from the bridge and C′ is the capacity of unit length of the wire. In the condenser part of the lines of force will pass through air and part through the dielectric; hence C will be of the form $C_0 + KC_1$ where K is the specific inductive capacity of the dielectric. Hence if l is the distance of maximum deflexion when the dielectric is replaced by air, l' when filled with a dielectric whose specific inductive capacity is known to be K′, and l'' the distance when filled with the dielectric whose specific inductive capacity is required, we easily see that—

$$\frac{\cot\frac{2\pi l}{\lambda} - \cot\frac{2\pi l'}{\lambda}}{\cot\frac{2\pi l}{\lambda} - \cot\frac{2\pi l''}{\lambda}} = \frac{1-K'}{1-K}$$

an equation by means of which K can be determined. It was in this way that Drude investigated the specific inductive capacity with varying frequency, and found a falling off in the specific inductive capacity with increase of frequency when the dielectrics contained the radicle OH. In another method used by him[38] the wires were led through long tanks filled with the liquid whose specific inductive capacity was required; the velocity of propagation of the electric waves along the wires in the tank being the same as the velocity of propagation of an electromagnetic disturbance through the liquid filling the tank, if we find the wave length of the waves along the wires in the tank, due to a vibration of a given frequency, and compare this with the wave lengths corresponding to the same frequency when the wires are surrounded by air, we obtain the velocity of propagation of electromagnetic disturbance through the fluid, and hence the specific inductive capacity of the fluid.

§ 9. *Velocity of Propagation of Electromagnetic Effects through Air.*—The experiments of Sarasin and De la Rive already described (see § 5) have shown that, as theory requires, the velocity of propagation of electric effects through air is the same as along wires. The same result had been arrived at by the writer,[39] although from the method he used greater differences between the velocities might have escaped detection than was possible by Sarasin and De la Rive's method. The velocity of waves along wires has been directly determined by Blondlot[40] by two different methods. In the first the detector consisted of two parallel plates about 6 cm. in diameter placed a fraction of a millimetre apart, and forming a condenser whose capacity C was determined in electromagnetic measure by Maxwell's method. The plates were connected by a rectangular circuit whose self-induction L was calculated from the dimensions of the rectangle and the size of the wire. The time of vibration T is equal to $2\pi\sqrt{LC}$. (The wave length corresponding to this time is long compared with the length of the circuit, so that the use of this formula is legitimate.) This detector is placed between two parallel wires, and the waves produced by the exciter are reflected from a movable bridge. When this bridge is placed just beyond the detector vigorous sparks are observed, but as the bridge is pushed away a place is reached where the sparks disappear; this place is distance $\lambda/4$ from the detector, when λ is the wave length of the vibration given out by the detector. The sparks again disappear when the distance of the bridge from the detector is $3\lambda/4$. Thus by measuring the distance between two consecutive positions of the bridge at which the sparks disappear λ can be determined, and v, the velocity of propagation, is equal to λ/T. As the means of a number of experiments Blondlot found v to be $3{\cdot}02 \times 10^{10}$ cm./sec. which, within the errors of experiment, is equal to 3×10^{10} cm./sec., the velocity of light. A second method used by Blondlot,[41] and one which does not involve the calculation of the period, is as follows:—A and A′ (Fig. 45) are two equal Leyden jars coated inside and outside with tin-foil. The outer coatings form two separate rings a, a_1; a', a'_1, and the inner coatings are connected with the poles of the induction coil by means of the metal pieces b, b'. The sharply pointed conductors p and p', the points of which are about ½ mm. apart, are connected with the rings of the tin-foil a and a', and two long copper wires pca_1, $p'c'a'_1$, 1029 cm. long connect these points with the other rings a_1, a_1'. The rings aa', a_1a_1', are connected by wet strings so as to charge up the jars. When a spark passes between b and b', a spark at once passes between pp', and this is followed by another spark when the waves travelling by the paths $a_1\,cp$, $a_1'c'p'$ reach p and p'. The time between the passage of these sparks, which is the time taken by the waves to travel 1029 cm., was observed by means of a rotating mirror, and the velocity measured in 15 experiments varied between $2{\cdot}92 \times 10^{10}$ and $3{\cdot}03 \times 10^{10}$ cm./sec., thus agreeing well with that deduced by the preceding method. Other determinations of the velocity of electromagnetic propagation have been made by Lodge and Glazebrook,[42] and by Saunders.

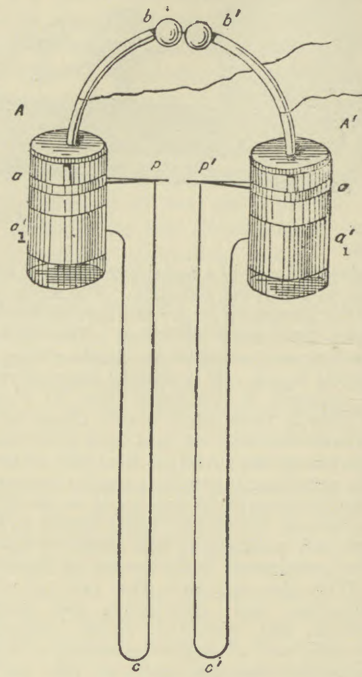

Fig. 45.

On Maxwell's electromagnetic theory the velocity of propagation of electromagnetic disturbance should equal the velocity of light, and also the ratio of the electromagnetic unit of electricity to the electrostatic unit. A large number of determinations of this ratio have been made, the more recent of which are given in the following table:—

Observer.	Date.	Ratio $10^{10}\times$.
Klemencic,[43]	1884	3·019 cm./sec.
Himstedt,[44]	1888	3·009 cm./sec.
Rowland,[45]	1889	2·9815 cm./sec.
Rosa,[46]	1889	2·9993 cm./sec.
J. J. Thomson and Searle,[47]	1890	2·9955 cm./sec.
Webster,[48]	1891	2·987 cm./sec.
Pellat,[49]	1891	3·009 cm./sec.
Abraham,[50]	1892	2·992 cm./sec.
Hurmuzescu,[51]	1895	3·002 cm./sec.

The mean of these determinations is $3{\cdot}001 \times 10^{10}$ cm./sec., while the mean of the last five determinations of the velocity of light in air is given by Himstedt[52] as $3{\cdot}002 \times 10^{10}$ cm./sec. From these experiments we conclude that the velocity of propagation of an electromagnetic disturbance is equal to the velocity of light, and to the velocity required by Maxwell's theory.

In experimenting with electromagnetic waves it is in general more difficult to measure the period of the oscillations than their wave length. Rutherford[53] has used a method by which the period of the vibration can easily be determined; it is based upon the theory of the distribution of alternating currents in two circuits ACB, ADB in parallel. If A and B are respectively the maximum currents in the circuits ACB, ADB, then

$$\frac{A}{B} = \sqrt{\frac{S^2+(N-M)^2p^2}{R^2+(L-M)^2p^2}}$$

when R and S are the resistances, L and N the coefficients of self-induction of the circuits ACB, ADB respectively, M the coefficient of mutual induction between the circuits, and p the frequency of the currents. Rutherford detectors were placed in the two circuits, and the circuits adjusted until they showed that A=B; when this is the case

$$p^2=\frac{R^2-S^2}{N^2-L^2-2M(N-L)}.$$

If we make one of the circuits, ADB, consist of a short length of a high liquid resistance, so that S is large and N small, and the other circuit ACB of a low metallic resistance bent to have considerable self-induction, the preceding equation becomes approximately $p=S/L$, so that when S and L are known p is readily determined.

Theory of Some Simple Cases of Electromagnetic Waves.

§ 10. *Equations of the Electromagnetic Field when the Medium is at Rest.*—Faraday's law of the induction of currents in a variable magnetic field (viz., that the electromotive force taken round a closed circuit is equal to the rate of diminution in the number of lines of magnetic induction passing through the circuit), when expressed analytically, leads to the three equations

$$\left.\begin{aligned}-\frac{da}{dt}&=\frac{dZ}{dy}-\frac{dY}{dz}\\ -\frac{db}{dt}&=\frac{dX}{dz}-\frac{dZ}{dx}\\ -\frac{dc}{dt}&=\frac{dY}{dx}-\frac{dX}{dy}\end{aligned}\right\}\text{A},$$

where X, Y, Z are the components of the electric intensity parallel to the axes of x, y, z respectively, and a, b, c are the components of the magnetic induction. The vector whose components are $\frac{dZ}{dy}-\frac{dY}{dz}$, $\frac{dX}{dz}-\frac{dZ}{dx}$, $\frac{dY}{dx}-\frac{dX}{dy}$ is often called the curl of the vector whose components are X, Y, Z; thus if B is the magnetic induction and E the electric force, we may write equations A in the form

$$\frac{dB}{dt}=-\text{cl. E},$$

where cl. E denotes the curl of the vector E. Another fundamental law of electromagnetic action is that the work done on a unit pole travelling round any closed circuit is equal to 4π times the current passing through the circuit, whatever the nature of the substances through which the circuit passes: the analytical expression of this law is

$$\left.\begin{aligned}4\pi u&=\frac{d\gamma}{dy}-\frac{d\beta}{dz}\\ 4\pi v&=\frac{da}{dz}-\frac{d\gamma}{dx}\\ 4\pi w&=\frac{d\beta}{dx}-\frac{da}{dy}\end{aligned}\right\}\text{B},$$

where u, v, w are the components of the electric current, and a, β, γ the components of the magnetic force. If i is the current, H the magnetic force (i and H being vectors), we may write these equations as

$$4\pi i=\text{cl. H}.$$

The electric current contemplated in this law may arise in one or other of three ways:—it may be wholly or in part an ordinary conduction current obeying Ohm's law, such as flows through metals or electrolytes, or it may be a convection current arising from the motion of charged ions, or it may be a dielectric current which on Maxwell's theory exists whenever the electric field is changing. In order that all currents may flow in closed circuits, which is essential on Maxwell's theory, the magnitude of the dielectric current must be $\frac{K}{4\pi}\frac{dE}{dt}$; hence if σ is the specific resistance of the medium we have

$$i=\frac{E}{\sigma}+\frac{K}{4\pi}\frac{dE}{dt}+\Sigma qe,$$

where e is the charge on an ion and q its velocity (q is to be regarded as a vector), while Σ denotes the sum of the product of these quantities for all the ions in the field.

§ 11. We shall begin with the case of an insulating medium in which there are no ions; in this case $i=\frac{K}{4\pi}\frac{dE}{dt}$, and equations B become

$$\left.\begin{aligned}K\frac{dX}{dt}&=\frac{d\gamma}{dy}-\frac{d\beta}{dz}\\ K\frac{dY}{dt}&=\frac{da}{dz}-\frac{d\gamma}{dx}\\ K\frac{dZ}{dt}&=\frac{d\beta}{dx}-\frac{da}{dy}\end{aligned}\right. \quad . \quad . \quad . \quad . \quad (1).$$

If μ is the magnetic permeability, and if the variable magnetization is entirely induced, we may put $a, b, c=\mu(a, \beta, \gamma)$, and from equations A and (1) on elimination of X, Y, Z, remembering that

$$\frac{da}{dx}+\frac{d\beta}{dy}+\frac{d\gamma}{dz}=0$$

$$\frac{dX}{dx}+\frac{dY}{dy}+\frac{dZ}{dz}=0,$$

we get

$$\mu K\frac{d^2a}{dt^2}=\frac{d^2a}{dx^2}+\frac{d^2a}{dy^2}+\frac{d^2a}{dz^2}.$$

We have equations of precisely the same form for β, γ, and X, Y, Z; hence these quantities all satisfy Poisson's equation [54]

$$\frac{1}{v^2}\frac{d^2\phi}{dt^2}=\frac{d^2\phi}{dx^2}+\frac{d^2\phi}{dy^2}+\frac{d^2\phi}{dz^2} \quad . \quad . \quad . \quad (2),$$

which is known to represent an effect propagated with a velocity v through the medium, hence changes in magnetic and electric force travel through the medium with the finite velocity $1/\sqrt{\mu K}$.

If the electric disturbance travels as a plane wave, so that X, Y, Z, a, β, γ, are proportional to $\epsilon^{\iota\frac{2\pi}{\lambda}(vt-(lx+my+nz))}$ where λ is the wave length, l, m, n, the direction cosines of the normal to the wave front, and $v=1/\sqrt{\mu K}$, then we have from equations (A) and (1), if $p=2\pi v/\lambda$

$$\iota p\mu a=\iota\frac{2\pi}{\lambda}(mZ-nY); \qquad K\iota pX=\iota\frac{2\pi}{\lambda}(n\beta-m\gamma);$$

$$\iota p\mu\beta=\iota\frac{2\pi}{\lambda}(nX-lZ); \qquad K\iota pY=\iota\frac{2\pi}{\lambda}(l\gamma-na);$$

$$\iota\pi\mu\gamma=\iota\frac{2\pi}{\lambda}(lY-mX); \qquad K\iota pZ=\iota\frac{2\pi}{\lambda}(ma-l\beta);$$

hence

$$la+m\beta+n\gamma=0,\ lX+mY+nZ=0,$$

$$aX+\beta Y+\gamma Z=0,$$

$$v\mu H=E,$$

where H is the resistant magnetic force and E the resultant electric force. Hence we see that both the magnetic and electric forces are at right angles to the direction of propagation of the wave, the electric and magnetic forces are at right angles to each other, and the product of the magnetic induction and the velocity of propagation is equal to the electric force.

Poisson's equation takes a very simple form when the solution is periodic and depends only on the distance from a fixed point. If the frequency of the solution is p, and if r is the distance from the point, then since ϕ varies as $\epsilon^{\iota pt}$, $\frac{d^2\phi}{dt^2}=-p^2\phi$, and since ϕ only depends upon r,

$$\frac{d^2\phi}{dx^2}+\frac{d^2\phi}{dy^2}+\frac{d^2\phi}{dz^2}=\frac{d^2\phi}{dr^2}+\frac{2}{r}\frac{d\phi}{dr};$$

hence

$$\frac{d^2\phi}{dr^2}+\frac{2}{r}\frac{d\phi}{dr}+\frac{p^2}{v^2}\phi=0,$$

or

$$\frac{d^2}{dr^2}(r\phi)+\frac{p^2}{v^2}r\phi=0$$

The solution of this equation is

$$r\phi=A\epsilon^{\iota\frac{p}{v}r}+B\epsilon^{-\iota\frac{p}{v}r},$$

or restoring the time factor

$$\phi=A'\frac{\epsilon^{\iota p\left(t+\frac{r}{v}\right)}}{r}+B'\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}.$$

If the waves start from the origin and there is no reflexion the solution will consist of the second term only, as the first term represents a wave travelling towards the origin. When there is reflexion both terms must be retained. Since Poisson's equation is linear if ϕ is a solution, $\frac{d^l}{dx^l}\frac{d^m}{dy^m}\frac{d^n}{dz^n}\phi$ will also be a solution when l, m, n, are positive integers; and starting with this primary solution we may by differentiation arrive at the solution of more complicated problems, just as in electrostatics, starting with $1/r$ as the potential due to a unit charge, we obtain the potential for complex distributions of electricity. In the case of electric waves we substitute $\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}$ for $1/r$.

§ 12. We shall now proceed to consider some special cases of electric waves, taking first a case investigated by Hertz,[55] that of the vibrating electric doublet. By a doublet is meant a system of two equal and oppositely electrified particles placed near together. The direction of the line joining the particles is the axis of the doublet, and the product of one of the charges into the distance between them is its moment. We shall suppose that the moment varies harmonically, and is proportional to the real part of $\epsilon^{\iota pt}$; such a doublet would be produced if we had a positive charge e moving parallel to the axis of z, its distance from the origin being $l \cos pt$, while the distance of the negative charge is $-l \cos pt$. The moment of this doublet is the real part of $m\epsilon^{\iota pt}$ where $m=2le$. For a doublet of constant moment m with its axis along the axis of z, and its centre at the origin, the components X, Y, Z of the electric force at a point at a distance r from the origin are given by the equations

$$X=\frac{m}{K}\frac{d^2}{dxdz}\frac{1}{r},\quad Y=\frac{m}{K}\frac{d^2}{dydz}\frac{1}{r},\quad Z=-\frac{m}{K}\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)\frac{1}{r}.$$

Hence if the moment is $m\epsilon^{\iota pt}$, and if the greatest distance between the charges is small compared with v/p, the components of the electric force due to the vibrating doublet will be given by the equations

$$X=\frac{m}{K}\frac{d^2}{dxdz}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r},\quad Y=\frac{m}{K}\frac{d^2}{dydz}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r};$$

$$Z=-\frac{m}{K}\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}.$$

It follows from equations A that α, β, γ, the components of the magnetic force, will be given by the equations

$$\mu\alpha=\frac{m\iota p}{Kv^2}\frac{d}{dy}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r};\quad \mu\beta=-\frac{m\iota p}{Kv^2}\frac{d}{dx}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r};\quad \gamma=0;$$

or since $\mu K v^2=1$, by

$$\alpha=m\iota p\frac{d}{dy}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r};\quad \beta=-m\iota p\frac{d}{dx}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r};\quad \gamma=0 \qquad (3).$$

Performing the differentiations and taking the real parts of the expressions, we find

$$X=\frac{xzm}{r^2K}\left\{\frac{3}{r^3}\cos p\left(t-\frac{r}{v}\right)-\frac{3}{r^2}\frac{p}{v}\sin p\left(t-\frac{r}{v}\right)-\frac{p^2}{v^2}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right)\right\},$$

$$Y=\frac{yz}{r^2}\frac{m}{K}\left\{\frac{3}{r^3}\cos p\left(t-\frac{r}{v}\right)-\frac{3}{r^2}\frac{p}{v}\sin p\left(t-\frac{r}{v}\right)-\frac{p^2}{v^2}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right)\right\}$$

$$Z=\frac{m}{K}\left[\frac{3z^2-r^2}{r^2}\left\{\frac{1}{r^3}\cos p\left(t-\frac{r}{v}\right)-\frac{1}{r^2}\frac{p}{v}\sin p\left(t-\frac{r}{v}\right)\right\}+\frac{x^2+y^2}{r^2}\frac{p^2}{v^2}\frac{1}{r}\cos p\left(-\frac{r}{v}\right)\right]$$

$$\alpha=mp\frac{y}{r}\left\{\frac{1}{r^2}\sin p\left(t-\frac{r}{v}\right)+\frac{p}{v}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right)\right\}$$

$$\beta=-mp\frac{x}{r}\left\{\frac{1}{r^2}\sin p\left(t-\frac{r}{v}\right)+\frac{p}{v}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right)\right\}$$

$$\gamma=0.$$

Thus $\alpha X+\beta Y+\gamma Z=0$, so that the electric force is everywhere at right angles to the magnetic force, and is in the plane through the axis of z; the lines of magnetic force are circles with their centres along and their planes at right angles to the axis of z. At a distance from the centre large compared with v/p, the last terms inside the brackets are the most important, and retaining only these, the equations take the simple form,

$$X=-\frac{m}{K}\frac{p^2}{v^2}\frac{xz}{r^2}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right),$$

$$Y=-\frac{m}{K}\frac{p^2}{v^2}\frac{yz}{r^2}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right),$$

$$Z=\frac{m}{K}\frac{p^2}{v^2}\frac{x^2+y^2}{r^2}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right),$$

$$\alpha=\frac{mp^2}{v}\frac{y}{r}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right),$$

$$\beta=-\frac{mp^2}{v}\frac{x}{r}\frac{1}{r}\cos p\left(t-\frac{r}{v}\right),$$

$$\gamma=0.$$

In this case $Xx+Yy+Zz=0$, so that the electric force is at right angles to the radius. If E is the resultant electric force, and H the resultant magnetic force,

$$E=\frac{m}{K}\frac{p^2}{v^2}\frac{\sin\theta}{r}\cos p\left(t-\frac{r}{v}\right),$$

$$H=\frac{mp^2}{v}\frac{\sin\theta}{r}\cos p\left(-\frac{r}{v}\right).$$

The magnetic force is at right angles to the radius and also to the electric force, and we see that, as in the plane wave, $v\mu H=E$. The lines of electric force at a great distance from the oscillator are represented in Fig. 46; it will be seen that they consist of a series of detached bundles, which travel outwards with the velocity v. The detachment of these bundles from the lines of force which originally stretched from one pole to the other of the doublet is shown in Fig. 47, which is taken from Hertz's paper. It will be noticed that a dent gradually develops in the lines of force and gets deeper and deeper until two portions of the lines meet. When this happens the line of force breaks off into two portions, one of which rushes into the doublet while the other travels outwards and produces one of the bundles of lines of force shown in Fig. 46. The point at which the lines break off is evidently in the plane $z=0$, and since at this point the equation $Z=0$ has two equal roots, the point is determined by $Z=0$, $\frac{dZ}{dr}=0$. These equations give $r=\sqrt{2}v/p$, so that the rupture of the lines of force always occurs at a fixed point. Diagrams of the lines of force of a vibrator whose vibrations are damped by radiation have been drawn by Pearson and Lee.[56]

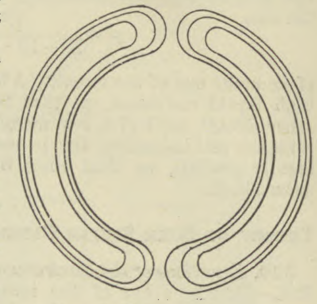

Fig. 46.

§ 13. *Energy radiated from the Vibrator.*—The movement of these bundles of lines of electric force away to an infinite distance from the vibrator is accompanied by a flow of energy outwards through space, as the lines of force carry energy with them. Thus if the oscillations of the vibrator are to be maintained energy must be supplied to it. To calculate the amount of energy radiated per unit time we make use of a theorem due to Poynting,[57] which states that the movement of energy in the electromagnetic field is the same as if the energy at any point moved along the normal to the plane containing the magnetic force and the electric force at that point, the amount of energy flowing in unit time across a unit area at right angles to the flow being equal to $HE\sin\theta/4\pi$ where H is the magnetic and E the electric force, and θ the angle between these vectors. If we apply this theorem to find the flow of energy across a sphere with its centre at the centre of the vibrator, and with so great a radius that over its surface the magnetic and electric forces are both transverse, the quantity of energy flowing per unit time across unit area of the surface of this sphere is equal to

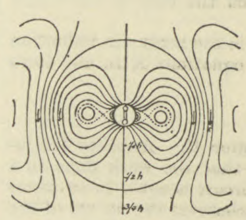

Fig. 47.

$$\frac{1}{4\pi}\frac{m^2}{K}\frac{p^4}{v^3}\frac{1}{r^2}\sin^2\theta\cos^2 p\left(t-\frac{r}{v}\right).$$

The total flow of energy across the surface of the sphere is therefore

$$\frac{2}{3}\frac{m^2}{K}\frac{p^4}{v^3}\cos^2 p\left(t-\frac{r}{v}\right) \quad . \quad . \quad . \quad (4),$$

the average value of which is $\frac{1}{3}\frac{m^2}{K}\frac{p^4}{v^3}$. If the vibrations are to be maintained energy must be supplied at this rate to the vibrator.

§ 14. *Magnetic Force due to a moving electrified Sphere.*—Let us consider the doublet as arising from the motion in opposite directions with equal velocity along the axis of z, of two oppositely charged particles, the distance of one particle from the origin being represented by $l\cos pt$, that of the other by $-l\cos pt$. Now the magnetic force by equation (3) due to this doublet is equal to

$$2el\sin\theta p\sin p\left(t-\frac{r}{v}\right)\frac{1}{r^2}+2el\sin\theta p^2\cos p\left(t-\frac{r}{v}\right)\frac{1}{vr}.$$

This may be written

$$-2eu\sin\theta\frac{1}{r^2}-2e\dot{u}\sin\theta\frac{1}{vr} \qquad . \quad (5),$$

where u, $\dot{u}$ are respectively the velocities and accelerations of the positive particle at the time $t-r/v$. Now since the electromagnetic effects are propagated with a velocity v, the magnetic effect at a point r at the time t must have started from the moving particle at the time $t-r/v$, and must depend on the condition of the sphere at that time. It is also clear that the magnetic effects due to the positive and negative particles are equal. Thus equation (5) shows that from a moving particle there starts a wave of magnetic force proportional to the velocity, whose magnitude at a distance r from the particle is $uc \sin\theta/r^2$, where u is the velocity of the particle, the lines of magnetic forces being circles with the direction of motion of the particle as axis. Accompanying this is another wave proportional to the acceleration, producing at a distance r a magnetic force equal to $e\dot{u}\sin\theta/vr$, the direction of the magnetic force being the same as in the velocity wave.[58] Thus while the magnetic force in the velocity wave varies inversely as the square of the distance, that in the "acceleration" wave only varies inversely as the distance. The importance of the second wave in comparison with the first will increase as the distance increases. If the particle is moving uniformly there is no "acceleration" wave, and the magnetic force at a distance r is $eu\sin\theta/r^2$. Thus a uniformly moving particle produces the same magnetic field as an element of current placed at the particle and pointing along its direction of motion.[59] The magnetic effects due to moving electrified charges have been detected by Rowland[60] in experiments made for this purpose.

From equation (4) we see that the rate at which energy is leaving the vibrating doublet is on the average

$$\frac{1}{3}\frac{m^2}{\mathrm{K}}\frac{p^4}{v^3};$$

this is equal for each particle to

$$2.\frac{2}{3}\frac{e^2}{\mathrm{K}v^3}(\text{mean value of } \dot{u}^2).$$

Thus work must be done on the particle to replace the energy radiated into space; in other words, there will be a resistance offered to the motion of the particle if its acceleration is finite. This resistance is such that the work spent in overcoming it in a time δt is equal to the energy radiated in that time.

§ 15. *Electric Oscillations on a perfectly conducting Sphere.*—We can apply the preceding analysis to the case of a conducting sphere, charged so that the density of the surface electrification at a point is proportional to $\cos\theta$ where θ is the angle which the radius to the point makes with the axis of z. If the field were steady the components of the electric force would be given by equations of the form

$$\mathrm{X}=m\frac{d^2}{dxdz}\frac{1}{r},\quad \mathrm{Y}=m\frac{d^2}{dydz}\frac{1}{r},\quad \mathrm{Z}=-m\left\{\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right\}\frac{1}{r};$$

hence when the charge is free to move over the surface and the electric field to vary, the components of the force will be given by the equations

$$\mathrm{X}=m\frac{d^2}{dxdz}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r},\quad \mathrm{Y}=m\frac{d^2}{dydz}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r},$$

$$\mathrm{Z}=-m\left\{\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right\}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}.$$

In this case it is one of the objects of the problem to determine p. This can be done from the condition that the electric force at the surface of the sphere must be radial, as a finite tangential force at the surface of the sphere would in consequence of the perfect conductivity correspond to an infinite current. If a is the radius of the sphere, then when $r=a$ we must have

$$\frac{\mathrm{X}}{x}=\frac{\mathrm{Y}}{y}=\frac{\mathrm{Z}}{z}.$$

Substituting the values of X, Y, Z we find that this condition leads to the equation

$$\frac{p^2}{v^2}a^2-\iota\frac{p}{v}a=1,$$

the roots of which are

$$\frac{pa}{v}=\frac{1}{2}\iota\pm\frac{\sqrt{3}}{2}.$$

Thus the time of vibration is $4\pi a/\sqrt{3}v$, and the wave length $4\pi a/\sqrt{3}$.[61] The amplitude of the vibration falls to $1/e$ of its original value after a time $2a/\mathrm{V}$, that is, after the time taken by light to pass across the diameter of the sphere. In the time occupied by one complete vibration the amplitude falls to $\epsilon^{-2\pi/\sqrt{3}}$ or about $\frac{1}{35}$ of its original value. Thus the vibrations will hardly make a complete oscillation before they are practically extinguished. This very rapid extinction is due to the radiation of energy from the sphere. The state of a sphere charged initially so that the normal force at its surface is equal to $2s\cos\theta$ is after a time t represented by the equations

$$\mathrm{P}=\frac{4s\cos\theta}{\sqrt{3}r^2}a^3\left\{1-\frac{a}{r}+\frac{a^2}{r^2}\right\}^{\frac{1}{2}}\epsilon^{-\frac{vt-(r-a)}{2a}}\cos(\phi+\delta)$$

$$\Theta=\frac{2s\sin\theta}{\sqrt{3}}\frac{a}{r}\left(1-\frac{a}{r}\right)\left(1+\frac{a}{r}+\frac{a^2}{r^2}\right)^{\frac{1}{2}}\epsilon^{-\left(\frac{vt-(r-a)}{2a}\right)}\cos(\phi+\delta')$$

$$\gamma=\frac{2s\sin\theta}{\sqrt{3}}\frac{a}{vr}\left\{1-\frac{a}{r}+\frac{a^2}{r^2}\right\}^{\frac{1}{2}}\epsilon^{-\frac{vt-(r-a)}{2a}}\cos(\phi+\delta''),$$

P, Θ being the normal and tangential components of the electric force, and γ the magnetic force.

$$\phi=\frac{\sqrt{3}}{2a}\{vt-(r-a)\};\quad \tan\delta=\left(\frac{2r}{a}-1\right)\Big/\sqrt{3}$$

$$\tan\delta'=\frac{r-a}{r+a}\frac{1}{\sqrt{3}},\quad \tan\delta''=\frac{1-\frac{2a}{r}}{\sqrt{3}}$$

those equations hold for positive values of ϕ, *i.e.*, after a wave starting from the sphere and travelling with velocity v has had time to reach the point under consideration. When r is very great compared with a, P is small compared with Θ and $\Theta=v\gamma$.

We can get the time of vibration of distributions of electricity represented by the higher harmonics by a similar process. If the electrification is proportional to the n^{th} zonal harmonic we put

$$\mathrm{X}=m\frac{d^{n+1}}{dxdz^n}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r},\quad \mathrm{Y}=m\frac{d^{n+1}}{dydz^n}\frac{\epsilon^{p\left(t-\frac{r}{v}\right)}}{r},$$

$$\mathrm{Z}=-m\left(\frac{d^2}{dx^2}+\frac{d^2}{dz^2}\right)\frac{d^{n-1}}{dz^{n-1}}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r.},$$

and proceed as before.

§ 16. *Scattering of Electric Waves by small dielectric Spheres.*—This problem may be solved by analysis similar to that used in the preceding investigations. If the length of the incident wave is long compared with the radius of the sphere, the intensity of the electric field due to the incident wave will be practically constant over the sphere. Let the incident wave be travelling parallel to the axis of x, let the electric intensity in it be parallel to the axis of z, and equal to the real part of $\mathrm{Z}_0\epsilon^{\iota p\left(t-\frac{x}{v}\right)}$, let K be the specific inductive capacity of the sphere, and a its radius; then if this sphere were placed in a constant electric field where the external force was Z_0, the components X, Y, Z at a point outside the sphere of the electric intensity due to the polarization of the dielectric sphere would be given by the equations

$$\mathrm{X}=\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3\frac{d^2}{dxdz}\frac{1}{r},\quad \mathrm{Y}=\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3\frac{d^2}{dydz}\frac{1}{r},$$

$$\mathrm{Z}=-\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)\frac{1}{r}.$$

These equations suggest that when the field is variable the components of the electric intensity due to the sphere are given by the equations

$$\mathrm{X}=\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3\frac{d^2}{dxdz}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r},\quad \mathrm{Y}=\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3\frac{d^2}{dydz}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}$$

$$\mathrm{Z}=-\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}.$$

The forces inside the sphere may easily be calculated, but they are not required for the present investigations. Corresponding to these values of the electric force we have, if α, β, γ are the components of the magnetic force,

$$\alpha=\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3\iota p\frac{d}{dy}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r},\quad \beta=-\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3\iota p\frac{d}{dx}\frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r},\quad \gamma=0$$

when it is to be understood that only the real part of these expressions is to be taken. The magnetic force inside the sphere corresponding to the internal electric field is continuous with that outside. These expressions satisfy all the boundary conditions if the sphere is not magnetic, for since pa/v is by hypothesis very small, the expressions for the electric force close to the sphere are very approximately the same as those in the electrostatic problem, which satisfy the boundary conditions of continuity of the tangential electric force and of the normal electric polarization; if the sphere is non-magnetic there is no discontinuity in the magnetic force and magnetic induction. Both the external field and that calculated from the preceding equations satisfy this condition. The values of X, Y, Z, α, β, γ can be got from the equations in § 12 by putting $m=\frac{\mathrm{K}-1}{\mathrm{K}+2}\mathrm{Z}_0a^3$; at a considerable number of wave lengths from the sphere they take the simple form

$$\mathrm{X}=-\mathrm{Z}_0a^3\frac{\mathrm{K}-1}{\mathrm{K}+2}\frac{xz}{r^2}\frac{p^2}{v^2}\cos p\left(t-\frac{r}{v}\right)\frac{1}{r}$$

$$\mathrm{Y}=-\mathrm{Z}_0a^3\frac{\mathrm{K}-1}{\mathrm{K}+2}\frac{yz}{r^2}\frac{p^2}{v^2}\cos p\left(t-\frac{r}{v}\right)\frac{1}{r}$$

$$Z = Z_0 a^3 \frac{K-1}{K+2} \frac{x^2+y^2}{r^2} \frac{p^2}{v^2} \cos p\left(t-\frac{r}{v}\right)\frac{1}{r}$$

$$\alpha = Z_0 a^3 \frac{K-1}{K+2} \frac{p^2}{v} \frac{y}{r} \frac{\cos p\left(t-\frac{r}{v}\right)}{r},$$

$$\beta = -Z_0 a^3 \frac{K-1}{K+2} \frac{p^2}{v} \frac{x}{r} \frac{\cos p\left(t-\frac{r}{v}\right)}{r}, \gamma = 0.$$

Thus X, Y, Z, α, β all vanish along the axis of z, and there is no wave scattered by the sphere in this direction. This problem of the scattering of waves by dielectric spheres was solved by Lord Rayleigh.[62] We see that for a given value of Z_0 and a, the magnitude of the forces in the scattered wave vary as p^2, that is, inversely as the square of the wave length of the incident wave. The energy in the scattered wave varies inversely as the fourth power of the wave length. Thus on the electromagnetic theory of light, according to which light consists of electromagnetic waves, the intensity of the light scattered by small particles varies inversely as the fourth power of the wave length. The part of the incident light in which the electric force is along the axis of z does not give rise to any scattered light along this axis. Thus when ordinary light is incident on small particles the scattered light in a direction at right angles to the incident light must be plane polarized, the plane of polarization being such that the electric force is at right angles to the plane through the observer and the incident beam; this implies that the scattered light is polarized in the plane through the observer and the incident beam. For the application of the theory of the scattering of light by small particles to the explanation of the blue of the sky the reader is referred to a series of papers by Lord Rayleigh;[63] in one of these he has shown that the scattering may be produced by the molecules of the air without the aid of any extraneous small particles.

§ 17. *Scattering of Electric Waves by perfectly conducting Spheres.*—When a train of plane electric waves is incident on a perfectly conducting sphere, the expressions for the scattered waves are not quite so simple as those in the last case. In the perfectly conducting sphere the total electric force at the surface must be radial, and the total magnetic force entirely tangential; in the case of the dielectric sphere just treated the magnetic force in the scattered wave is entirely tangential, and so there is nothing to balance the normal component of the magnetic force in the incident wave. The following values of the components of the electric and magnetic forces will be found to satisfy the conditions that the tangential electric, and normal magnetic force vanish over the sphere. The electric intensity in the incident wave is supposed to be represented by the real part of $Z_0\epsilon^{\iota p\left(t-\frac{x}{v}\right)}$, and to be parallel to z; the magnetic force will be parallel to y and equal to the real part of $(Z_0/v)\epsilon^{\iota p\left(t-\frac{x}{v}\right)}$. The radius, a, of the conducting sphere is very small compared with the length of the wave.

$$X = Z_0 a^3 \frac{d^2}{dxdz} \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r} - \frac{1}{2}\iota p \frac{Z_0 a^3}{v} \frac{d}{dz} \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}$$

$$Y = Z_0 a^3 \left(\frac{d^2}{dydz}\right) \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}$$

$$Z = -Z_0 a^3 \left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right) \frac{\epsilon^{\iota p\left(-\frac{r}{v}\right)}}{r} + \frac{1}{2}\iota p \frac{Z_0 a^3}{v} \frac{d}{dx} \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}$$

$$\alpha = Z_0 a^3 \iota p \frac{d}{dy} \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r} - \frac{1}{2} \frac{Z_0 a^3}{v} \frac{d^2}{dxdy} \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}$$

$$\beta = -Z_0 a^3 \iota p \frac{d}{dx} \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r} + \frac{1}{2} \frac{Z_0 a^3}{v} \left(\frac{d^2}{dx^2}+\frac{d^2}{dz^2}\right) \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}$$

$$\gamma = -\frac{1}{2} \frac{Z_0 a^3}{v} \frac{d^2}{dydz} \frac{\epsilon^{\iota p\left(t-\frac{r}{v}\right)}}{r}$$

At a distance from the sphere, large compared with the wave length, these expressions reduce to

$$X = Z_0 \frac{a^3}{r} \frac{p^2}{v^2} \left(\frac{xz}{r^2}+\frac{1}{2}\frac{z}{r}\right) \cos p\left(t-\frac{r}{v}\right)$$

$$Y = Z_0 \frac{a^3}{r} \frac{p^2}{v^2} \frac{yz}{r^2} \cos p\left(t-\frac{r}{v}\right)$$

$$Z = -Z_0 \frac{a^3}{r} \frac{p^2}{v^2} \left(1-\frac{z^2}{r^2}+\frac{1}{2}\frac{x}{r}\right) \cos p\left(t-\frac{r}{v}\right)$$

$$\alpha = -\frac{Z_0}{V} \frac{a^3}{r} \frac{p^2}{v^2} \left(\frac{1}{2}\frac{xy}{r^2}+\frac{y}{r}\right) \cos p\left(t-\frac{r}{v}\right)$$

$$\beta = -\frac{Z_0}{V} \frac{a^3}{r} \frac{p^2}{v^2} \left(\frac{y^2-r^2}{2r^2}-\frac{x}{r}\right) \cos p\left(t-\frac{r}{v}\right)$$

$$\gamma = -\frac{Z_0}{V} \frac{a^3}{r} \frac{p^2}{v^2} \frac{1}{2} \frac{yz}{r^2} \cos p\left(t-\frac{r}{v}\right)$$

Thus $xX+yY+zZ=0$, $\alpha x+\beta y+\gamma z=0$, $X\alpha+Y\beta+Z\gamma=0$, so that both the electric and magnetic forces are at right angles to the radius, and the magnetic and electric forces are at right angles to each other. We see from the preceding expressions that the electric and magnetic forces both vanish when $y=0$ and $x/r=-\frac{1}{2}$, thus the scattered wave due to the incidence of a plane wave on a conducting sphere vanishes along a line making an angle of 60° with the direction of the incident wave measured backwards from the sphere, and in the plane through the centre of the sphere at right angles to the magnetic force in the incident wave. In the case of the non-conducting sphere this angle was 90° instead of 60°.[64] The preceding investigation applies to a perfect conductor. We shall show later that when a wave in which the frequency of vibration is p falls upon a conductor of specific resistance σ, it only penetrates the conductor to a depth comparable with $\sqrt{\sigma/p}$. If, then $\sqrt{\sigma/p}$ is small compared with the radius of the sphere, *i.e.*, if σ/pa^2 is small, we may treat the sphere as a perfect conductor. As p is equal to $2\pi V/\lambda$, this condition requires $\sigma\lambda/2\pi Va^2$ to be small, hence as by hypothesis λ/a is very large we can only apply this theory when σ/Va is exceedingly small.

§ 18. *Reflexion and Refraction of Electric Waves by Insulators.*—Let us take the plane of the paper as the plane of incidence and of xy, and let $x=0$ be the equation to the reflecting surface. In the case when the electric force in the wave is in the plane of incidence, if V is the velocity of the wave in air, λ its wave length in air, and i the angle of incidence, the incident wave may be represented by the real part of $A\epsilon^{\iota\frac{2\pi}{\lambda}(x\cos i+y\sin i+Vt)}$. This will give rise to a reflected wave which may be represented by the real part of $A'\epsilon^{\iota\frac{2\pi}{\lambda}(-x\cos i+y\sin i+Vt)}$. If r is the angle of refraction, V′ the velocity, and λ' the wave length in the refracting medium, the refracted wave may be represented by the real part of

$$A''\epsilon^{\iota\frac{2\pi}{\lambda'}(x\cos r+y\sin r+V't)}.$$

Since at the reflecting surface, $x=o$, the incident and reflected and refracted waves must keep time with each other, the coefficients of t in all the exponentials must be the same; the coefficients of y must also be the same, since the relation between the waves must be the same at all parts of the reflecting surface. Hence we have

$$\frac{\sin i}{\lambda}=\frac{\sin r}{\lambda'}\,;\ \frac{V}{\lambda}=\frac{V'}{\lambda'},\ \text{or}\ \frac{\sin i}{V}=\frac{\sin r}{V'}.$$

The last equation is the well-known law of refraction. To determine the values of A′ and A″ in terms of A, we have the condition that the electric force parallel to the surface of separation must be continuous as we pass from one medium to another. The electric force parallel to the surface in the air is

$$(A-A')\cos i\,\epsilon^{\iota\frac{2\pi}{\lambda}(y\sin i+Vt)},$$

and in the refracting medium it is

$$A''\cos r\,\epsilon^{\iota\frac{2\pi}{\lambda'}(y\sin r+V't)},$$

hence we have

$$(A-A')\cos i = A''\cos r.$$

The electric polarization normal to the surface must also be continuous; in the air this is

$$(A+A')\sin i\,\epsilon^{\iota\frac{2\pi}{\lambda}(y\sin i+Vt)} \div 4\pi;$$

in the refracting medium it is

$$KA''\sin r\,\epsilon^{\iota\frac{2\pi}{\lambda'}(y\sin r+V't)} \div 4\pi,$$

when K is the specific inductive capacity of the refracting medium. Equating these expressions we have

$$(A+A')\sin i = KA''\sin r;$$

hence we find

$$A' = A\frac{K\tan r-\tan i}{K\tan r+\tan i}$$

$$A'' = A\frac{\sin 2i}{\sin i\cos r+K\cos i\sin r}.$$

If the refracting medium is non-magnetic $V^2/V'^2 = \sin^2 i/\sin^2 r = K$. Substituting this value for K we find

$$A' = A\frac{\tan(i-r)}{\tan(i+r)}$$

$$A'' = 4A\frac{\sin r\cos i}{\sin 2i + \sin 2r}.$$

Thus the reflected wave vanishes when $i+r=\frac{\pi}{2}$. Trouton,[65] who has investigated experimentally the reflexion of electric waves from a paraffin wall 3 feet thick, found that when the electric force was in the plane of incidence the reflected wave vanished at a particular angle of incidence; but if the electric force was at right angles to the plane of incidence the reflected ray never vanished. This observation has an important application to the electromagnetic theory of light, for we know that when light is polarized at right angles to the plane of incidence the reflected wave vanishes when the directions of the refracted and reflected waves are at right angles, but that it never vanishes when the light is polarized in the plane of incidence. Thus the electric force is at right angles to the plane of polarization while the magnetic force is in that plane.

§ 19. We can easily verify that the energy transmitted along the incident beam is equal to the sum of the energies transmitted along the reflected and refracted beams; for by Poynting's theorem the energy passing unit section of a beam per unit time is $EH/4\pi$, where E is the electric and H the magnetic force. But in a plane wave $E=V\mu H$, where μ is the magnetic permeability, hence the rate at which energy passes through unit area of the beam is $E^2/V\mu 4\pi$. Thus the average rate at which it passes across unit area of the incident beam is $A^2/8\pi V$, across the reflected beam $A'^2/8\pi V$, and across unit area of the refracted beam $A''^2/8\pi\mu V'$. Now, if the area of cross section of the incident beam is unity, that of the reflected beam will also be unity, and that of the refracted beam $\cos r/\cos i$; hence the energy transmitted along the incident beam will equal the sum of the energies transmitted along the reflected and refracted beam if

$$\frac{A^2}{V} = \frac{A'^2}{V} + \frac{A''^2}{\mu V'}\,\frac{\cos r}{\cos i}$$

This relation follows at once from the values of A′ and A″ given above.

Let us next consider the case when the electric force is at right angles to the plane of incidence. Let, as before,

$$A\epsilon^{\iota\frac{2\pi}{\lambda}(x\cos i + y\sin i + Vt)},\quad A'\epsilon^{\iota\frac{2\pi}{\lambda}(-x\cos i + y\sin i + Vt)}$$

represent respectively the electric force in the incident and reflected waves, and

$$A''\epsilon^{\iota\frac{2\pi}{\lambda'}(x\cos r + y\sin r + V't)}$$

that in the refracted wave; then the magnetic forces will be in the plane of incidence and will be proportional to A/V, A'/V, $A''/V'\mu$. Since the magnetic force parallel to the surface of separation is continuous we have

$$(A - A')\cos i = A''\frac{V}{V'\mu}\cos r,$$

and since the magnetic induction at right angles to the surface of separation is continuous,

$$(A + A')\sin i = A''\frac{V}{V'}\sin r.$$

Solving these equations we get

$$A' = A\frac{(\mu\tan r - \tan i)}{\mu\tan r + \tan i};\quad = -A\frac{\sin(i-r)}{\sin(i+r)}\text{ if } \mu=1,$$

$$A'' = \frac{2A\mu\cos i\sin r}{\cos r\sin i + \mu\cos i\sin r},\quad = \frac{2A\cos\iota\sin r}{\sin(\iota+r)}\text{ if } \mu=1.$$

In this case the reflected wave never vanishes. Assuming the electromagnetic theory of light, these and the preceding investigations give the intensity of the reflected and refracted beams when plane polarized light is incident upon a reflecting surface.

§ 20. *Reflexion of Electric Waves by a Plate of Dielectric of finite thickness.*—We shall suppose that the plate is bounded by the parallel planes $x=0$, $x=-h$, and shall limit ourselves to the case of normal incidence; the general case of oblique incidence is discussed in J. J. Thomson's *Recent Researches on Electricity and Magnetism*, p. 407. Let the incident ray be represented by $A\epsilon^{\iota\frac{2\pi}{\lambda}(x+Vt)}$, and the reflected ray by $A'\epsilon^{\frac{2\pi}{\lambda}(-x+Vt)}$. In the plate there will be waves travelling in both directions; let one of these be represented by $B\epsilon^{\iota\frac{2\pi}{\lambda'}(x+V't)}$, and the other by $B'\epsilon^{\iota\frac{2\pi}{\lambda'}(-x+V't)}$, and let the emergent wave be represented by $C\epsilon^{\iota\frac{2\pi}{\lambda}(x+Vt)}$. Then introducing the boundary conditions at $x=0$ and $x=-h$, and solving the four equations we find if the plate is non-magnetic

$$A' = -A(K-1)\left(\epsilon^{\iota\frac{2\pi}{\lambda'}h} - \epsilon^{-\iota\frac{2\pi}{\lambda'}h}\right)\div\Delta,$$

$$B = 2A\left(\frac{V}{V'}+1\right)\epsilon^{\iota\frac{2\pi}{\lambda'}h}\div\Delta,$$

$$B' = 2A\left(\frac{V}{V'}-1\right)\epsilon^{\iota\frac{-2\pi}{\lambda'}h}\div\Delta,$$

$$C = 4A\frac{V}{V'}\epsilon^{\frac{2\pi}{\lambda}h}\div\Delta,$$

where

$$\Delta = (K+1)\left(\epsilon^{\iota\frac{2\pi}{\lambda'}h} - \epsilon^{-\iota\frac{2\pi}{\lambda'}h}\right) + 2\sqrt{K}\left(\epsilon^{\iota\frac{2\pi}{\lambda'}h} - \epsilon^{\iota\frac{2\pi}{\lambda'}h}\right).$$

Thus corresponding to the incident wave $A\cos\frac{2\pi}{\lambda}(x+Vt)$ we have a reflected wave represented by

$$-A(K-1)\sin\frac{2\pi}{\lambda'}h\,\cos\left\{\frac{2\pi}{\lambda}(-x+Vt)+\frac{\pi}{2}-\vartheta\right\}\div D,$$

two waves in the plate represented respectively by

$$A\left(\frac{V}{V'}+1\right)\cos\left\{\frac{2\pi}{\lambda'}(x+h+V't)-\vartheta\right\}\div D$$

and

$$A\left(\frac{V}{V'}-1\right)\cos\left\{\frac{2\pi}{\lambda'}(-(x+h)+V't)-\vartheta\right\}\div D,$$

and a wave emerging from the plate represented by

$$2A\frac{V}{V'}\cos\left\{\frac{2\pi}{\lambda}(x+h+Vt)-\vartheta\right\}\div D,$$

where $D^2=(K+1)^2\sin^2\frac{2\pi}{\lambda'}h + 4K\cos^2\frac{2\pi}{\lambda'}h$; $\tan\vartheta = \frac{K+1}{2\sqrt{K}}\tan\frac{2\pi}{\lambda'}h$.

Thus we see that when $2\pi h/\lambda'$ is very small the reflected wave is very feeble. This is what we should naturally expect, as we could not expect to get appreciable reflexion unless the thickness of the plate were comparable with the length of the wave. Trouton[66] has verified that there is no appreciable reflexion of electric waves from window glass unless it is covered with moisture which makes it a conductor. The reflected wave vanishes whenever $2\pi h/\lambda'$ is a multiple of π, or whenever the thickness of the plate is a multiple of half the wave length of the wave in the plate. Trouton used as a reflecting plate a wall built of paraffin bricks, a method which enabled him to try the effect of varying the thickness of the plate; he found that after reaching the thickness at which the reflected wave became sensible by making the wall still thicker, the reflected wave became again insensible when the wall reached a certain thickness. The case is analogous to the colours of thin plates where we have darkness when the thickness of the plate is a multiple of half the wave length. The intensity of the electric force in the plate is proportional to

$$\frac{V}{V'}\cos\frac{2\pi}{\lambda'}(x+h)\cos\left(\frac{2\pi}{\lambda'}V't-\vartheta\right) - \sin\frac{2\pi}{\lambda'}(x+h)\sin\left(\frac{2\pi}{\lambda'}V't-\vartheta\right);$$

thus the average value of the square of the electric force is proportional to

$$\frac{V^2}{V'^2}\cos^2\frac{2\pi}{\lambda'}(x+h) + \sin^2\frac{2\pi}{\lambda'}(x+h).$$

The maxima of this expression occur when $x+h$ is a multiple of $\lambda^1/_2$. Thus if the substance of the plate is changed by the action of the electric field the plate would develop a periodic structure, the wave length of which would be half that of the electric waves in the plate.

§ 21. *Reflexion of Waves by Conductors; Opacity of Conductors.*—In conductors there are, in addition to the polarization currents which are proportional to the rate of increase of the electric intensity, conduction currents which, obeying Ohm's law, are proportional to the electric intensity. Thus in a conductor, if i is the current and E the electric intensity,

$$i = \frac{K}{4\pi}\frac{dE}{dt} + \frac{E}{\sigma},$$

where σ is the specific resistance of the substance. Substituting this value for the current in equations B we find that the components of the electric intensity and of the magnetic force satisfy equations of the form

$$K\mu\frac{d^2X}{dt^2}+\frac{4\pi\mu}{\sigma}\frac{dX}{dt}=\frac{d^2X}{dx^2}+\frac{d^2X}{dy^2}+\frac{d^2X}{dz^2}.$$

Suppose now we have an electric wave travelling through the air and striking normally against a conductor, the plane of separation between the air and the conductor being the plane $x=0$. Let the electric intensity in the incident wave be represented by the real part of $A\epsilon^{\iota\frac{2\pi}{\lambda}(Vt+x)}$. Then if E is the electric intensity in the wave in the conductor, it satisfies the differential equation

$$K\mu\frac{d^2E}{dt^2}+\frac{4\pi\mu}{\sigma}\frac{dE}{dt}=\frac{d^2E}{dx^2}.$$

The frequency of the electric intensity in the conductor must be the same as that in the air; hence E must be proportional to $\epsilon^{\iota pt}$ if $p=2\pi V/\lambda$. On this supposition the equation for E becomes

$$\frac{d^2E}{dx^2}+E\left(\mu Kp^2-\frac{4\pi\mu\iota p}{\sigma}\right)=0;$$

hence E will be of the form $\epsilon^{\iota(pt+nx)}$ where $n^2=\mu Kp^2-\frac{4\pi\iota\mu p}{\sigma}$. Thus n is a complex quantity of the form $a+\iota\beta$. We must take the root which has β negative, for in the conductor x is negative, and if β were positive the expression would represent a disturbance continually increasing in intensity as the distance from the surface of the conductor increases. Let the electric intensity in the conductor be represented by $B\epsilon^{\iota(pt+nx)}$, and let the reflected wave in the air be represented by $A'\epsilon^{\iota\frac{2\pi}{\lambda}(Vt-x)}$; then since the electric force parallel to the surface of separation is continuous

$$A+A'=B,$$

and since the magnetic force parallel to the surface is, by equations A (§ 10), $(1/\mu\iota p)$ (dE/dx) and is continuous, we have

$$\frac{2\pi}{\lambda}(A-A')=\frac{Bn}{\mu},$$

hence

$$A'=A\frac{\left(1-\frac{\lambda n}{2\pi\mu}\right)}{1+\frac{\lambda n}{2\pi\mu}}$$

$$B=\frac{2A}{1+\frac{\lambda n}{2\pi\mu}}.$$

Now $n^2=\mu Kp^2-4\pi\frac{\mu\iota p}{\sigma}$; the ratio of the first term in this expression to the real part of the second is $\mu Kp\sigma/4\pi\mu$. But $K=K'/V^2$ where K′ is the ratio of the specific inductive capacity of the conductor to that of air, and V the velocity of light, *i.e.*, 3×10^{10} cm./sec.; hence the preceding ratio is equal to $K'p\sigma/36\pi\times10^{20}$. If we put in the value of σ for the ordinary metals we see that unless K′ is enormous this ratio is exceedingly small even when the frequency is as large as it is in the waves which constitute visible light. Even for electrolytes it is exceedingly small for electric waves a few millimetres in wave length, and the longer the wave length the smaller it becomes. We shall, therefore, in the expression for n^2 neglect the term μKp^2 in comparison with $4\pi\mu p/\sigma$, but when we can do this $n\lambda/2\pi\mu$ is exceedingly large; hence approximately $A'=-A$

$$B=\left\{\frac{2\mu\sigma}{V\lambda}\right\}^{\frac{1}{2}}\epsilon^{\iota\frac{\pi}{4}}A.$$

Thus the reflected wave is represented by $-A\cos\frac{2\pi}{\lambda}(Vt-x)$. To this approximation the electric force parallel to the surface of the conductor vanishes at the surface. The transmitted wave is represented by

$$A\sqrt{\frac{2\mu\sigma}{V\lambda}}\epsilon^{2\pi\sqrt{\frac{\mu V}{\sigma\lambda}}x}\cos\left(\frac{2\pi}{\lambda}Vt+2\pi\sqrt{\frac{\mu V}{\sigma\lambda}}x+\frac{\pi}{4}\right).$$

In the conductor x is always negative, so that the amplitude of the transmitted wave is small to begin with, and diminishes rapidly in consequence of the exponential term.

§ 22. *Transmission of Electric Waves through a conducting Plate.*[67]—Let us take the case of electric waves incident normally upon a conducting plate bounded by the planes $x=0$, $x=-h$. Using the same notation as before, let the incident wave be represented by $A\epsilon^{\iota\frac{2\pi}{\lambda}(Vt+x)}$, the reflected wave by $A'\epsilon^{\iota\frac{2\pi}{\lambda}(Vt-x)}$, the wave in the plate by $B\epsilon^{\iota(pt+nx)}$ and $B'\epsilon^{\iota(pt-nx)}$, and the transmitted wave by $C\epsilon^{\iota\frac{2\pi}{\lambda}(Vt+x)}$. The boundary conditions at the two surfaces of the plate give four equations from which we deduce

$$A'=-A(n^2/\mu^2-4\pi^2/\lambda^2)\left(\epsilon^{\iota nh}-\epsilon^{-\iota nh}\right)\div D,$$

$$B=\frac{4\pi A}{\lambda}(n/\mu+2\pi/\lambda)\epsilon^{\iota nh}\div D,$$

$$B'=\frac{4\pi}{\lambda}A(n/\mu-2\pi/\lambda)\epsilon^{-\iota nh}\div D,$$

$$C=\frac{8\pi}{\lambda}A(n/\mu)\epsilon^{\iota\frac{2\pi}{\lambda}h}\div D,$$

where

$$D=(n^2/\mu^2+4\pi^2/\lambda^2)\left(\epsilon^{\iota nh}-\epsilon^{-\iota nh}\right)+(4\pi/\lambda)(n/\mu)\left(\epsilon^{\iota nh}+\epsilon^{-\iota nh}\right).$$

When nh is large we see that $A'=-A$, and the electric force parallel to the plate vanishes at the surface of the plate. The magnitude of nh is $(4\pi\mu ph^2/\sigma)^{\frac{1}{2}}$, and the condition that the force should vanish at the surface is that this quantity should be large. For metals very small values of h are sufficient to satisfy this condition; thus for waves one metre in length in air and for an iron plate, nh is about 1500 h, so that if the plate were only 1/15 mm. thick nh would be equal to 10, and as ϵ^{10} is a very large number the reflexion is practically perfect. We see from this example how it is that tin-foil and gold-leaf are practically perfect reflectors for very rapid electric waves. With electrolytes, on the other hand, for which σ may easily be as large as 10^{10}, it will require a plate many millimetres thick to produce complete reflexion. The case of nh large is practically that of the infinitely thick plate previously considered. Let us now consider the case of a plate so thin that nh is small; in this case there are two subcases to consider—(1) when $n^2h\lambda/2\pi\mu$ or $4\pi Vh/\sigma$ is small; (2) when it is large. In case (1)

$$A'=-\frac{\iota\lambda n^2h}{2\pi\mu A},\ B=\frac{1}{2}A,\ B'=\frac{1}{2}A,\ C=A;$$

thus the reflected wave is represented by $\frac{4\pi Vh}{\sigma}A\cos\frac{2\pi}{\lambda}(Vt-x)$, the waves in the plate by

$$\frac{1}{2}A\cos\left(\frac{2\pi}{\lambda}Vt+2\pi\sqrt{\frac{\mu V}{\sigma\lambda}}x\right)+\frac{1}{2}A\cos\left(\frac{2\pi}{\lambda}Vt-2\pi\sqrt{\frac{\mu V}{\sigma\lambda}}x\right),$$

and the transmitted wave by $A\cos\frac{2\pi}{\lambda}(Vt+x+h)$.

In the second case when $n^2h\lambda/2\pi\mu$ is large we have approximately

$$A'=-A;\ B=2\pi A\mu/\iota n^2h\lambda,\ B'=2\pi A\mu/\iota n^2h\lambda,\ C=4\pi A\epsilon^{\frac{\iota 2\pi h}{\lambda}}/n^2h\lambda.$$

Thus the reflected wave is approximately $-A\cos\frac{2\pi}{\lambda}(Vt-x)$, the waves in the plate

$$\frac{\sigma}{4\pi Vh}A\left\{\cos\left(\frac{2\pi}{\lambda}Vt+2\pi\sqrt{\frac{\mu V}{\sigma\lambda}}x\right)+\cos\left(\frac{2\pi}{\lambda}Vt-2\pi\sqrt{\frac{\mu V}{\sigma\lambda}}x\right)\right\},$$

and the transmitted wave $\frac{\sigma}{2\pi Vh}A\cos\frac{2\pi}{\lambda}(Vt+x+h)$.

Thus the thickness of the slab which produces a given diminution in the intensity of the transmitted wave is proportional to the specific resistance. This result has been applied by the writer[68] and Erskine[69] to compare the resistance of electrolytes under the very rapidly alternating electric forces which occur in electric waves. These investigations have shown that the ratio of the resistances of electrolytes under electric forces changing their direction several million times a second is the same as under steady currents. Similar measurements by a somewhat different method have been made by Zeemann.[70]

The preceding equations are general, and if we know the values of λ, σ, and h, we can from them calculate the amplitudes of the various waves. Thus. take the case of a wave of light for which $\lambda=6\times10^{-5}$ cm. incident on a plate of gold-leaf whose thickness is $\lambda/25$, σ for gold under steady current may be taken as 2×10^3. Substituting these values in the equations when nh is large we find $C/A=\cdot0001$ approximately, so that the intensity of the transmitted wave would only be about 10^{-8} of the incident wave. This indicates that such a film would be practically opaque. Experiments on the transparency of thin metallic plates made by W. Wien[71] and others have shown that such plates have a much greater transparency than is indicated by the preceding figures. For example, the intensity of the transmitted wave in the case of the film of gold-leaf just considered is found to be not much less than

$\frac{1}{3}$ of that of the incident one. This enormous discrepancy seems to indicate that when the electric force is changing its direction with the rapidity which it does in the case of waves of light, the effective resistance of metals is much greater than under steady currents; we shall return to this point when we consider the propagation of an electric wave through a medium containing ions.

The theory of reflexion of electric waves from a grating of parallel wires has been discussed by the writer [72] and Lamb. [73]

§ 23. *Waves along Wires.*—A most important case of electric waves is when there is a wire in the field parallel to the direction of their propagation. The wire acts as a guide to the waves, which may in a certain sense be said to run along it. The reader will find a full discussion of this problem in papers by the writer, [74] by Heaviside, [75] and in recent ones by Sommerfeld [76] and by Mie. [76] We shall confine ourselves here to an outline of the method by which the problem can be solved. Let us first take the case when the only conductor in the field is a cylindrical wire of radius a, the axis of which we shall take as the axis of z. Let P, Q, R, a, b, c be the components of the electric force and the magnetic induction respectively parallel to the axes of x, y, z, and let us suppose that the electric field is symmetrical about the axis of z. Then in the air around the wire R satisfies the equation

$$\frac{d^2R}{dx^2}+\frac{d^2R}{dy^2}+\frac{d^2R}{dz^2}=\frac{1}{v^2}\frac{d^2R}{dt^2},$$

where v is the velocity of propagation of electromagnetic disturbance through the air. If R varies as $\epsilon^{\iota(mz+pt)}$ this equation becomes

$$\frac{d^2R}{dx^2}+\frac{d^2R}{dy^2}-R\left(m^2-\frac{p^2}{v^2}\right)=0 \quad . \quad . \quad . \quad (1),$$

or since the field is symmetrical about the axis of z

$$\frac{d^2R}{d\rho^2}+\frac{1}{\rho}\frac{dR}{d\rho}-R\left(m^2-\frac{p^2}{v^2}\right)=0 \quad . \quad . \quad . \quad (2),$$

where $\rho^2=x^2+y^2$.

Since the field is symmetrical about the axis of z we may put

$$P=\frac{dX}{dx},\quad Q=\frac{dX}{dy},$$

where X is a function of ρ and z, which satisfies a differential equation of the type (1) or (2). Since

$$\frac{dP}{dx}+\frac{dQ}{dy}+\frac{dR}{dz}=0,$$

we have

$$\frac{d^2X}{dx^2}+\frac{d^2X}{dy^2}+\iota mR=0,$$

or

$$X\left(m^2-\frac{p^2}{v^2}\right)+\iota mR=0;$$

hence

$$P=-\frac{\iota m}{m^2-\frac{p^2}{v^2}}\frac{dR}{dx},\quad Q=-\frac{\iota m}{m^2-\frac{p^2}{v^2}}\frac{dR}{dy};$$

From the equations of the type

$$\frac{da}{dt}=\frac{dQ}{dz}-\frac{dR}{dy}$$

we get

$$a=-\frac{\iota p}{v^2}\frac{1}{m^2-\frac{p^2}{v^2}}\frac{dR}{dy},\quad b=\frac{\iota p}{v^2}\frac{1}{m^2-\frac{p^2}{v^2}}\frac{dR}{dx},\quad c=0.$$

or

$$a=\frac{p}{mv^2}Q,\quad b=-\frac{p}{mv^2}P,\ c=0.$$

Thus the lines of magnetic force are circles with their centres long the axis of z, and their planes at right angles to it.

In the wire itself, R satisfies an equation of the form

$$\frac{d^2R}{dx^2}+\frac{d^2R}{dy^2}+\frac{d^2R}{dz^2}=\frac{4\pi\mu}{\sigma}\frac{dR}{dt},$$

where μ is the magnetic permeability, and σ the specific resistance of the wire. In this equation we have neglected the term $\mu K d^2R/dt^2$ in comparison with $(4\pi\mu/\sigma)(dR/dt)$, and for all metallic conductors this is legitimate unless the waves are smaller than the wave length of light. Introducing the conditions that the field is symmetrical about the axis of z, and that R varies as $\epsilon^{\iota(mz+pt)}$, we get

$$\frac{d^2R}{d\rho^2}+\frac{1}{\rho}\frac{dR}{d\rho}-R\left(m^2+\frac{4\pi\mu\iota p}{\sigma}\right)=0.$$

We find also

$$P=-\frac{\iota m}{m^2+\frac{4\pi\mu\iota p}{\sigma}}\frac{dR}{dx};\quad Q=-\frac{\iota m}{m^2+\frac{4\pi\mu\iota p}{\sigma}}\frac{dR}{dy};$$

and

$$a=-\frac{\frac{4\pi\mu}{\sigma}}{m^2+\frac{4\pi\mu\iota p}{\sigma}}\frac{dR}{dy},\quad b=\frac{\frac{4\pi\mu}{\sigma}}{m^2+\frac{4\pi\mu\iota p}{\sigma}}\frac{dR}{dx},\quad c=0.$$

Thus all the quantities both in the air and the metal can be expressed in terms of the z component of the electric force. Now, both in the air and the metal, R satisfies a differential equation of the form

$$\frac{d^2R}{d\rho^2}+\frac{1}{\rho}\frac{dR}{d\rho}-q^2R=0 \quad . \quad . \quad . \quad . \quad (3),$$

where in the air $q^2=m^2-\frac{p^2}{v^2}$; in the metal $q^2=m^2+4\pi\mu\iota p/\sigma$.

The solution of this equation is

$$R=AJ_0(\iota q\rho)+BK_0(\iota q\rho),$$

where J_0 and K_0 are Bessel's functions of the first and second kinds. The expressions for $J_0(x)$ and $K_0(x)$ are (see Art. SPHERICAL HARMONICS)

$$J_0(x)=1-\frac{1}{(1!)^2}\left(\frac{x}{2}\right)^2+\frac{1}{(2!)^2}\left(\frac{x}{2}\right)^4-\frac{1}{(3!)^2}\left(\frac{x}{2}\right)^6+\dots$$

$$K_0(x)=J_0(x)\left\{\log\frac{2}{x}+\frac{\pi}{2}+C\right\}-2\left\{J_2(x)-\frac{1}{2}J_4(x)+\frac{1}{3}J_6(x)\dots\right\}$$

where

$$J_n(x)=\frac{1}{n!}\left(\frac{x}{2}\right)^n\left(1-\frac{1}{1.n+1}\left(\frac{x}{2}\right)+\frac{1}{1.2(n+1)(n+2)}\left(\frac{x}{2}\right)\dots\right)$$

and $C=\cdot577\dots=\log\gamma$, where $\gamma=1\cdot781\dots$

For large values of x the following approximate expressions are useful:—

$$J_0(x)=\sqrt{\frac{1}{\pi\iota x}}\left(\epsilon^{\iota\left(x+\frac{\pi}{4}\right)}-\epsilon^{-\iota\left(x+\frac{\pi}{4}\right)}\right),$$

$$K_0(x)=\sqrt{\frac{\pi}{2x}}\,\epsilon^{\iota\left(x+\frac{\pi}{4}\right)}.$$

From these expressions we see that when $x=0$, $K_0(\iota x)$ is infinite, and when x is infinite $J_0(\iota x)$ is infinite. Thus in the wire where ρ may vanish R is represented by the J_0 function, and in the air where ρ may become infinite R is represented by the K_0 function. Thus in the wire we have

$$R=AJ_0(\iota n\rho)\epsilon^{\iota(mz+pt)},$$

where $n^2=m^2+4\pi\mu\iota p/\sigma$, and in the air

$$R=BK_0(\iota\kappa\rho)\epsilon^{\iota(mz+pt)},$$

where $\kappa^2=m^2-p^2/v^2$.

The magnetic induction at right angles to ρ in the wire is

$$\frac{4\pi\mu}{\sigma n^2}\frac{dR}{d\rho}=\frac{4\pi\mu\iota}{\sigma n}AJ'_0(\iota n\rho)\epsilon^{\iota(mz+pt)}$$

where

$$J'_0(\iota n\rho)=\frac{dJ_0(\iota n\rho)}{d(\iota n\rho)}.$$

The magnetic induction at right angles to ρ in the air is equal to

$$\frac{\iota p}{v^2\kappa^2}\frac{dR}{d\rho}=-\frac{p}{v^2\kappa}BK'_0(\iota\kappa\rho)\epsilon^{\iota(mz+pt)}$$

where

$$K'_0(\iota\kappa\rho)=\frac{d.K_0(\iota\kappa\rho)}{d.\iota\kappa\rho}.$$

The boundary conditions at the surface of the wire when $\rho=a$ are (1) that the electric force parallel to the surface is continuous, *i.e.*, that R is continuous; this gives $AJ_0(\iota na)=BK_0(\iota\kappa a)$; and (2) that the magnetic force parallel to the surface is continuous; this gives

$$\frac{4\pi\iota}{\sigma n}AJ'_0(\iota na)=-\frac{p}{v^2\kappa}BK'_0(\iota\kappa a).$$

Eliminating A and B from these equations we get

$$\frac{\sigma nJ'_0(\iota na)}{4\pi\iota J'_0(\iota na)}=-\frac{\kappa v^2}{p}\frac{K_0(\iota\kappa a)}{K'_0(\iota\kappa a)} \quad . \quad . \quad (4),$$

a transcendental equation to determine n. In all cases of electric waves along wires where the wave length is large compared with the radius of the wire κa is very small. When κa is very small

$$K_0(\iota\kappa a)=\log\frac{2\gamma}{\iota\kappa a},\ \text{and}\ K'_0(\iota\kappa a)=-\frac{1}{\iota\kappa a}.$$

Substituting these values in (4) we get

$$\frac{\iota na\sigma}{4\pi}\frac{J_0(\iota na)}{J'_0(\iota na)}=-\frac{2\gamma^2v^2}{p}\left(\frac{\iota\kappa a}{2\gamma}\right)^2\log\left(\frac{2\gamma}{\iota\kappa a}\right)^2$$

or if $z=\left(\frac{\iota\kappa a}{2\gamma}\right)^2$

$$\frac{\iota na\sigma}{4\pi}\frac{J_0(\iota na)}{J'_0(\iota na)}=\frac{2\gamma^2v^2}{p}z\log z \quad . \quad . \quad (5).$$

§ 24. *Slowly Varying Currents.*—Let us first take the case when na is small. Then we have approximately $J_0(\iota na)=1, J'_0(\iota na)=-\frac{1}{2}(\iota na)$, and equation (5) becomes

$$z\log z=-\frac{\iota\sigma p}{4\pi\gamma^2v^2}\quad . \quad . \quad . \quad . \quad (6).$$

As $v=3\times10^{10}$, it follows that with the specific resistances which are possessed by the metals the right-hand side of this equation will be very small, since to make it large would require a value of p which would be practically incompatible with the condition na small. An approximate solution of the equation $z\log z=-y$ where y is small is $z_1=-y/\log y$, a second approximation is $z_2=-y/\log z_1$, a third $z_3=-y/\log z_2$, and so on. Proceeding in this way, we find for a first approximation to the solution of equation (6)

$$\kappa^2=\frac{p\sigma}{\pi v^2a^2\log(p\sigma/4\pi\gamma^2v^2)}\left\{\iota+\frac{\pi}{2}\frac{1}{\log(p\sigma/4\pi\gamma^2v^2)}\right\};$$

therefore

$$m^2=\frac{p^2}{v^2}-\frac{p\sigma}{\pi v^2a^2\log(p\sigma/4\pi\gamma^2v^2)}\left\{\iota+\frac{\pi}{2}\frac{1}{\log(p\sigma/4\pi\gamma^2v^2)}\right\}.$$

The second term within the bracket is very small and may be neglected, and except in special cases p^2/v^2 will be small compared with the remaining term, as the ratio of this term to p^2/v^2 is $(\sigma/\pi a^2p)/\log(p\sigma/4\pi\gamma^2v^2)$; but since na is small $\sigma/\pi a^2p$ is large, and the logarithm will not in general be sufficiently large to neutralize the large numerator of this fraction. Neglecting p^2/v^2 we have

$$m^2=\frac{p\sigma\iota}{\pi v^2a^2\log(p\sigma/4\pi\gamma^2v^2)}$$

or

$$m=-\sqrt{\frac{-p\sigma}{2\pi v^2a^2\log(p\sigma/4\pi\gamma^2v^2)}}(1-i).$$

Now R varies as $\epsilon^{\iota(mz+pt)}$, hence R will be proportional to

$$\epsilon^{-\alpha z}\cos(pt-\alpha z),\text{ where }\alpha=\{-p\sigma/2\pi v^2a^2\log(p\sigma/4\pi\gamma^2v^2)\}^{\frac{1}{2}}.$$

This indicates a velocity of propagation equal to p/α or to

$$v\{2\pi pa^2\log(4\pi\gamma^2v^2/p\sigma)/\sigma\}^{\frac{1}{2}},$$

the amplitude of the vibration dying away to $1/e$ of its original value after traversing a length $1/\alpha$, which is only $(1/2\pi)$ of the wave length. Thus waves of this kind move more slowly than disturbances which are propagated through the dielectric. If **R** is the resistance of unit length of the wire, *i.e.*, $\sigma/\pi a^2$, and if $\Gamma=1/v^2\log(p\sigma/4\pi\gamma^2v^2)$, the wave along the wire is represented by

$$\epsilon^{-(p\mathbf{R}\Gamma/2)^{\frac{1}{2}}z}\cos\left((p\mathbf{R}\Gamma/2)^{\frac{1}{2}}z-pt\right).$$

§ 25. *Wire with Return Metallic Circuit.*—The physical meaning of Γ becomes clearer when the electric conditions are made precise by supposing that the dielectric is enclosed by a conducting cylinder coaxial with the wire. If the radius of the internal boundary of this cylinder is b, proceeding as in the simpler problem we find the following equation connecting p and m—

$$\kappa^2=-\frac{\iota p^2}{v^2}\left\{\frac{\mu}{na}\frac{J_0(\iota na)}{J'_0(\iota na)}-\frac{\mu'}{n'b}\frac{K_0(\iota n'b)}{K'_0(\iota n'b)}\right\}\frac{1}{\log(b/a)}\quad . \quad (7),$$

where μ' is the magnetic permeability of the outer conduction and

$$n'^2=m^2+4\pi\mu'\iota p/\sigma'$$

σ' being the specific resistance of the outer conductor. When na is very small equation (7) becomes

$$\kappa^2=-\frac{\iota p^2}{V^2}\left\{\frac{2\iota\mu}{n^2a^2}-\frac{\mu'}{n'b}\frac{K_0(\iota n'b)}{K'_0(\iota n'b)}\right\}\frac{1}{\log(b/a)}\quad . \quad (8).$$

The first term is very large as na is small, the second term is zero when b is infinite, and even when b is so small that $n'b$ is a small quantity. For the ratio of the second term inside the bracket to the first is equal to

$$\frac{\mu'}{2\mu}n^2a^2\log\frac{2\gamma}{\iota n^2b}$$

and is thus exceedingly small unless $n'b$ is vanishingly small compared with na. Hence very approximately equation (8) gives since $\kappa^2=m^2-p^2/v^2$

$$m^2=\frac{p^2}{v^2}\left\{1-\frac{\iota\sigma}{2\pi pa^2}\frac{1}{\log(b/a)}\right\},$$

or approximately

$$m^2=-\frac{p}{v^2}\frac{\iota\sigma}{2\pi a^2}\frac{1}{\log(b/a)}$$

If **R** is the resistance and Γ the capacity of unit length of the wire in electromagnetic measure, $\mathbf{R}=\sigma/\pi a^2$ and $\Gamma=1/2V^2\log(b/a)$, hence

$$m^2=-\iota p\mathbf{R}\Gamma\text{ or }m=-(p\mathbf{R}\Gamma)^{\frac{1}{2}}\left(\frac{1}{\sqrt{2}}-\frac{\iota}{\sqrt{2}}\right).$$

Thus the velocity of propagation is $(2p/\mathbf{R}\Gamma)^{\frac{1}{2}}$, the amplitude dies away to $1/e$ of its original value after passing over a distance $(2/\mathbf{R}\Gamma p)^{\frac{1}{2}}$; the greater the frequency the greater the velocity and the more rapid the damping. As a numerical example, let us take the case of a cable transmitting electrical vibrations, whose period is 1/100 of a second; let the copper core be 4 millimetres in diameter, and the external radius of the gutta-percha covering be 2·5 times the radius of the copper. In this case **R** is $1{\cdot}3\times10^{-5}$ ohms and in absolute units $1{\cdot}3\times10^4$, while Γ is about 15×10^{-22}; hence the velocity of propagation is about 8×10^9 cm./sec., and the disturbance will travel about $1{\cdot}28\times10^7$ cm. before falling to $1/e$ of its initial value. This is an illustration of the velocity of a very long wave. With very fine wires the condition na small can be fulfilled with quite short waves. Thus take the case of a platinum wire 2×10^{-4} cm. in radius, carrying a wave whose wave length in air would be 1 metre; then since σ for platinum is about $1{\cdot}4\times10^4$, and p for this wave length $2\pi\times3\times10^8$, we see that na is small. Substituting the value of p, a, σ in equation (6), we find that the velocity of propagation is only about 80 per cent. of that of an electromagnetic disturbance through air, and the amplitude of the vibration will fall to $1/e$ of its original value after passing over a distance of about 17 cm.

The relation $m^2=-\iota p\mathbf{R}\Gamma$ is the one at which we should arrive for the propagation of a disturbance along a cable if we neglected the effects of electromagnetic induction. The equation satisfied by the current I along the wire is in this case $\mathbf{R}\Gamma\frac{dI}{dt}=\frac{d^2I}{dz^2}$. As in this case the effects of self-induction are neglected, the disturbance is propagated by "diffusion" rather than by ordinary wave propagation. This remark applies to the case we are considering. Whenever na is small we are dealing with diffusion and not true wave propagation; hence when we study electric waves by their effects along wires we must be careful that na is large. For if this quantity is small, the velocity of propagation depends upon the frequency, and there is no more a definite velocity of propagation of an arbitrary disturbance lasting for not too short a time, than there is a definite velocity of propagation of heat through a conducting solid.

If na is small nr will be small everywhere within the wire, and if nr is small $J_0(\iota nr)$ is approximately unity. Hence the electric force parallel to the axis of the wire, and therefore the electric current, is in this case uniform over the cross section of the wire; when this is the case the problem of waves along wires is one of diffusion. A reference to the equations giving the components of the electric force along and perpendicular to the axis of the wire shows that inside the wire the force is everywhere approximately parallel to the axis, while in the dielectric at the surface of the wire the electric force is approximately radial. At a distance from the wire comparable with the wave length this ceases to be true, and the lines of force are bent so that at some points they are parallel to the axis of the wire. The strong damping of the waves in this case is due to the absorption of energy caused by the heating of the wire by the current flowing through it. Fig. 48 represents the lines of electric force in a case of this kind. It is taken from Sommerfeld's paper.[76]

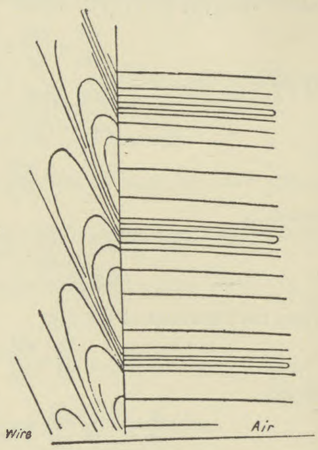

Fig. 48.

§ 26. *Case of High Frequency Currents or very good Conductors.*—When p is so large or σ so small that na is a very large quantity, the preceding considerations no longer hold. If na is very large $J'_0(\iota na)=-iJ_0(\iota na)$ and equation (5) becomes

$$z\log z=-\frac{ip\sigma}{8\pi\gamma^2v^2}na$$
$$=M(1-i),$$

where

$$M=\frac{a}{4\gamma^2v^2}\left\{\frac{\mu\sigma p^3}{2\pi}\right\}^{\frac{1}{2}}.$$

In deducing this equation we have substituted for na the approximate value $\sqrt{4\pi\mu p/\sigma}$. The approximate solution of this equation is

$$z=z_0\epsilon^{\iota\phi} \text{ where } z_0=-\frac{M\sqrt{2}}{\log M\sqrt{2}} \text{ and } \phi=-\pi/4.$$

Since $z=(\iota\kappa a/2\gamma)^2$ and $\kappa^2=m^2-p^2/v^2$, we get

$$m^2=\frac{p^2}{v^2}+\frac{a}{v^2a}\left(\frac{\mu\sigma p^3}{2\pi}\right)^{\frac{1}{2}}\frac{1}{\log M\sqrt{2}}(1-i),$$

as the real part of the second term on the right-hand side is very small compared with p^2/v^2, we have approximately

$$m^2=\frac{p^2}{v^2}\left\{1-\left(\frac{\mu\sigma}{2\pi pa^2}\right)^{\frac{1}{2}}\frac{1}{\log M\sqrt{2}}i\right\},$$

or

$$m=\frac{p}{v}\left\{1-\tfrac{1}{2}\left(\frac{\mu\sigma}{2\pi pa^2}\right)^{\frac{1}{2}}\frac{1}{\log M\sqrt{2}}i\right\} \quad . \quad . \quad . \quad (9).$$

If we take the case when the air is bounded by a conducting cylinder whose internal radius is b, we arrive at a similar expression, the only difference being that instead of log M$\sqrt{2}$ we have 2 log b/a. Since p/m is the velocity with which a disturbance is propagated along the wire, we see from equation (9) that in this case the velocity of propagation is v, and is independent of the frequency; the amplitude of the disturbance falls to $1/e$ after passing over a distance equal to $\lambda(2pa^2/\mu\pi\sigma)^{\frac{1}{2}}\log(M\sqrt{2})$, when λ is the wave length $2\pi v/p$. By hypothesis pa^2/σ is large, so that the disturbance will travel over many wave lengths before falling to $1/e$ of its original value. The phenomena in this case are much simpler than in the preceding ones. All disturbances now travel with the velocity with which light travels through the dielectric, and the electric force in the dielectric is at right angles to the wire (this follows at once from the equations for P and Q in terms of R, § 23, as in this case κ is very small compared with m). The electric force in the wire is approximately parallel to the axis of the wire, but a very interesting feature of this case is that the electric force, and therefore the current, are practically confined to the skin close to the surface of the wire.

§ 27. *Distribution of the Currents in the Wire.*—To calculate the variation in the electric force as the distance from the surface of the wire increases, we may proceed as follows. Let the total current flowing through the cross section of the wire at the place z, and the time t, be the real part of $I_0\epsilon^{\iota(mz+pt)}$; now the magnetic force tangential to the surface of the wire is at the surface

$$\frac{4\pi\iota}{\sigma n}AJ'_0(\iota na)\epsilon^{\iota(mz+pt)},$$

and since the line integral of this taken round the circumference of the wire is equal to $4\pi I_0\epsilon^{\iota(mz+pt)}$, we get

$$A=-\frac{\iota\sigma n}{2\pi a}\,\frac{I_0}{J'_0(\iota na)}.$$

Thus in the wire

$$R=-\frac{\iota\sigma n}{2\pi a}\,\frac{I_0}{J'_0(\iota na)}J_0(\iota nr)\epsilon^{\iota(mz+pt)}.$$

When as in this case na is large, then at a point near the surface of the wire,

$$J'_0(\iota na)=-\frac{\iota\epsilon^{na}}{\sqrt{2\pi na}};\quad J_0(\iota nr)=\frac{\epsilon^{nr}}{\sqrt{2\pi nr}}.$$

Substituting these values, and taking the real part of R, we get

$$R=\left\{\frac{\mu p\sigma}{\pi ar}\right\}^{\frac{1}{2}}I_0\epsilon^{-(2\pi\mu p/\sigma)^{\frac{1}{2}}(a-r)}\cos\psi,$$

where

$$\psi=mz+pt-(2\pi\mu p/\sigma)^{\frac{1}{2}}(a-r)+\frac{\pi}{4}.$$

Similarly we find that the radial electric force in the cylinder is equal to

$$-\frac{p}{v}\frac{\sigma I_0}{2\pi\sqrt{ar}}\epsilon^{-(2\pi\mu p/\sigma)^{\frac{1}{2}}(a-r)}\sin\left(\psi-\frac{\pi}{4}\right),$$

and the tangential magnetic force to

$$\frac{2}{\sqrt{ar}}I_0\epsilon^{-(2\pi\mu p/\sigma)^{\frac{1}{2}}(a-r)}\cos\left(\psi-\frac{\pi}{4}\right).$$

Since all these expressions contain the factor $\epsilon^{-(2\pi\mu p/\sigma)^{\frac{1}{2}}(a-r)}$, we see that the maximum values of these quantities at a distance $(\sigma/2\pi\mu p)^{\frac{1}{2}}$ from the surface are only $(1/e)$ of their maximum values at the surface, and they diminish in geometrical progression as the distance from the boundary increases in arithmetical progression. Thus the currents are practically confined to a thin skin at the surface of the wire, and we may take $(\sigma/2\pi\mu p)^{\frac{1}{2}}$ as the measure of the thickness of this skin. For currents making 100 vibrations per second, the thickness of the skin for soft iron with a magnetic permeability of 1000 is about ·5 mm., and for copper it is about 7·5 mm. For electric waves 1 metre wave length, the skin for iron is only about ·0001 mm., while for copper it is about 15 times as great. In these cases there is an enormous concentration of the current in the surface layers, producing a great increase in the apparent resistance. We see from the equation for R that the maximum value of R = (maximum value of current through the wire) × $(\mu p\sigma/\pi a^2)^{\frac{1}{2}}$. Thus we may look upon $(\mu p\sigma/\pi a^2)^{\frac{1}{2}}$ as the apparent resistance per unit length of the wire to these alternating currents. It is the same as the resistance to a steady current of a tube whose radius is a, and whose thickness is $1/\sqrt{2}$ times the thickness of the skin.

It is instructive to look upon the transmission of waves along wires from the point of view of Poynting's theorem (see § 13). According to this view the energy does not travel through the wire, but through the dielectric; when the energy from the dielectric passes into the wire it is gradually converted into heat. Now when we were considering the reflexion of waves from metallic plates we saw that we got practically complete reflexion when h, the thickness of the plate, was great enough to make nh large, while the waves were transmitted through the plate when nh is small. Thus in the case of wires when na is large the waves striking against the wires will be completely reflected, and their energy will remain in the dielectric, which when nh is small they will pass through the metal, and part of their energy will be dissipated in heating the wire. We should thus expect that there would be considerable damping in the second case and very little in the first, and this, as we have seen, is the case.

There will be a surface charge of electricity on the wires, and this will give rise to an electrostatic potential ϕ, whose value can be easily calculated. If s is the surface density of the electricity on the wire, the charge on unit length is $2\pi as$; hence if KC is the capacity per unit length of the wire, K being the specific inductive capacity of the dielectric, and C a function of the size of the wire and its distance from other conductors, we have, ϕ being the value of the surface of the wire,

$$\phi=\frac{2\pi as}{KC}.$$

If $I_0\epsilon^{\iota(mz+pt)}$ is the total current through the wire at the place z and the time t, then—

$$\frac{d}{dz}(I_0\epsilon^{\iota(mz+pt)})=-2\pi a\frac{ds}{dt},$$

or since all the quantities vary, as $\epsilon^{\iota(mz+pt)}$, we have

$$\frac{m}{p}I_0\epsilon^{\iota(mz+pt)}=-2\pi as.$$

Hence

$$\phi=-\frac{m}{pKC}I_0\epsilon^{\iota(mz+pt)}.$$

When na is very large, $p/m=v$ the velocity of propagation of electromagnetic disturbances through the dielectric, and if the dielectric is non-magnetic and we use the electromagnetic system of units $K=1/v^2$, thus the preceding equation becomes

$$\phi=\frac{v}{C}I_0\epsilon^{\iota(mz+pt)}.$$

We can apply this equation to find the reflected and transmitted currents when the circumstances suddenly change along the wire.

§ 28. *Wave reflected at the Junction of two Dielectrics.*—Suppose the plane $z=0$ separates two dielectrics, in the first of which the velocity of propagation of electromagnetic action is v, and in the second v'. Let $I_0\epsilon^{\iota(mz+pt)}$ be the incident current coming along the wire from the first medium to the second, $I'_0\epsilon^{\iota(-mz+pt)}$ the reflected current, and $I_1\epsilon^{\iota(mz+pt)}$ the current in the second medium, then

$$I_1=I_0+I'_0 \quad . \quad . \quad . \quad . \quad (1).$$

The potential at $z=0$ in the first medium is $(v/C)(I_0-I'_0)\epsilon^{\iota pt}$, and in the second $v'/CI_1\epsilon^{\iota pt}$. As the potential is continuous we have

$$v'I_1=v(I_0-I'_0) \quad . \quad . \quad . \quad . \quad (2).$$

From (1) and (2) we get

$$I'_0=-\frac{v'-v}{v'+v}I_0$$

$$I_1=\frac{2v}{v'+v}I_0$$

formulæ, which, as we might have expected, since the energy is entirely in the dielectric, are of the same type as those giving the reflected and transmitted waves when electromagnetic waves are incident on a reflecting surface and there are no wires in the field.

§ 29. *Reflexion from a Condenser at the End of the Wire.*—Let us suppose that a condenser whose capacity is C_1 is joined to the end of the wire at $z=0$; let the incident current be $I_0\epsilon^{\iota(mz+pt)}$ and the reflected current $I'_0\epsilon^{\iota(-mz+pt)}$, then at $z=0$ the rate at which electricity is running into the condenser is $(I_0+I'_0)\epsilon^{\iota pt}$. If ϕ is the potential of the plate of the condenser connected with the wire, the other plate being to earth, the change in the condenser is $C_1\phi$, and the rate at which it is increasing $C_1(d\phi/dt)$. Now

$$\phi=\frac{v}{C}(I_0-I'_1)\epsilon^{\iota pt},$$

hence

$$I_0+I'_0=\frac{vC_1}{C}\iota p(I_0-I'_0)$$

or

$$I'_0=\frac{\frac{vC_1}{C}\iota p-1}{\frac{vC_1}{C}\iota p+1}I_0$$

$$=-\epsilon^{-2\iota\theta}I_0$$

$$\text{if}\tan\theta=\frac{vC_1p}{C};$$

thus if the incident current is represented by $\cos(mz+pt)$ the reflected current will be $-\cos\left(pt-m\left(z+\frac{2\theta}{m}\right)\right)$. Thus the magnitude of the reflected current is equal to that of the incident; this we could have seen as there is no loss of energy; there is, however, a change of phase. If there is no capacity at the end the current is reversed in direction; when there is a small capacity the change of phase is such as would be produced if the wire were prolonged to a distance $2v^2C_1/C=2C_1/KC=2$ capacity at the end divided by capacity per unit length of the wire.

§ 30. *Time of Oscillations of a System consisting of a Wire connecting two equal Condensers.*—Suppose that we have a system where a wire of length $2l$ connects two equal condensers, each having a capacity C_1, the other plates of the condenser being at zero potential. Let the current in the wire be regarded as the sum of two currents, one represented by $I_0\cos(mz+pt)$ and the other by $I'_0\cos(-mz+pt)$, and let the origin from which z is measured be the middle of the wire; then when $z=-l$, the current flowing into the condenser, is $I_0\cos(-ml+pt)+I'_0\cos(ml+pt)$, and the charge in the condenser is $C_1\phi=\frac{C_1v}{C}\{I_0\cos(-ml+pt)-I'_0\cos(ml+pt)\}$.

Hence

$$I_0\cos(-ml+pt)+I'_0\cos(ml+pt)$$
$$=\frac{C_1v}{C}\cdot\frac{d}{dt}\{I_0\cos(-ml+pt)-I'_0\cos(ml+pt)\}.$$

Equating coefficients of $\cos pt$ and $\sin pt$ we get

$$\text{(1)}\qquad I_0=I'_0;\ \frac{\cot ml}{ml}=\frac{C_1v^2}{Cl}$$

or

$$\text{(2)}\qquad I_0=-I'_0;\ \frac{\tan ml}{ml}=-\frac{C_1v^2}{Cl};$$

these give the values of m, and hence the periods of the vibration. Let us consider the first equation. Taking first the solution when the wave length is long compared with the length of the wire, ml is very small and equation (1) becomes

$$1=m^2\frac{v^2C_1l}{C},$$

or since $mv=p$

$$p^2\frac{C_1l}{C}=1.$$

If the ends of the wire are connected one to one plate of a condenser and the other to the other, instead of to the plates of separate condensers, the second plates of which are kept at potential zero, we can prove in a similar way that when ml is small the equation for p is

$$p^2\frac{2C_1l}{C}=1\quad.\quad.\quad.\quad.\quad(3).$$

Now when the currents are varying so rapidly that na is large, $1/C=L$ where L is the coefficient of self-induction of the wire per unit length. For if I is the current in the wire the electromagnetic energy is equal to

$$\frac{1}{2}\int LI^2dz$$

where dz is an element of the wire. The electrostatic energy is equal to

$$\frac{1}{2}\int KC\phi^2dz,$$

where ϕ is the electrostatic potential, but in this case

$$\phi=\frac{r}{C}I$$

so that the electrostatic energy is equal to

$$\frac{1}{2}\int\frac{Kv^2}{C}I^2dz,$$

or since $Kv^2=1$ to

$$\frac{1}{2}\int\frac{I^2}{C}dz.$$

Since the mean electrostatic energy is equal to the mean electromagnetic, we have $L=1/C$. Thus equation (3) becomes

$$p^22Cl'L=1,$$

or if $L'=2lL$, *i.e.*, if L′ is the coefficient of self-induction of the circuit

$$p=\frac{1}{\sqrt{L'C_1}}.$$

This is the value given by Lord Kelvin in 1853 in his paper on the oscillatory discharge of a condenser.[77]

Let us now consider the value of m given by (1) when C_1v^2/Cl is small. In this case we see from the equation that $ml=(2n+1)\frac{\pi}{2}+x$ where x is small and n is an integer. Substituting this value of ml in (1) we find

$$x=-\{2n+1\}\frac{\pi}{2}\frac{C_1v^2}{Cl},$$

or, if λ is the wave length $=2\pi/m$

$$\lambda=\frac{4l}{2n+1}\left\{1+\frac{C_1v^2}{C}\right\}.$$

Thus when C_1v^2/C is small the effect of the condenser at the end on the wave length is the same as if the condenser were removed, and the length of the wire increased by $C_1v^2/2C$. If we know the wave length of the electrical vibrations emitted by the system and also C_1, we can from this equation determine C_1 the capacity of the condenser at the end. If we fill the space between the plates of the condenser with different substances, and determine the corresponding value of the capacities, we can compare the specific inductive capacities of the substances when exposed to alternating electric forces of the frequency corresponding to the wave length. This method has been employed by Drude.[78]

§ 31. *Reflexion from a Wire without Self-induction.*—If the end of the wire is connected with a place of zero potential by a resistance R without self-induction, then if ϕ is the potential at the end of the wire, the current through the resistance R is equal to ϕ/R. Hence if I_1 and I_2 are respectively the recedent and reflected currents

$$I_1+I_2=\frac{1}{R}\phi.$$

But $\phi=\frac{v}{C}(I_1-I_2)$. Substituting these values we find

$$I_2=\frac{\frac{v}{RC}-1}{\frac{v}{RC}+1}I_1.$$

This equation was first obtained by Heaviside.[79] The reflected current is smaller than the incident current, and so there is loss of energy by the reflexion. In the special case where $RC=v$ the reflected wave vanishes and all the energy is absorbed by the resistance.

§ 32. *Reflexion from a leaky Condenser.*—If the material separating the plates of the condenser is not a perfect insulator, but has a finite resistance R, there will be a conduction current through it equal to ϕ/R. The rate at which the charge accumulates on the plate is $\frac{C_1d\phi}{dt}$; hence at the end of the wire the condition is, if I_1 and I_2 are respectively the incident and reflected currents,

$$I_1+I_2=C_1\frac{d}{dt}\phi+\frac{\phi}{R}$$

where

$$\phi=\frac{v}{C}I_1-\frac{v}{C}I_2.$$

Substituting these values we find

$$I_2=\rho\epsilon^{-\iota\theta}I_1$$

where

$$\rho^2=\frac{(\xi-1)^2+\eta^2p^2}{(\xi+1)^2+\eta^2p^2}$$

$$\tan\theta=\frac{2\eta p}{1-\xi^2-\eta^2p^2},$$

where

$$\xi = v/\mathrm{RC}. \quad \eta = v\mathrm{C}_1/\mathrm{C};$$

ρ is the coefficient of damping, and θ the change in phase at reflexion. We can measure θ if we determine λ, the length of the wave with which the circuit is in resonance; in order, however, that the resonance should be appreciable the damping must be small. To find λ let A, B be the ends of the wire, and suppose a disturbance starts from B, travels to A, is reflected there back to B, and is again reflected. If after the second reflexion the phase differs by 2π, or by a multiple thereof, from the phase of the disturbance at starting, the resonance will be greatest. Now in travelling from B to A the loss of phase is $2\pi(2l/\lambda)$ if $2l = \mathrm{AB}$; at reflexion from A there is the loss of phase θ, and there are equal losses of phase from the backward journey and reflexion at B. Hence for resonance we have

$$\frac{8\pi l}{\lambda} + 2\theta = 2n\pi,$$

when n is an integer, or

$$\frac{4\pi l}{\lambda} = n\pi - \theta,$$

or

$$\tan\frac{4\pi l}{\lambda} = \tan(n\pi - \theta) = -\tan\theta = -\frac{2\eta p}{1 - \xi^2 - \eta^2 p^2}.$$

Hence if we determine ρ and λ, we have from the equations in this section the means of calculating R and C_1, and therefore the specific resistance and specific inductive capacity of the medium separating the plates of the condenser. This method has been used by Drude, § 37.

§ 33. *Self-induction and effective Resistance of a Wire carrying an alternating Current.*—Returning to § 27 we see that without any limitation as to $n\mathrm{a}$ being large, we have

$$\phi = -\frac{mv^2}{p\mathrm{C}}\mathrm{I}_0\epsilon^{\iota(mz+pt)} \quad . \quad . \quad (1),$$

where C is the capacity of unit length of the wire. If the wire is surrounded by a cylindrical conductor of internal radius b, $\mathrm{C} = 1/2 \log b/\mathrm{a}$. Differentiating equation (1) with respect to z, and writing E for $-d\phi/dz$, we have

$$\mathrm{E} = 2\iota p\frac{m^2v^2}{p^2}\log(b/\mathrm{a})\,\mathrm{I}_0\epsilon^{\iota(mz+pt)}.$$

By equation (7), § 25, when the conductivity of the outer conductor is sufficiently large to make $n'b$ very large

$$\kappa^2 = m^2 - \frac{p^2}{v^2} = -\frac{\iota p^2}{v^2}\left\{\frac{\mu}{n\mathrm{a}}\frac{\mathrm{J}_0(\iota n\mathrm{a})}{\mathrm{J}'_0(\iota n\mathrm{a})}\right\}\frac{1}{\log(b/\mathrm{a})}$$

or since we have very approximately

$$n^2 = \frac{4\pi\mu\iota p}{\sigma}$$

$$m^2 = \frac{p^2}{v^2}\left(1 - \frac{1}{4\pi p}\frac{n\sigma}{\mathrm{a}}\frac{\mathrm{J}_0(\iota n\mathrm{a})}{\mathrm{J}'_0(\iota n\mathrm{a})}\frac{1}{\log(b/\mathrm{a})}\right);$$

hence

$$\mathrm{E} = 2\iota p\left\{\log b/\mathrm{a} - \frac{1}{4\pi p}\frac{n\sigma}{\mathrm{a}}\frac{\mathrm{J}_0(\iota n\mathrm{a})}{\mathrm{J}'_0(\iota n\mathrm{a})}\right\}\mathrm{I};$$

I is the total current and is equal to $\mathrm{I}_0\epsilon^{\iota(mz+pt)}$.

Now (J. J. Thomson, *Recent Researches*, p. 275)

$$\iota n\mathrm{a}\frac{\mathrm{J}_0(\iota n\mathrm{a})}{\mathrm{J}'_0(\iota n\mathrm{a})} = -2 - \frac{n^2\mathrm{a}^2}{4} + \frac{n^4\mathrm{a}^4}{96} - \frac{n^6\mathrm{a}^6}{1536} + \frac{n^8\mathrm{a}^8}{23040} - \frac{13n^{10}\mathrm{a}^{10}}{4423680} + \ldots$$

Substituting this value and writing for n^2 its approximate value $4\pi\mu\iota p/\sigma$ we find

$$\mathrm{E} = \mathrm{P}\iota p\mathrm{I} + \mathrm{QI} = \mathrm{P}\frac{d\mathrm{I}}{dt} + \mathrm{QI} \quad . \quad . \quad . \quad (2),$$

where

$$\mathrm{P} = 2\log b/\mathrm{a} + \frac{1}{2}\mu - \frac{1}{48}\frac{\pi^2\mu^3p^2\mathrm{a}^4}{\sigma^2} + \frac{13}{8640}\frac{\pi^4\mu^5p^4\mathrm{a}^8}{\sigma^4} - \ldots$$

$$\mathrm{Q} = \frac{\sigma}{\pi\mathrm{a}^2}\left\{1 + \frac{1}{12}\frac{\pi^2p^2\mu^2\mathrm{a}^2}{\sigma^2} - \frac{1}{180}\frac{\pi^4p^4\mu^4\mathrm{a}^8}{\sigma^4}\ \ldots\right\}$$

Now if L is the coefficient of self-induction of a circuit and R its resistance, the external electromotive force when the current I is flowing through the circuit $= \mathrm{L}\frac{d\mathrm{I}}{dt} + \mathrm{RI}$.

Comparing this equation with (2) we may call P the self-induction and Q the effective resistance per unit length of the wire, and we see that these depend on the frequency of the current flowing through the wire. The expressions for P and Q show that as the frequency increases the self-induction diminishes, and the effective resistance increases; both these effects arise from the fact that as the frequency increases the current gets more and more concentrated in the outer layers of the wire. The expressions for the self-induction and the effective resistance are the same as those given by Maxwell (*Electricity and Magnetism*, § 690), with the exception that in Maxwell a constant A is written for $\log b/\mathrm{a}$, and μ is put equal to unity. It was Heaviside, however, who first explicitly called attention to the great effect produced by the frequency on the self-induction and resistance of a wire. When $p = 0$, *i.e.*, when the currents are steady $\mathrm{P} = 2\log(b/\mathrm{a}) + \frac{1}{2}\mu$: thus the self-induction of a straight iron wire is very much greater than that of one made of a non-magnetic metal.

When $n\mathrm{a}$ is very large $\mathrm{J}'_0(\iota n\mathrm{a}) = -\iota\mathrm{J}_0(\iota n\mathrm{a})$ and we have

$$\mathrm{E} = 2\iota p\left\{\log(b/\mathrm{a}) + \left(\frac{\sigma\mu}{4\pi p\mathrm{a}^2}\right)^{\frac{1}{2}}\left(\frac{1}{\sqrt{2}} - \frac{\iota}{\sqrt{2}}\right)\right\}\mathrm{I};$$

in this case the self-induction $\mathrm{P} = 2\log(b/\mathrm{a}) + (\sigma\mu/2\pi p\mathrm{a}^2)^{\frac{1}{2}}$ and the effective resistance $\mathrm{Q} = (\sigma\mu p/2\pi\mathrm{a}^2)^{\frac{1}{2}}$.

When $n\mathrm{a}$ is so small that P and Q may be regarded as independent of p, or when the period is given, equation (2) may be transformed into a form which is often convenient. We have

$$-\frac{d\phi}{dz} = \mathrm{P}\frac{d\mathrm{I}}{dt} + \mathrm{QI} \quad . \quad . \quad . \quad (3).$$

Now if s is the surface density of the electricity on the wire $2\pi\mathrm{a}s = \mathrm{C}\phi$, where C is the capacity per unit length of the wire and we have

$$2\pi\mathrm{a}\frac{ds}{dt} = -\frac{d\mathrm{I}}{dz} \text{ or } \mathrm{C}\frac{d\phi}{dt} = -\frac{d\mathrm{I}}{dz};$$

hence (3) becomes

$$\mathrm{P}\frac{d^2\mathrm{I}}{dt^2} + \mathrm{Q}\frac{d\mathrm{I}}{dt} = \frac{1}{\mathrm{C}}\frac{d^2\mathrm{I}}{dz^2},$$

which is sometimes called the telegraphic equation, as representing the variation of the current along a telegraph wire. It has been discussed by Poincaré,[80] Picard,[81] Boussinesq,[82] and very exhaustively by Heaviside.[83] Putting $\mathrm{I}' = \epsilon^{-\frac{\mathrm{Q}t}{2\mathrm{P}}}\mathrm{I}$ it may be transformed to

$$\frac{d^2\mathrm{I}'}{dt^2} = \frac{1}{\mathrm{CP}}\frac{d^2\mathrm{I}'}{dz^2} + \frac{\mathrm{Q}^2}{4\mathrm{P}^2}\mathrm{I}' \quad . \quad . \quad . \quad (4).$$

If $\mathrm{I}' = \mathrm{F}(x)$; $\frac{d\mathrm{I}'}{dt} = f(x)$ when $x = 0$ the solution of (4)[84] is

$$\mathrm{I}' = \frac{1}{2}\frac{d}{dt}\int_0^\pi t\mathrm{F}\left(x + \frac{t}{\sqrt{\mathrm{CP}}}\cos\alpha\right)\mathrm{J}_0\left(\frac{\iota\mathrm{Q}}{2\mathrm{P}}t\sin\alpha\right)\sin\alpha d\alpha.$$

$$+\frac{1}{2}\int_0^\pi tf\left(x + \frac{t}{\sqrt{\mathrm{CP}}}\cos\alpha\right)\mathrm{J}_0\left(\frac{\iota\mathrm{Q}}{2\mathrm{P}}t\sin\alpha\right)\sin\alpha d\alpha$$

§ 34. *Passage of an Electric Wave through a Medium containing Ions; anomalous Dispersion of Electric Waves.*—To take a simple case, let us consider a plane wave travelling parallel to the axis of z, the electric force in the wave being parallel to x and the magnetic force to y. In the medium through which the wave is travelling let there be a number of charged ions, and let the x co-ordinates of these be ξ_1, ξ_2, . . . The ions will be moved by the electric field and will produce a convective current equal to $\Sigma ed\xi/dt$, where the summation refers to the ions in unit volume round the point where the current is measured. The charges on the ions will produce an electric field, and in considering the dielectric currents in the field we must remember that the part due to the variation of the electric field due to the charged ions has already been included in the convection current $\Sigma ed\xi/dt$. Hence if X_0 is the part of the field not arising from the charged atoms the dielectric current will be $\mathrm{K}_0 d\mathrm{X}_0/dt$ where K_0 is the specific inductive capacity of the space when free from atoms. Thus equations B and A (§ 10) become

$$\mathrm{K}_0\frac{d\mathrm{X}_0}{dt} + 4\pi\Sigma e\frac{d\xi}{dt} = -\frac{d\beta}{dz}$$

$$\frac{d\mathrm{X}_0}{dz} = -\frac{d\beta}{dt} \text{ (if the medium is non-magnetic),}$$

so that

$$\frac{d^2\mathrm{X}_0}{dt^2} + \frac{4\pi}{\mathrm{K}_0}\Sigma e\frac{d^2\xi}{dt^2} = \frac{1}{\mathrm{K}_0}\frac{d^2\mathrm{X}_0}{dz^2} \quad . \quad . \quad (1).$$

Now if m be the mass of an ion, $\alpha_1\xi_1$ the force tending to bring the ion back to $\xi = 0$, and $\mathrm{R}_1\frac{d\xi_1}{dt}$ is the frictional resistance acting on the ion,

$$m_1\frac{d^2\xi_1}{dt^2} + \mathrm{R}_1\frac{d\xi_1}{dt} + \alpha_1\xi_1 = (\mathrm{X}_0 + \mathrm{X})e \quad . \quad . \quad (2),$$

where X is the force arising from the charges on the ion. To find X we notice that the system is electrically neutral when all the ξ's vanish, and that when an ion is displaced through ξ, the electrical effect is the same as that of an electric doublet whose axis is parallel to x, and whose moment is $e\xi$. The electric field is that due to a system of electric doublets the sum of whose moments per unit volume is $\Sigma e\xi$. To find the electric force due to these at a point, describe with that point as centre a sphere whose radius is large compared with the range of molecular action, but small compared with the length of the wave passing through the medium, so that inside this sphere the conditions may be taken as uniform. X will be the electric force due to the doublets in this sphere, and this will be the same as the magnetic force due to a system of little magnets provided the electrical moment of the doublet is equal to the magnetic moments of the magnets. The force due to the magnets is $4\pi I/3$, when I is the intensity of magnetization, *i.e.*, the sum of the moments of the magnets per unit volume; hence $X=\frac{4\pi}{3}\frac{e\xi}{K_0}$; where the factor K_0 is put equal to unity when e is measured in electrostatic units, and to $1/V_0^2$ when e is measured in electromagnetic units, V_0 being the velocity of light through the ether.

Let us suppose that all the quantities are proportionate to $\epsilon^{\iota pt}$; then from equation (2) we have

$$\xi=\frac{\left(X_0+\frac{4\pi}{3K_0}\Sigma e\xi\right)e}{a+R\iota p-mp^2}$$

hence if

$$\Theta=\Sigma\frac{e^2}{a+R\iota p-mp^2}$$

$$\Sigma e\xi=\frac{X_0\Theta}{1-\frac{4\pi\Theta}{3K^0}}$$

hence equation (1) becomes if X_0 varies as $\epsilon^{\iota(pt-mz)}$

$$-p^2X_0-\frac{p^2 4\pi\Theta}{1-\frac{4\pi\Theta}{3K_0}}\frac{X_0}{K_0}=-\frac{m^2}{K_0}X_0 \quad . \quad . \quad . \quad (3).$$

If V is the velocity of propagation through this medium filled with ions, V_0 the velocity through empty space, then $V=p/m$, $V_0^2=1/K_0$, and if ν is the refractive index of the medium, since $\nu^2=V_0^2/V^2=m^2/p^2K_0$, we have by equation (3)

$$1+\frac{4\pi\Theta/K_0}{1-4\pi\Theta/3K_0}=\nu^2,$$

or

$$\frac{4\pi}{3}\frac{\Theta}{K_0}=\frac{\nu^2-1}{\nu^2+2}.$$

This equation is given by Lorentz.[85] If p_1 is the free period of the ion when there are no frictional terms, $a_1=mp_1^2$; hence if there are N_1 molecules having periods p_1, N_2 having p_2, and so on.

$$\Theta=\frac{N_1e^2}{m_1(p_1^2-p^2)+R_1\iota p}+\frac{N_2e^2}{m_2(p_2^2-p^2)+R_2\iota p}+\ldots$$

This equation gives the refractive index in terms of the frequency, and is therefore the dispersion formula. To find the general character of the results to which it leads, let us take the simple case where all the ions are equal, and there is only one period, and no frictional resistance. Then

$$\frac{\nu^2-1}{\nu^2+2}=\frac{4\pi}{3}\frac{Ne^2V_0^2}{m(p_0^2-p^2)}.$$

The curve whose abscissæ are p^2 and ordinates ν^2 is shown in Fig. 49; we see that when p^2 is less than $p_0^2-\frac{4\pi}{3}\frac{Ne^2V_0^2}{m}$, ν^2 increases with p, and the dispersion is said to be normal as the refractive index for short waves is greater than that for long. Since ν^2 must be positive, the curve must be discontinuous between L when $p^2=p_0^2-\frac{4\pi}{3}\frac{Ne^2V_0^2}{m}$, and M where $p^2=p_0^2+\frac{8\pi}{3}\frac{Ne^2V_0^2}{m}$, and there can be no corresponding real values of ν^2:—that is, waves with frequencies between these values cannot be propagated through the medium, but are totally reflected from it. At the point L on the curve the velocity of propagation of waves through the medium is infinitely small, at the point M it is infinitely great, and after passing M ν becomes real again, but is always less than unity, and approaches unity as the limit when the frequency is infinitely rapid. In this region beyond M the refractive index is less, though the wave lengths are smaller, than for the region before L; the dispersion is said to be anomalous. A mechanical model showing these peculiarities of wave propagation has been described by Vincent.[86] If we include frictional terms, *i.e.*, the term ιRp in our expression for Θ, then though ν is complex, there is always a real part. In the curve which now represents the relation between the real part of ν^2 and p^2 (Fig. 50), there is no break, but throughout the range of values of p^2 in which there is no propagation of the waves without friction, there is very intense absorption, indicated by the dot and dash line. The long waves on one side of the absorption band have a greater index of refraction than the short waves on the other side. If p_1 and p_2 are the values corresponding to the points l, k, between which the absorption is most intense, ν is infinite for the frequency p_1 and zero for the frequency p_2. Hence, neglecting the frictional terms, we have

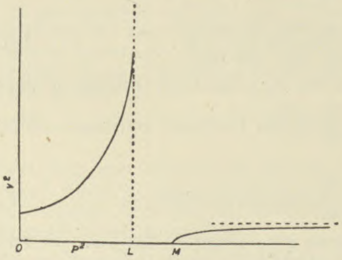

Fig. 49.

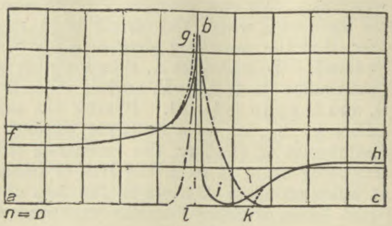

Fig. 50.

$$p_1^2=p_0^2-\frac{4\pi}{3}\frac{Ne^2V_0^2}{m},\ p_2^2=p_0^2+\frac{4\pi}{3}\frac{2Ne^2V_0^2}{m}.$$

The specific inductive capacity K of the medium under steady electric force is the value of ν^2 when $p=0$, hence

$$\frac{K-1}{K+2}=\frac{4\pi}{3}\frac{Ne^2V_0{}^2}{mp_0^2} \quad . \quad . \quad . \quad . \quad (1).$$

Substituting for $Ne^2V_0^2/m$ in the preceding equations we get

$$p_1^2=p_0^2\frac{3}{K+2},\ p_2^2=p_0^2\frac{3K}{K+2},\ \text{or}\ p_2^2=Kp_1^2.$$

Thus if the specific inductive capacity is large there will be a long range of frequencies for which there is very intense absorption. Anomalous dispersion of electric waves has been observed in many dielectrics. In liquids it was observed by Cole[87] for ethyl-alcohol. Drude[88] has made very extensive researches on this subject in a large number of liquids, the most conspicuous being glycerine, amyl-alcohol, acetic and formic acids; he found that the existence of anomalous dispersion was closely related with the chemical composition, the liquids showing it in a marked degree containing the hydrosyl radicle OH. If we assume the truth of the theory of dispersion just given, it follows that the anomalous dispersion of the electric waves must be due to a small number of molecules or aggregates of molecules being mixed with the fluid, and not to a property possessed by each individual molecule of the fluid. As an example, glycerine has been shown to exhibit anomalous dispersion for waves over a range which includes $p=2\pi\times2{\cdot}5\times10^7$, $p=2\pi\times1{\cdot}5\times10^8$, $p=2\pi\times4\times10^8$, numbers from which we conclude that p_0 is of the order of magnitude $2\pi\times10^8$. Now from equation (1) we must have $4\pi Ne^2V_0^2/3mp_0^2$ less than 1. Putting in this expression the smallest admissible value of e, viz., the charge on the hydrogen ion in electrolysis, and for m the largest admissible value, which if the effect were due to the individual molecules is the mass of the molecule of glycerine, we find that $Ne^2V_0^2/mp^2$ would be of the order 10^7. As this quantity must be less than unity we see that our supposition is inadmissible, and we conclude that the anomalous dispersion of glycerine and other fluids, and the high value of their specific inductive capacity in steady electric fields, is due to the presence of a small number of bodies in an exceptional state. The remarkable experiments of Dewar and Fleming[89] on the specific inductive capacities of liquids at very low temperatures, such as that of boiling liquid air, seem in harmony with this result, for they have shown that the abnormally high values for the specific inductive capacity which are characteristic of many liquids at ordinary temperatures disappear, and are replaced by values which are approximately the squares of the refractive indices of the substances at ordinary temperatures—a result which indicates that at very low temperatures the dissociation, or whatever action produced the bodies, which when mixed with the glycerine caused the high specific inductive capacity, no longer exists. Dewar and Fleming have examined a very large number of solutions, and find marked differences in the temperatures at which the great drop in the specific inductive capacity takes places. The nature of these differences is shown by the following curve (Fig. 51), the ordinates of which represent the specific inductive capacity and the abscissæ the temperatures.

Some solids exhibit anomalous dispersion. Thus the experiments made by Blondlot[90] and the writer[91] on the specific inductive capacity of glass show that it is higher for steady electric forces than for those which accompany electric waves. Lowe[92] found that while the specific inductive capacity of glass for electrical waves was smaller than in a steady electric field, the difference was not so large as that observed by Blondlot and the writer. Anomalous dispersion for electric waves has been observed in beryl by Fomm and Graetz.[93] Further experiments in electrical dispersion will be found described in papers by Marx,[94] Löwe,[95] Cole[96] and Thwing.[97]

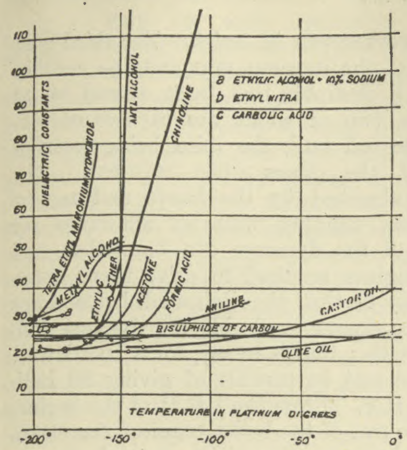

Fig. 51.

§ 35. We have seen that, on the theory of anomalous dispersion sketched above, the anomalous dispersion of electric waves a few centimetres long involves the existence of systems other than the ordinary molecules of the dielectric; we can press this result further, and show that on this theory the luminous vibrations given out by gases, or at any rate by some gases, cannot proceed from all the molecules; but that only a comparatively small number, which are probably in a special state, are luminous. For we see that if K is the specific inductive capacity of the gas under steady electric force, *i.e.*, when $p=o$,

$$\frac{K-1}{K+2}=\Sigma\frac{4\pi Ne^2}{3K_0 mp_1^2}$$

where p_1 is the frequency of one of the free periods of the molecule. Since $K_0p_1^2=4\pi^2/\lambda_1^2$ when λ_1 is the wave length of this vibration, we have

$$\frac{K-1}{K+2}=\Sigma\frac{Ne^2}{3\pi m}\lambda_1^2.$$

Let us take the case of hydrogen and confine our attention to the vibration corresponding to the red line for which $\lambda_1=6\cdot5\times10^{-5}$ cm. For hydrogen at atmospheric pressure $K-1=2\cdot7\times10^{-4}$. Thus

$$Ne=\frac{6\pi\times10^4}{(c/m)}$$

We have reason to think that e/m is about 10^7, in which case $Ne=1\cdot9\times10^{-2}$. If N^1 is the number of hydrogen molecules in unit volume, then by the laws of electrolysis $N^1e=\cdot4$, and hence $N/N^1=1/20$ nearly. Thus the number of systems vibrating with the period p_1 is small compared with the number of molecules. We have only considered the effect of one line in the spectrum of hydrogen. If we took into account the other lines the discrepancy between N and N^1 would be still further increased. Hence we conclude that if this theory of anomalous dispersion is true the source of the hydrogen lines is a comparatively small number of systems in a special state.

§ 36. *Scattering of Electric Waves by the refracting Medium. Opacity of the Medium.*—If ξ is the displacement of an ion under the external electric force X_0, then by § 34

$$e\xi=\frac{X_0c^2}{1-\dfrac{4\pi\Theta}{3K_0}}\,\frac{1}{m(p_1^2-p^2)+Rip}.$$

The effect of the displaced ion is the same as that of an electric doublet whose moment is $e\xi$; this doublet has a frequency p, and gives rise to a system of electric waves expressed by the equations in § 12. The radiation of these waves involves an expenditure of energy per unit time for each doublet equal to

$$\frac{2}{3}(c\xi)^2\frac{p^4}{V_0}.$$

If between two planes of unit area at right angles to z, separated by the distance dz, there are Ndz doublets, then the energy radiated from this region in unit time is

$$\frac{1}{3}\frac{NdzX_0^2}{V_0}\,\frac{c^4}{\left(1-\dfrac{4\pi\Theta}{3K_0}\right)^2}\,\frac{p^4}{(m(p_1^2-p^2)+Rip)^2}.$$

To supply this energy, the energy transmitted in unit time by the incident wave across the further plane must be less than that transmitted across the nearer plane by this amount. But by Poynting's theorem this difference is equal to

$$-\frac{d}{dz}\left(\frac{X_0^2}{4\pi V_0}\right)dz;$$

hence $$\frac{d}{dz}\left(\frac{X_0^2}{4\pi V_0}\right)=-\frac{2NX_0^2}{3V_0}\,\frac{c^4}{\left(1-\dfrac{\pi\Theta}{3K_0}\right)^2}\,\frac{p^4}{(m(p_1^2-p^2)+Rip)^2}.$$

Solving this equation we have

$$X_0^2=C\epsilon^{-hz},$$

where $$h=\frac{8\pi}{3}\,\frac{Ne^4}{\left(1-\dfrac{4\pi\Theta}{3K_0}\right)^2}\,\frac{p^4}{(m(p_1^2-p^2)+Rip)^2};$$

this may be written

$$h=\frac{8\pi^3(\mu^2-1)^2}{3N\lambda^4},$$

where μ is the refractive index, λ the wave length. Thus, even when there is no conductivity, there is opacity due to the scattering of the waves by the ions. This effect has been investigated by Lord Rayleigh[98] in connexion with the blue colour of the sky. For waves whose frequency is very great compared with the free vibrations of the system, $h=4\pi Ne^4/3m^2$; in this case the opacity becomes in the limit independent of the frequency.

(J. J. T.)

ELECTRICITY SUPPLY.

I. General Principles.

THE improvements made in the dynamo and electric motor between 1870 and 1880, and also in the details of the arc and incandescent electric lamp towards the close of that decade, induced engineers to turn their attention to the question of the private and public supply of electric current for the purpose of lighting and power. T. A. Edison [1] and St G. Lane Fox [2] were among the first to see the possibilities and advantages of public electric supply, and to devise plans for its practical establishment. In the case of private plants, provision has to be made for a source of electric current. In spite of a great amount of ingenuity devoted to the development of the primary battery and the thermopile, no means of generation of large currents is so economical and convenient as the dynamo (see Dynamo).

Private plants. Hence a private electric generating plant involves the erection of a dynamo, which may be driven either by a steam, gas, or oil engine, or by power obtained by means of a turbine from a low or high fall of water. It may be either directly coupled to the motor, or driven by a belt; and it may either be a continuous-current machine or an alternator; and, if the latter, either single-phase or polyphase. The convenience of being able to employ storage batteries in connexion with a private-supply system is so great that, unless power has to be transmitted long distances, the invariable rule is to employ a continuous-current dynamo. Where space is valuable, this is always coupled direct to the motor; and if a steam engine is employed, an enclosed engine is most cleanly and compact. Where coal or heating gas is available, a gas engine is exceedingly convenient, since it requires little attention. Where coal gas is not available, as in country houses, a Dowson gas-producer can be employed, or an oil engine. In connexion with the generator, it is almost the invariable custom to put down a secondary battery (see Accumulators), to enable the supply to be given after the engine has stopped. If the building to be lighted is at some distance from the engine-house, the battery should be placed in the basement of the building, and underground or overhead conductors, to convey the charging current, brought to it from the dynamo. It is usual, in the case of electric lighting installations, to reckon all lamps in their equivalent number of 8 candle-power (c.p.) incandescent lamps. In lighting a private house or building, the first thing to be done is to settle the total number of incandescent lamps and their size, whether 32 c.p., 16 c.p., or 8 c.p. Five c.p. lamps can be used with advantage in small bedrooms and passages. Each candle-power can be taken as equivalent to 3½ watts, or the 8 c.p. lamp as equal to 30 watts, the 16 c.p. lamp to 60 watts, and so on. Hence if the equivalent of 100 8 c.p. lamps is required in a building, the maximum electric power supply available must be 3000 watts, or 3 kilowatts. It is of course prudent to make allowance for extensions. The next matter to consider is the pressure of supply. If the battery can be in a position near the building to be lighted, it is best to use 100-volt incandescent lamps and enclosed arc lamps, which can be worked singly off the 100-volt circuit. If, however, the lamps are scattered over a wide area, or in separate buildings somewhat far apart, as in a public school, college, asylum, or hospital, it may be better to select 200 volts as the supply pressure. Arc lamps can then be worked two in series. The third step is to select the size of the dynamo unit and the amount of spare plant. It is desirable that there should be at least three dynamos, two of which are capable of taking the whole of the full load, the third being reserved to replace either of the others when required. The total power to be absorbed by the lamps and motors (if any) being given, together with an allowance for extensions, the size of the dynamos can be settled, and the power of the engines required to drive them determined. A good rule is that the indicated horse-power (I.H.P.) of the engine should be double the dynamo full-load output in kilowatts; that is to say, for a 10-kilowatt dynamo an engine should be capable of giving 20 indicated (not nominal) H.P. From the I.H.P. of the engine, if a steam engine, the size of the boiler required for steam production becomes known. For small plants it is safe to reckon that, including waste, boiler capacity should be provided equal to evaporating 40 pounds of water per hour for every I.H.P. of the engine. The locomotive boiler is a convenient form; but where large amounts of steam are required, some modification of the Lancashire boiler or the water-tube boiler is generally adopted. In settling the electromotive force of the dynamo to be employed, attention must be paid to the question of charging secondary cells, if any. If a secondary battery is employed in connexion with 100-volt lamps, it is usual to put in 53 or 54 cells. The electromotive force of these cells varies between 2·2 and 1·8 volts as they discharge; hence the above number of cells is sufficient for maintaining the necessary electromotive force. For charging, however, it is necessary to provide 2½ volts per cell, and the dynamo must therefore have an electromotive force of 135 volts, *plus* any voltage required to overcome the fall of potential in the cable connecting the dynamo with the secondary battery. Supposing this to be 10 volts, it is safe to install dynamos having an electromotive force of 150 volts, since by means of resistance in the field circuits this electromotive force can be lowered to 110 or 115 if it is required at any time to dispense with the battery. The size of the secondary cell to be selected will be determined by the nature of the supply to be given after the dynamos have been stopped It is usual to provide sufficient storage capacity to run all the lamps for three or four hours without assistance from the dynamo.

As an example taken from actual practice, the following figures give the capacity of the plant put down to supply 500 8 c.p. lamps in a hospital. The dynamos were 15-unit machines, having a full-load capacity of 100 amperes at 150 volts, each coupled direct to an engine of 25 I.H.P.; and a double plant of this description was supplied from two steel locomotive boilers, each capable of evaporating 800 pounds of water per hour. One dynamo during the day was used for charging the storage battery of 54 cells; and at night the discharge from the cells, together with the current from one of the dynamos, supplied the lamps until the heaviest part of the load had been taken; after that the current was drawn from the batteries alone. In working such a plant it is necessary to have the means of varying the electromotive force of the dynamo as the charging of the cells proceeds. When they are nearly exhausted, their electromotive force is less than 2 volts; but as the charging proceeds, a counter electromotive force is gradually built up, and the engineer in charge has to raise the voltage of the dynamo in order to maintain a constant charging current. This is effected by having the dynamos designed to give normally the highest E.M.F. required, and then inserting resistance in their field circuits to reduce it as may be necessary.

Turning next to the consideration of public electric supply, we may divide the methods at present in successful operation into two broad divisions, namely, (1) continuous-current systems and (2) alternating-current systems.

[1] British Patent Specifications, No. 5306 of 1878, and No. 602 of 1880.
[2] *Ibid.*, No. 3988 of 1878.

Leaving out of consideration a discussion of the conditions under which continuous-current or alternating-current systems are most applicable, we may describe briefly the general outlines of the methods adopted under each heading. *Continuous-current* systems are either low- or high-pressure. In the former the current is generated by dynamos at some pressure less than 500 volts, generally about 460 volts, and is supplied to users at half this pressure by means of a three-wire system of distribution, with or without the addition of storage batteries. The general arrangements of a *low-pressure* continuous-current supply station are as follow:—If steam is the motive power selected, it is generated under all the best conditions of economy by a battery of boilers, and supplied to engines which are now almost invariably coupled direct, each to its own dynamo, on one common bed-plate; a multipolar dynamo is very frequently employed, coupled direct to an enclosed engine. In choosing the size of unit to be adopted, the engineer has need of considerable experience and discretion, and also a full knowledge of the nature of the public demand for electric current. The over-all efficiency of a steam dynamo—that is, the ratio between the electrical power output, reckoned say in kilowatts, and the I.H.P. of the engine, reckoned in the same units—is a number which falls rapidly as the load decreases; but at full load may reach some such value as 80 or 85 per cent. It is common to specify the efficiency, as above defined, which must be attained by the plant at full load, and also the efficiencies at quarter- and half-load which must be reached or exceeded. Hence in the selection of the size of the units the engineer is guided by the consideration that whatever units are in use shall be as nearly as possible fully loaded. If the demand on the station is chiefly for electric lighting, it varies during the hours of the day and night with tolerable regularity. If the output of the station, either in amperes or watts, is represented by the ordinates of a curve, the abscissæ of which represent the hours of the day, this load-diagram is a curve as shown in Fig. 1, having a

Public supply.

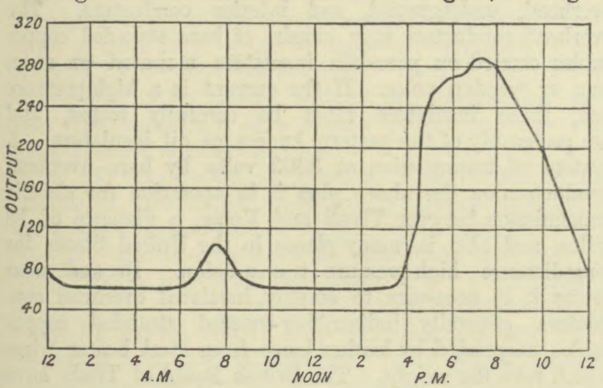

Fig. 1.

high peak somewhere between 6 and 8 p.m. The area enclosed by this load-diagram compared with the area of the circumscribing rectangle is called the *load-factor* of the station. This varies from day to day during the year, but on the average is not generally above 10 or 12 per cent., and it may be lower. Thus the total output from the station is only some 10 per cent. on an average of that which it would be if the supply were at all times equal to the maximum demand. Roughly speaking, it generally amounts to this, that the total output of an electric supply station furnishing current chiefly for electric lighting is at best equal to about two hours' supply during the day at full load. Hence during the greater part of the twenty-four hours a large part of the plant is lying idle. It is usual to provide certain small sets of steam dynamos, which are called the daylight machines, for supplying the demand during the day and later part of the evening, the remainder of the machines being called into requisition only for a short time. Provision must be made for sufficient reserve of plant, so that the breakdown of one or more sets will not cripple the output of the station. Assuming current to be supplied at about 460 volts by different and separate steam dynamos, the machines are connected through proper amperemeters and voltmeters with two bars on a main switchboard, called *omnibus bars*, so that any one can be put in connexion or removed. From this switchboard proceed a number of insulated conductors, called the positive and negative feeders. The switchboard is generally divided into three parts—one panel for the connexion of the positive feeders with the positive terminals of the generators, one for the negative feeders and negative generator terminals, while from the third (or middle-wire panel) proceed an equal number of middle-wire feeders. These sets of middle conductors are led out into the district to be supplied with current, and are there connected into a distributing system, consisting of three separate insulated conductors, respectively called the positive, middle, and negative distributing mains. The lamps in the houses are connected between the middle and negative and middle and positive mains by smaller triple supply and service wires. As far as possible the number of lamps installed on the two sides of the system are kept equal; but since it is not possible to control the consumption of current, it becomes necessary to provide at the station two small dynamos, called the *balancing machines*, connected respectively between the middle and positive and the middle and negative omnibus bars. These machines may have their shafts connected together, or they may be separate steam dynamos; their function is to supply the difference in the total current circulating through the whole of the lamps respectively on the two opposite sides of the middle wire. If storage batteries are employed in the station, it is usual to install two complete batteries, which are placed in a separate battery room and connected between the middle omnibus bars and the two outer omnibus bars. The extra electromotive force required to charge these batteries is supplied by two small dynamos, called *boosters*. It is not unusual to join together the two balancing dynamos and the two boosters on one common bed-plate, the shafts being coupled and in line, and to employ the balancing machines as electromotors to drive the boosters as required. The use of the boosters is to supply the extra half-volt per cell over and above the switchboard pressure which is required to drive the charging current through the battery towards the end of the charging operation.

In the *high-pressure* continuous-current system of supply the current is generated at a pressure of 1000 or 2000 volts, and transmitted from the generating station by conductors, called high-pressure feeders, to certain sub-centres or transformer centres, which are either buildings above ground, or cellars, or excavations under the road. In these transformer centres are placed machines, called *continuous-current transformers* (see TRANSFORMERS), which transform the electric energy and create a secondary electric current at a lower pressure, perhaps 100 or 150 volts, to be supplied by distributing mains to users. From these sub-centres insulated conductors are run back to the generating station, by which the engineer can start or stop the continuous-current rotatory transformers, and at the same time inform himself as to their proper action, and the electromotive force at the secondary terminals. This system was first put in practice in Oxford, England, and hence has been sometimes called by British engineers "the Oxford System." It is now in operation in a number of places in England, such as Wolverhampton, Walsall, and Shoreditch in London. It has the advantage that in connexion with the low-pressure distributing system, secondary batteries can be employed, so that a storage of electric energy is effected. Further, continuous-current arc lamps can be worked in series off the high-pressure mains, that is to say, sets of 20 to 40 arc lamps can be operated for the purpose of street lighting by means of the high-pressure continuous current.

The *alternating-current* systems in operation at the present time are the single-phase system, with distributing transformers or transformer sub-centres, and the polyphase systems, in which the alternating current is transformed down into an alternating current of low pressure, or, by means of rotatory transformers, into a continuous current. The general arrangement of a *single-phase* alternating-current system is as follows:—The generating station contains a number of alternators producing single-phase alternating current, either at 1000, 2000, or sometimes, as at Deptford and other places, 10,000 volts. These machines are sometimes worked in parallel, that is to say, all furnish their current to two common omnibus bars on a high-pressure switchboard, and each is switched into circuit at the moment when it is brought into step with the other machines, as shown by some form of *phase-indicator*. A number of high-pressure feeders are carried from the main switchboard to various transformer sub-centres, or else run throughout the district to which current is to be furnished. In some cases, instead of the high-pressure feeders starting from omnibus bars, each alternator works independently, and the feeders are grouped together on the various alternators as required. If the system laid down is the transformer sub-centre system, then at each of these sub-centres is placed a battery of alternating-current transformers, having their primary circuits all joined in parallel to the terminals of the high-pressure feeder, and their secondary circuits all joined in parallel on a distributing main, suitable switches and cut-outs being interposed. The pressure of the current is then transformed down by these transformers to the required supply pressure. The secondary circuits of these transformers are generally provided with three terminals, so as to supply the low-pressure side on a three-wire system. It is not advisable to connect together directly the secondary circuits of all the different sub-centres, because then a fault or short circuit on one secondary system affects all the others. In banking together transformers in this manner in a sub-station it is necessary to take care that the transformation ratio and secondary drop (see TRANSFORMERS) are exactly the same, otherwise one transformer will take more than its full share of the load, and will become overheated. The transformer sub-station system can only be adopted where the area of supply is tolerably compact. Where the consumers lie scattered over a large area, it is necessary to carry the high-pressure mains throughout the area, and to place a separate transformer or transformers in each building. From a financial point of view, this *house-to-house system* of alternating-current supply, generally speaking, is less satisfactory in results than the transformer sub-centre system. In the latter the transformers can be switched off, either by hand or by automatic apparatus, during the time when the load is light, and then no power is expended in magnetizing their cores. But with the house-to-house system the whole of the transformers continually remain connected with the high-pressure circuits; hence in the case of supply stations which have only an ordinary electric lighting load, and therefore a load-factor not above 10 per cent., the efficiency of distribution is considerably diminished.

The single-phase alternating-current system is defective in that it cannot be readily combined with secondary batteries for the storage of electric energy. Hence in many places preference is now given to the *polyphase system*. In such a system a polyphase alternating current, either two or three phase, is transmitted from the generating station at a pressure of 5000 to 10,000 volts, or sometimes higher, and at various sub-stations is transformed down, first by static transformers into an alternating current of lower pressure, say 500 volts, and then by means of rotatory transformers into a continuous current of 500 volts or lower, for use for lighting or traction. A remarkable system of this kind has been established at Niagara. A portion of the water at the Falls is employed to drive 5000 h.p. turbines, placed at the bottom of a deep chase; these drive 5000 h.p. two-phase alternators, fixed on the ground surface 150 feet above the turbines, and the two-phase current thus generated at 5000 volts is transmitted to various sub-centres, where it is transformed as already described. Large systems of distribution by polyphase currents transformed into continuous current are now in operation in New York, and similar systems have been established in London. When stations supply current not only for lighting but for traction, the current for the latter purpose must be generated at a pressure of 500 volts, and it is an economical arrangement to employ continuous-current machines which are wound to generate 500 to 550 volts, but can have their electromotive force reduced by resistance in the fields to between 400 and 460 volts. Such machines can be used either to operate a three-wire 230-volt lamp system of electric lighting or an electric traction system of 500 volts, being used chiefly in the day-time for traction and in the evenings for lighting.

Distribution.

The distribution of electric energy involves the arrangement of a system of insulated conductors, the conducting material being invariably copper having a conductivity of not less than 98 per cent. according to Matthiessen's standard (see ELECTRICITY, I.). These conductors may be divided into three classes—overhead, underground, and interior conductors. The overhead conductors may consist of bare stranded copper cables carried on porcelain insulators mounted on stout iron or wooden poles. If the current is a high-pressure one, these insulators must be carefully tested, and are preferably of the pattern known as oil insulators. A system of transmission at 5000 volts by bare overhead conductors on the above plan is in operation for electric transmission between Tivoli and Rome, a distance of 18 miles, and also in many places in the United States for long-distance high-pressure transmission. In and near towns it is necessary to employ insulated overhead conductors, generally indiarubber-covered stranded copper cables, suspended by leather loops from steel bearer wires which take the weight. The British Board of Trade have elaborated rules for the construction of overhead lines to transmit large electric currents. Where telephone and telegraph wires pass over such overhead electric lighting wires, they have to be protected from falling on the latter by means of guard wires. By far the largest part, however, of electric distribution is now carried out by *underground conductors*, which are either bare or insulated. Bare copper conductors may be carried underground in culverts or chases, air being in this case the insulating material, as in the overhead system. A culvert and covered chase is constructed under the road or side-walk, and properly shaped oak crossbars are placed in it carrying glass or porcelain insulators, on which stranded copper cables, or, preferably, copper strips placed edgeways, are stretched and supported. The advantages of this method of construction are cheapness and the ease with which connexions can be made with service lines for house supply; the disadvantages are the somewhat large space in which coal gas leaking out of case pipes can accumulate, and the difficulty of keeping the culverts at all times free from rain-water. Moisture has a tendency to collect on the negative insulators, and hence to make a dead earth on the negative side of the main; while unless the culverts are well ventilated, explosions from mixtures of coal gas and air are liable to occur. Insulated cables are insulated with a material which is in itself waterproof, or with one which is only waterproof in so far as it is enclosed in a waterproof tube, *e.g.*, of lead. Gutta-percha and indiarubber are examples of materials of the former kind. Gutta-percha, although practically everlasting when in darkness and laid under water, as in the case of submarine cables, has not been found satisfactory for use with large systems of electric distribution, although much employed for telephone and telegraph work. Insulated cables are of three classes:—(*a*) *Insulated cables drawn into pipes.* In this system of distribution cast-iron or stoneware pipes, or special stoneware conduits, or conduits made of a material called bitumen concrete, are first laid underground in the street. These contain a number of holes or "ways," and at intervals drawing-in boxes are placed which consist of a brick or cast-iron box having a water-tight lid, by means of which access is gained to a certain section of the conduit. Wires are used to draw in the cables, which are either indiarubber or lead-covered, the copper being insulated by means of paper, impregnated jute, or other similar material. The advantages of a drawing-in system are that spare ways can be left when the conduits are put in, so that at a future time fresh cables can be added without breaking up the roadway. (*b*) *Armoured cables.* A very extensively used system of distribution is by means of armoured cables. In this case the copper conductors, two, three, or more in number, may be twisted together or arranged concentrically, and are insulated by means of specially prepared jute or paper insulation, overlaid with a continuous tube of lead. Over the lead, but separated by a hemp covering, is put a steel armour consisting of two layers of steel strip, wound in opposite directions and kept in place by an external covering. Such a cable can be laid directly in the ground without any preparation other than the excavation of a simple trench, junction-boxes being inserted at intervals to allow of branch cables being taken off. (*c*) *Cables in bitumen.* One of the earliest systems of distribution employed by Edison consisted in fixing two segment-shaped copper conductors in a steel tube, the interspace between the conductors and the tube being filled in with a bitumen compound. A later plan is to lay down an iron trough, in which the cables are supported by wooden bearers at proper distances, and fill in the whole with natural bitumen. This system has been carried out extensively by the Callendar Cable Company. Occasionally concentric lead-covered and armoured cables are laid in this way, and then form an expensive but highly efficient form of insulated conductor. In selecting a system of distribution regard must be paid to the nature of the soil in which the cables are laid. Lead is easily attacked by soft water, although under some conditions it is apparently exceedingly durable, and an atmosphere containing coal gas is injurious to indiarubber.

The third large class of conductors comprises those placed in the interior of houses and buildings. These generally consist of indiarubber covered cables, laid in wood casing. The copper wire must be tinned and then covered, first with a layer of unvulcanized pure indiarubber, then with a layer of vulcanized rubber, and lastly one or more layers of protective cotton, twist or tape. No conductor of this character employed for interior house-wiring should have a less insulation resistance than 300 megohms per mile when tested with a pressure of 600 volts after soaking 24 hours in water. The wood casing should, if placed in damp positions or under plaster, be well varnished with waterproof varnish. As far as possible all joints in the run of the cable should be avoided, and after the wiring is complete, careful tests for insulation should be made. The Institution of Electrical Engineers of Great Britain have drawn up rules to be followed in interior house-wiring, and the principal fire offices, following the lead of the Phœnix Fire Office, of London, have made regulations which, if followed, are a safeguard against bad workmanship and resulting possibility of damage by fire. Where fires having an electric origin have taken place, it has invariably been traced to some breach of these rules. Opinions differ, however, as to the value and security of this method of laying interior conductors in buildings, and two or three alternative systems have been much employed. In one of these, called the *interior conduit* system, highly insulating waterproof and practically fireproof tubes or conduits replace the wooden casing; these being either of plain insulating material, or covered with brass or steel armour, may be placed under plaster or against walls. They are connected by bends or joint-boxes. The insulated wires being drawn into them, any short circuit or heating of the wire cannot give rise to a fire, as it can only take place in the interior of a non-inflammable tube. A third system of electric light wiring is the safety concentric system, in which concentric conductors are used. The inner one, which is well-insulated, consists of a copper-stranded cable. The outer may be a galvanized iron strand, a copper tape or braid, or a brass tube, and is therefore necessarily connected with the earth. A fourth system consists in the employment of twin insulated wires twisted together and sheathed with a lead tube; the conductor thus formed can be fastened by staples against walls or laid under plaster or floors. The general arrangement for distributing current to the different portions of a building for the purpose of electric lighting is to run up one or more rising mains, from which branches are taken off to distributing boxes on each floor, and from these boxes to carry various branch circuits to the lamps. At the distributing boxes are collected the cut-outs and switches controlling the various circuits. When alternating currents are employed, it is usual to select as a type of conductor either twin-twisted conductor or concentric; and the employment of these types of cable, rather than two separate cables, is essential in any case where there are telephone or telegraph wires in proximity, for otherwise the alternating current would create inductive disturbances in the telephone circuit. A concentric cable, however, possesses considerable electrostatic capacity, and when employed in connexion with high-pressure alternators or transformers gives rise to certain peculiar effects, called resonance effects. The general nature of these is best understood by considering the action of a condenser connected to the terminals of an alternator.

Interior conductors.

Let an alternator have its terminals closed by a condenser of capacity C; let the connexion be through a conductor having resistance R and inductance L; let $p=2\pi n$ where n is the frequency; and let V_0 be the maximum value of the alternating potential difference of the alternator terminals, and V_1 be that at the condenser terminals. Then assuming the potentials vary harmonically, it is easy to show that

$$V_0^2/V_1^2/=(1-CLp^2)^2+C^2R^2p^2.$$

(See J. Hopkinson, *Proc. Inst. Elec. Eng.*, 1884, p. 513; Fleming, *Ibid.*, 1891, p. 362.) The ratio V_1/V_0 can therefore be greater than unity, and the ratio is a maximum when $C=L/(R^2+p^2L^2)$. Hence if an alternator is run at a constant speed and excitation, and a conductor, such as a long length of concentric cable, is attached to its terminals, the actual potential difference between the concentric conductors may be many times greater than that of the open circuited alternator. This rise of pressure is called a *resonance effect*, and the engineer must be on his guard against it when testing long lengths of concentric cable, because if the length should be such as to give the critical capacity corresponding to the other conditions present in the circuit, the actual enhanced electric pressure on the cable may be sufficient to break it down. With high frequency these effects are more marked, and it is possible to have a progressive rise in potential all along a conductor connecting a condenser to an alternator as we proceed away from the alternator terminals. Thus Tesla (*Electrician*, March 6, 1891) has observed that when a condenser was connected by wires 20 feet long to an alternator whose frequency was 20,000 per second, there was a progressive rise in the difference of potential between the wires as points were taken nearer and nearer to the condenser. These condenser or resonance effects were observed on a large scale and investigated during the laying-out of the scheme of electric supply by alternating currents from Deptford to London carried out by Ferranti (see Fleming, *Journ. Inst. Elec. Eng.* vol. xx. p. 383). In that system there are several large concentric conductors having a length of 6 miles, and it was found that if the mains were switched into connexion with the alternators when kept running at constant speed and excitation, the potential difference between the mains, measured anywhere, was greater than that between the alternator terminals when the mains were not connected. If the cable is open-circuited at the far end, a current will still be found flowing through the armature of an alternator connected to it. This is called the condenser current or *capacity current* of the cable. If C is the total capacity of the cable in microfarads and $p=2\pi n$, where n is half the number of alternations per second, then, the maximum or R.M.S. (effective) value of the condenser current being called I and the potential difference between the conductors V, then on the assumption that V varies harmonically, but not otherwise, we have

$$I=CpV/10^6.$$

Thus, if the capacity of a concentric main is, say, 0·3 microfarad per mile, and the length 10 miles, the capacity current which would flow through an alternator connected with it, having an effective electromotive force of 10,000 volts and a frequency of 100, would be $10 \times 0{\cdot}3 \times 2 \times 100 \times 10{,}000/18 = 132/7 = 19$ amperes nearly. It might happen, however, if the right resonance condition were established, that the impressed electromotive force, and therefore the capacity current, would be grearly augmented on connecting the cable to the alternator. The capacity in microfarads (C) of a concentric main of length L centimetres, insulated with a dielectric having an inductive capacity K, is easily calculated from the formula

$$C=\frac{1}{9\times10^5}\times\frac{KL}{2\log_\epsilon D/d},$$

and hence since one mile = 160,933 cms., the capacity per mile is given by

$$C=\frac{160{,}933}{4{,}145{,}400}\quad\frac{K}{\log_{10}D/d}$$

where D is the inner diameter of the outer tube or conductor, d the outer diameter of the inner tube or conductor, and K the dielectric constant of the insulator. This is very nearly equal to

$$\frac{K}{25\log_{10}\frac{D}{d}}.$$

Thus if $D=2d$, the logarithm is nearly 0·3, and if the dielectric is indiarubber, K would be nearly equal to 4, hence the capacity per mile would be nearly one-half of a microfarad. It has been shown, however, that the capacity of a condenser, as measured by alternating electric currents, depends to a small extent upon the wave form of the alternating electromotive force.

In addition to these steady resonance effects, there are peculiar initial conditions which arise when long concentric cables are switched into connexion with alternating-current generators. In this case violent oscillations of potential may take place, giving rise to excessive electric strains, if the cables, when feeding alternating-current transformers, are suddenly switched into or out of connexion with the generators. Long concentric cables should therefore never be so connected, but always be brought into or out of connexion with the generators through a resistance or impedance, which can be gradually removed or put in. It is necessary to avoid making sudden changes in the capacity or self-induction of an alternating-current system of supply, especially when the electromotive force is large, or else oscillations of potential of excessive amplitude are set up which break down the insulation of the conductors at some point.

A subject which has attracted much attention is the amount and measurement of the true power-absorption in the dielectric of cables. All ordinary dielectrics, such as indiarubber, paper, gutta-percha, or bitumen, absorb and dissipate energy when electric strain through them is reversed. This is usually called dielectric hysteresis loss. The ratio of the true power absorbed by an alternating-current cable to the product of the impressed voltage and condenser current is called the power-factor, and may amount to about 2 to 3 per cent. For further information the reader may consult the record of a useful discussion following on a paper by Mr W. M. Mordey. (See *Proc. Inst. Elec. Eng. Lond.*, February 1901.)

(J. A. F.)

II. Electric Lighting.

The utilization of electric energy for the purpose of Electric Lighting is effected by devices called Electric Lamps, of which there are two varieties: (1) *Arc Lamps* and (2) *Incandescent Lamps*. Under these headings we may briefly consider the history, physical principles, and present practice of the Art of Electric Lighting. If a voltaic battery of a large number of cells has its terminal wires provided with rods of electrically-conducting carbon, and these are brought in contact and then slightly separated, a form of electric discharge takes place between them called *the electric arc*. It is not quite certain who first observed this effect of the electric current. The usually expressed opinion that Sir Humphry Davy, in 1801, first produced and studied the phenomenon is probably correct. In 1808, however, Davy had provided for him at the Royal Institution a battery of 2000 cells, with which he exhibited the electric arc on a large scale.

Arc Lamps.

The electric arc as a form of discharge may be produced between any conducting materials maintained at different potentials, provided that the source of electric supply is able to furnish a sufficiently large current; but for illuminating purposes pieces of hard graphitic carbon are most convenient. If some source of continuous electric current, such as a battery or dynamo, is connected to rods of such carbon, first brought into contact and then slightly separated, the following facts may be noticed:—With a low electromotive force of about 50 or 60 volts no discharge takes place until the carbons are in actual contact, unless the insulation of the air is broken down by the passage of a small electric spark. When this occurs, the space between the carbons is filled at once with a flame or luminous vapour, and the carbons themselves become highly incandescent at their extremities. If they are horizontal the flame takes the form of an arch springing between their tips; hence the name *arc*. This varies somewhat in appearance according to the nature of the current, whether continuous or alternating, and according as it is formed in the open air or in an enclosed space to which free access of oxygen is prevented. Electric arcs between metal surfaces differ greatly in colour according to the nature of the metal. When formed by an alternating current of high electromotive force they resemble a lambent flame, flickering about and producing a somewhat shrill humming sound.

Electric arcs may be classified into *continuous-* or *alternating-current arcs*, and *open* or *enclosed arcs*. Observing a carbon arc, we notice that if the current is continuous the positive carbon becomes much hotter at the end than the negative, and that in the open air it is worn away, partly by combustion, becoming hollowed out at the extremity into a *crater*. At the same time the negative carbon gradually becomes pointed, and also wears away, though much less quickly than the positive. In the continuous-current open arc the greater part of the light proceeds from the highly incandescent positive crater. When the arc is examined through dark glasses, or by the optical projection of its image upon a screen, a violet band or stream of vapour is seen to extend between the two carbons, surrounded by a nebulous golden flame or aureole. If the carbons are maintained at the right distance apart the arc remains steady and silent, but if the carbons are impure, or the distance between them too great, the true electric arc rapidly changes its place, flickering about and frequently becoming extinguished; when this happens it can only be restored by bringing the carbons once more into contact. If the current is alternating, then the arc is symmetrical, and both carbons possess nearly the same appearance. If it is enclosed in a vessel nearly air-tight, so as to prevent the access of free oxygen, the rate at which the carbons are burnt away is greatly reduced, and if the current is continuous the positive carbon is no longer cratered out and the negative no longer so much pointed as in the case of the open arc.

Carbons.

Davy used for his first experiments rods of wood charcoal which had been heated and plunged into mercury to make them better conductors. Not until much later (1843) was it proposed by Foucault to employ pencils cut from the hard graphitic carbon deposited in the interior of gas retorts. In 1846 Greener and Staite patented a process for manufacturing carbons for this purpose, but it was not until after the invention of the Gramme dynamo in 1870 that any great demand existed for them. Carré in France in 1876 began to manufacture arc lamp carbons of high quality from coke, lampblack, and syrup. Now they are made by taking some specially refined form of finely divided carbon, such as the soot or lampblack formed by cooling the smoke of burning paraffin or tar, or by the carbonization of organic matter, and making it into a paste with gum or syrup. This carbon paste is forced through dies of appropriate size and shape by means of a hydraulic press, the rods thus formed being subsequently baked with such precautions as to preserve them perfectly straight. In some cases they are *cored*, that is to say, have a longitudinal hole down them, filled in with a softer carbon. Sometimes, too, they are covered with a thin layer of copper by electro-deposition. They are supplied for the market in sizes varying from 4 or 5 to 30 or 40 millimetres in diameter, and from 8 to 16 inches in length. The value of carbons for arc lighting purposes greatly depends on their purity and freedom from ash in burning, and on perfect uniformity of structure. For ordinary purposes they are generally round in section, but for certain special uses, such as lighthouse work, they are made fluted or with a star-shaped section. The positive carbon is usually of larger section than the negative. For continuous-current arcs a cored carbon is generally used as a positive, and a smaller solid carbon as a negative. Countless researches have been made on the subject of carbon manufacture, and the art has been brought to great perfection. Special manuals must be consulted for further information.

Physical phenomena.

The physical phenomena of the electric arc are best examined by forming a carbon arc between two carbon rods of the above description, held in line in a special apparatus, and arranged so as to be capable of being moved to or from each other with a slow and easily regulated motion. An arrangement of this kind is called *a hand-regulated arc lamp* (see Fig. 2). If such an arc lamp is connected to a source of electric supply having an electromotive force preferably of 100 volts, and if some resistance is included in the circuit, say about 5 ohms, a steady and continuous arc is formed when the carbons are brought together and then slightly separated. Its appearance may be most conveniently examined by projecting its image upon a screen of white paper by means of an achromatic lens. A very little examination of the distribution of light from the arc shows that the illuminating or candle-power is not the same in different directions. If the carbons are vertical and the positive carbon is the upper of the two, the illuminating power is greatest in a direction at an angle inclined about 40 or 50 degrees below the horizon, and at other directions has different values, which may be represented by the lengths of radial lines drawn from a centre, the extremities of which define a curve called the *illuminating curve* of the arc lamp (see Fig. 3). Considerable differences exist between the forms of the illuminating-power curves of the continuous and alternating current and the open or enclosed arcs. The chief portion of the emitted light proceeds from the incandescent crater; hence the form of the illuminating-power curve, as shown by Trotter in 1892, is due to the apparent area of the crater surface which is visible to an eye regarding the arc in that direction.

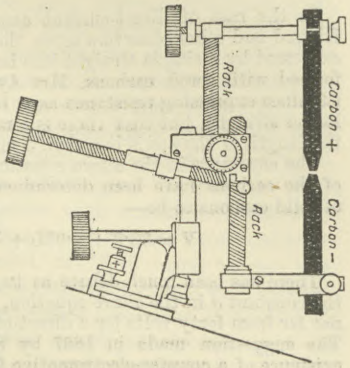

Fig 2.

The form of the illuminating-power curve varies with the length of the arc and relative size of the carbons. Leaving out of account for the moment the properties of the arc as an illuminating agent, the variable factors with which we are concerned are (i.) the current through the arc; (ii.) the potential difference of the carbons; (iii.) the length of the arc; and (iv.) the size of the carbons. Taking in the first place the typical direct-current arc between solid carbons, and forming arcs of different lengths and with carbons of different sizes, it will be found that, beginning at the lowest current capable of forming a true arc, the potential difference of the carbons (the arc P.D.) decreases as the current increases. Up to a certain current strength the arc is silent, but at a particular critical value P.D. suddenly drops about 10 volts, the current at the same time rising 2 or 3 amperes. At that moment the arc begins to *hiss*, and in this hissing condition, if the current is still further increased, P.D. remains constant over wide limits. This drop in voltage on hissing was first noticed by Niaudet (*La Lumière Electrique*, vol. iii. p. 287). It has been shown by Mrs Ayrton (*Journ. Inst. Elec. Eng.* vol. xxviii. p. 200) that the hissing is mainly due to the oxygen which gains access from the air to the crater, when the latter becomes so large by reason of the increase of the current as to overspread the end of the positive carbon. According to A. Blondel and Luggin, hissing takes place whenever the current density becomes greater than about 0·3 or 0·5 ampere per square millimetre of crater area.

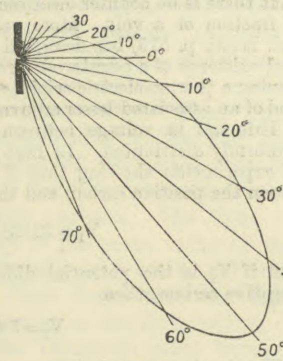

Fig. 3.

The relation between the current, the carbon P.D., and the length of arc in the case of the direct-current arc has been investigated by many observers with the object of giving it mathematical expression.

Let V stand for the potential difference of the carbons in volts, A for the current through the arc in amperes, L for the length of the arc in millimetres, R for the resistance of the arc; and let a, b, c, d, &c., be constants. Edlund in 1867, and other workers after him, considered that their experiments showed that the relation between V and L could be expressed by a simple linear equation,

$$V = a + bL.$$

Later researches by Mrs Ayrton (*Electrician*, vol. xli. p. 720) have, however, shown that for a direct-current arc of given size with solid carbons, the observed values of V can be better represented as a function both of A and of L of the form

$$V = a + bL + \frac{c + dL}{A}.$$

In the case of direct-current arcs formed with solid carbons, Edlund and other observers agree that the arc resistance R may be expressed by a simple straight line law, $R = e + fL$. If the arc is formed with cored carbons, Mrs Ayrton has demonstrated that the lines expressing resistance as a function of arc length are no longer straight, but that there is a rather sudden dip down when the length of the arc is less than 3 mm.

The constants in the above equation for the potential difference of the carbons have been determined by Mrs Ayrton in the case of solid carbons to be—

$$V = 38{\cdot}9 + 2{\cdot}07L + \frac{11{\cdot}7 + 10{\cdot}5L}{A}.$$

There has been much debate as to the meaning to be given to the constant a in the above equation, which has a value apparently not far from forty volts for a direct-current arc with solid carbons. The suggestion made in 1867 by Edlund,[1] that it implied the existence of a counter-electromotive force in the arc, was opposed by Luggin in 1889,[2] Lecher in 1888,[3] and by Stenger in 1892;[4] whereas von Lang and Arons, in 1896,[5] concluded that experiment indicated the presence of a counter-electromotive force of 20 volts. A. Blondel concludes, from experiments made by him in 1897,[6] that there is no counter-electromotive force in the arc greater than a fraction of a volt. More recently Duddell (*Proc. Roy. Soc.* vol. lxviii. p. 518) has described experiments tending to prove the real existence of a counter-electromotive force in the arc, probably having a thermo-electric origin, residing near the positive electrode, and of an associated lesser adjuvant *e.m.f.* near the negative carbon.

This fall in voltage between the carbons and the arc is not uniformly distributed. In 1898 Mrs Ayrton described the results of experiments showing that if V_1 is the potential difference between the positive carbon and the arc, then

$$V_1 = 31{\cdot}28 + \frac{9 + 3{\cdot}1L}{A};$$

and if V_2 is the potential difference between the arc and the negative carbon, then

$$V_2 = 7{\cdot}6 + \frac{13{\cdot}6}{A}.$$

The total potential difference between the carbons, minus the fall in potential down the arc, is therefore equal to the sum of $V_1 + V_2 = V_3$.

$$\text{Hence } V_3 = 38{\cdot}88 + \frac{2^2{\cdot}6 + 3{\cdot}1L}{A}.$$

The difference between this value and the value of V, the total potential difference between the carbons, gives the loss in potential due to the true arc. These laws are simple consequences of straight-line laws connecting the work spent in the arc at the two electrodes with the other quantities. If W be the work spent in the arc on either carbon, measured by the product of the current and the potential drop in passing from the carbon to the arc, or *vice versâ*, then for the positive carbon $W = a + bA$, if the length of arc is constant, $W = c + dL$, if the current through the arc is constant, and for the negative carbon $W = e + fA$.

In the above experiments the potential difference between the carbons and the arc was measured by using a third exploring carbon as an electrode immersed in the arc. This method, adopted by Lecher, Uppenborn, S. P. Thompson, and Fleming, is open to the objection that the introduction of the third carbon may to a considerable extent disturb the distribution of potential.

The total work spent in the continuous-current arc with solid carbons may, according to Mrs Ayrton, be expressed by the equation

$$W = 11{\cdot}7 + 10{\cdot}5L + (38{\cdot}9 + 2{\cdot}07L)A.$$

It will thus be seen that the arc, considered as a conductor, has the property that if the current through it is increased, the difference of potential between the carbons is decreased, and in one sense, therefore, the arc may be said to act as if it were a *negative resistance.* Messrs Frith and Rodgers (*Electrician*, vol. xxxviii. p. 75) have suggested that the resistance of the arc should be measured by the ratio between a small increment of carbon potential difference and the resulting small increment of current; in other words, by the equation dV/dA, and not by the ratio simply of V : A. Considerable discussion has taken place whether an electrical resistance can have a negative value, belonging as it does to the class of scalar mathematical quantities. Simply considered as an electrical conductor, the arc resembles an intensely heated rod of magnesia or other refractory oxide, the true resistance of which is decreased by rise of temperature. Hence an increase of current through such a rod of refractory oxide is accompanied by a decrease in the potential difference of the ends. This, however, does not imply a negative resistance, but merely the presence of a resistance with a negative temperature coefficient.

Other physical investigations have been concerned with the intrinsic brightness of the crater. It has been asserted by many observers, such as Blondel, Abney, S. P. Thompson, Trotter, Violle, and others, that this is practically independent of the current passing, but great differences of opinion exist as to its value. Abney's values lie between 39 and 116, Trotter's between 80 and 170 candles per square millimetre. Blondel in 1893 made careful determinations of the brightness of the arc crater, and came to the conclusion that it was 160 candles per square millimetre. More recently J. E. Petavel has found a value of 147 candles per square millimetre for current densities varying from ·06 to ·26 amperes per square millimetre (*Proc. Roy. Soc.* vol. lxv. p. 475). Violle also, in 1893, supported the opinion that the brightness of the crater per square millimetre was independent of the current density, and from certain experiments and assumptions as to the specific heat of carbon, he asserted the temperature of the crater was about 3500° C. It has been concluded that this constancy of temperature, and therefore of brightness, is due to the fact that the crater is at the temperature of the boiling-point of carbon, and in that case its temperature should be raised by increasing the pressure under which the arc works. W. E. Wilson in 1895 attempted to measure the brightness of the crater under various pressures, and found that under five atmospheres the resistance of the arc appeared to increase and the temperature of the crater to fall, until at a pressure of 20 atmospheres the brightness of the crater had fallen to a dull red. In a later paper W. E. Wilson and G. Fitzgerald stated that these preliminary experiments were not confirmed, and their later researches throw considerable doubt on the suggestion that it is the boiling-point of carbon which determines the temperature of the crater. (See *Electrician*, vol. xxxv. p. 260, and vol. xxxviii. p. 343.) On the whole, although valuable work has been done in exploring the physics of the electric arc, much knowledge yet remains to be gained before we can be said to understand the full meaning of this simple physical phenomenon, which is hardly likely to be fully interpreted before our information is greatly increased as to the process by which electric current is transmitted through gas or vapour.

Alternating-current arc.

The study of the alternating-current arc has proved to be fertile in suggesting a number of new experimental problems for investigators. In this case all the factors, namely, current, carbon P.D., resistance, and illuminating power, are periodically varying; and as the electromotive force reverses itself periodically, at certain instants the current through the arc is zero. Owing to the fact that the current can be interrupted for a moment without extinguishing the arc, it is possible to work the electric arc from an alternating current generator without apparent intermission in the light, provided that the frequency is not much below 50. During the moment that the current is zero the carbon continues to glow. Each carbon in turn becomes, so to speak, the crater carbon, and the illuminating power is therefore symmetrically distributed. The curve of illumination is as shown in Fig. 4. The nature of the variation of the current and arc P.D. can be examined by one of two methods, or their modifications, originally due to Joubert and A. Blondel. Joubert's method, which has been perfected by many observers, consists in attaching to the shaft of the alternator a contact which closes a circuit

at an assigned instant during the phase. This contact is made to complete connexion either with a voltmeter or with a galvanometer placed as a shunt across the carbons or in series with the arc. By this arrangement these instruments do not read, as usual, the root-mean-square value of the arc P.D. or current, but give a constant indication determined by, and indicating, the instantaneous values of these quantities at some assigned instant during the phase. By progressive variation of the phase-instant at which the contact is made, the successive instantaneous values of the electric quantities can be measured and plotted out in the form of curves. This method has been much employed by Blondel, Fleming, Steinmetz, Tobey and Walbridge, Frith, Görges, and many others. The second method, due to Blondel, depends on the use of the *Oscillograph*, which is a galvanometer having a needle or coil of very small periodic time of vibration, say $\frac{1}{2000}$th part of a second or less, so that its deflections can follow the variations of current passing through the galvanometer. An improved form of oscillograph, devised by Duddell, consists of two fine wires, which are strained transversely to the lines of flux of a strong magnetic field (see MEASURING INSTRUMENTS, ELECTRIC). The current to be examined is made to pass up one wire and down the other, and these wires are then slightly displaced in opposite directions. A small mirror attached to the wires is thus deflected rapidly to and fro in synchronism with the variations of the current. From the mirror a ray of light is reflected which falls upon a photographic plate made to move across the field with a uniform motion. In this manner a photographic trace can be obtained of the wave form. By this method we are enabled to watch the variations of electric quantities in an alternating current arc. The variation of illuminating power can be followed by examining and measuring the light of the arc through slits in a revolving stroboscopic disc, which is driven by a motor synchronously with the variation of current through the arc.

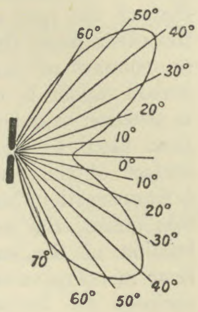

Fig. 4.

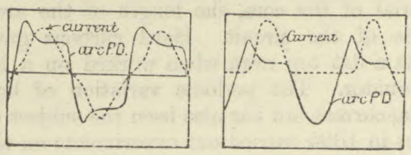
Without entering into an exact historical summary of discovery, it suffices to say that the general phenomena of the alternating-current arc are as follow:—If the arc is supplied by an alternator of low inductance, and soft or cored carbons are employed to produce a steady and silent arc, the potential difference of the carbons periodically varies in a manner not very different from that of the alternator on open circuit. If, however, hard carbons are used, the alternating-current arc deforms the shape of the alternator electromotive force curve; the carbon P.D. curve may then have a very different form, and becomes, in general, more rectangular in shape, usually having a high peak at the front. The arc also impresses the deformation on the current curve. Blondel in 1893 (*Electrician*, vol. xxxii. p. 161) gave a number of potential and current curves for alternating-current arcs, obtained by the Joubert contact method, using two movable coil galvanometers of high resistance to measure respectively potential difference and current. Blondel's deductions were that the shape of the current and volt curves is greatly affected by the nature of the carbons, and also by the amount of inductance and resistance in the circuit of the alternator. Blondel, Ayrton, Sumpner, and Steinmetz have all observed that the alternating-current arc, when hissing or when formed with uncored carbons, acts like an inductive resistance, and that there is a lag between the current curves and the potential difference curves. Hence the *power-factor*, or ratio between the true power and the product of the root-mean-square values of arc current and carbon potential difference, in this case is less than unity. For silent arcs Blondel found power-factors lying between 0·88 and 0·95, and for hissing ones, values such as 0·70. Ayrton and Sumpner stated that the power-factor may be as low as 0·5. Joubert, as far back as 1881, noticed the deformation which the alternating-current arc impresses upon the electromotive force curve of an alternator, giving an open circuit a simple harmonic variation of electromotive force. Tobey and Walbridge in 1890 gave the results of a number of observations taken with commercial forms of alternating-current arc lamps, in which the same deformation was apparent. Blondel in 1896 came to the conclusion that with the same alternator we can produce carbon P.D. curves of very varied character, according to the material of the core, the length of the arc, and the inductance of the circuit. Hard carbons gave a P.D. curve with a flat top even when worked on a low inductance alternator. The periodic variation of light in the alternating-current arc has also been the subject of inquiry. H. Görges in 1895 carried out experiments on this subject at Berlin, and applied a stroboscopic method to steady the variations of illuminating power. Fleming and Petavel also employed a similar arrangement, driving the stroboscopic disc by a synchronous motor (*Phil. Mag.*, April 1896). The light passing through slits of the disc was selected in one particular period of the phase, and by means of a lens could be taken from any desired portion of the arc or the incandescent carbons. The light so selected was measured relatively to the mean value of the horizontal light emitted by the arc, and accidental variations were thus eliminated. They found that the light from any part is periodic, but owing to the slow cooling of the carbons never quite zero, the minimum value happening a little later than the zero value of the current. The light emitted by a particular carbon when it is the negative, does not reach such a large maximum value as when it is the positive. The same observers brought forward experiments which seemed to show that for a given expenditure of power in the arc the alternating current arc in general gives less mean spherical candle-power than the continuous current one.

The effect of the wave form on the efficiency of the alternating-current arc has engaged the attention of many workers. Rössler and Wedding in 1894 gave an account of experiments with alternating-current arcs produced by alternators having electromotive force curves of very different wave forms, and they stated that the efficiency or mean spherical candle-power per watt expended in the arc was greatest for the flattest of the three wave forms by nearly 50 per cent. Burnie in 1897 gave the results of experiments of the same kind. His conclusion was, that since the light of the arc is a function of the temperature, that wave form of current is most efficient which maintains the temperature most uniformly throughout the half period. Hence, generally, if the current rises to a high value soon after its commencement, and is preserved at that value, or nearly at that value, during the phase, the efficiency of the arc will be greater when the current curve is more pointed or peaked. An important contribution to our knowledge concerning alternating-current arc phenomena was made in 1899 by Messrs W. Duddell and E. W. Marchant, in a paper containing valuable results obtained with their improved oscillograph.[1] They studied the behaviour of the alter-

[1] *Journ. Inst. Elec. Eng.* vol. xxviii. p. 1. The authors of this paper give numerous instructive curves taken with the oscillograph, showing the form of the arc P.D. and current curves for a great variety of alternating-current arcs.

nating-current arc when formed both with solid carbons, with cored carbons, and with carbon and metal rods. They found that with solid carbons the arc P.D. curve is always square-shouldered and begins with a peak, as shown in Fig. 5 (*a*), but with cored carbons it is more sinusoidal. Its shape depends on the total resistance in the circuit, but is almost independent of the type of alternator, whereas the current wave form is largely dependent on the machine used, and on the nature and amount of the impedance in the circuit; hence the importance of selecting a suitable alternator for operating alternating-current arcs. The same observers drew attention to the remarkable fact that if an arc is formed between a carbon and metal rod, say a zinc rod, there is a complete interruption of the current over half a period corresponding to that time during which the carbon is positive; this suggests that the rapid



(*a*) (*b*)

Fig. 5.

cooling of the metal facilitates the flow of the current from it, and resists the flow of current to it. The dotted curve in Fig. 5 (*b*) shows the current curve form in the case of a copper rod. By the use of the oscillograph Messrs Duddell and Marchant showed that the hissing continuous-current arc is intermittent, and that the current is oscillatory and may have a frequency of 1000 per second. They also showed that enclosing the arc increases the arc reaction, the front peak of the potential curve becoming more marked and the power-factor of the arc reduced.

If a continuous-current electric arc is formed in the open air with a positive carbon having a diameter of about 15 millimetres, and a negative carbon having a diameter of about 9 millimetres, and if a current of 10 amperes is employed, the potential difference between the carbons is generally from 40 to 50 volts. Such a lamp is therefore called a 500 watt arc. Under these conditions the carbons each burn away at the rate of about one inch per hour, actual combustion taking place in the air which gains access to the highly-heated crater and negative tip; hence the most obvious means of preventing this disappearance is to enclose the arc in an air-tight glass vessel. Such a device was tried very early in the history of arc lighting. The result of using a completely air-tight globe, however, is that the contained oxygen is removed by combustion with the carbon, and carbon vapour or hydrocarbon compounds diffuse through the enclosed space and deposit themselves on the cool sides of the glass, which is thereby obscured. It was, however, shown by L. B. Marks (*Electrician*, vol. xxxi. p. 502, and vol. xxxviii. p. 646) in 1893, that if the vessel is not completely closed, and if the arc is an arc formed with a small current and relatively high voltage, namely, 80 to 85 volts, it is possible to admit air in such small amount that though the rate of combustion of the carbons is reduced, yet the air destroys by oxidation the carbon vapour escaping from the arc, and so prevents the obscuration of the glass containing-vessel. An arc lamp operated in this way is called an enclosed arc lamp (see Fig. 6). The top of the enclosing bulb is closed by a gas check plug which admits through a small hole a limited supply of air. The peculiarity of an enclosed arc lamp operated with a continuous current is that the carbons do not burn to a crater on the positive, and a sharp tip or mushroom on the negative, but preserve nearly flat surfaces. This feature

Enclosed arc lamps.

affects the distribution of the light. The illuminating curve of the enclosed arc, therefore, has not such a strongly marked maximum value as that of the open arc, but on the other hand the true arc or column of incandescent carbon vapour is less steady in position, wandering round from place to place on the surface of the carbons. As a compensation, however, for this defect, the actual combustion of the carbons per hour in commercial forms of enclosed arc lamp is about one-twentieth part of that of an open arc lamp taking the same current.

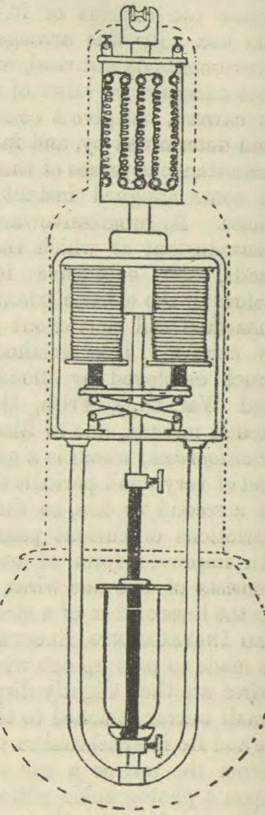


Fig. 6.

Before leaving the discussion of the physical phenomena of the electric arc, one or two other facts in connexion with it may be mentioned. It was shown by Fleming in 1890 that the column of incandescent carbon vapour constituting the true arc possesses a unilateral conductivity (*Proc. Roy. Inst.* vol. xiii. p. 47). If a third carbon is dipped into the arc so as to constitute a third pole, and if a small voltaic battery of a few cells, with a galvanometer in circuit, is connected in between the middle pole and the negative carbon, it is found that when the negative pole of the battery is in connexion with the negative carbon the galvanometer indicates a current, but does not when the positive pole of the battery is in connexion with the negative carbon of the arc.

The arc as an illuminant.

Turning next to the consideration of the electric arc as a source of light, we have already noticed that the illuminating power in different directions is not the same. If we imagine an electric arc, formed between a pair of vertical carbons, to be placed in the centre of a hollow sphere painted white on the interior, then it would be found that the various zones of this sphere are unequally illuminated. If the points in which the carbons when prolonged would intercept the sphere are called the poles, and the line where the horizontal plane through the arc would intercept the sphere is called the equator, we might consider the sphere divided up by lines of latitude into zones, each of which would be differently illuminated. The total quantity of light or the total illumination of each zone is the product of the area of the zone and the intensity of the light falling on the zone measured in candle-power. We might regard the sphere as uniformly illuminated with an intensity of light such that the product of this intensity and the total surface of the sphere was numerically equal to the surface integral obtained by summing up the products of the areas of all the elementary zones and the intensity of the light falling on each. This mean intensity is called the *mean spherical candle-power* of the arc. If the distribution of the illuminating power is known and given by an illumination curve, the mean spherical candle-power can be at once deduced by a construction due to M. Rousseau (*La Lumière Electrique*, vol. xxxvii. p. 415).

Let BMC (see Fig. 7) be a semicircle which by revolution round the diameter BC sweeps out a sphere. Let an arc be situated at A, and let the element of the circumference PQ = ds sweep out a zone of the sphere. Let the intensity of light falling on this zone be I. Then if θ = the angle MAP and $d\theta$ the incremental angle PAQ, and if R is the radius of the sphere, we have

$$ds = Rd\theta\ ;$$

also, if we project the element PQ on the line DE we have

$$ab = ds \cos\theta,$$
$$\therefore\ ab = R\cos\theta d\theta$$

and $$Iab = IR\cos\theta d\theta.$$

Let r denote the radius PT of the zone of the sphere, then

$$r = R\cos\theta.$$

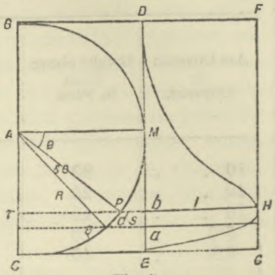

Fig. 7.

Hence the area of the zone swept out by PQ is equal to

$$2\pi R\cos\theta\ ds = 2\pi R^2\cos\theta d\theta$$

in the limit, and the total quantity of light falling on the zone is equal to the product of the mean intensity or candle-power I in the direction AP and the area of the zone, and therefore to

$$2\pi IR^2\cos\theta d\theta.$$

Let I_0 stand for the mean spherical candle-power, that is, let I_0 be defined by the equation

$$4\pi R^2 I_0 = 2\pi R\Sigma(Iab)$$

where $\Sigma(Iab)$ is the sum of all the light actually falling on the sphere surface, then

$$I_0 = \frac{1}{2R}\Sigma(Iab)$$
$$= \frac{\Sigma(Iab}{2RI max}\ I max$$

where $I max$ stands for the maximum candle-power of the arc. If, then, we set off at b a line bH perpendicular to DE and in length proportional to the candle-power of the arc in the direction AP, and carry out the same construction for a number of different observed candle-power readings at known angles above and below the horizon, the summits of all ordinates such as bH will define a curve DHE. The mean spherical candle-power of the arc is equal to the product of the maximum candle-power ($I max$), and a fraction equal to the ratio of the area included by the curve DHE to its circumscribing rectangle DFGE. The area of the curve DHE multiplied by $2\pi/R$ gives us the *total flux of light* from the arc.

Owing to the inequality in the distribution of light from an electric arc, it is impossible to define the illuminating power by a single number in any other way than by stating the mean spherical candle-power. All such commonly used expressions as "an arc lamp of 2000 candle-power" are, therefore, perfectly meaningless.

Photometry of arc. The photometry of arc lamps presents particular difficulties, owing to the great difference in quality between the light radiated by the arc and that given by any of the ordinarily used light standards. (For standards of light and photometers, see LIGHT.) All photometry depends on the principle that if we illuminate two white surfaces respectively and exclusively by two separate sources of light, we can by moving the lights bring the two surfaces into such a condition that their *illumination* or *brightness* is the same without regard to any small colour difference. The quantitative measurement depends on the fact that the illumination or brightness produced upon a surface by a source of light is inversely as the square of the distance of the source. The trained eye is capable of making a comparison between two surfaces illuminated by different sources of light, and pronouncing upon their equality or otherwise in respect of brightness, apart altogether from a certain colour difference; but in order that this should be capable of being done with accuracy, it is essential that the two illuminated surfaces, the brightness of which is to be compared, shall be absolutely contiguous and not separated by any harsh line. The process of comparing the light from the arc directly with that of a candle or other similar flame standard is exceedingly difficult, owing to the much greater proportion and intensity of the violet rays in the arc. The most convenient practical working standard is an incandescent lamp run at a high temperature, that is, at an efficiency of about $2\frac{1}{2}$ watts per candle. If it has a sufficiently large bulb, and has been *aged* by being worked for some time previously, it will at a constant voltage preserve a constancy in illuminating power sufficiently long to make the necessary photometric comparisons, and it can itself be compared at intervals with another standard incandescent lamp, or with a flame standard such as a Harcourt pentane lamp.

In measuring the candle-power of arc lamps it is necessary to have some arrangement by which the brightness of the rays proceeding from the arc in different directions can be measured. For this purpose the lamp may be suspended from a support, and a radial arm arranged to carry three mirrors, so that in whatever position the arm may be placed, it gathers light proceeding at one particular angle above or below the horizon from the arc, and this light is reflected out finally in a constant horizontal direction. An easily-arranged experiment enables us to determine the constant loss of light by reflection at all the mirrors, since that reflection always takes place at 45 degrees. The ray thrown out horizontally can then be compared with that from any standard source of light by means of a fixed photometer, and by sweeping round the radial arm the photometric or illuminating curve of the arc lamp can be obtained. From this we can at once determine the nature of the illumination which would be produced on a horizontal surface if the arc lamp were suspended at a given distance above it. Let A (see Fig. 8) be an arc lamp placed at a height h(=AB) above a horizontal plane. Let ACD be the illuminating power curve of the arc, and hence AC the candle-power in a direction AP.

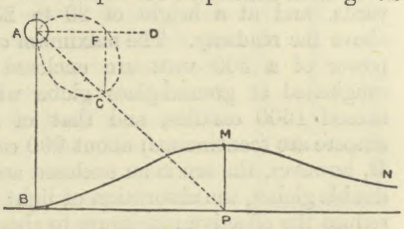

Fig. 8.

The illumination (I) or brightness on the horizontal plane at P is equal to $\frac{AC}{(AP)^2}$ $\cos APM = \frac{FC}{h^2+x^2} = I$ where BP = x. Hence if the candle-power curve of the arc and its height above the surface are known, we can describe a curve BMN, whose ordinate PM will denote the brightness on the horizontal surface at any point P. It is easily seen that this ordinate must have a maximum value at some point. This brightness is best expressed in *candle-feet*, taking the unit of illumination to be that given by a standard candle on a white surface at a distance of one foot. If any number of arc lamps are placed above a horizontal plane, the brightness at any point can be calculated by adding together the illuminations due to each respectively.

Street arc lighting. In the practical use of arc lamps for street and public lighting, the question of the distribution of light on the horizontal surface is all-important. The aim should be to produce as far as possible a uniform illumination sufficient for visual purposes. We form an opinion on the success of such lighting by observing the mean, maximum, and minimum illumination. In order that street surfaces may be well lighted, the minimum illumination should not fall below 0·1 candle-foot, and in general, in well-lighted streets, the maximum illumination will be 1 candle-foot and upwards. By means of an illumination photometer, such as that of Preece and Trotter, it is easy to measure the illumination in candle-feet at any point in a street surface, and to plot out a number of contour lines of equal illumination. Experience has shown that to obtain satisfactory results the lamps must be placed on a high mast 20 or 25 feet above the roadway surface. These posts are now generally made of cast-iron in various ornamental forms (see Fig. 9), the necessary conductors for conveying the current up to the lamp being taken inside the iron mast. (The pair of incandescent lamps half-way down the standard are for use in the middle of the night, when the arc lamp would give more light than is required; they are lighted by an automatic switch whenever the arc is extinguished.) The lamp itself is generally enclosed in an opalescent spherical globe, which is woven over with wire-netting so that in case of fracture the pieces may not cause damage. The necessary trimming, that is, the replacement of carbons, is effected either by lowering the lamp or, preferably, by carrying round a portable ladder enabling the trimmer to reach it. For the purpose of public illumination it is very usual to employ a lamp taking 10 amperes, and therefore absorbing about 500 watts. Such a lamp is called a 500 watt arc lamp, and it is found that a satisfactory illumination is given for most street purposes by placing 500 watt arc lamps at distances varying from 40 to 100 yards, and at a height of 20 to 25 feet above the roadway. The maximum candle-power of a 500 watt arc enclosed in a roughened or ground-glass globe will not exceed 1500 candles, and that of a 6·8 ampere arc (continuous) about 900 candles. If, however, the arc is an enclosed arc with double globes, the absorption of light would reduce the effective maximum to about 200 c.p. and 120 c.p. respectively. When arc lamps are placed in public thoroughfares not less than 40 yards apart, the illumination anywhere on the street surface is practically determined by the two nearest ones. Hence the total illumination at any point may be obtained by adding together the illuminations due to each arc separately. Given the photometric polar curves or illuminating-power curves of each arc taken outside the shade or globe, we can therefore draw a curve representing the resultant illumination on the horizontal surface. It is obvious that the higher the lamps are placed, the more uniform is the street surface illumination, but the less its average value; thus two 10 ampere arcs placed on masts 20 feet above the road surface and 100 feet apart will give a maximum illumination of about 1·1 and a minimum of about 0·15 candle-feet in the interspace (see Fig. 10). If the lamps are raised on 40-feet posts the maximum illumination will fall to 0·3, and the minimum will rise to 0·2. For this reason some engineers have advocated very high masts, and masts have been employed as high as 90 feet. In docks and railway yards high masts (50 feet) are an advantage, because the strong contrasts due to shadows of trucks, carts, &c., then become less marked, but for street illumination they should not exceed 30 to 35 feet in height. Taking the case of 10 ampere and 6·8 ampere arc lamps in ordinary opal shades, the following figures have been given by Trotter as indicating the nature of the resultant horizontal illumination:—

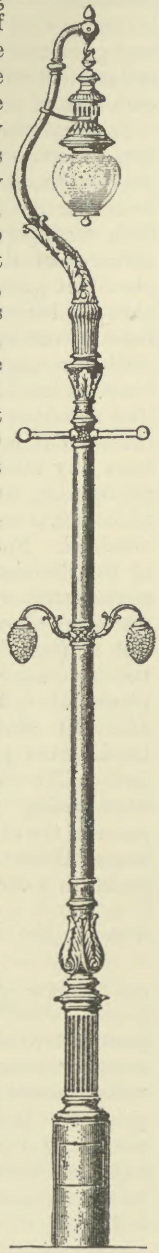

Fig. 9.

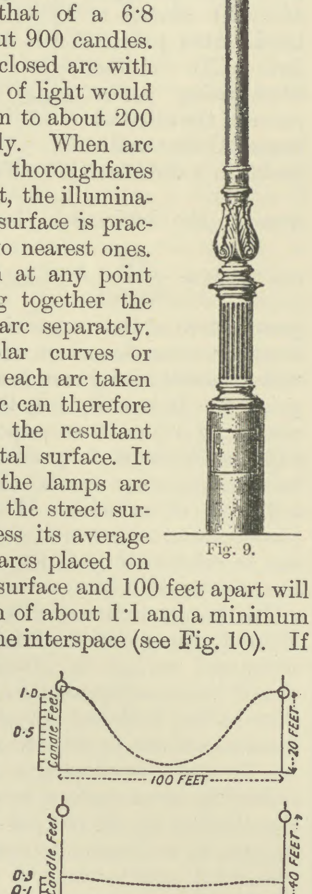

Fig. 10.

Arc Current in Amperes.	Height above Road in Feet.	Distance apart in Feet.	Horizontal Illumination in Candle-Feet.	
			Maximum.	Minimum.
10 . .	20	120	1·85	0·12
10 . .	25	120	1·17	0·15
10 . .	40	120	·5	0·28
6·8 .	20	90	1·1	0·21
6·8 .	40	120	0·3	0·17

As regards distance apart, a very usual practice is to place the lamps at spaces equal to six to ten times their height above the road surface. Blondel (*Electrician*, vol. xxxv. p. 846) gives the following rule for the height (h) of the arc to afford the maximum illumination at a distance (d) from the foot of the lamp-post, the continuous current arc being employed:—

For naked arc	$h=0·95\ d.$
,, arc in rough glass globe . .	$h=0·85\ d.$
,, ,, opaline globe . . .	$h=$,,
,, ,, opal globe . . .	$h=0·5\ d.$
,, ,, holophane globe . .	$h=0·5\ d.$

These figures show that the distribution of light on the horizontal surface is greatly affected by the nature of the enclosing globe. For street illumination naked arcs, although sometimes employed in works and factory yards, are entirely unsuitable, since the result produced on the eye by the bright point of light is to paralyse a part of the retina and contract the pupil, hence rendering the eye less sensitive when directed on feebly illuminated surfaces. Accordingly, diffusing globes have to be employed. It is usual to place the arc in the interior of a globe of from 12 to 18 inches in diameter. This may be made of ground glass, opal glass, or be a dioptric globe such as the holophane. The two former are strongly absorptive, as may be seen from the results of experiments by Messrs Guthrie and Redhead. The following table shows the astonishing loss of light due to the use of opal globes:—

	Naked Arc.	Arc in Clear Globe.	Arc in Rough Glass Globe.	Arc in Opal Globe.
Mean spherical c.p. .	319	235	160	144
Mean hemispherical c.p. .	450	326	215	138
Percentage value of transmitted light . . .	100	53	23	19
Percentage absorption .	0	47	77	81

By using Trotter's, Fredureau's, or the holophane globe, the light may be so diffused that the whole globe appears uniformly luminous, and yet not more than 20 per cent. of the light is absorbed. Taking the absorption of an ordinary opal globe into account, it is not usual to find that a 500 watt arc gives more than 500 c.p. as a maximum candle-power. Even with a naked 500 watt arc the mean spherical candle-power is not generally more than 500 c.p., or at the rate of 1 c.p. per watt. The maximum candle-power for a given electrical power is, however, greatly dependent on the current density in the carbon, and to obtain the highest current density the carbons must be as thin as possible. (See T. Hesketh, "Notes on the Electric Arc," *Electrician*, vol. xxxix. p. 707.)

The practical employment of the electric arc as a means of illumination is dependent upon mechanism for automatically keeping two suitable carbon rods in the proper position, and moving them so as to enable a steady arc to be maintained. Means must be provided for holding the carbons in line, and when the lamp is not in operation they must fall together, or come together when the current is switched on, so as to start the arc. As soon as the current passes, they must be moved slightly apart, and gripped in position immediately the current reaches its right value, being moved farther apart if the current increases in strength, and brought together if it decreases. Moreover, it must be possible for a considerable length of carbon to be fed through the lamp as required.

Arc lamp mechanism.

Once early devised form of arc-lamp mechanism was a system of clock-work driven by a spring or weight, which was started and stopped by the action of an electromagnet; in modern lighthouse lamps a similar mechanism is still employed. There is no need to occupy space by reference to the early arc-lamp mechanism of Staite (1847), Foucault (1849), Serrin (1857), and Duboscq (1858). These, and a host of later inventors, devised numerous forms of mechanical and clock-work lamps. The modern self-regulating type may be said to have been initiated in 1878 by the differential lamp of von Hefner-Alteneck, and the clutch lamp of C. F. Brush. The general principle of the former may be explained as follows:—There are two solenoids, placed one above the other. The lower one, of thick wire, is in series with the two carbon rods forming the arc, and is hence called the *series coil*. Above this there is placed another solenoid of fine wire, which is called the *shunt coil*. Suppose an iron rod to be placed so as to be partly in one coil and partly in another; then when the coils are traversed by currents, the iron core will be acted upon by forces tending to pull it into these solenoids. If the iron core be attached to one end of a lever, the other end of which carries the upper carbon, it will easily be seen that if the carbons are in contact and the current is switched on, the series coil alone will be traversed by the current, and its magnetic action will draw down the iron core, and therefore pull the carbons apart and strike the arc. The moment the carbons separate, there will be a difference of potential between them, and the shunt coil will then come into action, and will act on the core so as to draw the carbons together. Hence the two solenoids act in opposition to each other, one increasing and the other diminishing the length of the arc, and maintaining the carbons in the proper position. In the actual lamp of this type the upper carbon is in reality attached to a rod having a side-rack gearing, with a train of wheels governed by a pendulum. The action of the series coil on the mechanism is to first lock or stop the train, and then lift it as a whole slightly. This strikes the arc. When the arc is too long, the series coil lowers the gear and finally releases the upper carbon, so that it can run down by its own weight. The principle of a shunt and series coil operating on an iron core in opposition is the basis of the mechanism of a number of arc lamps. Thus the lamp invented by Krizik and Piette, called the Pilsen Lamp, comprises an iron core made in the shape of a double cone or spindle (see Fig. 11), which is so arranged in a brass tube that it can move into or out of a shunt and series coil, wound the one with fine and the other with thick insulated wire, and hence regulate the position of the carbon attached to it. The movement of this core is made to feed the carbons directly without the intervention of any clock-work, as in the case of the Hefner-Alteneck lamp.

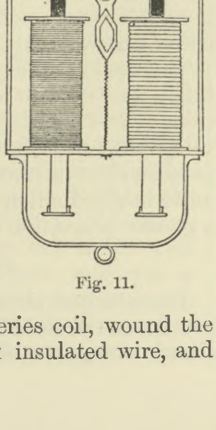

Fig. 11.

In the clutch-lamp mechanism the lower carbon is fixed, and the upper carbon rests upon it by its own weight and that of its holder. The latter consists of a long rod passing through guides, and is embraced somewhere by a ring capable of being tilted or lifted by a finger attached to the armature of an electromagnet, the coils of which are in series with the arc. When the current passes through the magnet it attracts the armature, and by tilting the ring lifts the upper carbon-holder, and hence strikes the arc. If the current diminishes in value, the upper carbon drops a little by its own weight, and the feed of the lamp is thus effected by a series of small lifts and drops of the upper carbon (see Fig. 12) Another element sometimes employed in arc-lamp mechanism is the brake-wheel regulator. This is a feature of one form of the Brockie and of the Crompton-Pochin lamps. In these the movement of the carbons is effected by a cord or chain which passes over a wheel, or by a rack geared with the brake wheel. When the current is passing through the lamp, the wheel is free to move, and the carbons fall together; but when the current is switched on, the chain or cord passing over the brake wheel, or the brake wheel itself, is gripped in some way, and at the same time the brake wheel is lifted so that the arc is struck.

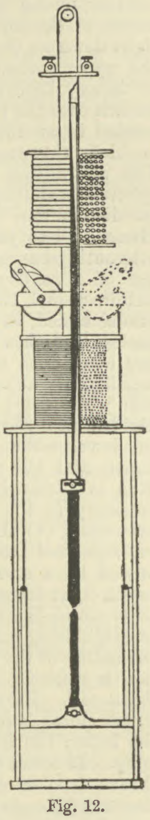

Fig. 12.

Although countless forms of self-regulating device have been invented for arc lamps, nothing has survived the test of time so well as the typical mechanisms which work with carbon rods in one line, one or both rods being moved by a controlling apparatus as required. The early forms of semi-incandescent arc lamp, such as those of Werdermann and others, have dropped out of existence. These were not really true arc lamps, the light being produced by the incandescence of the extremity of a thin carbon rod pressed against a larger rod or block. The once famous Jablochkoff candle has also disappeared from practice. This was invented in 1876, and consisted of two carbon rods about 4 mm. in diameter, placed parallel to each other and separated by a partition of kaolin, steatite, or other refractory non-conductor. Alternating currents were employed, and the candle was set in operation by a match or starter of high-resistance carbon paste which connected the tips of the rods. When this burned off, a true arc was formed between the parallel carbons, the separator volatilizing as the carbons burned away. Although much ingenuity and capital were expended on this system of lighting between 1877 and 1881, it no longer exists. One cause of its disappearance was its relative inefficiency in light-giving power when compared with other forms of carbon arc taking the same amount of power, and a second equally important reason was the waste in carbons. If the arc of the electric candle was accidentally blown out, no means of relighting existed; hence the great waste in half-burnt candles. Wilde, Jamin, Rapieff, and others endeavoured to provide a remedy, but without success. Of late years great advantages have attended the introduction of the *enclosed arc lamp*, in consequence of the economy effected in carbon consumption and in the labour-cost of trimming.

It is impossible to give here detailed descriptions of a fraction of the arc-lamp mechanisms devised, and it must suffice to indicate the broad distinctions between various types. (1) Arc lamps may be either *continuous-current* or *alternating-current* lamps. For outdoor public illumination the former are greatly preferable, as owing to the form of the illuminating power-curve they send the light down on the road surface where it is most required, provided the upper carbon is the positive one. For indoor, public room, or factory lighting, *inverted arc* lamps are sometimes employed. In this case the positive carbon is the lower one, and the lamp is carried in an inverted metallic reflector shield, so that the light is chiefly thrown up on the ceiling, whence it is diffused all round. The alternating current arc is not only less efficient in mean spherical candle-power per watt of electric power absorbed, but its distribution of light is disadvantageous for street purposes. Hence of late years, when arc lamps have to be worked off an alternating-current circuit for public lighting it is usual to make use of a *rectifier*, which rectifies the alternating current into a unidirectional though pulsating current. (2) Arc lamps may be also classified, as above described, into *open* or *enclosed arcs*. The enclosed arc has the advantage that it can be made to burn for 200 hours with one pair of carbons, whereas open arc lamps are usually only able to work 8, 16, or 32 hours without recarboning, even when fitted with double carbons. (3) Arc lamps are further divided into *focussing* and *non-focussing* lamps. In the former the lower carbon is made to move up as the upper carbon moves down, and the arc is therefore maintained at the same level. This is advisable for arcs included in a globe, and absolutely necessary in the case of lighthouse lamps and lamps for optical purposes. (4) Another subdivision is into *hand-regulated* and *self-regulated* lamps. In the hand-regulated arcs the carbons are moved by a screw attachment as required, as in some forms of search-light lamp and lamps for optical lanterns. The carbons in large search-light lamps are usually placed horizontally. (5) The self-regulating lamps may be classified into groups depending upon the nature of the regulating appliances. In some cases the regulation is controlled only by a *series coil*, and in others only by a *shunt coil*. Examples of the former are the original Gülcher and Brush clutch lamp, and some modern enclosed arc lamps; and of the latter, the Siemens "band" lamp, and the Jackson-Mensing lamp. In series coil lamps the variation of the current in the coil throws into or out of action the carbon-moving mechanism; in shunt coil lamps the variation in voltage between the carbons is caused to effect the same changes. Other types of lamp involve the use both of shunt and series coils acting against each other. A further classification of the self-regulating lamps may be found in the nature of the carbon-moving mechanism. This may be some modification of the Brush ring clutch, hence called *clutch* lamps; or some variety of *brake wheel*, as employed in Brockie and Crompton lamps; or else some form of *electric motor* is thrown into or out of action and effects the necessary changes. In many cases the arc-lamp mechanism is provided with a *dash-pot*, or contrivance in which a piston moving nearly air-tight in a cylinder prevents sudden jerks in the motion of the mechanism, and thus does away with the "hunting" or rapid up-and-down movements to which some varieties of clutch mechanism are liable. As with the dynamo, the struggle for existence has gradually eliminated the less efficient forms of mechanism, and a few particular types survive which combine the maximum of efficiency in action with least cost of manufacture. One very efficient form is illustrated in the Thomson lamp and Brush-Vienna lamp. In this mechanism a shunt and series coil are placed side by side, and have iron cores suspended to the ends of a rocking arm held partly within them. Hence, according as the magnetic action of the shunt or series coil prevails, the rocking arm is tilted backwards or forwards. When the series coil is not in action the *motion* is free, and the upper carbon-holder slides down, or the lower one slides up, and starts the arc. The series coil comes into action to withdraw the carbons, and at the same time locks the mechanism. The shunt coil then operates against the series coil, and between them the carbon is fed forwards as required. The control to be obtained is such that the arc shall never become so long as to flicker and become extinguished, when the carbons would come together again with a rush, but the feed should be smooth and steady, the position of the carbons responding quickly to each change in the current.

Arrangement. Arc lamps may be arranged either (i.) in series, (ii.) in parallel, or (iii.) in series parallel. In the first case a number, say 20, may be traversed by the same current, in that case supplied at a pressure of 1000 volts. Each must have a magnetic cut-out, so that if the carbons stick together or remain apart the current to the other lamps is not interrupted, the function of such a cut-out being to close the main circuit immediately any one lamp ceases to pass current. Arc lamps worked in series are generally supplied with a current from a constant current dynamo, which maintains an invariable current of, say 10 amperes, independently of the number of lamps on the external circuit. If the lamps, however, are worked in series off a constant potential circuit, such as one supplying at the same time incandescent lamps, provision must be made by which a resistance coil can be substituted for any one lamp that is removed or short-circuited. In the case when lamps are worked in parallel, each lamp is independent, but it is then necessary to add a resistance in series with the lamp. By special devices three lamps can be worked in series of 100 volt circuits. Alternating-current arc lamps can be worked off a high-tension circuit in parallel by providing each lamp with a small transformer. In some cases the alternating high-tension current is *rectified* and supplied as a unidirectional current to lamps in series. If single alternating-current lamps have to be worked off a 100 volt alternating-circuit, each lamp must have in series with it a choking coil or economy coil, to reduce the circuit pressure to that required for one lamp. Alternating-current lamps take a larger *effective* current, and work with a less effective or virtual carbon P.D., than continuous current arcs of the same wattage.

Cost. The cost of working public arc lamps is made up of several items. There is first the cost of supplying the necessary electric energy, then the cost of carbons and the labour of recarboning, and, lastly, an item due to depreciation and repairs of the lamps. An ordinary open type 10 ampere arc lamp, burning carbons 15 and 9 mm. in diameter for the positive and negative, and working every night of the year from dusk to dawn, uses about 600 feet of carbons per annum. If the positive carbon is 18 mm. and the negative 12 mm., the consumption of each size of carbon is about 70 feet per 1000 hours of burning. It may be roughly stated that at the present prices of arc-lamp carbons the cost is about 15s. per 1000 hours of burning; hence if such a lamp is burnt every night from dusk to midnight the annual cost in that respect is about £1, 10s. The annual cost of labour per lamp for trimming is in Great Britain from £2 to £3 per annum; hence, approximately speaking, the cost per annum of maintenance of a public arc lamp burning every night from dusk to midnight is about £4 to £5, or perhaps £6, per annum, depreciation and repairs included. Since such a 10 ampere lamp uses half a Board of Trade unit of electric energy every hour, it will take 1000 Board of Trade units per annum, burning every night from dusk to midnight; and if this energy is supplied, say at 3d. per unit, the annual cost of energy will be about £12, and the upkeep of the lamp, including carbons, labour for trimming and repairs, will be about £16 to £18 per annum. The cost for labour and carbons is considerably reduced by the employment of the enclosed arc lamp, but owing to the absorption of light produced by the inner enclosing globe, and the necessity for generally employing a second outer globe, there is a lower resultant candle-power per watt expended in the arc. Enclosed arc lamps as now made (1899), burn without attention for 200 hours, singly on 100 volt circuits, or two in series on 200 volt circuits, and in addition to the cost of carbons per hour being only about one-twentieth of that of the open arc, have another advantage in the fact that there is a more uniform distribution of light on the road surface, because a greater proportion of light is thrown out horizontally.

Incandescent Lamps.

Incandescent electric lighting, although not the first, is yet in one sense the most obvious method of utilizing electric energy for illumination. It was evolved from the early observed fact that a conductor is heated when traversed by an electric current, and that if it has a high resistance and a high melting-point it may be rendered incandescent, and therefore become a source of light. Naturally every inventor turned his attention to the employment of wires of refractory metals, such as platinum or alloys of platinum-iridium, &c., for the purpose of making an incandescent lamp, and in the middle and latter half of the 19th century many attempts of this kind were made. No reference need be made to the experiments of De Moleyns in 1841, King and Starr in 1845, Watson in 1853, and Staite in 1848, for in spite of their ingenuity these inventors achieved no satisfactory result. Part, however, of their want of success is attributable to the fact that in their day the problem of the economical production of electric current by the dynamo machine had not been solved. In 1878 Edison directed his attention to the same subject, and devised lamps in which a platinum wire was employed as the light-giving agent, carbon being made to adhere round it by pressure. Abandoning this, he next directed his attention to the construction of an "electric candle," consisting of a thin cylinder or rod formed of finely-divided metals, platinum, iridium, &c., mixed with refractory oxides, such as magnesia, or zirconia, lime, &c. This refractory body was placed in a closed vessel and heated by being traversed by an electric current. In a further improvement he proposed to use a block of refractory oxide, round which a bobbin of fine platinum or platinum-iridium wire was coiled. Every other inventor who worked at the problem of incandescent lighting seems to have followed nearly the same path of invention. Long before this date, however, the notion of employing carbon as a substance to be heated by the current had entered the minds of inventors; even in 1845 King had employed a small rod of plumbago as the substance to be heated. It was obvious, however, that carbon could only be so heated when in a space destitute of oxygen, and accordingly King placed his plumbago rod in a barometric vacuum. Konn in 1872, and Kosloff in 1875, followed in the same direction.

Carbon filament lamp.

Without entering into a detailed history of the development of incandescent electric lighting, we may say that no real success attended the efforts of inventors until it was finally recognized, as the outcome of the work by J. W. Swan, T. A. Edison, and, in a lesser degree, Lane Fox and Sawyer and Mann, that the conditions of success were as follow:—First, the substance to be heated must be carbon in the form of a thin wire rod or thread, technically termed a *filament*; second, this must be supported and enclosed in a vessel formed entirely of glass; third, the vessel must be exhausted as perfectly as possible; and fourth, the current must be conveyed into and out of the carbon filament by means of platinum wires hermetically sealed through the glass. By successive stages inventors were led to perfect all the details of the process of manufacturing an incandescent electric lamp in its present form. One great difficulty was the production of the carbon filament. Early inventors, such as King, Sawyer, and Mann, and others, had attempted to cut out a suitably shaped piece of carbon from a solid block; but Edison and Swan were the first to show that the proper solution of the difficulty was to carbonize an organic substance to which the necessary form had been previously given. For this purpose cardboard, paper, and ordinary thread were originally employed, and even, according to Edison, a mixture of lampblack and tar rolled out into a fine wire and bent into a spiral. At one time Edison employed a filament of bamboo, carbonized after being bent into a horse-shoe shape. Swan used a material formed by treating ordinary crochet cotton-thread with dilute sulphuric acid, the "parchmentized thread," thus produced being afterwards carbonized. In the modern incandescent lamp the filament is generally constructed by preparing first of all a form of soluble cellulose. Carefully purified cotton-wool is dissolved in some solvent, such as a solution of zinc chloride, and the viscous material so formed is forced by hydraulic pressure through a die. The long thread thus obtained, when hardened, is a semi-transparent substance resembling cat-gut, and when carefully carbonized at a high temperature gives a very dense and elastic form of carbon filament. It is cut into appropriate lengths, which after being bent into horse-shoes, double-loops, or any other shape desired, are tied or folded round carbon formers and immersed in plumbago crucibles, packed in with finely divided plumbago. The crucibles are then heated to a high temperature in an ordinary combustion or electric furnace, whereby the organic matter is destroyed, and a skeleton of carbon remains. The higher the temperature at which this carbonization is conducted, the denser is the resulting product. The filaments so prepared are sorted and measured, and short leading-in wires of platinum are attached to their ends by a carbon cement or by a carbon depositing process, carried out by heating electrically the junction of the carbon and platinum under the surface of a hydrocarbon liquid. They are then mounted in bulbs of lead glass having the same coefficient of expansion as platinum, through the walls of which, therefore, the platinum wires can be hermetically sealed. The bulbs pass into the exhausting-room, where they are exhausted by some form of mechanical or mercury pump. During this process an electric current is sent through the filament to heat it, in order to disengage the gases occluded in the carbon, and exhaustion must be so perfect that no luminous glow appears within the bulb when held in the hand and touched against one terminal of an induction coil in operation. Finally, the lamp is provided with a collar having two sole plates on it, to which the terminal wires are attached, or else the terminal wires are simply bent into two loops; in a third form, the Edison screw

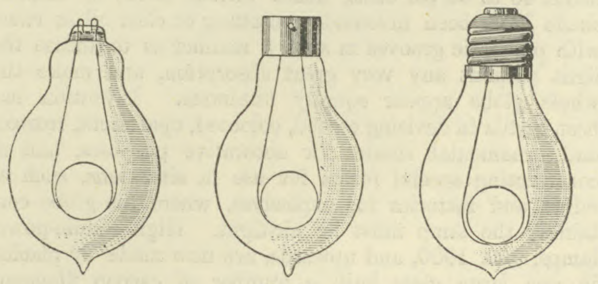

Fig. 13.

terminal, it is provided with a central metal plate, to which one end of the filament is connected, the other end being joined to a screw collar. The collars and screws are formed of thin brass embedded in plaster of Paris, or in some material like vitrite or black glass (cp. Fig. 13).

In order to put the lamp into connexion with the circuit supplying the current, it has to be fitted into a socket or holder. Three of the principal types of holder in use are the bottom contact (B.C.) or Dornfeld socket, the Edison screw-collar socket, and the Swan or loop socket. In the Dornfeld socket (Fig. 14, *a* and *a'*) two spring pistons, in contact with the two sides of the circuit, are fitted into the bottom of a short metallic tube having bayonet joint slots cut in the top. The brass collar on the lamp has two pins, by means of which a bayonet connexion is made between it and the socket; and when this is done, the spring pins are pressed against the sole plates on the lamp. In the Edison socket (Fig. 14, *b*) a short metal tube with an insulating lining has on its interior a screw sleeve, which is in connexion with one wire of the circuit; at the bottom of the tube, and insulated from the screw sleeve, is a central metal button, which is in connexion with the other side of the circuit. On screwing the lamp into the socket, the screw collar of the lamp and the boss or plate at the base of the lamp make contact with the corresponding parts of the socket, and complete the connexion. In some cases a form of switch is included in the socket, which is then termed the key-holder. For loop lamps the socket consists of an insulated block, having on it two little hooks, which engage with the eyes of the lamp. This insulating block also carries some form of spiral spring or pair of spring loops, by means of which the lamp is pressed away from the socket, and the eyes kept tight by the hooks. This spring or Swan socket (Fig. 14, *c*) is found useful in places where the lamps are subject to vibration, for in such cases the Edison screw collar cannot well be used, because the vibration loosens the contact of the lamp in the socket. The sockets may be fitted with appliances for holding ornamental shades or conical reflectors. The incandescent filament being a sharp and very brilliant line of light, makes a disagreeable impression upon the eye if looked at directly; hence various devices are adopted for moderating its brilliancy and distributing the light. A simple method is to sand-blast the exterior of the bulb, whereby it acquires an appearance similar to that of ground glass, or the bare lamp may be enclosed in a suitable glass shade. Such shades, however, if made of opalescent or semi-opaque glass, absorb a large proportion of the light, about 40 to 60 per cent.; hence various forms of dioptric shade have been invented, consisting of clear glass ruled with prismatic grooves in such a manner as to diffuse the light without any very great absorption, and make the whole globe appear equally luminous. Invention has been fertile in devising etched, coloured, opalescent, frosted, and ornamental shades for decorative purposes, and in constructing special forms for use in situations, such as mines and factories for explosives, where the globe containing the lamp must be air-tight. High candle-power lamps, 500, 1000, and upwards, are now made by placing in one large glass bulb a number of carbon filaments arranged in parallel between two rings, which are connected with the main leading-in wires. When incandescent lamps are used for optical purposes it is necessary to compress the filament into a small space, so as to bring it into the focus of a lens or mirror. The filament is then coiled or crumpled up into a spiral or zigzag form. Such lamps are called *focus lamps.* Incandescent lamps are technically divided into several broad divisions, called respectively high and low voltage lamps, high and low efficiency lamps, standard and fancy lamps. The difference between high and low efficiency lamps is based upon the relation of the power absorbed by the lamp to the candle-power emitted. Every lamp when manufactured is marked with a certain figure, called the *marked volts.* This is understood to be the electromotive force in volts which must be applied to the lamp terminals to produce through the filament a current of such magnitude that the lamp will have a practically satisfactory life, and give in a horizontal direction a certain candle-power, which is also

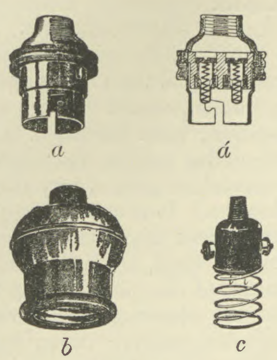

Fig. 14.

marked upon the glass. The numerical product of the current in amperes passing through the lamp, and the difference in potential of the terminals measured in volts, gives the total power taken up by the lamp in watts; and this number divided by the candle-power of the lamp (taking generally a horizontal direction) gives the *watts per candle-power.* This is an important figure, because it is determined by the temperature; it therefore determines the quality of the light emitted by the lamp, and also fixes the average duration of the filament when rendered incandescent by a current. Even in a good vacuum the filament is not permanent. Apart altogether from accidental defects, which may sooner or later cause it to break, the carbon is slowly volatilized, and carbon molecules are also projected in straight lines from different portions of the filament. This process not only causes a change in the nature of the surface of the filament, but also a deposit of carbon on the interior of the bulb, whereby the glass is blackened and the candle-power of the lamp reduced. The volatilization increases very rapidly as the temperature rises. Hence at points of high resistance in the filament, more heat being generated, a higher temperature is attained, and the scattering of the carbon becomes very rapid; in such cases the filament is sooner or later cut through at the point of high resistance. In order that incandescent lighting may be practically possible, it is essential that the lamps shall have a certain *average life*, that is, duration; and this useful duration is fixed not merely by the possibility of passing a current through the lamp at all, but by the rate at which the candle-power diminishes. The decay of candle-power is called the *ageing* of the lamp, and the useful life of the lamp may be said to be that period of its existence before it has deteriorated to a point when it gives only 75 per cent. of its original candle-power. It is found that in practice carbon filament lamps, as at present made, cannot be worked at a higher efficiency than 2½ watts per candle-power without a too rapid duration and a too short life. Hence lamp manufacturers classify lamps into various classes, marked for use say at 2½, 3, 3½, and 4 watts per candle. A 2½ watt per candle lamp would be called a *high-efficiency lamp*, and a 4 watt per candle lamp would be called a *low-efficiency* lamp. Under ordinary circumstances the low-efficiency lamp would probably have a longer life, but its light would be less suitable for many purposes of illumination in which colour discrimination is required. The possibility of employing high-efficiency lamps depends greatly on the uniformity of the electric pressure of the supply. If the voltage is exceedingly uniform, then high-efficiency lamps can be satisfactorily employed; but they are not adapted for standing the variations in pressure which are liable to occur with public supply-stations, since, other things being equal, their filaments are less substantial. The classification of lamps into high and low voltage lamps is based upon the watts per candle-power corresponding to the marked volts. When incandescent lamps were first introduced, the ordinary working voltage was 50 or 100, but at the present time a large number of public supply-stations furnish current to consumers at a pressure of 200 or 250 volts. This increase was necessitated by the enlarging area of supply in towns, and therefore the necessity for conveying through the same subterranean copper cables a large supply of electric energy without increasing the maximum current value and the size of the cables. This can only be done by employing a higher working electromotive force; hence arose a demand for incandescent lamps having marked volts of 200 and upwards, technically termed high-voltage lamps. The employment of higher pressures in public supply-stations has necessitated greater care in the selection of the lamp fittings, and in the manner of carrying out the wiring work. Switches, sockets, fuses, ceiling roses, &c., which are adequate for use with 100 volts become unsuitable when employed with higher pressures, because of the greater risk of starting an electric arc between adjacent metallic parts. The advantages, however, of higher supply pressures, from the point of view of supply-stations, are undoubted. At the same time the consumer desires a lamp of a higher efficiency than the ordinary carbon filament lamp. The demand for this has resulted in inventors turning their attention to substances other than carbon which can be rendered incandescent by the electric current.

Recent improvements.

The luminous efficiency of any source of light, that is to say, the percentage of rays emitted which affect the eye as light compared with the total radiation, is dependent upon its temperature. In an ordinary oil lamp the luminous rays do not form much more than 3 per cent. of the total radiation. In the carbon-filament incandescent lamp, when worked at about 3 watts per candle, the luminous efficiency is about 5 per cent.; and in the case of the arc lamp the radiation from the crater contains about 10 to 15 per cent. of eye-affecting radiation. Hence any improvement in the incandescent lamp must involve the use of a substance which is capable, without destruction, of enduring a higher temperature than the carbon filament. The temperature of a carbon filament working at about 3 watts per candle is not far from the melting-point of platinum, that is to say, is nearly 1775° C. If it is worked at a higher efficiency, say 2·5 watts per candle-power, the temperature rises rapidly, and at the same time the volatilization and molecular scattering of the carbon is rapidly increased, so that the average duration of the lamp is very much shortened. An improvement, therefore, in the efficiency of the incandescent lamp can only be obtained by finding some substance which will endure heating to a higher temperature than the carbon filament. Inventors turned their attention many years ago, with this aim, to the refractory oxides and similar substances. Jablochkoff in 1877 described and made a lamp consisting of a piece of kaolin, which was brought to a state of incandescence first by passing over it an electric spark, and afterwards maintained in a state of incandescence by a current of lower electromotive force. Lane Fox and Edison, in 1878, proposed to employ platinum wires covered with films of lime, magnesia, steatite, or with the rarer oxides, zirconia, thoria, &c.; and Lane Fox, in 1879, suggested as an incandescent substance a mixture of particles of carbon with the earthy oxides. These earthy oxides—magnesia, lime, and the oxides of the rare earths, such as thoria, zirconia, erbia, yttria, &c. —possess the peculiarity that at ordinary temperatures they are practically non-conductors, but if heated to very high temperatures, their resistance at a certain point rapidly falls, and they become fairly good conductors. Hence if they can once be brought into a state of incandescence a current can pass through them and maintain them in that state. On the other hand, at this temperature they give up oxygen to carbon; hence no mixtures of earthy oxides with carbon are permanent when heated.

Nernst lamp.

Nernst in 1897, however, patented an incandescent lamp in which the incandescent body consists entirely of a slender rod or filament of magnesia. If such a rod is heated by the oxyhydrogen blowpipe to a high temperature it becomes conductive, and can then be maintained in an intensely luminous condition by passing a current through it after the flame is withdrawn. Nernst found that by mixing together, in suitable proportions, magnesia with oxides of the rare earths, he was able to prepare a material which can be formed into slender rods and threads, and which is rendered sufficiently conductive to pass a current with an electromotive force as low as 100 volts, merely by being heated for a few moments with a spirit lamp, or even by the radiation from a neighbouring platinum spiral brought to a state of incandescence. The Nernst lamp, therefore, consists of a slender rod of the mixed oxides attached to platinum wires by an oxide paste. The rod is surrounded by, or brought into proximity with, a coil of platinum wire which can be heated to incandescence, and the radiation from which suffices to heat the oxide rod to a point at which it is able to pass sufficient current to maintain itself in a state of incandescence. When this condition is reached, the current is automatically cut off from the platinum coil. Oxide filaments of this description need not be enclosed in an exhausted glass vessel, and they can be brought, without risk of destruction, to a temperature considerably higher than a carbon filament; hence the lamp has a higher luminous efficiency. Many attempts have been made to cover over the carbon filament in a glow lamp with such substances, as thoria, zirconia, and the rare oxides, generally under the conception that at the same temperature such a surface would radiate a larger proportion of luminous rays than carbon; but all such attempts have been a failure, from the fact that these oxides are rapidly reduced by contact with carbon at any temperature near the melting-point of platinum.

In the manufacture of carbon-filament lamps a process is very generally applied to the carbon which is technically termed "treating." The carbon filament, when formed, is placed in a vessel surrounded by an atmosphere of hydrocarbon, such as coal gas or vapour of benzol. If current is then passed through the filament the hydrocarbon vapour is decomposed, and carbon is thrown down upon the filament in the form of a lustrous and dense deposit having an appearance like steel when seen under the miscroscope. This deposited carbon is not only much more dense than ordinary carbonized organic material, but it has a much lower specific electric resistance. An untreated carbon filament is generally termed the primary carbon, and a deposited carbon the secondary carbon. In the process of treating, the greatest amount of deposit is at any places of high resistance in the primary carbon, and hence it tends to cover up or remedy the defects which may exist. The bright steely surface of a well-treated filament is a worse radiator than the rougher black surface of an untreated one, hence it does not require the expenditure of so much electric power to bring it to the same temperature, and probably on account of its greater density it deteriorates or ages much less rapidly.

Photometry and testing.

The arrangement most suitable for the photometry and testing of incandescent lamps is a gallery or room large enough to be occupied by several workers, the walls being painted dead black. The photometer, preferably one of the Lummer-Brodhun form, is set up on a gallery or bench. On one side of it must be fixed a working standard, which may be an incandescent lamp; if this has a glass bulb much larger than the ordinary lamp, it will not so easily become blackened by a deposit of carbon. Its candle-power can be compared, at regular intervals and known voltages, with that of some accepted flame standard, such as that of Vernon Harcourt; in a lamp factory or electrical laboratory it is convenient to have a number of such large bulb standard lamps. This working standard should be maintained at a fixed distance on one side of the photometer, such that when worked at a standard voltage it creates an illumination of one candle-foot on one side of the photometer disc. The incandescent lamp to be examined is then placed on the other side of the photometer disc on a travelling carriage, so that it can be moved to and fro. Arrangements must be made to measure the current and the voltage of this lamp under test, and this is most accurately accomplished by employing a potentiometer. (see MEASURING INSTRUMENTS, ELECTRIC). The holder which carries the lamp should be of such a description that the lamp can be held with its axis in any required position; in making normal measurements the position of the lamp should be with its axis vertical, the filament being so situated that none of the turns or loops overlie one another as seen from the photometer disc. Observations can then be made of the candle-power corresponding to different currents and voltages.

The candle-power of the lamp varies with the other variables in accordance with exponential laws of the following kind:—

If A is the current in amperes through the lamp, V the voltage or terminal potential difference, W the power absorbed in watts, *c.p.* the maximum candle-power, and *a*, *b*, *c*, &c., constants, it has been found that A and *c.p.* are connected by an exponential law such that,

$$c.p. = aA^x$$

where x is a number lying between 5 and 6, generally equal to 5·5 or 5·6. Also it has been found that $c.p. = bW^3$ very nearly, and that

$$c.p. = cV^y \text{ nearly}$$

where c is some other constant, and y is a number nearly equal to 6. It is obvious that if the candle-power of the lamp varies very nearly as the 6th power of the current and of the voltage, the candle-power must vary as the cube of the wattage.

Abney and Festing have also given a formula connecting candle-power and watts equivalent to $c.p. = (W-d)^2$ where d is a constant.

Curves delineating the relation of these variables for any incandescent lamp are called its *characteristic-curves.* The life or average duration is a function of $W/c.p.$, or of the *watts per candle-power,* and therefore of the voltage at which the lamp is worked. It follows from the above relation that the watts per candle-power vary inversely as the fourth power of the voltage.

From limited observations it seems that the average life of a carbon-filament lamp varies as the fifth or sixth power of the watts per candle-power. If V is the voltage at which the lamp is worked and L is its average life, then L varies roughly as the twenty-fifth power of the reciprocal of the voltage, or

$$L = a V^{-25}.$$

A closer approximation to experience is given by the formula

$$\log_{10} L = 13{\cdot}5 - \frac{V}{10} - \frac{V^2}{20{,}000}.$$

(See J. A. Fleming, "Characteristic Curves of Incandescent Lamps," *Phil. Mag.*, May 1885.)

Allusion has already been made to the fact that carbon-filament glow lamps by use deteriorate in light-giving power. This is due to two causes. As already explained, carbon is scattered from the filament and deposited upon the glass, and also changes take place in the filament which cause it to become reduced in temperature, even when subjected to the same terminal voltage. In many lamps it is found that the first effect of running the lamp is to slightly increase its candle-power, even although the voltage be kept constant; this is the result of a small decrease in the resistance of the filament. The heating to which it is subjected slightly increases the density of the carbon at the outset; this has the effect of making the filament lower in resistance, and therefore it takes more current at a constant voltage. The greater part, however, of the subsequent decay in candle-power is due to the deposit of carbon upon the bulb, as shown by the fact that if the filament is taken out of the bulb and put into a new clean bulb the candle-power in the majority of cases returns to its original value. Since the lamp ceases to be as useful, considered as a transforming device, when the candle-power falls below a certain percentage of the original value, it has been suggested that for every lamp there is a certain point in its career which may be called the "smashing-point," when it is advantageous to replace it by a new one.

Ageing of lamps.

Variations of pressure in the electric supply exercise a very prejudicial effect upon the light-giving qualities of incandescent lamps. If for instance glow lamps, nominally of 100 volts, are supplied from a public electric lighting-station, in the mains of which the pressure varies between 90 and 110 volts, their life will be greatly abbreviated, and they will become blackened much sooner than would be the case if the pressure were perfectly constant. Since the candle-power of the lamp varies very nearly as the fifth or sixth power of the voltage, it follows that a variation of 10 per cent. in the electromotive force creates a variation of nearly 50 per cent. in the candle-power. Thus a 16 candle-power glow lamp, marked for use at 100 volts, was found on test to give the following candle-powers at voltages varying between 90 and 105:—At 105 volts it gave 22·8 c.p.; at 100 volts, 16·7 c.p.; at 95 volts, 12·2 c.p.; and at 90 volts, 8·7 c.p. Thus a variation of 25 per cent. in the candle-power was caused by a variation in voltage of only 5 per cent. The same kind of variation in working voltage exercises also a marked effect upon the average duration of the lamp. The following figures show the results of some tests on typical 3·1 watt lamps run at voltages above the normal, taking the average life when worked at the marked volts (namely, 100) as 1000 hours:—

At 101	volts	the life was	818	hours.
,, 102	,,	,,	681	,,
,, 103	,,	,,	662	,,
,, 104	,,	,,	452	,,
,, 105	,,	,,	374	,,
,, 106	,,	,,	310	,,

To remedy these effects, self-acting regulators have been devised by which the voltage at the points of consumption is kept constant, even although it varies at the point of generation. If, however, such a device is to be effective, it must operate very quickly, as even the momentary effect of increased pressure is felt by the lamp. It is only therefore in those cases where the working pressure can be kept exceedingly constant that high-efficiency lamps can be advantageously employed, otherwise the cost of lamp renewals more than counterbalances the economy in the cost of power. The slow changes that occur in the resistance of the filament make themselves evident by an increase in the per watts candle-power. The following table shows some typical figures indicating the results of ageing in a 16 candle-power carbon-filament glow lamp:—

Voltage regulators.

Hours Run.	Candle-Power.	Watts per Candle-Power.
0 . .	16·0	3·16
100 . .	15·8	3·26
200 . .	15·86	3·13
300 . .	15·68	3·37
400 . .	15·41	3·53
500 . .	15·17	3·51
600 . .	14·96	3·54
700 . .	14·74	3·74

The above table shows a gradual increase in watts per candle-power. This, however, does not imply necessarily an increase in the total power taken by the lamp, but is merely the consequence of the decay in candle-power produced by the blackening of the lamp. It is clear, therefore, that in estimating the value of an incandescent lamp for illuminating purposes the user must take into account not merely the price of the lamp and the initial watts per candle-power, but the rate of decay of the lamp.

The scattering of carbon from the filament to the glass bulb produces interesting physical effects, which have been studied by Edison, Preece, and Fleming. If into an ordinary carbon-filament glow lamp a platinum plate is sealed, not connected to the filament but attached to a third terminal, then it is found that when the lamp is worked with continuous current a galvanometer connected in between the middle plate and the positive terminal of the lamp indicates a current, but not when connected in between the negative terminal of the lamp and the middle plate. If the middle plate is placed between the legs of a horse-shoe-shaped filament, it becomes blackened most quickly on the side facing the negative leg. The above effect, commonly called the *Edison effect*, is connected with an electric discharge and convection of carbon which takes place between the two extreme ends of the filament, and, as experiment seems to show, consists in the conveyance of an electric charge, either by carbon molecules or something smaller than molecules. There is, however, an electric discharge between the ends of the filament, which rapidly increases with the temperature of the filament and the terminal voltage; hence one of the difficulties of manufacturing high-voltage glow lamps, that is to say, glow lamps for use on circuits having an electromotive force of 200 volts and upwards, is the discharge which thus takes place across from one leg of the filament to the other.

Edison effect.

A brief allusion may next be made to the mode of use of incandescent lamps for interior and private lighting. At the present time hardly any other method of distribution is adopted than that of an arrangement *in parallel*; that is to say, each lamp on the circuit has one terminal connected to a wire which finally terminates at one pole of the generator, and its other terminal connected to a wire leading to the other pole. The lamp filaments are thus arranged between the conductors like the rungs of a ladder. In series with each lamp is placed a switch and a fuse or cut-out. The lamps themselves are attached to some variety of ornamental fitting, or in many cases suspended by a simple pendant, consisting of an insulated double flexible wire attached at its upper end to a ceiling rose, and carrying at the lower end a shade and socket in which the lamp is placed. Lamps, however, hung in this manner, head downwards, are disadvantageously used because their *end-on candle-power* is not generally more than 60 per cent. of their maximum candle-power. For descriptions of the immense varieties of ornamental fittings employed, special manuals must be consulted. Suffice it to say here that in interior lighting one of the great objects to be attained is a uniformity of illumination and the avoidance of harsh shadows. This can be achieved by a proper distribution of the lamps. It is impossible to give any hard and fast rules as to what number must be employed in the illumination of any room, as a great deal depends upon the nature of the reflecting surfaces, such as the walls, ceilings, &c. A room papered with dark paper, or having dark oak panels, will require double as many lights to produce satisfactory interior illumination, as will be the case in a room whose walls are very light in colour, or which contains many mirrors. As a rough guide, it may be stated that for every 100 square feet of floor surface one 16 candle-power lamp placed about 8 feet above the floor will give a dull illumination, two will give a good illumination, and four will give a brilliant illumination. We generally judge of the nature of the illumination in a room by our ability to read comfortably in any position. In order that this may be done, the horizontal illumination on the book should not be less than one candle-foot. The following table shows approximately the illuminations in candle-feet, in various situations, derived from actual experiments:—

Domestic use.

In a well-lighted room on the floor or tables	1·0 to 3 c.f.
On a theatre stage	3 to 4 c.f.
On a railway platform	·05 to ·5 c.f.
In a picture gallery	·65 to 3·5 c.f.
The mean daylight in May in the interior of a room	30 to 40 c.f.
In full sunlight	7000 to 10,000 c.f.
In full moonlight	1/60th to 1/100th c.f.

From an artistic point of view, one of the worst methods of lighting a room is by pendant lamps, collected in single centres in large numbers. Properly speaking, the lights ought to be distributed in different portions of the room, and so shaded that the naked filament is nowhere visible to the eye, but the light is received only by reflection from surrounding objects. Ornamental effects are frequently produced by means of candle lamps in which a small incandescent lamp, imitating the flame of a candle, is placed upon a white porcelain tube as a holder, and these small units are distributed and arranged in electroliers and brackets. It conduces to economy in the consumption of electric energy if a sufficient number of switches is provided, so that only those lights which are actually required need be used. For details as to the various modes of placing conducting wires in houses, and the various precautions for safe usage, the reader is referred to the article I. GENERAL PRINCIPLES above.

We may conclude with a brief reference to the historical development of electric lighting in Great Britain. In the year 1879 the Government had its attention directed for the first time to electric lighting as a possible subject for legislation, and a consideration of the existing state of electric lighting was referred to a Select Committee of the House of Commons. No legislative action, however, was taken at that time—in fact, the invention of the incandescent lamp was incomplete. Edison's British master-patent was only filed in Great Britain in November 1879. In 1882 an important Electrical Exhibition was held at the Crystal Palace, and the perfected electric incandescent lamp was for the first time seen by the public in large numbers. Owing, however, to the legislative enactments of the first Electric Lighting Act, 1882, progress was at first retarded, and it was not until after 1888, when the Electric Lighting Amendment Act was passed, that much advance began to be made in the development of electric lighting. After an important inquiry held by the Board of Trade in May 1889, rapid progress began to be made, and from and after that date public and private electric lighting has extended at an enormous rate. At the end of 1893 there were rather over one million 8 candle-power lamps in use in Great Britain; at the end of 1895, about two millions; at the end of 1896, about three millions; at the end of 1898, five millions; and at the end of 1899, rather over seven millions.

Additional information on the subjects treated above may be found in the following books and original papers:—

III. Electric Traction.

Electric traction, as treated in this article, will refer to the operation of vehicles for the transportation of passengers and goods upon tracks, as distinguished from what are known as telpherage systems on the one hand, and automobiles intended to run on common roads on the other.

History.

Possibly the first electric motor was that made by the Abbe Dal Negro, in Italy, in 1830. As early as 1835, Thomas Davenport, a blacksmith of Brandon, Vt., U.S.A., constructed and exhibited an automobile electric car, operated by batteries carried upon it. Robert Davidson, of Aberdeen, Scotland, began experimenting about 1838 with the electric motor as a means of traction, and constructed a very powerful engine, weighing five tons and carrying a battery of forty cells. This locomotive made several successful trips on Scottish railways, but was finally wrecked by jealous employees of the railway while it was lying in the car sheds at Perth. In 1840 a provisional patent was granted in England to Henry Pinkus, which described a method of supplying electric energy to a moving train from fixed conductors. A little later, in 1845, French and Austrian patents granted to Major Alexander Bessolo described practically what is to-day the third-rail system. In 1847 Professor Moses G. Farmer, of Maine, U.S.A., built a model locomotive operated by electricity, which he exhibited at Dover, New Hampshire, and later at other places in New England. Shortly afterwards Professor C. G. Page, of the Smithsonian Institution, in Washington, constructed an electric railway motor, which made a trip on April 29, 1851, from Washington, D.C., to Bladensburg, Md., over the Baltimore and Ohio Railway. This machine carried 100 Grove's cells, and attained speeds as high as 19 miles an hour. Perhaps the beginning of modern electric traction may be said to date from 1879, when the firm of Siemens & Halske put in operation the first electric railway at the Industrial Exposition in Berlin. In America it was not until a year later that real work began, and Mr T. A. Edison built an experimental line near his laboratory in Menlo Park, N.J. In 1880 a locomotive driven by accumulators was constructed and operated at a linen bleaching establishment at Breuil en Auge, in France; and in 1881 a similar car was worked upon the Vincennes tramway line. On May 12, 1881, the first commercial electric railway for regular service was opened for operation at Lichterfelde, in Germany. The first really noteworthy road was that constructed at the Giant's Causeway at Portrush, in the North of Ireland. This line was 6 miles long, and the power was obtained from turbine wheels actuated by a cascade on the river Rush. The method of supply was, curiously enough, the third-rail. In 1883 invention in electric railways seems to have taken a decided advance in America. It was in this year that the conflicting interests of Edison and S. D. Field were consolidated; and at the same time Van Depoele and Daft began their experimental work, which later resulted in numerous commercial railways. Next year Messrs Bentley & Knight opened to the public in Cleveland, Ohio, U.S.A., a railway operated by an open-slot conduit, and for the first time worked in competition with horse traction on regular street railway lines. For the next two years much experimental work was done, but it may be said with fairness that the first of the thoroughly modern systems, in which a large railway was equipped and operated under service conditions by electricity, was the line built in Richmond, Va., U.S.A., by Frank J. Sprague in 1887. This railway had 13 miles of track, and started with an equipment of forty cars. It has been in continuous and successful commercial operation ever since. The original Richmond system was in all its essential particulars the overhead trolley system now in use. Many improvements have been made in the construction of the motors, the controllers, the trolleys, and the various details of car equipment and overhead construction, but the broad principles have not been departed from. The success of the Richmond line called the attention of tramway managers to the advantages of electricity as a motive power, and its substitution for other systems has progressed with astonishing rapidity. In the United States practically all the horse and cable tram-lines have been or are being provided with one form or another of electric traction, and Europe also is at present actively engaged in changing from the older methods of tramway operation to electrical methods. In the United States the original city lines have been extended into the suburbs, and interurban lines have been built, so that there are continuous electric lines of several hundred miles in length. The interurban service has developed electric railways competing with steam railways in speed and in the size and comfort of the cars. Electric locomotives have been constructed for special purposes. In Baltimore, Md., U.S.A., the Baltimore and Ohio Railroad has a tunnel which, with its covered approaches, is over a mile and a half long, and in which is a grade of 42 feet to the mile. The steam locomotive gases, due especially to the very heavy freight trains that were hauled, made the operation of the tunnel impossible. Electric locomotives were built and put in operation in 1895. These machines weigh 96 tons, all of the weight being on the drivers, and they can haul trains of over 2000 tons up the grade. Other locomotives of various sizes and designs have also been built.

Advantages.

At the present time it may fairly be said that electricity has shown its superiority over its competitors—horses and moving cables—for tramway work. It is cheaper and more flexible. The relative cost of operation varies, of course, with the local conditions, but a fair average estimate would be that cable lines cost 25 per cent. more to operate than electric, and horse lines 100 per cent. more. The increased speed of the electric cars and the comfort rendered possible by larger vehicles always increase the receipts when horse traction is replaced by electric, while the latter, as compared with the cable, allows better and easier control of the car and a much greater possible speed variation. The installation of an overhead electric line costs less than a cable system, though the expense of a conduit electric line is about the same. By the extension of the urban tramway systems into the suburbs and the construction of interurban lines, electricity has come into competition with steam. Here the conditions are different. For ordinary suburban service the electric cars, running through the city streets and on the highways, cannot, in speed, compete with steam trains operated on private rights of way. The fact that they run more frequently and can be entered anywhere along the line gives them an advantage, and within limited distances they have taken a large proportion of suburban traffic from steam railways. For long-distance service, in order to compete with steam, a speed much greater than that used on ordinary tram lines must be used, while owing to the time spent on the car more attention must be paid to the comfort of the passenger. Speed and comfort being equal, the great advantage of electricity is that, when it is used, the most economical way of transporting a given number of passengers between two points is in a large number of small trains; with steam the converse is true. A frequent service is a great attraction to passengers. But when the freight question is considered, the tables are turned. The most favourable condition for freight haulage is with trains of maximum size. This is in accordance with the requirements of economy in steam transportation, but gives the maximum investment and minimum economy for an electric system. Moreover, the comparatively slow freight trains would make a high-speed service impossible at short intervals on the same tracks. We may conclude, then, that at the present time electricity does not compare favourably with steam either for heavy freight service or for through passenger service where frequent trains are not required. For smaller distances, where short train-intervals are of importance in attracting traffic, electricity has advantages over steam both for passenger and express service.

Systems of electric traction may be divided broadly into two classes, the one employing continuous, the other alternating currents to drive the motors. Both of these classes may be further divided with reference to the conducting system employed between the source of current and the motor. The system may also be divided according to operative units into three classes—the single car, the train pulled by one or more directly controlled locomotives or motor cars, and the train operated by two or more motor cars under a common secondary control. This last is called the "multiple unit system."

Continuous-Current Systems.—The applications of continuous current to electric traction comprise six principal varieties, with numerous modifications and combinations. In all of them the motors are operated under a constant, or approximately constant, potential difference. The system in which cars were connected in series by automatic switches, in limited use in the United States in 1888 and 1889, has now disappeared, and the parallel system of connexion, in which the cars are bridged across between the two sides of a conducting system maintained at a substantially constant voltage, has become practically universal.

Single trolley. The overhead conductor and track-return construction is the standard for street railway work in most of the cities where electric traction is employed, though there are some notable exceptions. In its present development the system may be said to have grown out of the work of Sprague in Richmond in 1887. Over the track is suspended a bare wire, generally of hard-drawn copper, known as the trolley wire. The normal practice is to use a wire not less than 0·325 of an inch in diameter to assure permanence, since smaller wires wear out rapidly from the friction of the trolley and the burning of the surfaces of contact. The wire is usually of circular cross section. Sometimes wires of other sections have been used, notably one having a cross section similar to the figure 8, but the advantage of these forms is problematical, while the difficulty attending their proper installation is considerable. In some cases the working conductor, or trolley wire, is suspended at one side of the track, connexion with it being made by a side-bearing trolley, but its usual place is directly over the track, as this arrangement leads to simpler and more efficient construction of trolleys, &c. For certain special cases, where very large currents are employed, the overhead conductor is made of bar metal or structural shapes. In the Boston (Mass.) subway, where the traffic is very heavy, a bar of rectangular section is used, supported at frequent intervals from the roof. In the Baltimore and Ohio Railroad's tunnel at Baltimore, Md., the steel working conductor originally consisted of two Z bars forming a trough, the current being collected by an iron shoe, but this form has been replaced by a sectional third rail. But whatever the nature of the conductor, it is usually insufficient to carry the current necessary for the operation of the system without excessive loss. Recourse is therefore had to feeders or reinforcing conductors. These may be of any form, but are most frequently copper wires or cables of large section, connected at intervals of a few hundred feet to the working conductor. They are sometimes carried on poles, but municipal ordinances frequently require their installation in underground conduits. In general, it is customary to divide the working conductor into sections of from 1000 to 5000 feet in length, insulated from one another and fed separately through manual or automatic cut-out switches, so that an accident causing a short-circuit or break in continuity on one section will not impair the operation of others.

In ordinary street railway construction there are two methods of suspending the trolley wire in vogue. The most usual construction is to hang it from insulators attached to transverse wires running between pairs of poles set on opposite sides of the track. Bracket arms attached to poles are often used, especially on suburban lines; they are frequently double, or T-shaped, and placed between the two tracks of a double-track line. In the standard construction for either variety of suspension, the insulators are bell-shaped, and composed of some hard moulded or vitreous material. The trolley wire is supported by a clamp about 9 inches long, which embraces about three-quarters of its circumference. This clamp is usually made of bronze, and is now generally fastened to the trolley wire by a screw, causing the two parts of the clamp to close upon the wire as would the jaws of a vice, or is automatic, clamping the wire the more tightly as the strain upon it increases. It was formerly considered expedient to solder the wire into the clamp, but this practice is now generally abandoned. The insulating bell is so designed that its material is subjected only to compression stresses by the weight of the wire. It is provided at its upper part with a single catch for attachment to the transverse wire, or to the bracket arm. If a span wire is used, it is fastened to the poles, there being turn buckles to tighten it, while a strain insulator on either side gives a double insulation between it and the poles. With a bracket construction it was formerly the custom to attach the insulator directly to the arm, but the blow of the trolley broke great numbers of insulators, and it has therefore become the practice to adopt some more flexible method of attachment, a number of different forms being in use. The poles between which the span wires are stretched, or to which the bracket arms are attached, are of wood or iron. They are firmly set in the ground, usually with concrete.

In order to provide a proper return path for the current, the track must be made electrically continuous. This is accomplished by bonding the individual lengths of rail together in some way, or by actually welding them together to form a continuous length. There are many types of rail-bonding. In most of them holes are drilled in the ends of adjacent rails, and a copper conductor inserted between them, its ends being in some way forced against the walls of the holes. In one type the bond is in the form of a hollow cylinder, the ends of which are inserted in the holes in the rails, and a tapered steel pin driven in so as to expand the cylinder out against the rail. In another form the end of the bond is a solid cylinder, which is upset by hydraulic pressure, forcing it against the rail. A semi-plastic amalgam of mercury has been used to give a contact between the adjacent rails and the tie-plate connecting them. The most usual practice is to use a short bond covered and protected by the tie-plates. Tracks used for a return circuit are cross-bonded at intervals. It very often happens that the track return has too great an electrical resistance. In this case it is reinforced by conductors connected to it at intervals, and extending back to the power-house. Neglect to provide a proper return circuit has caused a great loss of energy and excessive electrolytic action in many places. The lightning arresters provided on overhead lines are placed on the poles at intervals determined by the location of the line.

Double trolley. In a few places the municipal authorities, in order to avoid the disturbances on telephone lines due to the fluctuation of the trolley current, and the electrolysis of gas and water pipes which may arise from a grounded return, have required the erection of a double overhead system. In this each track has two trolley wires forming a complete metallic circuit. The largest system of this kind is in Cincinnati, Ohio, U.S.A., where in 1900 there were over 225 miles of tramlines. The system has the advantages to which it owes its existence, but the multiplicity of wires at crossings, right-angle turnouts, &c., is so complicated that automatic switching cannot be attempted. The man in charge of the car removes the double trolley from the wires at such points, and replaces it when they are passed. The construction adopted, except as regards the points mentioned, is practically similar to that already described for the track-return system.

Open-slot conduit. A very large number of patents have been granted in various countries for electric traction systems in which one or both of the fixed conductors are installed in a conduit underground, communication being had with them by means of an open slot, into which projects a current-taking device of some nature carried by the car as it moves along. A system of this character was installed many years ago at Blackpool, in England, and later one was very successfully operated in Budapest. The first large and important installation of this character to be made was in Washington, D.C., U.S.A., where a considerable system of street railways was changed from horse operation to this new method. The success of this system, and of experiments made on Lenox Avenue, in New York city, led to the construction of many miles of railways of the conduit type in the latter city. American practice in conduit construction has become fairly well standardized. The conduit is oval in shape, its major axis being vertical, and is formed of concrete. An excavation about 30 inches deep is first made, and in this are laid cast-iron yokes weighing 410 ℔ each, and spaced 5 feet apart, centre to centre. Every third yoke contains bearings for a hand-hole plate, and weighs about 600 ℔. These yokes surround the conduit proper, and are provided with extensions on each side, for the attachment of the rails. In the older construction the rails were laid directly upon the iron of the yokes, steel wedges and shims being used under them for the final alignment of the rails. In the more recent construction, on the Third Avenue Railroad in New York City, a wooden stringer, 6 by $6\frac{3}{4}$ inches in size, is laid along from yoke to yoke on the bearing surfaces, and the rail laid upon this. The rail is held down on the yoke by means of two bolts at each bearing-point, these bolts having turned-up heads which embrace the foot of the rail. The slot-rails, or Z bars forming the two jaws of the $\frac{5}{8}$ inch slot, are bolted to the upper part of the yokes. The weights of metal used per linear yard of construction of this type are: cast-iron, including both types of yokes, 500 ℔; track rails, 214 ℔; slot rails, 116 ℔; conductor rails, 42 ℔; conduit plate, 16 ℔—nearly 400 ℔ of rolled steel per yard. After the rails, which are of a high girder type, are fastened in place, thin plates of sheet steel are bent into the oval holes in the yokes, extending from yoke to yoke, and forming the inner surface of the completed conduit. Around this is carefully laid a shell, 4 inches thick, of Portland cement concrete. The yokes are furnished with lugs which serve to retain temporarily wooden boards forming a mould in which the concrete is rammed. Sectional wooden shapes serve to hold the thin steel lining in place while the concrete is hardening. Around this concrete tube, and on each side of it, to form a basis for the street pavement, is laid a mass of coarser concrete. In each side of the special yokes is placed an insulator of porcelain, protected by a cast-iron shell, and carrying a support for the conductor-rail, which is of T-shaped steel, weighing 21 ℔ per yard. It is in 30-foot lengths, and is supported every 15 feet by the insulators, the ends of separate rails being matched at and held by an insulator support. This rail is, of course, bonded with copper bonds. Two such conductor-rails are installed in the conduit 6 inches apart, the flat faces corresponding to the upper surface of the T being placed toward each other. Elaborate provisions for drainage and inspection are also provided, depending upon the situation of the tracks and nature of the street. The current is fed to the conductor-rails by heavy copper conductors of from 500,000 to 1,000,000 circular mils. cross-section, insulated and lead-covered, laid in ducts alongside of or between the two tracks of double-track systems. Connexion is made between the cars and the conductor-rails by means of a "plough," carried by a hard steel plate, which is channelled to receive the insulated wires leading up to the controller on the car. The plough carries two cast-iron rubbing-blocks, which are pressed outward into contact with the conductor-rails by springs, the two being, of course, very carefully insulated from each other and from the other metal-work of the plough. It has been found expedient in practice to reverse the polarity of the current used on these conduit roads from time to time, since electrolytic deposits, formed by small leakage currents in the vicinity of insulators, &c., are thus redissolved before they become a source of trouble. This system is much more expensive to install than the overhead trolley system, but experience has shown that it can be as economically operated. Most of the troubles that have occurred have been due to lack of experience, but on the whole they have not been more serious than those experienced with overhead systems.

Closed conduit. The great expense of the open conduit has led numerous inventors to bring out systems of operating electric railways by means of closed conduits, or sectional third rails, in which the working-conductor is laid on the surface of the ground between the rails, and is connected with the source of current only as the car passes over each section. In this way the immediate section or portion of the working-conductor under the car is electrically active, but other sections are not, and all danger to the passage of street traffic is removed. Up to 1900, nearly one thousand patents for this type of railway construction had been granted by the United States Patent Office alone. So far the system has been introduced in but few places, but its performance has been more than promising, and it is thought that it will be more extensively adopted in the future. Among the more important railways at present equipped with it may be mentioned one in Paris, using the Diatto system, and one at Monte Carlo, where the Westinghouse system is installed. In both these the current is supplied by means of "buttons" or metallic discs laid flush with the surface of the street between the tracks, and connected through switches to a working-conductor. Under the car is installed a current-taking device in the shape of a long runner or skate, which runs over the buttons and is appropriately connected with a storage battery on the car, so that when it touches one of the buttons current is sent from the battery through a system of electromagnets operating the switches which connect that particular button to the feeding system, and thus the runners are enabled to pick up current for the operation of the motors on the car. The various systems differ in the method of connecting the contact rail or button with the live conductors: in some a magnet on the car works a mechanism to make the desired contact, in others a current from batteries on the car actuates a switch located near the track, in others still compressed air is employed for the purpose, as in the new system being installed in the Baltimore and Ohio tunnel at Baltimore.

Third-rail system. The third-rail system, which is a development of the overhead trolley and track-return system, has been applied to several large and important railway installations, especially in the United States, and in the prolongation of the Orléans Railway in Paris from the Place Valhubert to the new station at the Quai d'Orsay. Its name almost sufficiently indicates its method of operation. A rail similar to the track-rails is laid upon insulators and forms the working-conductor. On the elevated railways in New York, Brooklyn, Boston, and Chicago a pressure of about 600 volts is used between this rail and the running-rails which form the return circuit. Contact is made with the third rail by means of a bronze or cast-iron shoe, either resting upon the rail by its own weight, or pressed down upon it by springs. This is generally attached to some part of the truck of the car in preference to any part of the body of the car, so as to avoid any vibration or swaying due to the movement of the body upon its springs. The third-rail system has been adopted in many instances where large and powerful trains are to be operated on private rights of way, but it is nowhere in use for electric traction upon highways or in streets where there is any passing of foot passengers or vehicles. An excellent example of such construction may be found in the Albany and Hudson Railroad, which connects the City of Albany with the town of Hudson, in New York State. Here the length of the road is about 32 miles, the track being of standard gauge and laid with a 60-pound T-rail. A T-rail of the same size, raised about 1 foot above the level of the running-rails, is used for the electrical conductor, and is installed on insulators situated 5 feet apart on the ends of the cross-ties. All these rails are well bonded with copper bonds at the joints, and at road crossings, which on this railroad are at grade, the third rail is omitted for a distance nearly equal to the length of a train. Appropriate cast-iron shoes, fixed to the trucks of the front and rear cars of a train, bridge the space, so that the forward shoes are running on the rail past the break before the rear shoes leave it. Upon this railroad motors of considerable size and power are used, and both passengers and freight in their original cars, as received from connecting steam railways, are transported. Other examples of third-rail construction occur in the underground systems of the City and South London Railway, the Waterloo and City Railway, and the Central London Railway in London, and the Versailles Division of the Western Railway of France. Experiments of great interest and value have been made by the New York, New Haven, and Hartford Railroad, upon a section of its track in the State of Connecticut, with a very simple system of third-rail construction, in which the conductor-rail is placed between the running-rails. This rail is of a curious, special section resembling the letter A, and is merely laid upon wooden blocks saturated with insulating materials, its form being such as to deflect rain and other moisture away from the insulators. Very high speeds have been attained on this section of track, upon which motor cars haul the standard equipment of freight, baggage, and passenger cars of the railway.

Accumulators. One of the oldest forms of electric traction is by accumulators. In brief, its principle is that storage batteries, or accumulators, are carried on the car, which becomes a veritable automobile. It has been the usual practice to install about eighty cells giving a pressure of 160 to 175 volts at the motors; these are recharged after the car has run about 25 miles. In general, the accumulators are not charged in place, but the car is supplied with a new set, fully charged, at the end of a run of about the length mentioned. The system has been installed in a very large number of places in Europe and America, but has never shown the gratifying commercial success which the direct-conduction systems exhibit, on account of the high cost and depreciation of storage batteries. In some places, notably in Hanover, Germany, where legislative ordinances have forbidden the overhead conducting system in city streets, a combination has been used whereby accumulator cars run in the city districts from the energy stored in their batteries, and in the suburbs operate directly as overhead trolley cars, the batteries being charged at the same time from the overhead system.

Alternating-Current Systems.—There has been much discussion on the subject of electric traction by means of alternating or polyphase currents, but little work has been done. The polyphase current is much used as a means of distributing energy from a central power-station over extended lines of railways, but is generally converted into direct current through the agency of rotary converters, and fed to the lines as such. There are, however, a few railways working directly with induction motors upon a three-phase system of supply. Prominent among these may be mentioned the Jungfrau Railway in Switzerland. Upon this line the rails are used as one of the three conductors, and two trolley wires are suspended above the track. The locomotive is provided with two trolleys, one running upon each wire, and consists simply of an induction motor coupled through appropriate gearing to the mechanism of the truck. For starting, a large resistance is introduced into the rotor, or secondary, circuit of the motors by means of collecting rings placed upon its shaft, upon which bear brushes. This resistance is cut out as the speed increases, until it is all withdrawn and the rotor is short-circuited, when full speed is attained. It has been found that potential differences of about 500 volts in each phase can safely be handled, and it is claimed that the one or two railways using alternating currents have shown gratifying results in practice. It is believed that the equipment of long lines of railway, having comparatively infrequent and heavy trains, will furnish an opportunity for the wider introduction of polyphase systems, and that the latter will be largely developed in connexion with the electrical operation of existing steam railways.

In the system elaborated by Messrs Ganz, of Budapest, and known as the "Cascade" system, an arrangement is introduced analogous to the "series-parallel" method used in direct current working. There are two motors, or a multiple of two, to each car or locomotive, just as there are two cylinders in a compound engine, and the two are in mechanical connexion with each other. One of them, which may be called the primary, is wound for a higher tension than the other (the secondary), and the maximum speed of the latter is only half that of the former. The three-phase current, which has a frequency of 15, is conveyed by means of two overhead trolley wires and the rails upon which the trains run. It enters the stator coils of the primary motor, and thereby sets up an induced current in the rotor of that motor, which, of course, begins to revolve. The frequency of this induced current is proportional to the "slip" between the rotor and the revolving field of the stator, and will therefore gradually decrease as the speed of the motor increases up to the speed of synchronism. This induced current generated in the primary rotor, supposing that the train is being started from rest, is led to the stator of the secondary motor, and the rotor of this in turn has a current generated in its coils of a frequency proportional to its "slip." This second current is taken through a variable resistance in circuit with the secondary rotor. Supposing now that the two motors, which are mechanically linked together, have attained half the full speed for which the machine is designed—that is, the full speed of which the secondary motor is capable—then the "slip" of the primary motor being 50 per cent., the frequency of the current induced in its rotor and passing through the stator of the secondary motor must be about 7½, and the secondary motor will be running about synchronously with the current it is receiving. Thus the energy from the main supply is all being taken by the primary stator, which hands on half to the secondary motor to be converted into motion, and itself transforms the other half into mechanical effort. At this stage of half-speed the secondary motor has done its share in accelerating the train and becomes useless, because as soon as it begins to be run faster than the speed for which it is constructed it ceases to act as a motor and becomes a generator, exerting a retarding influence on the speed of revolution instead of helping it. At this point, therefore, it is cut off from electrical connexion with the primary motor, and allowed to run idle, the variable resistance that was joined up with its rotor being transferred to that of the primary. Acceleration now proceeds by the aid of the primary motor alone, the resistance being automatically altered from its maximum to zero as the motor increases its speed from half to full and approximates to synchronous running. Under no circumstances is it possible to exceed the maximum designed speed, even when going down a hill, for as soon as the speed of the motor is forced beyond that for which it is intended it ceases to be a motor, and becoming a generator experiences a negative torque which checks its pace. When it is desired to stop the train the same property is utilized; the secondary motor is put in series with the primary, and, as its rotor is then being driven at double its normal speed, it also is subjected to a negative torque, which continues until the machine has been brought to half-speed. In this way the greater part of the kinetic energy of the moving train is absorbed by being reconverted into electrical energy, and the mechanical brakes are called upon to do comparatively little in effecting a stop. There is thus a saving in the wear of the tires and brake blocks and also of the rails, since it is not possible to skid the wheels. The current of 3000 volts being almost certainly fatal if taken through the body, very careful precautions are adopted to prevent accidents. Thus the driver does not actually touch any of the switches by which the train is controlled, but they are all operated by means of compressed air; the same agency is used to raise the trolley poles up to the trolley wires, and to work the variable resistance. This last is of a liquid form, but instead of the metal plates being lowered into the solution (which is of carbonate of soda) the liquid is forced up against the plates by the air pressure to the required height. Breakage of a trolley wire is also guarded against by an arrangement whereby its snapping, or even its undue sagging owing to elongation, closes a short circuit and by melting safety fuses instantly renders the line dead. This cascade system has been adopted in substitution for steam-power on the Lecco, Sondrio, and Chiavenna line in Italy, 66 miles long.

Generation of current. The question of the generation and the distribution of the current only belongs to this article in so far as electric traction has introduced peculiarities in the type of apparatus or the methods of its use. In a continuous-current station the current is generated at an approximately constant potential, varying from 500 volts to 700 volts on different systems. As the load is apt to fluctuate, except in large stations, within wide limits, the machinery must be built to stand the most severe usage. The engines are more massive than would be necessary for constant loads, and the dynamos must be built to stand sudden overloads without destructive sparking; usually, indeed, they are considerably over-compounded, not so much for the sake of raising the voltage, as to strengthen the field and prevent sparking on overload. When a number of machines are to be run in parallel—as is usually the case—they are provided with "equalizing" switches, which serve to throw the series fields in parallel. As a result, if one of the machines tends to increase its armature current beyond its proper amount, the current in the series fields does not increase with it, but retains its normal proportion. The armature reaction and resistance fall of potential in this machine would both tend to increase, and its armature potential, and therefore its current, would return to its proper value. From the dynamos the current from each machine goes through an ammeter and automatic circuit-breaker to the main "omnibus" bars, then through the station ammeter to the feeder "omnibus" bars, then through ammeters and circuit-breakers to the feed-cables. As a rule, watt-meters are provided to measure the output of the station, and if an overhead system is being supplied, lightning arresters are installed. Where continuous currents are used to operate cars at considerable distances from the generating stations, "boosters" are used. These are series-wound dynamos driven at a constant speed, through which the current that is to feed the distant section of the line is passed. Usually the characteristic of the booster is so calculated that the amount by which it raises the voltage for a given current just equals the fall of potential in the feeding-line for the same current. The result is that the potential at the end of the line will be the same as that at the station. The question of economy, as between putting in additional copper and wasting energy in the booster, is easily calculated; the advantage is more and more on the side of the latter as the distance increases and the service becomes more infrequent. It is necessary to the satisfactory operation of a system that the variations of voltage should not be too great, so boosters sometimes become a practical necessity, irrespective of the question of strict economy. As traction systems have been combined and extended, the area of operation of many of the companies has grown so that a number of direct-current stations are used for a single system. The limit of distance to which electric energy can be economically supplied at the comparatively low voltages employed is not great, and the advantage of having one or two large stations to supply a system, in place of a number of smaller ones, is evident. This fact has led to the use of high-potential alternating currents for the distribution of energy, the voltage being reduced at the points of consumption, and in most cases changed to a continuous current by rotary converters. At first difficulties, due to defects of the converters, were experienced, but these have been largely eliminated, and the system may be considered as satisfactory. If alternating currents are used for the car motors, the economical distribution of energy is greatly simplified, the rotaries being eliminated, and their first cost and losses and expense of operation saved. The expense of operating sub-stations containing rotary converters is necessarily large, and the capital outlay required for them is often greater than that for the generating station.

Cars. As a rule, the cars used for electric traction have varied but slightly from the type of tramway car prevalent in different localities. The tendency, however, has been to increase their size, and to make them more ornamental as well as more comfortable. For electric railway work, as distinguished from tramway work, the cars have followed the pattern that has become standard on steam lines. The trucks used for electric cars are made of steel, with heavy axles and heavy suspension bars for the electric motors. For smaller vehicles, a single four-wheel truck is used, the wheel base being limited by the curvature of the track, but not as a rule exceeding 7½ feet. For the longer and heavier cars, two four-wheel trucks are employed. If two motors are used on a double-truck car, and if the grades on the road are very heavy, the trucks are made on the maximum traction pattern, in which the greater part of the weight of the car is on the motor-driven wheels. For very large high-speed cars, trucks are used of practically the same type and weight as are employed on steam railways.

Motors. Electric motors for traction purposes have been highly elaborated and developed. At first they drove the car axles through belts or sprocket chains, the motor being sometimes attached to the car, sometimes to the truck. At Richmond, however, in 1887, the Sprague method of communicating the power from the motor axle to the car axle was put into practical operation, and this has with slight modifications been retained. It consisted of sleeving one end of the motor on the axle, suspending the other flexibly from the car body or truck, and driving from the armature through spur gearing. At first the motors were too small for the work demanded of them. Their high speed required a double reduction in gearing, their over-heating caused continual burn-outs, and the sparking at the commutators necessitated constant repairs. These defects were gradually eliminated. The motors were made larger, the quality of the iron and insulation was greatly improved, and finally a four-pole motor requiring only a single speed reduction by spur-gearing was produced. Since that time further improvements in material and design have been introduced, and the present motor has been evolved. Almost all the standard modern traction motors are of the same general design. The armature is built up of carefully tested iron discs, which are deeply slotted to make room for the coils. These are wound and insulated separately, and placed in the slots in the armature cove; sometimes they are held in place by binding wire, sometimes by wedges. The commutator is put in place and soldered, and the proper end-coverings put on. The magnet frame is made in two parts, of cast steel, enclosing the entire armature. A lid in the top casting gives access to the brushes, which are of carbon. The field coils are wound on forms and properly insulated. The machine is series-connected. When in operation it is practically water and dust proof, and with proper attention is a very durable piece of machinery. Although the standard design of motors is at present based on a single-reduction gearing, yet there are in operation traction-motors which are not geared. This is the case with those on the City and South London Railway, the Baltimore and Ohio tunnel locomotives, and in other special cases. In the City and South London machines the armature is directly on the axle; on the Baltimore and Ohio locomotives the motors are sleeved on the axles, there being a slight play between the sleeve and the axle, which allows a flexible support. The wheels are driven by arms projecting from the armature shaft.

There is no fixed method of rating the output of traction-motors. Most manufacturers, in giving a certain horse-power capacity, mean that at the given rating the motor will run an hour with a rise of a certain number of degrees, not that it can be run continuously at the power given. Another system of rating depends on the draw-bar pull which the motor can develop under normal conditions of voltage and speed. Uniformity is greatly needed.

Controllers. One of the most important parts of the equipment of an electric car or locomotive is the controlling device. In the early days of electric traction a number of different methods of regulating the speeds of the cars were used, but they have been reduced to practically one standard method. In the old Sprague system there were at first no resistances outside of the motors themselves, but the field coils of the motors were divided into sections, and by changing the relative connexions of these sections the total resistance of the circuit could be changed; at the same time, the strength of the field for a given total current was either increased or decreased. In other systems the fields and armatures of the motors were not changed in their relation to one another, but external resistances were cut out and in by the controller. It is evident that if we wish to change the speed of a car within wide limits, all the other factors remaining constant, there will be a very considerable loss by either of these methods of regulating, unless the relative connexions of the motor armatures can be changed. This can be done by putting the armatures in series where low speed is desired, and in parallel where the speed is to be increased. This method was tried in the early days of electric traction, at Richmond, and discarded, but it has been again taken up, and is now the standard method of regulation in ordinary tramway work. Roughly speaking, when the car is started the controller connects the two armatures in series with an external resistance, then cuts out the external resistance, then breaks the circuit, then throws the two armatures in parallel with an external resistance in series with them, and then cuts out this external resistance. By this method a considerable range of speed is attained at a fair efficiency. The controller consists of a cylinder having on it a number of copper segments so arranged that on rotating the cylinder different connexions are made between stationary fingers that bear on these segments. In the first types much difficulty was experienced from the burning of the segments and fingers, due to the sparking on breaking the circuit, but this has been to a large extent obviated by using magnetic blow-outs at the point of break. (A magnetic blow-out is simply a small magnet so arranged that the arc caused by breaking the circuit takes place in the magnetic field.) There is a reversing lever on the controllers separate from the controller handle. When it is desired to run trains of cars and to accelerate them rapidly, it is sometimes necessary to have more than one car equipped with motors. In this case all the motors must be controlled from one point, and a number of ingenious devices have been evolved to accomplish such "multiple control." In general, each car has its own controller, and the controllers are operated by either electric or pneumatic power from switches on each platform of any of the motor cars.

Brakes. For tram cars of ordinary sizes, hand-brakes are used, these being generally spindle brakes, with leverage enough to handle the comparatively heavy cars. When the size and speed of the car increase, however, these hand-brakes do not give sufficient control, and power brakes have to be adopted. Of these there are two general forms that have proved successful in practice and are largely used. The first is an air-brake, which is similar in its mechanical operation to the air-brake used on steam railroads. The compressed air required for the operation of the brake is obtained by means of an air-pump driven by an electric motor, the circuit of the motor being controlled by a switch actuated by the pressure of the air in the receiving tank. As this pressure rises to a predetermined value, the device acts and interrupts the supply of current to the motor, which is thus stopped. When the pressure falls below a determined minimum, the device operates in the opposite direction, and the motor and pump start. Sometimes, when the car has not to make many stops, the motor-driven compressor is dispensed with, and tanks stored with air at a high pressure operate the brakes during the trip or part of the trip. Of electric brakes there are several varieties. Perhaps the one most extensively employed consists of two iron discs, one keyed on the axle but capable of moving along it, and the other held firmly on the frame of the truck. By means of a coil set in a recess of annular form turned in the face of the latter the discs are magnetized transversely, and are drawn together with greater or less pressure, dependent on the amount of current that is allowed to pass. It is customary to arrange the current connexions in this form of electric brake so that when the handle of the controller is turned beyond the stopping position the current is cut off from the source of supply, and the motor running as a dynamo furnishes the current to work the brake.

Of the numerous accessories necessary in the operation of electric railways one of the most important is the trolley.

Trolleys.

For an overhead system this consists in general of a metallic rod or tube mounted upon the top of the car and pressed upward against the trolley wire by springs. At the upper end of this trolley pole is generally placed a bronze wheel which runs along the under surface of the wire. On the continent of Europe considerable use has been made of bow trolleys, which consist of light metallic bow-shaped structures, sustained in place by springs and running along on the under side of the wire against which they rub. The designs already patented for trolleys are almost innumerable. Besides the trolleys, cars are ordinarily equipped with switches which are used to break the trolley circuit, with fuses or automatic circuit-breakers, with electric lamps, lightning arresters, and with the necessary car wiring. The fuses or automatic circuit-breakers are used to guard against an excess of current through the motors, and when they are fitted the ordinary platform switch can be dispensed with. These automatic breakers can be set for any desired current. (L. DU.)

IV. Industrial Development.

The advantages resulting from the modern industrial development of electric engineering cannot be measured merely by the return upon capital invested. The indirect social benefits which have followed on electric invention are considerable and far-reaching, and examples are afforded in all the various departments of industry in which electricity has found application. The electric telegraph has proved a powerful agent in the detection and prevention of crime; the use of the electric light in houses improves health and aids cleanliness; electric traction is, by cheap fares and rapid transit, transforming the conditions of town life, and the adoption of electric power in factories is improving the morale and increasing the efficiency of labour. Thus whilst exerting elevating influences upon the advance of civilization, electricity is also an unseen factor tending to reduce the cost of production of commodities with which at first sight it has no association.

For the best commercial development of electrical science facilities are needed which can be granted only by the State or the local authorities. Wires have to be erected on poles, or attached to premises, or, preferably, placed underground, and electric traction involves interference with the public roads. It is undesirable that any of these operations should be carried on in the same place by more than one authority. This precludes effective competition; the electrical industry in Great Britain ripened at a time when public opinion was averse from the creation of further monopolies, and was disposed to think that railway, water, and gas companies had in the past received valuable concessions on terms which did not sufficiently safeguard the interests of the community. There are, unfortunately, no fixed principles governing the relations between the State or municipal authorities and commercial companies. The great development of industries by means of private enterprise in the early part of the nineteenth century produced a reaction which, between the years 1870 and 1901, had the effect of discouraging the creation by private enterprise of undertakings partaking of the nature of monopolies. The conditions which were imposed on these for the purpose of safeguarding the interests of the public were very tentative, and a former permanent secretary of the Board of Trade has stated that the remedies have sometimes proved injurious alike to the public and to the companies. One of these tentative and mischievous measures was the Tramways Act of 1870. Twelve years later it was followed by the Electric Lighting Act of 1882, and not one of the sixty-two Electric Lighting Provisional Orders granted to companies in 1883 under that Act was carried out. Capitalists declined to go on with a business which, if successful, could be taken away from them by local authorities at the end of twenty-one years upon terms of paying the then value, without regard to past or future profits, goodwill, or other like considerations. It was six years before Parliament recognized the mistake it had made by passing the Electric Lighting Act of 1882, and the Act of 1888 altered the period of purchase from twenty-one to forty-two years. Then, for the first time, electric lighting went ahead in Great Britain, although other countries had long previously enjoyed its benefits. The tramway companies, on the other hand, have never been relieved from their oppressive Act of Parliament, and their undertakings are now being bought up by local authorities at the price of the old rails and rolling stock. With the exception of a few undertakings in large cities or other favourable situations, tramway companies in Great Britain have proved failures, because, knowing that they would be bought up at the end of a few years, they have been unable to expend any capital on improvements. The adoption of electric traction involves a large outlay of capital, and no shareholder would agree to this expenditure with the risk of being bought out after the lapse of the few remaining years of the twenty-one years' period. This is the chief reason why there has been delay in substituting electric traction for older forms of tramway locomotion. There is, however, another reason which accounts for the non-success of tramways in Great Britain. The companies have, no doubt, been over-capitalized, though in many cases this is the result of the conditions imposed upon promoters by Parliament, the Board of Trade, and the local authorities. If an undertaking is surrounded by undue risks, obligations, and difficulties, it will cost more to establish and to complete than would be the case if it were a normally safe investment. The veto which the local authorities possess enables them to impose onerous conditions, which weak promoters accept rather than face the loss of the expenses they have incurred. These conditions take a variety of forms; but, unless the scheme is abandoned, they are expressed by inflated capital or reduced profits, or both, and they manifest themselves to the general public by the inability of the company to give satisfaction.

A tramway company should certainly contribute to the maintenance of the highways in proportion to the revenue which it is permitted to make. But as an authority on tramway law says, "that this amount should be left to be settled in each case by mere chance, by the fancy, the avarice, or any other motive of local officials—that, as it was put before the Committee of 1877, any kind of bargain, good or bad, pure or corrupt, may be insisted upon as the condition precedent to an application to Parliament for a public purpose, would appear far from desirable." [1] In the 1898 session of Parliament a Select Committee of both Houses, after hearing evidence tendered by the Board of Trade, local authorities, and electrical companies, reported as follows:—"The committee consider that the provisions of the Electric Lighting Act, 1888, which require the consent of the local authority as a condition precedent to the granting of a Provisional Order, should be amended. In their opinion, the local authority should be entitled to be heard before the Board of Trade, but should not have, so to speak, a provisional veto, only to be dispensed with in special cases by the Board of Trade."

The question of municipal trading in its bearing upon electrical industries has of late received much attention. Recent discussions in and out of Parliament concerning electric lighting and power-transmission schemes, telephones,

[1] Sutton, *The Tramway Acts.* London, 1883.

tramways, and light railways, show that further legislation is necessary for the proper development of electrical industries; and the direct issue is raised whether this development is to proceed upon lines of joint-stock capital or by means of municipal loans. Municipal enterprise usually involves the appointment of consulting engineers to advise whether and to what extent an undertaking should be carried out, and what system and type of apparatus should be adopted. In this respect there is an important difference in the conditions of the industry in England as compared with the United States and continental countries, where it is chiefly the manufacturing companies who determine the character of the demand. This difference accounts in a measure for the absence of uniformity of apparatus, systems of distribution, and of commercial methods in the electrical industries in Great Britain. Without standardization there cannot be production on a large scale, and consequently economy in manufacture is sacrificed, prices are relatively high, and deliveries slow. These are the chief causes which explain the backwardness of the electrical industries in England, and the reasons why American and German manufacturers have been able not merely to supplant English manufacturers in neutral markets, but even to compete with them seriously at home. The exports and imports of electrical materials indicate that the telegraph industry, which was established before the existing politico-economical influences were at work, has not suffered like the later departments of electrical engineering.

Electrical manufacturing firms and companies have laboured under many difficulties. The undue inflation of enterprise in 1881 and 1882 increased the difficulties surrounding the industry and created a keen competition for contracts, while business was almost entirely confined to the erection of separate installations of the electric light in ships, mills, factories, and residences. Prices of electrical machinery rapidly declined, and frequent alteration in design rendered profitable production on a large scale practically impossible. The manufacturing branch of the industry has not on the whole been profitable to the investor. Without including the heavy losses suffered as a result of the speculations in "Brush" licences (these were not losses in manufacturing), there have been several very considerable depreciations of capital, which probably more than neutralize all the dividends which manufacturing companies have paid. There has been very little solidarity among those interested in the commercial development of electricity, and except for the discussion of scientific subjects, there have been scarcely any organizations, having for their objects the protection and promotion of common interests.

The aggregate capital invested in shares and debentures of British electrical undertakings in 1900, apart from private firms, was £123,636,602, divided as follows:—

		No. of Undertakings.	Capital.
Telegraph (*a*)		29	£31,782,968
Telephone (*b*)		16	8,984,023
Electricity supply	Companies	108	12,434,827
	Municipalities (*c*)	169	13,776,372
Electric traction	Companies	75	26,149,859
	Municipalities	18	2,748,873
Manufacturing		135	21,708,180
Miscellaneous		103	6,051,500
		653	£123,636,602

(*a*) Does not include Government telegraphs.
(*b*) Does not include Government telephones.
(*c*) Loans authorized.

The capital, apart from Local Government capital, is mainly in the form of joint-stock enterprise. There are numerous private firms engaged in the business, but the capital they represent is estimated not to exceed five per cent. of the total. An analysis of the list of joint-stock companies shows that the principle of large financial combinations has not been characteristic of the English industry, as is the case in America and in Germany. In America the electrical industries have been controlled mainly by trusts and other powerful combinations, while in Germany the industrial banks have given them strong financial support. In the United Kingdom the capital has been provided chiefly by relatively small investors.

The following was the average rate of dividends paid for 1899 on the aggregate capital employed:—

Telegraph	4·98 per cent.
Telephone	4·91 ,,
Electricity supply	5·51 ,,
Electric traction	4·65 ,,
Manufacturing	7·52 ,,
Miscellaneous	5·79 ,,

Telegraphy.—The first practical trial of the telegraph was made in 1837 on the London and North-Western Railway, and for some years afterwards the use of the telegraph was almost entirely confined to railways. The Electric Telegraph Company—the first company formed to undertake the business of transmitting telegrams—was incorporated in 1846. For some time it restricted its operations to constructing and maintaining railway telegraphs, and was regarded as a commercial failure. Between 1846 and 1851, however, great improvements were made in the working of telegraphs, a cable was laid between Dover and Calais, and the telegraph industry began to make progress; numerous companies were formed, and keen competition led to considerable extensions of wires and reduction of tariffs, with the effect that the volume of business increased enormously. During the 10 years 1857–67 the Electric Telegraph Company's average receipts per message fell from 4s. 1¼d. to 2s. 0¾d., or just over half, but the number of messages during the same period increased from 881,271 to 3,351,910, or nearly fourfold. The working expenses were reduced in a progressively larger ratio—*e.g.*, in 1859 the average working expenses were 2s. 7d. per message, or more than 65 per cent. of the receipts, while in 1869 they were 1s. 0¼d. per message, or only 51 per cent. of the receipts. Much dissatisfaction was felt because the larger towns, where competition had been most keen, were unduly benefited, to the neglect of smaller towns, where the business was comparatively less profitable. In 1868–69 public opinion compelled the Government to acquire the business of the companies. At that time there were in the United Kingdom about 30 different companies, besides the railway companies, whose business was the transmission of telegrams, and several distinct systems were employed. The total number of telegraph offices, including railway stations transacting telegraph business, was 2500; it is now 11,188. The transfer of the telegraphs to the State took place on the 5th of February 1870, and further considerable reductions were at once made in the rates. A uniform tariff of 1s. per 20 words was established, and this reduced the average receipts during 1872 to 1s. 1d. per message. This tariff remained in force till the 1st of October 1885, when it was reduced to the existing rate of ½d. per word, with a minimum of 6d. per message.

The capital stock created for the purchases, &c., of telegraphs is upwards of £10,000,000, and the total deficiency, since the acquisition of the telegraphs by the State, of revenue to meet expenditure and the interest on stock created was, at the 31st of March 1899, £7,756,654. The monopoly of the Postmaster-General does not extend to the British Colonies and the ocean. The following figures show the amount of the capital of the existing British telegraph companies:—

No. of Undertakings, 29.

Ordinary and deferred capital . .	£20,261,470
Preference capital	7,459,130
Loan and debenture capital . .	4,062,368
Total, ...	£31,782,968

Since the early days of international telegraphy, conferences of representatives of Government telegraph departments and companies have been held from time to time, and in 1868 the International Bureau of Telegraphic Administrations was constituted at Berne, and a convention was formulated by which a central office was appointed to collect and publish information, and generally to promote the interests of international telegraphy. International service regulations have been drawn up, which possess equal authority with the convention, and constitute what may be regarded as the law relating to international telegraphy.

The total land lines of telegraphs throughout the world amount to over 781,000 miles, of which over 760,000 are aërial and 21,000 underground. The total length of conductors is 2,789,000 miles, of which 2,699,000 are aërial and 90,000 underground; of these there are in Great Britain and Ireland 32,881 miles of lines (32,023 aërial and 858 underground), with about 206,000 miles of conductors (179,500 aërial and 26,800 underground). Of submarine cables the total number is 1769, their length in nautical miles being 189,015; of these, 1349 cables of 20,324 nautical miles are owned by various Governments, and 420 cables of 168,691 miles by companies, most of which are incorporated in Great Britain. The world's cable fleet consists of about 42 steamers, having an aggregate gross tonnage of 69,204 tons, of which the British Government own the *Monarch* (1121 tons) and the *Alert* (369 tons). Companies registered in England own more than three-fourths of the rest.

All-British cable.

In 1896 a Committee was appointed to consider the proposal for laying a telegraph cable between British North America and the colonies of Australasia. The report of the Committee, which is dated January 1897, was presented to Parliament in April 1899, and dealt with the practicability of the project, the route, the cost, and the revenue. The Committee was of opinion that the cable should be owned and worked by the Governments interested, and that the general direction should be in the hands of a manager in London, under the control of a small board, on which the associated Governments should be represented. The English cable companies urged that State interference with private enterprise was neither justifiable nor necessary, as rates could be reduced and an alternative cable route to Australia arranged on reasonable terms without it, and that the Cape route would be the best alternative route. The Government policy would, they alleged, create an absolute and objectionable monopoly. In a correspondence[1] between the Eastern Telegraphic Companies and the Colonial Office the Companies pointed out:—That the late Mr. Raikes, when Postmaster-General, had stated that "it would be without precedent for the English Government itself to become interested in such a scheme in such a way as to constitute itself a competitor with existing commercial enterprises carried on by citizens of the British Empire. There would be a very serious question raised, and it will probably extend to other forms of British enterprise—for example, railways." That Mr. Leonard Courtney, when Secretary to the Treasury, had stated that "it would be highly inexpedient to encourage, upon light grounds, competition against a company in the position of the Eastern Telegraph Company, which has embarked large capital in existing lines." That the permanent official representing the Post Office before the Pacific Cable Committee had stated "that there was no precedent for the Imperial Government alone, or the Imperial Government associated with the Colonies, managing or seeking business for a line of this kind." The reply of the Colonial Office contains the following statements of general policy:—"With the progressive development of society the tendency is to enlarge the functions and widen the sphere of action of the central government, as well as of the local authorities, and to claim for them the more or less exclusive use of powers and the performance of services where the desired end is difficult to attain through private enterprise, or where the result of intrusting such powers or services to private enterprise would be detrimental to the public interest, through their being in that event necessarily conducted primarily for the benefit of the undertakers rather than of the public. This tendency is specially manifested in cases where, from the magnitude or other conditions of the enterprise, the public is deprived of the important safeguard of unrestricted competition. . . . In the case of inland telegraphs and of cable communication with the continent of Europe it has entirely superseded the private companies. Closely analogous to the action of the State in the cases referred to, is the action taken by municipal authorities, with the authority of the Legislature, in competing with or superseding private companies for the supply of electric light, gas, water, tramways, and other public services. . . . The service which Her Majesty's Government and the Colonies desire is one which neither the Eastern Telegraph Company nor any other private enterprise is prepared to undertake on terms which can be considered in comparison with the terms upon which it can be provided by the associated Governments. It is a public service as much as the carriage of parcels, the provision of life assurance, the building of light railways or of ships of war, and Her Majesty's Government cannot find any reason why in the one case a private enterprise with which the Government work may compete, should be considered entitled to compensation and not in the others." In November 1899 a committee was appointed by the Colonial Office for the further examination and elaboration of the scheme.

Much attention has been directed to what is called "Wireless Telegraphy." (See TELEGRAPHY, WIRELESS.)

Telephony.—The telephone industry in the United Kingdom has developed slowly and with difficulty. The first practical telephones were brought into England in 1877, and in the following year a company was formed to acquire and work Bell's patent. In 1879 the Edison Telephone Company, of London, was established, and proposals were set on foot to open telephone exchanges. In 1880 the Bell and Edison companies were amalgamated, under the title of the United Telephone Company. The Post Office opposed the opening of telephone exchanges, on the ground that the exclusive right to transact telegraph business conferred upon the Postmaster-General by the Telegraphs Act, 1869, was thereby infringed. In 1880 the Court decided that the telephone came within the definition of the term "telegraph." The companies did not appeal, and the Postmaster-General granted them licences. One of the conditions of the licences was the payment to the Post Office of a royalty of 10 per cent. of the gross receipts; the licences were for specified areas, and the companies had no power to make trunk lines between towns. In 1882 the London and Globe Telephone Company was formed, and obtained a licence in competition with the then existing exchanges; and in the same year the Postmaster-General granted licences for the establishment of exchanges even in towns where the Post Office had hitherto conducted the business. In 1884 the London and Globe Company was absorbed by the United

[1] Blue Book. Ed. 46, 1900.

Telephone Company. The Postmaster-General then decided to abolish all restrictions as to areas, and to throw the whole country open to the operations of the licensees. New licences were issued for a period expiring on the 31st December 1911, and determinable by six months' notice of purchase by arbitration in 1890, in 1897, and on 31st December 1904. Under these licences the companies were empowered to construct trunk lines between towns, the royalty payable to the Post Office remaining unaltered. In 1889 an amalgamation took place between the United Telephone Company and some of the subsidiary companies, the amalgamated company taking the name of one of the subsidiary companies, namely, the National Telephone Company Limited. This company has since absorbed most of the companies holding licences, and is now the only company in the United Kingdom carrying on telephonic exchange business. The New Telephone Company, incorporated in 1884, went into liquidation, but was resuscitated in 1892, and afterwards absorbed by the National Company. The Government having decided against purchase at the first period of option mentioned in the licences, adopted the policy set forth in a Treasury Minute presented to Parliament on the 27th May 1892. Amongst the proposals contained in this Minute was one that the telephone companies should connect their exchanges with post offices, so as to give subscribers additional facilities and the use of the trunk telephone wires of the State. It was also proposed that the companies should abandon their right to construct trunk wires, and that the Post Office should purchase from them such trunk wires as they had already erected, and gradually provide additional trunk wires, so as to ultimately provide a complete system of communication between all the important towns in the kingdom. A Bill carrying these proposals into effect, and giving the Treasury power to expend £1,000,000 (since increased) on the purchase and erection of trunk wires, received the royal assent on the 28th June 1892. On the 11th of August in the same year heads of arrangement were signed on behalf of the Government with the National Company and the New Telephone Company, but the agreement with the National Company embodying the arrangement was not executed till the 25th March 1896. It restricts the operations of the company to local areas, the trunk wires connecting those areas being in the hands of the Post Office. The price paid by the Government to the National Company for trunk wires was £459,114. The length of trunk routes taken over was 2651 miles, and the length of wire about 29,000 miles. Up to March 1900 the Post Office had erected 39,657 additional miles of telephone trunk wires.

The net receipts of the company for the year 1900 were £1,292,622, and the working expenses £808,181, or 62·5 per cent. of the receipts. The dividend on the ordinary shares has for some years past averaged 5⅜th per cent. The reserve fund amounts to £883,800. In December 1900 it had over 1000 exchanges and over 2300 call offices open, and 160,000 subscribers' lines. About 682,000,000 messages per annum are sent over its lines, at an average cost per message of about ·45 of a penny. The royalty paid to the Post Office in the year 1900 amounted to £140,074.[1]

In May 1898 a Select Committee of the House of Commons met "to inquire and report whether the telephone service is or is not calculated to become of such general benefit as to justify its being undertaken by municipal and other local authorities, regard being had to local finance; and if so, whether such local authorities should have power to undertake such service in the districts of other local authorities outside the area of their own jurisdiction, but comprised wholly or partially in the same telephone area; and what powers, duties, and obligations ought to be conferred or imposed upon such local authorities." In its report the committee expressed the opinion that general, immediate, and effective competition by either the Post Office or the local authority was necessary, and consider that a really efficient Post Office service afforded the best means for securing such competition.

On 8th May 1899 a Treasury Minute was issued upon the proposals for the development of the telephone system in the United Kingdom. It confirmed generally the conclusions arrived at by the committee:—(*a*) That the existing exchange service is not of general benefit to the country, and that it is not likely to become of general benefit so long as the present practical monopoly continues in the hands of a private company; (*b*) that competition by either the Post Office or the local authority is necessary in the public interest, and that the Post Office is not prevented, either by legal agreement or by good faith, from competing in any areas, either by itself or by means of licensees. The Minute also confirmed the proposals of the Postmaster-General:—(*a*) That licences should be granted to certain local authorities to transact telephone business within appropriate areas; and (*b*) that the Post Office should itself open telephone exchanges in London as soon as Parliament has provided the necessary funds. The licences to local authorities are of the same general character as that held by the National Company, and contain a provision that the local authorities licensed by the Postmaster-General shall connect their exchanges with post offices; licensed local authorities are to open call offices at post offices; and the restriction hitherto imposed upon renters of telephones, that they shall not allow their telephones to be used by other persons, is to be removed in all cases where messages are paid for on the "toll" system, whether the telephones are rented from the local authority or from the National Company. The royalties payable under these licences will be the same as those specified in the National Company's licences. All licences will be terminable on the 31st December 1911. Subject to the condition that the Government shall not purchase useless or antiquated plant,—including in this category single-wire circuits,—the licence to a local authority will provide that on the termination by the Postmaster-General of such licence, the local authority shall sell, and the Postmaster-General shall purchase, all plant then in use in the telephone service of the local authority which is suitable for the actual requirements at the time of the local service of the Post Office. The question of suitability will be left, if the parties differ, to the decision of an arbitrator, subject to the provision that no plant shall in any case be considered suitable which has been brought into use without the sanction of the Postmaster-General. The plant will be taken at its fair market value at the time of the purchase, without any addition in respect of compulsory purchase or goodwill. Where within a reasonable period *bonâ fide* competition between the National Company and any local authority is established in any area where the company is now working, similar treatment should be applied to so much of the plant of the company in such area as existed at the time when the competition was inaugurated. Further, if the company within a reasonable period gives intercommunication in such area between their exchanges and the exchanges of the local authority, on conditions approved by the Postmaster-General, the purchase will extend (on the same terms) to the plant of the company constructed (with the sanction of the Postmaster-General) after the commencement of the competition.

The Telegraphs (Telephonic Communication, &c.) Bill was subsequently introduced by the Government, and after much discussion in and out of Parliament, referred to the Standing Committee on Trade. It was amended in some respects, but in the main it gave effect to the recommendations contained in the Treasury Minute. It received the royal assent on 9th August 1899. The Postmaster-General decided to establish a competitive service with the National Company in the metropolitan area, and after considerable delay in laying the wires, the system was inaugurated in November 1901. The new Post Office rates however, instead of introducing a substantial competition, were almost the same as those of the National Company, and their announcement was followed by very general public complaint. (See also TELEPHONE, and POST OFFICE.) As a result of the Treasury Minute of May 1899, several corporations also decided to apply for licences to establish municipal telephone services.

[1] For a comparison of the English conditions with those obtaining on the continent of Europe, see Bennett, *Telephone Systems of the Continent of Europe*, pp. 2–16. Longmans, Green, & Co., London, 1895.

Telephonic communication, originally a purely urban affair, next became interurban and national; it has now become international. A cable for providing telephonic communication between London and Paris was laid across the Straits of Dover, from St Margaret's Bay to Sangatte, in 1891, and was connected to land wires specially erected for the purpose in both countries. The distance in miles is:—London to St Margaret's Bay, 84·5; St Margaret's Bay to Sangatte, 23·0; Sangatte to Paris, 200·0. There are extension lines in London to the General Post Office, to the Threadneedle Street Office (Stock Exchange), and to the West Strand Post Office, and connexion with Paris can be made at any of these points. The charge is eight shillings for three minutes, and two consecutive periods of three minutes may be arranged for.

A still later development is that by which users of the exchange telephone system can, by an extra payment of £10 per annum for receivers for four persons, be connected with the leading London theatres, music halls, and places of worship. The receiving apparatus is portable, and may be fitted in any room, and it can be installed in a few hours.

Light and Power Supply.—In March 1879 a Select Committee was appointed to consider whether municipal corporations should be authorized to adopt electric lighting schemes, and under what conditions, if at all, gas or other public companies should be authorized to do so. Some of the leading scientific authorities of the time gave evidence, but the conclusions arrived at were of a tentative character. The committee pointed out the desirability of giving facilities for conducting experiments, and recommended that the Legislature should show its willingness, when the demand arose, to give all reasonable powers for the development of electricity as a source of light and power. The Paris Exhibition in 1881, and the Electrical Exhibition at the Crystal Palace in the following year, combined with many improvements in electrical machinery and lamps, stimulated considerable enthusiasm for the subject. In the session of 1882 several Bills were promoted to confer on companies general powers to produce and supply electric light and power. This led the Board of Trade to introduce a Bill dealing with the whole question, and all the Bills were referred to a Select Committee. The Government Bill was amended, and received the royal assent on 18th August 1882. This Act conferred powers on undertakers to break open streets, and gave local authorities power to raise money for the purpose of electricity supply. The powers were conferred either by seven years' licence, which the Board of Trade might grant, with the consent of the local authorities; or by Provisional Order granted by the Board of Trade, with or without the consent of the local authorities. The Provisional Orders did not limit the period of the concession, but gave local authorities the option to buy up the land, buildings, plant, &c., upon the expiration of twenty-one years, or every subsequent seven years, at their value at the time of purchase, without any addition for compulsory purchase, goodwill, or other similar considerations.

Many companies were formed to acquire patents and carry on the electric light business, and a considerable amount of capital was subscribed. The exceedingly onerous character of the purchase clause of the 1882 Act was not realized, for during the session following the passing of the Act no less than sixty-nine Provisional Orders were confirmed by Parliament. But a reaction followed very quickly; in 1884 the Board of Trade received only four applications for Provisional Orders, and during the subsequent four years only one Order was granted. Only eight of these Orders are still in force. In 1884, upon the suggestion of the President of the Board of Trade, a Committee of Engineers and others interested was formed to draw up clauses amending the Act. A Bill based on the analogy of the Gas Acts, submitted by this committee, was not adopted by the Board of Trade, but was introduced in the House of Lords by Lord Rayleigh in 1886. At the same time Lord Bury introduced an alternative Bill, and thereupon the Government brought in a Bill of their own. The three Bills were referred to a Committee of the House of Lords, who recommended that the Government Bill as amended should be proceeded with. Political exigencies prevented the Government passing the Bill that year and the next. In the session of 1888 Lord Thurlow, then Chairman of the Brush Company, reintroduced the Bill, and it passed through Parliament, and received the royal assent on the 28th June 1888. The Act, though still requiring the consent of local authorities to the granting of Provisional Orders, gives the Board of Trade power, in exceptional cases, to dispense with the consent; and it amends the objectionable purchase clause of the 1882 Act by substituting forty-two years for twenty-one, and ten years for seven years, and by ameliorating the terms of purchase. Power is also given to the Board of Trade to vary the terms of sale in such manner as may be agreed upon between the local authority and the undertakers. The passing of this Act gave a new impetus to the establishment of electricity supply undertakings, and since 1888, 164 Provisional Orders have been granted to companies, and 353 to municipal authorities.

Recent developments.

During 1898 four Bills were introduced into Parliament which raised several new principles in connection with the supply of electric energy. 1. By a company desiring powers to purchase *compulsorily* certain lands for the extension of their existing generating station, such lands being within the area of supply under their Provisional Order.

The compulsory purchase clauses in the Lands Clauses Acts are expressly excluded from the Electric Lighting Acts. Sites for generating stations have been invariably purchased by agreement, and all Provisional Orders have contained a clause making undertakers liable for any nuisance committed by them. The result has been that even in cases where the nuisance has been inseparable from carrying on the undertaking, injunctions have been granted against undertakers, to the great detriment of the electric lighting industry.

2. By a company desiring to obtain powers to lay mains from their area of supply to a site which they had purchased for a generating station *outside* the area of supply.

Heretofore undertakers have been compelled to erect their generating stations within their area of supply, as the Board of Trade have always refused to grant orders for wayleaves.

3. By a company having no area of supply under the Electric Lighting Acts, but desiring to acquire powers to take lands for a generating station by compulsion, and to lay down mains for the purpose of supplying electric energy to *authorized undertakers only*.

4. By a company proposing to generate electricity at a central station in the Midlands, and to give a supply, in a district comprising in all an area of about 2000 square miles, to authorized undertakers, and also to ordinary consumers, notwithstanding the fact that in many of these places the local authorities already possessed Orders, and that consents of the local authorities had not been given in any case.

Powers to supply have been heretofore granted by Provisional Order or licence only, for which the consent of the local authority is a condition precedent.

These Bills were regarded as so important that a Joint-Committee of both Houses was appointed to consider the principles they involved. They were not dealt with by the committee in detail, except incidentally as showing the trend of the industry. The committee laid down general principles which they suggested should guide Parliament and the Board of Trade, and expressed the opinion that it must be decided in each individual case whether those principles should in whole or in part be applied, and whether any and what special conditions should be imposed.

The principles enunciated were :—(1) That the proved public advantages of electric energy in the generation of light and power warrant the granting to undertakers of compulsory powers for acquiring sites for generating stations, and lands or easements for pipes and mains therefrom, and other works. (2) That where the site for a generating station is acquired under compulsory powers, and is specified in the Provisional Order or Special Act, the undertakers should not be subjected to any further liability than that which is imposed by the common law in the case of persons exercising statutory powers and duties, but where the site for a generating station is acquired by agreement, the undertakers ought to be subject to the liability imposed by the common law. (3) That subject to observations contained in the report, these compulsory powers might also properly be given where the proposed site is not within the area of supply. (4) That where sufficient public advantage is shown, power might be given for the supply of electric energy over an area including districts of numerous local authorities, and involving plant of exceptional dimensions and high voltage, and that undertakings of this character might properly be authorized on conditions differing in some respects from those imposed by and under the existing Acts. This would include undertakers supplying energy chiefly in bulk or wholesale to other undertakers, whether local authorities or companies, whose areas of supply are wholly or partly within the area of such bulk or wholesale supplying company, and who distribute the energy so obtained to consumers. (5) As to giving compulsory powers of purchase of undertakings to local authorities, the committee, without questioning the policy of Parliament in having given such powers, observed : That when the power of purchase was granted in 1882 and 1888, no such schemes of supplying energy in bulk were contemplated as are now before Parliament. That when the power of purchase was thus granted, the question then before Parliament was chiefly one of light ; whereas although electric light is at present the predominant feature of the enterprises now before the public and Parliament, the application of electric energy in the form of power to an infinite variety of other purposes is likely to be in the near future the predominant feature and function of these undertakings. That the provisions of the Electric Lighting Act, 1888, enabling the local authority to purchase an undertaking after a term of years, are inapplicable, as a general rule, to the case of an undertaker supplying energy in bulk at high voltage, but as it might in special cases be desirable that the local authorities should have the right to purchase reserved to them, the Board of Trade should have power to insert the purchase clause in the Provisional Order, if the local authorities concerned can, in the opinion of the Board, show good cause for such a course. That in cases of the exemption from liability to purchase, some kind of sliding scale, as in the case of gas undertakings, should be imposed in the interest of consumers.

Bills Nos. 1 and 2 above referred to obtained the royal assent; Bill No. 3 was rejected; Bill No. 4, promoted by the General Power Distributing Company, passed, but was ultimately suspended till next session.

Another important question was raised in the session of 1898 by the Provisional Orders applied for by the Marylebone and Bermondsey Vestries for power to supply electricity. In each case an Order had already been granted, with the consent of the Vestry, to a company in 1889, and the Vestry has the right to purchase in 1931 so much of the undertaking as lies within the area of the local authority. The Bill confirming these Orders to the Vestries was read a second time in the House of Commons, and was referred to a Select Committee, who threw out the former but passed the latter. In the case of Bermondsey very little work had been done by the company. The Bill confirming the Bermondsey Order was passed by the House of Commons and read a first time in the House of Lords, but owing to a rule that a Confirmation Bill brought from the Commons cannot be read a second time after 28th June, no further progress was made.

The General Power Distributing Company's Bill was again proceeded with in the session of 1899, when the second reading was opposed on the ground that the measure would enable a private company to compete with municipal authorities, and would prevent such authorities from instituting new electric lighting schemes themselves. To propitiate the opponents of the measure, it was suggested that provisions should be introduced to exclude from its operation corporations to which it might be obnoxious. The President of the Board of Trade, on the understanding that that would be done, expressed the opinion that the Bill might be read a second time and referred to a Select Committee. The motion for the second reading was, however, negatived by 164 to 132. In 1900 parliamentary interest was again aroused in the question of the distribution of electric energy "in bulk" over large areas, Bills for this purpose having been deposited by several companies. The promoters of these Bills overcame the opposition of local authorities by agreeing not to compete with them, and to ask only for wayleave powers, subject to the consent in each case of the local authority, to lay their mains in the district so as to enable them to supply energy in bulk to local authorities and others authorized to distribute the energy.

A matter of serious import to investors in electric lighting undertakings, and in fact in all industrial undertakings founded on concessions granted by local authorities, is the decision of the Board of Trade and of Parliament to permit competition in the supply of electricity in the City of London, notwithstanding the agreement by which the Corporation of the City of London granted, "so far as they were able to do so," the exclusive right of supplying electricity for private purposes within the city. The Provisional Order granted by the Board of Trade to the Charing Cross and Strand Electricity Supply Corporation Limited was confirmed by Parliament, notwithstanding the strenuous opposition of the City of London Company.

Of the 525 Provisional Orders which are in force, 360 have been granted to local authorities and 165 to companies. Of those granted to local authorities, only 247 are in course of being carried out, while of those granted to companies, 132 are being carried out. From the published accounts of 239 undertakings it appears that at the end of 1899 companies had expended £11,445,133 on 92 undertakings, and local authorities £11,834,214 on 147 undertakings. The following figures give the average details of capital expenditure, stated in percentage, to total capital expenditure :—

Lands and buildings	18·47 per cent.
Plant and machinery	37·36 ,,
Mains	35·28 ,,
Meters	4·72 ,,
Instruments	1·53 ,,
Provisional orders, &c.	2·24 ,,

The number of lamps connected (equivalent to 8 candle-power) by 201 undertakings at the end of 1899 was 7,660,388, and the number of Board of Trade units sold by 193 undertakings was 125,116,615.

The following table gives details of average working expenses per Board of Trade unit sold (exclusive of Depreciation and Sinking Fund) :—

Year.	Number of Undertakings.	Generation.	Distribution.	Rents, Rates, and Taxes.	Management.	Special.
1895	60	2·45d.	·36d.	·35d.	·81d.	·1d.
1896	61	2·13d.	·26d.	·28d.	·62d.	·08d.
1897	84	1·97d.	·26d.	·24d.	·57d.	·06d.
1898	98	1·79d.	·25d.	·22d.	·49d.	·06d.
1899	118	1·77d.	·22d.	·19d.	·44d.	·05d.

A coloured diagram showing the average revenue per Board of Trade unit of electricity, and details of the cost of production of all electricity supply undertakings, is published annually with the *Manual of Electrical Undertakings*.

The following table shows the financial results of the supply of electricity by the undertakings in regard to which the figures are obtainable :—

Year	Number of Undertakings.	Revenue from Sale of Current.	Working Expenses.	Profit.	Per Cent. of Profit on Capital Expended.	Price obtained for Current.
Companies—		£	£	£		
1895	27	515,533	277,371	238,162	5·49	6·08d.
1896	29	616,382	314,996	301,386	6·33	5·77d.
1897	36	812,734	410,991	401,743	6·54	5·62d.
1898	37	897,628	480,280	417,348	5·51	5·51d.
1899	43	1,053,291	580,548	472,743	5·45	5·26d.
Municipalities—						
1895	33	206,868	119,632	87,235	4·92	5·32d.
1896	42	310,098	172,581	137,517	5·61	5·18d.
1897	54	502,947	265,074	237,873	5·73	4·68d.
1898	61	709,335	376,381	332,954	5·55	4·35d.
1899	75	988,404	555,682	432,722	4·90	4·06d.

The following table shows the average dividends paid during the years 1896–7–8–9 by the number of electricity supply companies mentioned :—

Year.	Number of Companies.	Aggregate Capital.	Average Ordinary Capital.	Average Preference Capital.	Average Loan and Debenture.	Total Average.
		£				
1896 .	35	5,176,301	5·22%	6·05%	4·69%	5·23%
1897 .	38	6,184,310	7·04%	5·97%	4·70%	6·28%
1898 .	44	8,284,212	5·57%	5·90%	4·46%	5·32%
1899 .	51	10,250,385	5·93%	5·82%	4·61%	5·51%

As municipalities do not pay dividends on the capital employed, the net result cannot be stated in the same way as in the case of companies. An analysis of municipal electricity accounts for the years ending December 1895–6–7 and March 1896–7–8, shows that the net profits earned by corporations supplying electricity amounted in the aggregate to £510,992, without taking into account reductions in the price of the current sold. During the years over which the analysis extends, £47,042 was taken from the rates, and £43,083 was applied in reduction of same.

Cost.

The supply of electric energy from central stations has now been systematically carried on for some nine or ten years, and the various items making up the cost of production have been analysed with great exactness. It is found that the cost of raw materials, namely, coal, water, and sundry stores, which are consumed in the actual generation of the electricity sold, forms only a small part of the total cost, the major portion of which is made up of the fixed charges and expenses of administration attributable to the time during which the works are unproductive. The reason for this is that it is not generally found expedient to store electricity in large quantities. In gas-works the production goes on throughout the twenty-four hours, but electricity-supply works generate the electricity for the most part at the moment it is used by the consumer. Electric lamps are normally in use on an average for only about four hours per day, and therefore the plant and organization are idle and unremunerative for about 20 hours out of the 24. It is necessary to have in readiness machinery capable of supplying the maximum possible requirements of all the consumers at any hour of the year—as, for instance, on Christmas Eve; and this accounts for a very large proportion of the total working expenses. The cost of supplying electricity depends more upon the *rate* of supply than upon the *quantity* supplied, or as the late Dr John Hopkinson put it: "The cost of supplying electricity for 1000 lamps for ten hours is very much less than ten times the cost of supplying the same number of lamps for one hour." Interest and sinking fund, rent, rates and taxes, salaries, wages, &c., are all of them, in a greater or less degree, governed by this potential maximum demand. These conditions exist in other industrial works, but there are few, if any, in which the standing charges are so high in relation to the running costs. Of course consumers vary largely, but the cost of supplying any one of them with a given amount of electricity is chiefly governed by the amount of his maximum demand at any one time.

The correct way to charge for electricity is to give liberal rebates to those consumers who make prolonged use of the plant regularly throughout the year—that is to say, the lower the maximum demand, and the more continuous the consumption, the better should be the discount. Such a tariff has been in use in Brighton for some years, and is being adopted by many other undertakings. The system necessitates the use of a special indicator (not to measure the quantity of electricity taken—that is done by the ordinary meter) to indicate the maximum number of lamps which the consumer has ever had on simultaneously during the period for which he is to be charged. In effect it shows the amount of plant which the station has had to keep on hand for his use. If the indicator shows that, say, twenty lamps is the greatest number which the consumer has turned on simultaneously, then he gets a large discount on all the current which his ordinary meter shows that he has taken beyond the equivalent of one hour's daily use of those twenty lamps. In Brighton the rate is 7d. per unit for the equivalent of one hour's daily use of the maximum demand, and 1d. per unit for all surplus. It is on this principle that it pays to supply current for tramways or other power purposes at a price which *primâ facie* is below the cost of production; it is only apparently so in comparison with the cost of producing electricity for lighting purposes. In the case of tramways the electricity is required for 15 or 16 hours per day. Electricity for a single lamp would cost on the basis of the Brighton system, for 15 hours per day only 1·86d. per unit. Therefore the much larger and very regular demand for current by tramways can be supplied at a very low figure as compared with the price of current for lighting. The cost of power if generated continuously on a large scale should not exceed ·25d. per Board of Trade unit, and even with interest on capital the cost should not exceed ½d. In many cities in the United States electric power is sold at from £12 to £25 per horse-power per year on the basis of 10 hours' operation per day; and at this price a good profit is made. Several contracts have been made in England for the supply of energy to tramways at 1½d. per Board of Trade unit on the basis of a minimum supply of about 300,000 units per annum, and at lower prices for larger quantities.

In ordinary practice it is found that 1000 cubic feet of gas are equal to 6 or 7 units of electricity, so that at 6d. per unit the cost of electric lighting would compare with gas at about 3s. to 3s. 6d. per 1000 cubic feet. A Board of Trade unit will supply one 8 candle-power lamp for 30 hours, or 30 such lamps for one hour. The price, however, is not the only measure of the relative economy of the two lights. In average use an incandescent lamp will last about 1000 hours, which is equal to about 12 months normal use; a good lamp will frequently last 2000 or 3000 hours before it actually breaks down, but it is not advisable to use lamps longer than 1000 hours, as after that the candle-power rapidly diminishes. The free supply of incandescent lamps by electricity-supply works is becoming general. Under this system a consumer is entitled to one 8 or 16 c.p. incandescent lamp free of charge, for every 60 units of electricity consumed in the year by the use of incandescent lamps only.

For large spaces arc lamps are more suitable and cheaper than incandescent lamps. The ordinary arc lamp, nominally of 2000 candle-power, consumes half a unit of electricity per hour. The carbons consumed in the arc lamps work out at a cost of less than $\frac{1}{4}$d. per lamp per hour.

Electric motors, which form an important branch of the electric-supply industry, can be adopted in a variety of ways for operating domestic and industrial apparatus requiring small power, and in calculating the consumption of electricity one may allow $\frac{8}{10}$ths of a unit per brake-horse-power hour. The capital expenditure for an electric motor is less than that for either a gas or oil engine, and motors can generally be obtained on hire or on the hire-purchase system.

Most new houses within an electricity-supply area are wired for electricity during construction. The cost of wiring varies according to number of lights and character of fittings; it may be taken at 15s. to £2 per lamp installed, including all necessary wire, switches, fuses, lamps, holders, casing, but not electroliers or shades. In many instances the supply undertakings carry out the wiring of houses, for an increased payment for the current, or arrange with a separate company to fix the wires and fittings in the houses, the charge being 1d. per unit upon all current used, with a minimum payment of 1s. per 8 candle-power lamp. This charge of 1d. per unit is collected by the supply undertaking for the wiring company. The consumer has to enter into an agreement, and if he is but a tenant, the landlord has to sign a memorandum to the effect that the wiring and fittings belong to the supply undertaking.

A recent development of municipal enterprise takes the form of the erection of blocks of "model" dwellings for the better housing of the working classes, and electric light is supplied in these dwellings, the charge for the current taking the form of an increased rent of 8d. per week for two rooms and 10d. per week for three rooms. One 16 c.p. lamp is fitted in the living room and one 8 c.p. lamp in each of the bedrooms, and the current is available each day at dusk and is turned off at midnight; in winter it can also be obtained from 5 a.m. until daylight.

In the opinion of most of the insurance companies "the electric light is the safest of all illuminants, and is preferable to any others when the installation has been thoroughly well put up." The Phœnix Fire Office rules were the first to be drawn up and are generally followed, but some other leading insurance offices have their own rules, under which risks are accepted without extra premium.

Electric Traction.—Until recent years comparatively very little progress has been made in Great Britain in the application of electricity to tramways, notwithstanding that in America, and on the continent of Europe, there has been for some years past a general movement in the direction of substituting electric power for horses, and also a tendency to supersede steam on railways. In large American cities the proportion of miles of tramway to the population varies from 1 mile for every 1300 persons to 1 mile for every 4000 persons. In Europe the proportion is from 1 mile for every 10,000 persons in Berlin, to 1 mile for every 55,000 persons in Cardiff.

The first street tramway was laid in 1860 at Birkenhead. In 1890 (20 years after the passing of the General Tramways Act) there were 922 miles worked by horses, cable, and steam, and 70 miles worked by electricity, while 439 Acts of Parliament authorizing tramways had been passed. There was a period of increasing activity in tramway promotion which culminated in 1882, when 43 Acts were passed. Then followed a period of decreasing activity until 1890, when only 2 Acts were passed. As soon as the effect of the purchase clause of the Tramways Act, 1870, and of the veto possessed by local authorities, was understood, there was a total cessation of new tramway enterprise until the potentialities of electric traction were realized, and until the law in regard to the promotion and working of tramways had been modified in a way to facilitate the use of electric power.

The decisions of the House of Lords in the cases of the tramways arbitrations at London and Edinburgh may be accepted as fixing the price to be paid for an undertaking on the basis of the Tramways Act. The arbitrator in the Edinburgh case assessed the value of the track per mile of single line at £5100, and allowed a sum of £2500 which had been expended on widening a bridge, also the expenses incurred in obtaining parliamentary powers. The tramway company had asked £305,000; they obtained £212,979 as the value of the undertaking, such value being simply what it would cost to construct the lines and necessary buildings, and provide necessary cars, horses, and machinery, less depreciation. The expenses of the arbitration were laid upon the corporation, those of the tramway company being taxed. In the London case £213,450 was demanded as the capitalized value of 4 miles 861 yards of single line. The arbitrator awarded £22,872 as the value of the track and the company's interest in a depôt; parliamentary costs, engineers' fees, and cost of street widening were also allowed; the sale of the cars, horses, &c., was effected at an agreed valuation between the parties. In the Leeds tramway a length of 22 miles of single track was valued at £58,000, or only £2636 per single mile; but the line is said to have been in bad condition. A more recent case is that of Wolverhampton. The company owned $8\frac{1}{2}$ miles, of which about $5\frac{1}{4}$ miles were within the borough. There had been only slight renewals of the track. The total price awarded to the company was £22,500, and this was made up of £11,000 for track, £7500 freehold depôts, £1800 for 75 horses, £1200 for 11 cars, harness, &c., and £1000 for parliamentary costs.

The principle on which clause 43 has thus far been interpreted is simply that of awarding such sum as it would cost to replace the part of the undertaking purchased, less a sum for depreciation, allowance being made for the expense of obtaining parliamentary authority to construct, and for other expenditure proper to the construction. Thus whether earning 1 per cent. or 10 per cent., two different undertakings, if in equal condition and costing the same to construct, would have to be sold at the same price.

In May 1893 a joint committee of both Houses was appointed to consider whether the grant of statutory powers to use electricity ought to be qualified by any prohibition or restriction as to earth-return circuits, or by any provisions as to leakage, induction, or similar matters; and as a result of the evidence presented, model clauses were drawn up to be inserted in Bills and Provisional Orders authorizing undertakers to use large electric currents and uninsulated return conductors. In February 1894 a conference took place between the Board of Trade and various parties interested in electric traction; and on the 6th March 1894 rules were issued by that department for preventing electrolytic action on gas or other pipes, and for minimizing, as far as practicable, injurious interference with the electric wires, lines, and apparatus of other parties. The model clauses, and the regulations of the Board of Trade, settled as they were after consultation with all parties concerned, afford every guarantee that in the application of electricity to tramways all interests are adequately protected.

The passing of the Light Railways Act, 1896, coupled with the confidence in the better commercial results of electric traction, gave new hope to the tramway *entrepreneur*. The Act contains no definition of "light railway," and tramways have been authorized under it; it relieves promoters of the heavy expenses of an application to Parliament; it contains no purchase clause, though in most cases a clause, which is the result of a bargain between the promoter and the local authority, is inserted in the Order; it provides for compulsory purchase of lands, and an even more important advantage of the Act is that it does not require the assent of the local authorities as a condition precedent to the promotion of a scheme. Many undertakings have already been sanctioned under this Act which it would have been impossible to promote under the Tramways Act. Nevertheless, the hopes which persons interested in the business entertained as to its operation have not been fully realized. It was believed that Parliament had recognized the evil of giving local authorities a veto; but promoters, even under this Act, have in many cases either to agree to conditions which make the undertaking commercially doubtful, or have to incur the risk of the Order being rejected, because the local authorities do not assent.

The following data [1] concerning the tramway industry in Great Britain before the general adoption of electric traction serve to show the progress made with tramways since the introduction of electric power. The total capital expenditure in 1890 amounted to about 13¾ millions, distributed as follows:—

	Capital Expenditure on Lines and Works open for Traffic.	Total Expenditure on Capital Account.	Length open for Traffic.	Number of Undertakings.
	£	£	Miles.	
Tramways belonging to Local Authorities	2,152,392	2,911,419	243·75	29
Tramways belonging to others	8,215,125	10,824,350	704·51	129
Total in United Kingdom	10,367,517	13,735,769	948·26	158

The expenditure on lines open in 1890 was equal to about £10,580 per mile. The working stock in 1890 was:—

27,719 horses, or 29·27 per mile open.
575 locomotives, or ·61 ,, ,,
3,801 cars 4·01 ,, ,,

The number of miles run amounted to 65,174,955 for the year; and taking the mean number of cars for the year at 3723, the mileage run per car averages 17,506 car miles for the year, or 48 miles per car per day. The average mileage per pair of horses was 12·5 per day. The gross receipts for the year amounted to £3,214,743, and the expenses to £2,402,800, or 75 per cent. of the receipts, leaving net receipts £811,943.

Since 1890 the tramway industry in Great Britain has been passing through a transition stage. On the one hand, in view of the right of local authorities to purchase the undertakings after 21 years, very few of the tramway companies have felt any inducement to develop their undertakings; and on the other, the gradual adoption of electricity as the motive-power has led to the reconstruction of the lines by local authorities. Some of the companies are enabled to substitute electricity by reason of arrangements with the local authorities to postpone the date for the exercise of their rights to purchase.

One of the fundamental advantages possessed by the more generally used methods of electric traction is that the energy is generated for all the cars at one or more central points, and is distributed over the entire system and expended at the points where the traffic requires it, and in proportion to its volume; while in the case of either horses or steam, and also in the case of the self-contained electric-accumulator car, and some other systems, each car requires to be accompanied, for the whole of its journey, by its own motive-power, which must be sufficient to start the car and carry the maximum load of passengers, and be able to overcome the steepest gradient. As the abnormal demand for power for these purposes is only occasional in time and place, it follows that there is considerable waste when the car is empty, or on the level, or at rest. Moreover, in the case of horse traction, about four-fifths of the horses required for the cars are resting or feeding, while only one-fifth are doing work; and the service of cars cannot be increased to meet an exceptional demand without permanently providing this wasteful margin of power. Likewise, in the case of steam tramways, an additional car cannot be put into use without an additional locomotive, which must be powerful enough to do the maximum work. The result of these conditions is an infrequent service of cars. With electric traction, if the traffic calls for a more frequent service, it can be provided without very largely increasing the working expenses. Additional capital expenditure has to be incurred to furnish more cars and other plant, but a much smaller increase of traffic will justify an addition to the number running. The greater facility with which electric cars are started, and the greater speed which can be attained, enable them to perform a much larger number of journeys. In America they frequently run between 100 and 200 miles per day. Other advantages of electric traction, such as its avoiding the objections arising out of the employment of horses or steam locomotives in the streets, are obvious. The net result of the adoption of electricity for tramways is not only that, up to a certain point, an increasing traffic can be carried at a relatively less cost of working, but this very fact tends to produce the increased traffic. An improved and quicker service encourages people to patronize the tram car who otherwise would never think of travelling in that fashion.

Cost of construction.

The cost of construction per mile of single line may be taken at £6000, and the overhead electric equipment at £2000, having regard to present enhanced prices; in addition, cars have to be provided, which cost about £650 each, and electrical power-houses, the cost of which are dependent upon their situation and capacity. Generally, it may be said that a new electric tramway cannot be completed in an urban district under £12,000 per mile single track.

For the Oldham Ashton Hyde tramway, which consists of 8·14 miles single track, the capital expenditure was £120,000, including the cost of the concession, but not the cost of the power-house, as in this case the electric energy is sold to the tramway company by the corporation of Ashton. In the case of the Potteries tramways and light railways, the capital expenditure on 30 miles was about £600,000. This includes power-houses, cost of concessions, and the acquisition and conversion of about 8 miles of tramways formerly worked by steam.

The following are particulars appertaining to a typical undertaking in England, consisting of 8 miles of road, 5¾ miles of single and 2¼ miles of double track. Working expenses per car mile:—

Power and running	Cost of current	1·00d.
	Wages	2·41d.
	Inspection and distribution	·31d.
	Uniforms, tickets, punches, car licences, and sundries	·44d.
Repairs and maintenance		·37d.
Administration and general expenses		·85d.
Total		5·38d.

The number of cars in use is 29, and the car miles run per annum are 580,000. The district served has a population of 250,000, and 4,050,000 passengers are carried yearly. The consumption of electricity amounts to 550,000 units. The fares charged average 1·6 miles for 1 penny. The drivers work on an average 60 hours per week, and receive 27s. per week; the conductors receive 22s. per week, and are supplied with uniforms. The receipts per car mile are 10·16d., and the total receipts per annum £24,500. The total expenses per annum amount to £14,500, equal to 59 per cent. of the receipts. The company is bound to run at least two cars each way every morning and every evening in the week, at such hours, not being later than 7 in the morning or earlier than 6 in the evening, as the company consider most convenient for workmen, at a fare not exceeding a ½d. per mile.

There is scope for considerable development of the overhead trolley system in Great Britain, notwithstanding that it possesses features which are tolerated only because its general advantages outweigh its æsthetic objections. There are several directions from which improvements may come. Many engineers look to the surface-contact system, others rely on the appearance of an accumulator so light in weight as to be suitable for tramway work. The open-slot conduit system has many advocates, but its physical difficulties in old cities are great, and its cost is prohibitive for most places. An important factor in the future development of the tramway industry is the question of municipalization. Whether the trolley is superseded by the conduit,

[1] D. Kinnear Clark's *Tramways, their Construction and Working.*

the surface-contact, or the accumulator system, tramway rails and consequent interference with the roads cannot be avoided. Hence on the one hand private enterprise is exposed to the retarding and deterring influences of local authorities, and on the other, local authorities are placed under the disability of being confined more or less to their respective districts. It has been said that tramway rails are a protest against bad roads. If the surface of public roads were better, automobiles would have a chance. Even as it is, private enterprise may decide to develop the business by means of automobiles, in spite of their smaller commercial efficiency, rather than incur the financial risk of constructing costly permanent way under limited tenure, and furthermore submit to the excessive demands for way-leaves and street widenings which are made by local authorities whenever a tramway or light railway is proposed. The attempts hitherto made in Great Britain to utilize electricity for automobile cabs and omnibuses have not been successful. The only possible methods are by primary batteries or by accumulators. The former may be dismissed as being much too expensive, and the latter, besides being too heavy and very costly in wear and tear, suffer from the inconvenience of requiring to be too frequently recharged, and in the absence of charging-stations near the routes traversed, a large amount of useless mileage must be run. For the propulsion of launches, however, accumulators have been found satistory. On the Thames such launches are regularly let out on hire during the summer. There are charging-stations at various points along the river.

Electric traction on railways.

The question of the equipment of main-line railways with electric power is one of the most important economic problems of the present day. In America branch railways of some of the trunk lines have already been electrically equipped, and on the continent of Europe advances have been made in the direction of demonstrating the practicability of working main-line railways by electricity. In England the only working instances of electric traction on railways in 1901 were those of the City and South London, the Liverpool Overhead, the Waterloo and City, and the Central London.

City and South London Railway.—Length of line open for traffic, 3 miles 53 chains (under construction, 3 miles 11½ chains). Working stock: 84 carriages and 28 locomotives. Capital subscribed: ordinary and preferred shares, £1,500,772; 4 per cent. debentures stock, £244,315. Passengers carried (exclusive of season ticket-holders) for the year 1899, 6,983,040. Receipts from passengers for the year 1899, £52,947. Train mileage for the year 1899, 477,227. Receipts from passengers per train mile run. 26·63d. Working expenses per train mile run:—

Maintenance	7d.
Power	5·9
Traffic expenses	6·1
Carriage repairs	·5
General expenses	1·9
Other expenses	·9
	16d.

Average dividend paid since 1892, 5 per cent. on preference shares per annum; on ordinary stock, 1½ per cent. per annum.

Liverpool Overhead Railway.—Length of line open for traffic, 6 miles 57 chains, double (tramway extensions under construction). Capital subscribed: ordinary and preference shares, £570,000; 4 per cent. debentures, £170,000. Passengers carried for the year 1899, 9,690,236. Train mileage for the year 1899, 778,252. Receipts from passengers for the year 1899, £77,971. Receipts from passengers per train mile run, 24·04d. Working expenses per train mile run:—

Maintenance	2·55d.
Power	4·24
Traffic expenses	5·59
Carriage repairs	·36
General expenses	1·35
Other expenses	1·31
	15·40d.

Average dividend paid since 1893: 5 per cent. on preference shares, 2¾ per cent. on ordinary shares per annum.

Waterloo and City Railway.—Length of line open for traffic, 1 mile 46 chains, double. Working stock: 4 trains, and 1 held in reserve. Capital subscribed: ordinary stock, £540,000; 3 per cent. debenture stock, £32,000. Passengers carried for the year 1899, 3,485,556, exclusive of 776 season ticket-holders. Passengers receipts, including season ticket-holders, for the year 1899, £26,577. Working expenses for the year 1899, £15,335. Dividends paid under agreement by London and South-Western Railway Company, 3 per cent. per annum.

Central London Railway.—Length of line constructed, 6 miles 34·7 chains, double. Capital subscribed, £2,850,000.

(E. GA.)

Electro-Chemistry.—The present article will deal with processes that involve the electrolysis of aqueous solutions, whilst those in which electricity is used in the manufacture of chemical products at furnace temperatures will be treated of under ELECTRO-METALLURGY, although, strictly speaking, in some cases (*e.g.* calcium carbide and phosphorus manufacture) they are not truly metallurgical in character. For the theory and elementary laws of electro-deposition, and for the construction and use of electric generators, whether chemical or mechanical, reference must be made to the articles on these subjects, while, for full details of industrial processes which can here be sketched only in outline, recourse must be had to the text-books and journals, of which some are named at the end of the article and others in the text. The importance of the subject may be gauged by a calculation made by Borchers in a paper (*Zeitschrift für Elektrochemie*, 1899, vol. vi. p. 61) on the position of the electro-chemical and electro-metallurgical industries, excluding electro-plating and -typing; this purports to show that when all the electro-chemical works at that time actually, or about to be, erected, should be working up to their full capacity, the annual value of their products, calculated at the prices ruling in 1899, would amount to nearly thirty million pounds sterling. It should be remembered, also, that all the aluminium, magnesium, sodium, potassium, calcium carbide, carborundum, and artificial graphite, now placed on the market, is made by electrical processes, and that the use of such processes for the refining of copper and silver, and in the manufacture of phosphorus, potassium, chlorate, and bleach, already pressing very heavily on the older non-electrical systems, is every year extending. The convenience also with which the energy of waterfalls can be converted into electric energy has led to the introduction of chemical industries into countries and districts where, owing to the absence of coal, they were previously unknown. Norway and Switzerland are rapidly growing into important producers of chemicals, and pastoral districts such as those in which Niagara or Foyers are situated, are being converted into manufacturing centres. In this way the development of the electro-chemical industry is in a marked degree altering the distribution of trade throughout the world.

Electrolytic Refining of Metals.—The principle usually followed in the electrolytic refining of metals is to cast the impure metal into plates, which are exposed as anodes in a suitable solvent, commonly a salt of the metal under treatment. On passing a current of electricity, of which the volume and pressure are adjusted to the conditions of the electrolyte and electrodes, the anode slowly dissolves, leaving the insoluble impurities in the form of a sponge, if the proportion be considerable, but otherwise as a mud or slime which becomes detached from the anode surface and must be prevented from coming into contact with the cathode. The metal to be refined passing into solution is concurrently deposited at the cathode. Soluble impurities which are more electro-negative than the metal under treatment must, if present, be removed by a preliminary process, and the voltage and other conditions must be so selected that none of the more electro-positive metals are co-deposited with the metal to be refined. From these and other considerations it is obvious that (1) the electrolyte must be such as will freely dissolve the metal to be refined; (2) the electrolyte must be able to dissolve the major portion of the anode, otherwise the mass of insoluble matter on the outer layer will prevent access of electrolyte to the core, which will thus escape refining; (3) the electrolyte should, if possible, be incapable of dissolving metals more electro-negative than that to be refined; (4) the proportion of soluble electro-positive impurities must not be excessive, or these substances will accumulate too rapidly in the solution and necessitate its frequent purification; (5) the current density must be so adjusted to the strength of the solution and to other conditions that no relatively electro-positive metal is deposited, and that the cathode deposit is physically suitable for subsequent treatment; (6) the current density should be as high as is consistent with the production of a pure and sound deposit, without undue expense of voltage, so that the operation may be rapid and the "turnover" large; (7) the electrolyte should be as good a conductor of electricity as possible, and should not, ordinarily, be altered chemically by exposure to air; and (8) the use of porous partitions should be avoided, as they increase the resistance and usually require frequent renewal.

Copper. The earliest serious attempt to refine copper industrially was made by Elkington, whose first patent is dated 1865. He cast crude copper, as obtained from the ore, into plates measuring about 24 in. by 8 in. by 1 in., each with a T-shaped support of wrought copper cast into the middle of one end. These plates were used as anodes, sheets of electro-deposited copper forming the cathodes. Six anodes were suspended, alternately with four cathodes, in a saturated solution of copper sulphate in a cylindrical fire-clay trough, all the anodes being connected in one parallel group, and all the cathodes in another. A hundred or more jars were coupled in series, the cathodes of one to the anodes of the next, and were so arranged that with the aid of side-pipes with leaden connexions and india-rubber joints the electrolyte could, once daily, be made to circulate through them all from the top of one jar to the bottom of the next. The current from a Wilde's dynamo was passed, apparently with a current density of 5 or 6 amperes per sq. ft., until the anodes were too crippled for further use, when they were removed, the T-supports (which were protected by wax from the action of the solution) were taken out and used again, and the fragments of the anodes were washed and re-melted. The cathodes, when thick enough, were either cast and rolled or sent into the market direct. Silver and other insoluble impurities collected at the bottom of the trough up to the level of the lower side-tube, and were then run off through a plug in the bottom into settling tanks, from which they were removed for metallurgical treatment. The electrolyte was used until the accumulation of iron in it was too great, but was mixed from time to time with a little water acidulated by sulphuric acid. This process has been described at some length, not only on account of its historic interest, but because in principle it is identical with that now used. The modifications introduced have been chiefly in details, in order to economize materials and labour, to ensure purity of product, and to increase the rate of deposition.

The chemistry of the process has been studied by Kiliani (*Berg- und Hüttenmännisches Zeitung*, 1885, p. 249), who found that, using the (low) current-density of 1·8 ampere per sq. ft. of cathode, and an electrolyte containing 1½ ℔ of copper sulphate and ½ ℔ of sulphuric acid per gallon, all the gold, platinum, and silver present in the crude copper anode remain as metals, undissolved, in the anode slime or mud, and all the lead remains there as sulphate, formed by the action of the sulphuric acid (or SO_4 ions); he found also that arsenic forms arsenious oxide, As_2O_3, which dissolves until the solution is saturated, and then remains in the slime, from which on long standing it gradually dissolves, after conversion by secondary reactions into arsenic oxide; antimony forms a basic sulphate which in part dissolves; bismuth partly dissolves and partly remains, but the dissolved portion tends slowly to separate out as a basic salt which becomes added to the slime; cuprous oxide, sulphide, and selenides remain in the slime, and very slowly pass into solution by simple chemical action; tin partly dissolves (but in part separates again as basic salt) and partly remains as basic sulphate and stannic oxide; zinc, iron, nickel, and cobalt pass into solution—more readily indeed than does the copper. Of the metals which dissolve, none (except bismuth, which is rarely present in any quantity) deposit at the anode so long as the solution retains its proper proportion of copper and acid, and the current-density is not too great. Neutral solutions are to be avoided because in them silver dissolves from the anode and, being more electro-negative than copper, is deposited at the cathode, while antimony and arsenic are also deposited, imparting a dark colour to the copper. Electrolytic copper should contain at least 99·92 per cent. of metallic copper, the balance consisting mainly of oxygen with not more than 0·01 per cent. in all of lead, arsenic, antimony, bismuth, and silver. Such a degree of purity is, however, unattainable unless the conditions of electrolysis are rigidly adhered to. It should be observed that the free acid is gradually neutralized, partly by chemical action on certain constituents of the slime, partly by local action between different metals of the anode, both of which effect solution independently of the current, and partly by the peroxidation (or aëration) of ferrous sulphate formed from the iron in the anode. At the same time there is a gradual substitution of other metals for copper in the solution, because although copper *plus* other (more electro-positive) metals are constantly dissolving at the anode, only copper is deposited at the cathode. Hence the composition and acidity of the solution, on which so much depends, must be constantly watched.

The dependence of the mechanical qualities of the copper upon the current-density employed is well known. A very weak current gives a pale and brittle deposit, but as the current-density is increased up to a certain point, the properties of the metal improve; beyond this point they deteriorate, the colour becoming darker and the deposit less coherent, until at last it is dark brown and spongy or pulverulent. The presence of even a small proportion of hydrochloric acid imparts a brown tint to the deposit. Baron v. Hübl (*Mittheil. der k. k. militär-geograph. Inst.*, 1886, vol. vi. p. 51) has found that with neutral solutions a 5 per cent. solution of copper sulphate gave no good result, while with a 20 per cent. solution the best deposit was obtained with a current-density of 28 amperes per sq. ft.; with solutions containing 2 per cent. of sulphuric acid, the 5 per cent. solution gave good deposits with current-densities of 4 to 7·5 amperes, and the 20 per cent. solution with 11·5 to 37 amperes, per sq. ft. The maximum current-densities for a *pure* acid solution at rest were: for 15 per cent. pure copper sulphate solutions, 14 to 21 amperes, and for 20 per cent. solutions 18·5 to 28 amperes per sq. ft.; but when the solutions were kept in gentle motion these maxima could be increased to 21–28 and 28–37 amperes per sq. ft. respectively. The necessity for adjusting the current-density to the composition and treatment of the electrolyte is thus apparent. The advantage of keeping the solution in motion is due partly to the renewal of solution thus effected in the neighbourhood of the electrodes, and partly to the neutralization of the tendency of liquids undergoing electrolysis to separate into layers, due to the different specific gravities of the solutions flowing from the opposing electrodes. Such an irregular distribution of the bath, with strong copper sulphate solution from the anode at the bottom and acid solution from the cathode at the top, not only alters the conductivity in different strata and so causes irregular current-distribution, but may lead to the current-density in the upper layers being too great for the proportion of copper there present. Irregular and defective deposits are therefore obtained. Provision for circulation of solution is made in the systems of copper-refining now in use. Wilde, in 1875, in depositing copper on iron printing-rollers, recognized this principle and rotated the rollers during electrolysis, thereby renewing the surfaces of metal and liquid in mutual contact, and imparting sufficient motion to the solution to prevent stratification; as an alternative he imparted motion to the electrolyte by means of propeller blades. Other workers have followed more or less on the same lines; reference may be made to the patents of Elmore, who sought to improve the character of the deposit by burnishing during electrolysis, of Dumoulin, and to a recent paper by Cowper-Coles (*Journ. Inst. Elec. Eng.*, 1900, vol. xxix. p. 258), who prefers to rotate the cathode at a speed that maintains a peripheral velocity of at least 1000 ft. per minute. Certain other inventors have applied the same principle in a different way. Thofehrn in America and Graham in England have patented processes by which jets of the electrolyte are caused to impinge with considerable force upon the surface of the cathode, so that the renewal of the liquid at this point takes place very rapidly, and current-densities per sq. ft. of 50 to 100 amperes are recommended by the former, and of 300 amperes by the latter. Graham has described experiments in this direction, using a jet of electrolyte forced (beneath the surface of the bath) through a hole in the anode upon the surface of the cathode. Whilst the jet was playing, a good deposit was formed with so high a current-density as 280 amperes per sq. ft., but if the jet was checked, the deposit (now in a still liquid) was instantaneously ruined. When two or more jets were used side by side the deposit was good opposite the centre of each, but bad at the point where two currents met, because the rate of flow was reduced. By introducing perforated shields of ebonite between the electrodes, so that the full current-density was only attained at the centres of the jets, these ill effects could be prevented. One of the chief troubles met with was the formation of arborescent growths around the edges of the cathode, due to the greater current-density in this region; this, however, was also obviated by the use of screens. By means of a very brisk rotation of cathode, combined with a rapid current of electrolyte, Swan has succeeded in depositing excellent copper at current densities exceeding 1000 amperes per sq. ft. The methods by which such results are to be obtained cannot, however, as yet be practised economically on a working scale; one great difficulty in applying them to the refining of metals is that the jets of liquid would be liable to carry with them particles of anode mud, and Swan has shown that the presence of solid particles in the electrolyte is one of the most fruitful causes of the well-known nodular growths on electro-deposited copper. Experiments on a working scale with one of the jet processes in America have, it is reported, been given up after a full trial.

In copper-refining practice, the current-density commonly ranges from 7·5 to 12 or 15, and occasionally to 18, amperes per sq. ft. The electrical pressure required to force a current of this intensity through the solution, and to overcome a certain opposing electromotive force arising from the more electro-negative impurities of the anode, depends upon the composition of the bath and of the anodes, the distance between the electrodes, and the temperature, but under the usual working conditions averages 0·3 volt for every pair of electrodes in series. In nearly all the processes now used, the solution contains about $1\frac{1}{2}$ to 2 lb of copper sulphate and from 5 to 10 oz. of sulphuric acid per gallon of water, and the space between the electrodes is from $1\frac{1}{2}$ to 2 in., whilst the total area of cathode surface in each tank may be 200 sq. ft., more or less. The anodes are usually cast copper plates about (say) 3 ft. by 2 ft. by $\frac{3}{4}$ or 1 in. The cathodes are frequently of electro-deposited copper, deposited to a thickness of about $\frac{1}{32}$ in. on black-leaded copper plates, from which they are stripped before use. The tanks are commonly constructed of wood lined with lead, or tarred inside, and are placed in terrace fashion each a little higher than the next in series, to facilitate the flow of solution through them all from a cistern at one end to a well at the other. Gangways are left between adjoining rows of tanks, and an overhead travelling-crane facilitates the removal of the electrodes. The arrangement of the tanks depends largely upon the voltage available from the electric generator selected; commonly they are divided into groups, all the baths in each group being in series. In the huge Anaconda Plant, for example, in which 150 tons of refined copper can be produced daily by the Thofehrn multiple system (not the jet system alluded to above), there are 600 tanks about $8\frac{1}{4}$ ft. by $4\frac{1}{2}$ ft. by $3\frac{1}{4}$ ft. deep, arranged in three groups of 200 tanks in series. The connexions are made by copper rods, each of which, in length, is twice the width of the tank, with a bayonet-bend in the middle, and serves to support the cathodes in the one and the anodes in the next tank. Self-registering voltmeters indicate at any moment the potential difference in every tank, and therefore give notice of short circuits occurring at any part of the installation. The chief differences between the commercial systems of refining lie in the arrangement of the baths, in the disposition and manner of supporting the electrodes in each, in the method of circulating the solution, and in the current density employed. The various systems are often classed in two groups, known respectively as the *Multiple* and *Series* systems, depending upon the arrangement of the electrodes in each tank. Under the multiple system anodes and cathodes are placed alternately, all the anodes in one tank being connected to one rod, and all the cathodes to another, and the potential difference between the terminals of each tank is that between a single pair of plates. Under the series system only the first anode and the last cathode are connected to the conductors; between these are suspended, isolated from one another, a number of intermediate bi-polar electrode plates of raw copper, each of these plates acting on one side as a cathode, receiving a deposit of copper, and on the other as an anode, passing into solution; the voltage between the terminals of the tank will be as many times as great as that between a single pair of plates as there are spaces between electrodes in the tank. In time the original impure copper of the plates becomes replaced by refined copper, but if the plates are initially very impure and dissolve irregularly, it may happen that much residual scrap may have to be remelted, or that some of the metal may be twice refined, thus involving a waste of energy. Moreover, the high potential difference between the terminals of the series tank introduces a greater danger of short-circuiting through scraps of metal at the bottom of the bath; for this reason, also, lead-lined vats are inadmissible, and tarred slate tanks are often used instead. A valuable comparison of the multiple and series systems has been published by Kellar (see *The Mineral Industry*, New York, 1899, vol. vii. p. 229). Kroupa and Barnett have calculated that the cost of refining is 8s. per ton of copper higher under the series than it is under the multiple system; but against this, it must be remembered that the new works of the Baltimore Copper Smelting and Refining Company, which are as large as those of the Anaconda Company, are using the Hayden process, which is the chief representative of the several series systems. In this system rolled copper anodes are used; these, being purer than many cast anodes, having flat surfaces, and being held in place by guides, dissolve with great regularity and require a space of only $\frac{5}{8}$ in. between the electrodes, so that the potential difference between each pair of plates may be reduced to 0·15–0·2 volt.

Borchers, in Germany, and Schneider and Szontagh, in America, have introduced a method of circulating the solution in each vat by forcing air into a vertical pipe communicating between the bottom and top of a tank, with the result that the bubbling of the air upward aspirates solution through the vertical pipe from below, at the same time aërating it, and causing it to overflow into the top of the tank. Obviously this slow circulation has but little effect on the rate at which the copper may be deposited. The electrolyte, when too impure for further use, is commonly recrystallized, or electrolysed with insoluble anodes to recover the copper.

The yield of copper per ampere (in round numbers, 1 oz. of copper per ampere per diem) by Faraday's law is never attained in practice; and although 98 per cent. may with care be obtained, from 94 to 96 per cent. represents the more usual current-efficiency. With 100 per cent. current-efficiency and a P.D. of 0·3 volt between the electrodes, 1 lb of copper should require about 0·154 electrical horse-power hours as the amount of energy to be expended in the tank for its production. In practice the expenditure is somewhat greater than this; in large works the gross horse-power required for the refining itself and for power and lighting in the factory may not exceed 0·19 to 0·2 (or in smaller works 0·25) horse-power hours per pound of copper refined.

Many attempts have been made to use crude sulphide of copper or matte as an anode, and recover the copper at the cathode, the sulphur and other insoluble constituents being left at the anode. The best known of these is the Marchese process, which was tested on a working scale at Genoa and Stolberg. As the operation proceeded, it was found that the voltage had to be raised until it became prohibitive, while the anodes rapidly became honeycombed through and, crumbling away, filled up the space at the bottom of the vat. The process was abandoned, but in a modified form appears to be now in use in Nijni Novogorod in Russia. Siemens and Halske introduced a combined process in which the ore, after being part-roasted, is leached by solutions from a previous electrolytic operation, and the resulting copper solution electrolysed. In this process the anode solution had to be kept separate from the cathode solution, and the membrane which had in consequence to be used, was liable to become torn, and so to cause trouble by permitting the two solutions to mix. Modifications of the process have therefore been tried.

Silver.

In the electrolytic refining of copper with acid sulphate solutions, practically the whole of the silver in the anode is left in the slime, from which it is readily recovered; but when the silver forms the bulk of the metal to be purified, a method must be used which will involve the solution of the silver itself at the anode and its deposition at the cathode. The only process to which reference need here be made is that of Mœbius. Under his earlier patent of 1884, cast crude silver anode plates, about $\frac{1}{2}$ in. thick, and thin rolled silver cathodes, were suspended in a $\frac{1}{2}$ per cent., slightly acid, solution of silver nitrate contained in tarred wooden tanks. The deposit from this solution even with low current-densities is pulverulent and non-coherent, and therefore during electrolysis wooden scrapers are automatically and intermittently passed over the surface of the cathode to detach the loose silver, which falls into cloth trays at the bottom of the tanks. These trays are removed at intervals, and the silver washed and cast into bars, which should contain over 99·9 per cent. of pure metal. The relatively electro-negative character of silver ensures that with moderate current densities no metal (other than precious metals) will be deposited with it; hence, while the solution is pure a current-density of 30 amperes per sq. ft. of cathode may be used, but as copper accumulates in it, the current density must be diminished to (say) 15 to 20 amperes per sq. ft., and a little extra nitric acid must be added, in order to prevent the co-deposition of copper. A pressure of 1·5 volt usually suffices when the space between the electrodes is 2 in. The tanks were arranged in groups of seven on the multiple system. Of the metals present in the anode, practically all, except gold, pass into solution but, under the right conditions, only silver should deposit. The whole of the gold is recovered as anode slime in cloth bags surrounding the anodes. Practical results with a large plant indicate an expenditure of 1·23 electrical horse-power hours per 100 oz. (Troy) of refined silver. In later installations, under the 1895 patent, the anodes are placed horizontally on a porous tray resting within the solution above an endless silver band revolving, also horizontally, over rollers placed near the ends of a long shallow tank. The revolving band forms the cathode, and at one end makes a rubbing contact with a travelling belt placed at an angle so that the crystals of silver detached thereby from the cathode are conveyed by it from the solution and deposited outside.

Alloy scrap containing chiefly copper with, say 5 or 6 per cent. of gold, and other metals, and up to 40 or 50 per cent. of silver, is often treated electrolytically. Obviously, with modifications, the Mœbius process could be applied. Other systems have been devised. Borchers uses the alloy, granulated, in an anode chamber separated from the cathode cell by a porous partition through which the current, but not electrolyte, can pass freely. The anode residue is collected in the angular bottom of the tank, the electrolyte passes from the anode chamber to a series of tanks in which the more electro-negative constituents (silver, &c.) are chemically separated, and thence to the cathode chamber, where the copper is deposited electrolytically, thence it passes again to the anode chamber and so completes the cycle. In one form of the apparatus a rotating cathode is used. Dietzel has described (*Zeitschrift für Elektrochem.*, 1899, vol. vi. p. 81) the working of his, somewhat similar, process at Pforzheim, where about 130 ℔ of the alloy were being treated by it daily in 1899. The alloy is cast into anode plates about ⅛ in. thick, and placed in the anode chamber beneath the cathode cell, and separated from it by linen cloth. In the upper compartment are two large revolving horizontal cathode cylinders. Acidified copper nitrate solution is run into this cell, copper is deposited, and the more or less spent solution then passes through the linen partition, and, taking up metal from the anodes by electrolytic solution, is run out of the trough through a series of vessels filled with copper by which the silver is precipitated by simple exchange; after acidification the resulting silver-free copper solution is returned to the cathode cell for the deposition of the copper, the solution being employed again and again until too impure for use.

Gold. Gold is left in the anode slime when copper or silver are refined by the usual processes, but if the gold preponderate in the anode these processes are inapplicable. A cyanide bath, as used in electroplating, would dissolve the gold, but is not suitable for refining, because other metals (silver, copper, &c.) passing with gold into the solution would deposit with it. Bock, however, in 1880 (*Berg- und Hüttenmännische Zeitung*, 1880, p. 411) described a process used at the North German Refinery in Hamburg for the refining of gold containing platinum with a small proportion of silver, lead, or bismuth, and a more recent patent specification (1896) and a paper by Wohlwill (*Zeitschrift f. Elektrochem.*, 1898, pp. 379, 402, 421) have thrown more light upon the process. The electrolyte is gold chloride (2·5-3 parts of pure gold per 100 of solution) mixed with from 2 to 6 per cent. of the strongest hydrochloric acid to render the gold anodes readily soluble, which they are not in the neutral chloride solution. The bath is used at 65° to 70° C. (150° to 158° F.), and if free chlorine be evolved, which is known at once by its pungent smell, the temperature is raised, or more acid is added, to promote the solubility of the gold. The bath is used with a current-density of 100 amperes per sq. ft. at 1 volt (or higher), with electrodes about 1·2 in. apart. In this process all the anode metals pass into solution except iridium and other refractory metals of that group, which remain as metals, and silver, which is converted into insoluble chloride; lead and bismuth form chloride and oxychloride respectively, and these dissolve until the bath is saturated with them, and then precipitate with the silver in the tank. But if the gold-strength of the bath be maintained, only gold is deposited at the cathode—in a loose powdery condition from pure solutions, but in a smooth detachable deposit from impure liquors. Under good conditions the gold should contain 99·98 per cent. of the pure metal. The tank is of porcelain or glazed earthenware, the electrodes for impure solutions are ½ in. apart (or more with pure solutions), and are on the multiple system, and the potential difference at the terminals of the bath is 1 volt. A high current-density being employed, the turn-over of gold is rapid—an essential factor of success when the costliness of the metal is taken into account. Platinum and palladium dissolved from the anode accumulate in the solution, and are removed at intervals of, say, a few months by chemical precipitation. It is essential that the bath should not contain more than 5 per cent. of palladium, or some of this metal will deposit with the gold. The slimes are treated chemically for the separation of the metals contained in them.

Many patents have been taken out for the electrolytic solution of gold from its ores; but the difficulty of extracting in this way so little, perhaps, as a fraction of an ounce of the metal from each ton of sand or other finely crushed material renders the problem an exceedingly difficult one. In some of the processes electrolytic chlorine is used, in some an attempt is made to render the gold particles anodes, whilst in others electrolysis is called in to aid the solvent power of mercury for the precious metal. It is unnecessary here to refer further to any of these. Electrolysis has, however, been successfully applied by Siemens and Halske to the recovery of gold from the potassium cyanide solutions now so largely employed to dissolve gold from ores and tailings. The solution of the double cyanide of gold and potassium formed by the action of potassium cyanide on gold in the presence of air is run off and washed from the ore, and is passed through a series of iron tanks, in which it is electrolysed between lead cathodes and iron anodes (which do not dissolve, although Prussian blue and other insoluble iron compounds are formed), with a current-density of about 0·04 to 0·06 amperes per sq. ft., at a pressure of about 4 volts. The lead cathodes with their adherent gold deposit are removed about once a month, and melted up, the gold being recovered by cupellation. Several modifications of the process have been proposed, *e.g.*, Andreoli uses lead peroxide anodes, and iron cathodes from which the gold is removed from time to time by a brief immersion in molten lead, and Cowper-Coles uses an aluminium cathode, from which the gold is readily stripped, being imperfectly adherent by reason of the film of oxide which always exists on the surface of aluminium.

Nickel. Thin deposits of nickel have long been obtained with readiness, but thick deposits are troublesome, as they tend to curl up and peel off the cathode surface. Cathode-nickel is now made both in England and in America, but the details of the process used have not been disclosed. Foerster (*Zeitschrift f. Elektrochem.*, 1897, vol. iv. p. 160) has, however, found that with a suitable current-density, using soluble nickel anodes and a neutral solution of nickel sulphate at 50°-90° C. (120°-200° F.), a perfect deposit of any desired thickness can be obtained. Thus with the electrodes 1·5 in. apart in a bath at 60° C. (140° F.) containing 1 ℔ of (metallic) nickel dissolved as sulphate per gallon, a current-density of 14·5-18·5 amperes per sq. ft., at 1-1·3 volt, gave a solid deposit ⅛ in. thick. Nickel chloride could be used, but less satisfactorily. Practically all the cobalt and iron present were deposited with the nickel, and this fact renders the problem of the continuous and direct electrolytic refining of nickel a very difficult one. According to the patent of Salve, iron, zinc, and cobalt can be separated electrolytically from nickel in solution by a process which necessitates intermittency and the use of insoluble anodes. André, Hoepfner, Ulke, and others have devised processes for the treatment of nickel ores, sulphides, or other compounds electrolytically.

Zinc. The deposition of pure zinc is beset with many difficulties. Zinc being more electro-positive even than nickel, all the heavy metals must be removed before its deposition is attempted. Moreover, unless the conditions are closely watched, it is liable to be thrown down in a spongy form. Kiliani found that the sponge was produced chiefly when a weak solution, or a low current-density, was used, and that hydrogen was usually evolved simultaneously; sound deposits resulted from the use of a current-density of 200 amperes, or more, per sq. ft., and strong solutions. The cause of the spongy deposit is variously explained, some (Siemens and Halske) ascribing it to the existence of a compound of zinc and hydrogen, and others, among whom are Nahnsen, Mylius and Fromm, Foerster and Borchers, trace it to the presence of oxide, produced, for example, either by the use of a solution containing a trace of basic salt of zinc (to prevent which the bath should be kept just—almost imperceptibly—acid), or by the presence of a more electro-negative metal, which, being co-deposited, sets up local action at the expense of the zinc. Many processes have been patented, the ore being acted upon by acid, and the resulting solution treated, by either chemical or electrolytic means, for the successive removal of the other heavy metals. The pure solution of zinc is then electrolysed. Ashcroft patented a process of dealing with complex ores of the well-known Broken Hill type, containing sulphides of silver, lead, and zinc, but the system was abandoned after a long trial on a practical scale. A full account of the process (*Trans. Inst. Min. and Met.*, 1898, vol. vi. p. 282) has been published by the inventor, describing the practical trial at the Cockle Creek Works. The ore was crushed, roasted, and leached with sulphuric acid (with or without ferric sulphate); the solution was purified and then electrolysed for zinc with lead anodes and with a current-density of 5 amperes per sq. ft. at 2·75 volts when diaphragms were used, or 2·5 volts when they were dispensed with, or with 10 amperes per sq. ft. at 3 or 2·5 volts respectively, the electrolyte containing 1·2 ℔ of zinc in the form of sulphate, and ½ to ¾ oz. of sulphuric acid, per gallon. The current efficiency was about 83 per cent. Canvas diaphragms were used to prevent the acid formed by electrolysis at the anode from mixing with the cathode liquor, and so hindering deposition. Hoepfner has patented several processes, in one of which (No. 13,336 of 1894) a rapidly rotating cathode is used in a chloride solution, a porous partition separating the tank into anode and cathode compartments, and the chlorine generated by electrolysis at the anode being recovered. Hoepfner's processes have been employed both in England and in Germany. Nahnsen's process, with an electrolyte containing alkali-metal sulphate and zinc sulphate, has been used in Germany, and a process invented by Dieffenbach has also been tried in that country. Siemens and Halske have proposed the addition of oxidizing agents such as free halogens, to prevent the formation of zinc hydride, to which they attribute the formation of zinc-sponge. Borchers and others deposit zinc from the fused chloride. In Borchers' process the chloride is heated partly by external firing partly by the heat generated owing to the use of a current-density of 90 to 100 amperes per sq. ft.

Lead and antimony. Keith electrolysed lead in an acetate solution, choosing this compound because, being organic and oxidizable in character, it prevents the formation of lead peroxide at the anode. It was tried, but its use appears to have been generally discontinued on a large scale. Tommasi has also introduced a process in which the acetates of lead and an alkali-metal are electrolysed. A certain amount of electrolytically refined antimony has been placed on the market. Siemens and Halske patented a process in which the antimony sulphide from the ore is dissolved in an alkaline sulphohydrate and electrolysed in a tank with two divisions, the anode compartment containing an alkaline chloride, and the cathode cell the antimony solution; in another process the antimony is deposited from the chloride. Borchers recommends the solution of the antimony sulphide in sodium sulphide, forming soluble sodium thio-antimonite; this solution is then electrolysed with iron electrodes, between which a pressure of about 2 volts produces a current-density of 9–14 amperes per sq. ft. at first. As the solution loses antimony by deposition, the current-density is reduced to 3·5–4 amperes per sq. ft. The antimony deposit from the sulphide process is loose, and therefore requires to be scraped off the cathode and fused together under a flux.

Electrotyping.—Reference should be made to the article Electro-Metallurgy, *Ency. Brit.*, 9th ed., vol. viii. In copying engraved plates for printing purposes, copper may be deposited upon the original plate, the surface of which is first rendered slightly dirty, by means of a weak solution of wax in turpentine or otherwise, to prevent adhesion. The reversed plate thus produced is then stripped from the first and used as cathode in its turn, with the result that even the finest lines of the original are faithfully reproduced. The electrolyte commonly contains about $1\frac{1}{2}$ lb of copper sulphate and $\frac{1}{2}$ lb of strong sulphuric acid per gallon, and is worked with a current-density of about 10 amperes per sq. ft., which should give a thickness of 0·000563 in. of copper per hour. As time is an object, the conditions alluded to under the head of copper refining as being favourable to the use of high current-densities should be studied, bearing in mind that a tough copper deposit of high quality is essential. Moulds for reproducing plates or art-work are often taken in plaster, beeswax mixed with Venice turpentine, fusible metal, or gutta-percha, and the surface being rendered conductive by powdered black-lead, copper is deposited upon it evenly throughout. The details of these processes may be found in the text-books referred to at the end of this article. For statuary, and "undercut" work generally, an elastic mould—of glue and treacle (80 : 20 parts)—may be used; the mould, when set, is waterproofed by immersion in a bichromate solution followed by exposure to sunlight, or in some other way. The best results, however, are obtained by taking a wax cast from the elastic mould, and then from this a plaster mould, which may be waterproofed with wax, black-leaded, and used as cathode. In art-work of this nature the principal points to be looked to in depositing are the electrical connexions to the cathode, the shape of the anode (to secure uniformity of deposition), the circulation of the electrolyte, and, in some cases, the means for escape of anode oxygen. Silver electrotyping is occasionally resorted to for special purposes.

Electroplating. — As the durability of the electro-deposited coat on plated wares of all kinds is of the utmost importance, the greatest care must be taken to ensure its complete adhesion. This can only be effected if the surface of the metal on which the deposit is to be made is chemically clean, and the cleansing processes referred to in the article Electro-Metallurgy (*Ency. Brit.*, 9th ed.) must be rigorously applied. Grease must be removed by potash, whiting, or other means, and tarnish by acid or potassium cyanide, washing in plenty of water being resorted to after each operation. The vats for depositing may be of enamelled iron, slate, glazed earthenware, glass, lead-lined wood, &c. The current-densities and potential differences frequently used for some of the commoner metals are given in the following table, taken from M'Millan's *Treatise on Electro-Metallurgy*. It must be remembered, however, that variations in conditions modify the electromotive force required for any given process. For example, a rise in temperature of the bath causes an increase in its conductivity, so that a lower E.M.F. will suffice to give the required current-density; on the other hand, an abnormally great distance between the electrodes, or a diminution in acidity of an acid bath, or in the strength of the solution used, will increase the resistance, and so require the application of a higher E.M.F.

Metal.	Amperes.		Volts between Anode and Cathode.
	Per Sq. Decimetre of Cathode Surface.	Per Sq. In. of Cathode Surface.

Large objects are suspended in the tanks by hooks or wires, care being taken to shift their position and so avoid wire-marks. Small objects are often heaped together in perforated trays or ladles, the cathode connecting-rod being buried in the midst of them. These require constant shifting because the objects are in contact at many points, and because the top ones shield those below from the depositing action of the current. Hence processes have been patented in which the objects to be plated are suspended in revolving drums between the anodes, the rotation of the drum causing the constant renewal of surfaces and affording a burnishing action at the same time. Care must be taken not to expose goods in the plating-bath to too high a current-density, else they may be "burnt"; they must never be exposed one at a time to the full anode surface, with the current flowing in an empty bath, but either one piece at a time should be replaced, or some of the anodes should be transferred temporarily to the place of the cathodes, in order to distribute the current over a sufficient cathode-area. Burnt deposits are dark coloured, or even pulverulent, and useless. The strength of the current may also be regulated by introducing lengths of German silver or iron wire, carbon rod, or other inferior conductors in the path of the current, and a series of such resistances should always be provided close to the tanks. Ammeters to measure the volume, and voltmeters to determine the pressure of current supplied to the baths, should also be provided. Very irregular surfaces may require the use of specially shaped anodes in order that the distance between the electrodes may be fairly uniform, otherwise the portion of the cathode lying nearest to the anode may receive an undue share of the current, and therefore a greater thickness of coat. Supplementary anodes are sometimes used in difficult cases of this kind. Large metallic surfaces (especially external surfaces) are sometimes plated by means of a "doctor," which, in its simplest form, is a brush constantly wetted with the electrolyte, with a wire anode buried amid the hairs or bristles; this brush is painted slowly over the surface of the metal to be coated, which must be connected to the negative terminal of the electrical generator. Under these conditions electrolysis of the solution in the brush takes place. Iron ships' plates have recently been coated with copper in sections (to prevent the adhesion of barnacles), by building up a temporary trough against the side of the ship, making the thoroughly cleansed plate act both as cathode and as one side of the trough. Decorative plating-work in several colours (*e.g.*, "parcel-gilding") is effected by painting a portion of an object with a stopping-out (*i.e.*, a non-conducting) varnish, such as copal varnish, so that this portion is not coated. The varnish is then removed, a different design stopped out, and another metal deposited. By varying this process, designs in metals of different colours may readily be obtained.

Reference must be made to ELECTRO-METALLURGY (*Ency. Brit.*, 9th ed.) for a slight indication of the solutions commonly used, and to the text-books (see the end of this article) for a fuller account of the very varied solutions and methods employed for electroplating with silver, gold, copper, iron, and nickel. It should be mentioned here, however, that solutions which would deposit their metal on any object by simple immersion should not be generally used for electroplating that object, as the resulting deposit is usually non-adhesive. For this reason the acid copper-bath is not used for iron or zinc objects, a bath containing copper cyanide or oxide dissolved in potassium cyanide being substituted. This solution, being an inferior conductor of electricity, requires a much higher electromotive force to drive the current through it, and is therefore more costly in use. It is, however, commonly employed hot, whereby its resistance is reduced. *Zinc* is now commonly deposited by electrolysis on iron or steel goods which would ordinarily be "galvanized," but which for any reason may not conveniently be treated by the method of immersion in fused zinc. The zinc cyanide bath may be used for small objects, but for heavy goods the sulphate bath is employed. Cowper-Coles has patented a process in which, working with a high current-density, a lead anode is used, and powdered zinc is kept suspended in the solution to maintain the proportion of zinc in the electrolyte, and so to guard against the gradual acidification of the bath. *Cobalt* is deposited by a method analogous to that used for its sister-metal nickel. *Platinum*, *palladium*, and *tin* are occasionally deposited for special purposes. In the deposition of *gold* the colour of the deposit is influenced by the presence of impurities in the solution; when copper is present, some is deposited with the gold, imparting to it a reddish colour, whilst a little silver gives it a greenish shade. Thus so-called coloured-gold deposits may be produced by the judicious introduction of suitable impurities. Even pure gold, it may be noted, is darker or lighter in colour according as a stronger or a weaker current is used. The electro-deposition of *brass*—mainly on iron ware, such as bedstead tubes—is now very widely practised, the bath employed being a mixture of copper, zinc, and potassium cyanides, the proportions of which vary according to the character of the brass required, and to the mode of treatment. The colour depends in part upon the proportion of copper and zinc, and in part upon the current-density, weaker currents tending to produce a redder or yellower metal. Other alloys may be produced, such as bronze, or German silver, by selecting solutions (usually cyanides) from which the current is able to deposit the constituent metals simultaneously.

Electrolysis has in a few instances been applied to processes of manufacture. For example, Wilde produced copper printing surfaces for calico printing-rollers and the like by immersing rotating iron cylinders as cathodes in a copper bath. Elmore, Dumoulin, Cowper-Coles, and others have prepared copper cylinders and plates by depositing copper on rotating mandrels with special arrangements, to which allusion has already been made. Others have arranged a means of obtaining high conductivity wire from cathode-copper without fusion, by depositing the metal in the form of a spiral strip on a cylinder, the strip being subsequently drawn down in the usual way; at present, however, the ordinary methods of wire-production are found to be cheaper. Swan (*Journ. Inst. Elec. Eng.*, 1898, vol. xxvii. p. 16) also worked out, but did not proceed with, a process in which a copper wire whilst receiving a deposit of copper was continuously passed through the draw-plate, and thus indefinitely extended in length. Cowper-Coles (*Journ. Inst. Elec. Eng.*, 1898, vol. xxvii. p. 99) has very successfully produced true parabolic reflectors for projectors, by depositing copper upon carefully ground and polished glass surfaces rendered conductive by a film of deposited silver.

Electrolytic Manufacture of Chemical Products.—When aqueous solution of the salt of an alkali-metal is electrolysed, the metal reacts with the water, as is well known, forming caustic alkali, which dissolves in the solution, and hydrogen, which comes off as a gas. So early as 1851 a patent was taken out by Cooke for the production of caustic alkali without the use of a separate current, by immersing iron and copper plates on opposite sides of a porous (biscuit-ware) partition in a suitable cell, containing a solution of the salt to be electrolysed, at 21°–65° C. (70°–150° F.). The solution of the iron anode was intended to afford the necessary energy. In the same year another patent was granted to C. Watt for a similar process, involving the employment of an externally generated current. When an alkaline chloride, say sodium chloride, is electrolysed with one electrode immersed in a porous cell, while caustic soda is formed at the cathode, chlorine is deposited at the anode. If the latter be insoluble, the gas diffuses into the solution and, when this becomes saturated, escapes into the air. If, however, no porous division be used to prevent the intermingling by diffusion of the anode and cathode solutions, a complicated set of subsidiary reactions takes place. The chlorine reacts with the caustic soda, forming sodium hypochlorite, and this in turn, with an excess of chlorine and at higher temperatures, becomes for the most part converted into chlorate, whilst any simultaneous electrolysis of a hydroxide or water and a chloride (so that hydroxyl and chlorine are simultaneously liberated at the anode) also produces oxygen-chlorine compounds direct. At the same time, the diffusion of these compounds into contact with the cathode leads to a partial reduction to chloride, by the removal of combined oxygen by the instrumentality of the hydrogen there evolved. In proportion as the original chloride is thus reproduced, the efficiency of the process is of course diminished. It is obvious that, with suitable methods and apparatus, the electrolysis of alkaline chlorides may be made to yield chlorine, hypochlorites (bleaching liquors), chlorates, or caustic alkali, but that great care must be exercised if any of these products is to be obtained pure and with economy. Many patents have been taken out in this branch of electro-chemistry, but it is to be remarked that that granted to C. Watt traversed the whole of the ground. In his process a current was passed through a tank divided into two or three cells by porous partitions, hoods and tubes were arranged to carry off chlorine and hydrogen respectively, and the whole was heated to 120° F. by a steam jacket when caustic alkali was being made. Hypochlorites were made, at ordinary temperatures, and chlorates at higher temperatures, in a cell without a partition in which the cathode was placed horizontally immediately above the anode, to favour the mixing of the ascending chlorine with the descending caustic solution.

The relation between the composition of the electrolyte and the various conditions of current-density, temperature, and the like has been studied by Oettel (*Zeitschrift f. Elektrochem.*, 1894, vol. i. pp. 354 and 474) in connexion with the production of hypochlorites and chlorates in tanks without diaphragms, by Häussermann and Naschold (*Chemiker Zeitung*, 1894, vol. xviii. p. 857) for their production in cells with porous diaphragms, and by Haber and Grinberg (*Zeitschrift f. anorgan. Chem.*, 1898, vol. xvi. pp. 198, 329, 438) in connexion with the electrolysis of hydrochloric acid. Oettel, using a 20 per cent. solution of potassium chloride, obtained the best yield of hypochlorite with a high current-density, but as soon as 1¼ per cent. of bleaching chlorine (as hypochlorite) was present, the formation of chlorate commenced. The yield was at best very low as compared with that theoretically possible. The best yield of chlorate was obtained when from 1 to 4 per cent. of caustic potash was present. With high current-density, heating the solution tended to increase the proportion of chlorate to hypochlorite, but as the proportion of water decomposed is then higher, the amount of chlorine produced must be less and the total chlorine efficiency lower. He also traced a connexion between alkalinity, temperature, and current-density, and showed that these conditions should be mutually adjusted. With a current-density of 130–140 amperes per sq. ft., at 3 volts, passing between platinum electrodes, he attained to a current-efficiency of 52 per cent., and each (British) electrical horse-power hour was equivalent to a production of 1378·5 grains of potassium chlorate. In other words, each pound of chlorate would require an expenditure of nearly 5·1 E.H.P. hours One of the earliest of the more modern processes was that of Hermite, which consisted in the production of bleach-liquors by the electrolysis (according to the 1st edition of the 1884 patent) of magnesium or calcium chloride between platinum anodes carried in wooden frames, and zinc cathodes. The solution, containing hypochlorites and chlorates, was then applied to the bleaching of linen, paper-pulp, or the like, the solution being used over and over again. Many modifications have been patented by Hermite, one of the latest (1895) specifying the use of platinum gauze anodes, held in ebonite or other frames. Rotating zinc cathodes were used, with scrapers to prevent the accumulation of a layer of insoluble magnesium compounds, which would otherwise increase the electrical resistance beyond reasonable limits. The same inventor has patented the application of electrolysed chlorides to the purification of starch by the oxidation of less stable organic bodies, to the bleaching of oils, and to the purification of coal gas, spirit, and other substances. His system for the disinfection of sewage and similar matter by the electrolysis of chlorides, or of sea-water, has been tried, but for the most part abandoned on the score of expense. Reference may be made to papers written in the early days of the process by Cross and Bevan (*Journ. Soc. Chem. Industry*, 1887, vol. vi. p. 170, and 1888, vol. vii. p. 292), and to later papers by Schoop (*Zeitschrift f. Elektrochem.*, 1895, vol. ii. pp. 68, 88, 107, 209, 289).

Kellner, who in 1886 patented the use of cathode (caustic soda) and anode (chlorine) liquors in the manufacture of cellulose from wood-fibre, and has since evolved many similar processes, has produced an apparatus that has been largely used. It consists of a stoneware tank with a thin sheet of platinum-iridium alloy at either end forming the primary electrodes, and between them a number of glass plates reaching nearly to the bottom, each having a platinum gauze sheet on either side; the two sheets belonging to each plate are in metallic connexion, but insulated from all the others, and form intermediary or bi-polar electrodes. A 10–12 per cent. solution of sodium chloride is caused to flow upwards through the apparatus and to overflow into troughs, by which it is conveyed (if necessary through a cooling apparatus) back to the circulating pump. Such a plant has been reported as giving 0·229 gallon of a liquor containing 1 per cent. of available chlorine per kilowatt hour, or 0·171 gallon per E.H.P. hour. Kellner has also patented a "bleaching-block," as he terms it, consisting of a frame carrying parallel plates similar in principle to those last described. The block is immersed in the solution to be bleached, and may be lifted in or out as required. Knöfler and Gebauer have also a system of bi-polar electrodes, mounted in a frame in appearance resembling a filter-press.

Chlorate manufacture.

It is estimated that fully two-thirds of the annual production of chlorate is obtained by electrolytic methods. The experiments of Oettel and those of Häussermann and Naschold, above referred to, showed that the best results were obtained when the (anode) solution was maintained slightly alkaline throughout. The electrolyte should also be at a temperature of 70°–80° C. (160°–180° F.), as a better yield of chloride is then obtained; the current-density should also be high. Häussermann and Naschold, with a current-density of 31 amperes per sq. ft. of platinum anode surface (at 4 volts), obtained on a small scale a yield of 7·7 grains of chlorate per ampere hour, or a current-efficiency of 67 per cent. Oettel obtained about 52 per cent. in practice. These numbers are equivalent to an expenditure of 4·77, and 5·07, E.H.P. hours respectively, per pound of chlorate. In the practical working of the process, platinum or carbon electrodes were commonly employed. Platinum, however, is liable to become slowly attached when used as anode with chlorine, deposition taking place at its surface, although the action is far less with neutral chlorides than with hydrochloric acid as electrolyte, and carbon is subject to rapid disintegration unless the pores can be filled up, or a very dense form of it, such as graphite, be used. An alloy containing 90 per cent. of platinum and 10 of iridium is very largely employed, on account of its high power of resisting the attack of anode chlorine; and many other anode materials have been suggested for various purposes, among them being ferrosilicon, chromium phosphide, and lead peroxide. The Gall and Montlaur process is that most commonly used at the large Continental works. At Vallorbes, in Switzerland, 3000 H.P. were being consumed in this industry so far back as 1891. Here a 25 per cent. solution of potassium chloride was electrolysed in 270 rectangular lead-lined tanks, each holding 1765 cb. ft. of liquid, with thin (0·1 mm.) platinum-iridium anodes and iron cathodes, with a porous diaphragm between. The current-density was 460 amperes per sq. ft., and the pressure required to force this current through the liquid and diaphragm was 5 volts, the temperature of the bath being 45°–55° C. (115°–130° F.). The anode and cathode solutions were kept distinct, each having its own system of circulation. Potassium chlorate is far less soluble than the chloride, and the liquid rapidly becomes saturated with it; from this period, onward, the chlorate crystallizes out as fast as it is formed, and may be removed in the solid form for recrystallization for the market; meanwhile fresh chloride is constantly introduced, to take the place of that which has been converted into chlorate. At the St Michael Works in the Rhone Valley (France) the same process is employed, but the cathodes are of ferronickel covered by asbestos cloth. It is believed by Kershaw (*Elec. Review*, 1898, vol. xliii. p. 791) that the use of diaphragms has now been abandoned.

Alkali manufacture.

In any process by which it is attempted to utilize the caustic alkali produced at the cathode in the electrolysis of sodium chloride, it is obvious that the chlorine from the anode must be prevented from coming in contact with the cathode solution. Porous partitions have naturally been largely used in many electrolytic alkali processes; but they are costly, inasmuch as they entail the expenditure of electromotive force to urge the current through them and require more or less frequent renewal. Being subject to the action of caustic alkali on the one side, and of chlorine and hypochlorites on the other, it is not easy to find a substance of low electrical resistance that is able chemically to withstand the influence of both classes of corrosive. Moreover, no suitable porous partition yet found can entirely prevent intermingling of solutions and, therefore, loss.

Cooke and Watt were the first to patent electrolytic alkali manufacture, but before the invention of the dynamo no such process could compete economically with the existing chemical methods. Fitzgerald and Molloy patented a process in 1872; and Marx in 1887, in the first of a series of patents, protected the use of carbon dioxide gas in the electrolytic cell to precipitate sodium bicarbonate from the caustic soda solution formed by the electrolysis of common salt solutions, and so to remove it from the influence of chlorine. The principal processes lately in use on a practical scale, some of them still on their trial, are the Kellner, Castner-Kellner (now very extensively employed), the Hargreaves-Bird, the Richardson and Holland, the Le Sueur and the Hulin process. Of these, Richardson and Holland avoided the use of porous partitions by separating the anode and cathode compartments by a non-porous wall reaching above the top, but not down to the bottom, of the cell, so that electrolytic conduction could take place freely between the electrodes through the medium of the liquid beneath the division, yet the chlorine gas would for the most part escape upwards from the anode, and the hydrogen liberated at the cathode was depended upon to carry upwards the caustic alkali produced in the cathode cell. Obviously by this process it would be difficult entirely to prevent diffusion and also to obtain a caustic alkali free from admixture with the original chloride electrolyte. In another patent, open to the same objections, the same inventors protected the use of copper-oxide cathodes placed horizontally beneath the anodes; here the oxide would be reduced by the electrolytic hydrogen, and the caustic alkali formed would sink downwards from the electrode. This process has been used in paper-mills. In the Hargreaves-Bird apparatus (of which the first British patent was No. 18,039 of 1892) a combined porous cell and cathode is used; the cathode itself is of wire gauze, which is covered with a mixture of lime and asbestos dipped into a solution of silicate of soda, after drying, in order to bind the material together; the whole is then dried again. According to a later specification, a layer of Portland cement is

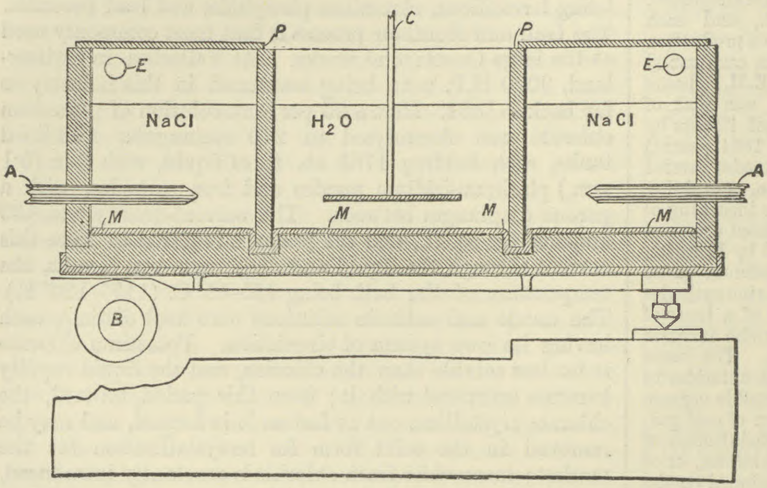

Fig. 1.

introduced between the gauze and the asbestos lime mixture, and means are taken to prevent the gauze being in absolute contact with the cement. There results a thin sheet, which forms one side of the electrolytic cell, the gauze being outwards. Electrolysis of the sodium chloride takes place as usual, the electrolyte passes, by osmosis, through the partition to the gauze, sodium is there deposited and, with the water present, forms caustic soda, which is washed away by a spray of water, the hydrogen liberated in the reaction escaping. If necessary, the caustic soda may be carbonated by bringing carbon dioxide into contact with the gauze during electrolysis. Hulin, in an early process, proposed to use a porous carbon cathode through which the solution filtered, the rate of flow being so adjusted that the whole of the salt was decomposed and only solution of cathode alkali escaped. Obviously, however, such regulation would be exceedingly difficult. In the Le Sueur process, which has been for some time used in certain American works, a porous division is used, and the liquid in the anode compartment is said to be maintained at a higher level than in the cathode cell, in order to lessen the loss by diffusion of alkaline liquid from the latter to the former. In Le Sueur's 1891 patent, it is provided that hydrochloric acid shall be added to the anode liquid to neutralize any caustic soda that may diffuse through.

Kellner has taken out many patents. In one of them a mercury cathode is used, which dissolves the sodium deposited, forming an amalgam that, on exposure to water, gives up its alkali and leaves a solution of caustic soda. Almost simultaneously Castner also patented a mercury process, which in its modified form is now in constant use. The tank, of which the principle is illustrated in Fig 1, may be 6 ft. long by 3 ft. wide by 3 in. deep, and is divided by vertical partitions P P (impervious to water) into three compartments. The whole of the floor is covered with a layer of mercury M, and beneath each partition a groove is cut in the bottom of the tank to allow mercury to flow between the compartments. It is essential, however, that at all times this passage should be filled with mercury, which acts as a seal, effectually preventing any interchange of solutions between the compartments. The cell is kept at a constant level at one end, but at the other end is alternately raised and depressed through a very small space by means of the cam B, so that a slight rocking motion is given, causing the mercury to flow gently to and fro without at any moment leaving space for the electrolyte to pass under the partitions. In each end compartment is a carbon anode A, placed horizontally just above the surface of the mercury, and beneath the level of a 20 per cent. solution of sodium chloride (NaCl); these compartments are covered, and are provided with pipes E to carry off the anode-chlorine. The middle compartment contains an iron cathode C immersed in water (H_2O), and is open above. Means are provided for the circulation of the anode liquors and to replenish them with salt; the cathode solution may be drawn off at will. In operation the current flows from the anode, where it deposits chlorine (ultimately given off in the gaseous form), through the sodium chloride solution to the mercury layer in the outer compartments, and thence by metallic conduction to the mercury in the centre compartment, and from this through the water to the cathode, where hydrogen is evolved. Thus the mercury forms an intermediary, bi-polar electrode, acting as cathode in the outer and as anode in the inner division. The sodium deposited on the mercury in the outer cells is at once dissolved, forming an amalgam. The amalgam-laden mercury mixes by the rocking action with the mercury in the inner cell, and there (being an anode) passes into the water, forming caustic soda. A current of 550 amperes and 4 volts per cell has been employed. No chlorine or chloride can escape into the cathode cell, and the caustic alkali may therefore contain 99½ per cent. of pure sodium hydroxide. A certain amount of energy-loss is inevitable, owing to the recombination of a little of the sodium dissolved in the mercury in the outer cells with chlorine, and with oxygen from the water (the chlorine contains commonly 3 to 5 per cent. of hydrogen, indicating that some water is attacked). But the constant flux of the mercury and loss of sodium in the inner cell should keep down the quantity of sodium in the mercury to about 0·02 per cent., so that the loss due to this cause is minimized. The same mercury is used constantly, and as it need not suffer appreciable loss, and only a thin layer is required, it does not add greatly to the cost of the process, one of the great recommendations of which is that a strong solution of a pure soda may be readily produced. In the Hulin process a furnace method is employed, molten lead being used as cathode, and carbon as anode, in a bath of fused lead and sodium chlorides, with a current-density of about 700 amperes per sq. ft. A rich alloy of sodium with lead is deposited. This is cast into plates and, on cooling, treated with water, whereby the sodium contained in it dissolves, forming caustic soda.

The following table, calculated into British units from Kershaw's account (*Engineering and Mining Journal*, 1899, vol. lxvii. p. 497) of the Hulin process at Clavaux, shows the comparative efficiencies of these processes from published data, the term current-efficiency showing the proportion of the actual yield per coulomb actually obtained, and the energy-efficiency the proportion use-

	Process.	E.M.F. required in Volts.	Actual Yield. Per Amp. Hr. in Grains. NaOH.	Per Amp. Hr. in Grains. Cl.	Per Kw-Hr. in lb. NaOH.	Per Kw-Hr. in lb. Cl.	Approx. H.P. Hrs. per Ton of Pure NaOH.	Approx. H.P. Hrs. per Ton of 70% Caustic Soda.	Efficiency per cent. Current.	Efficiency per cent. Energy.
Wet Processes	Hargreaves-Bird .	3·4	18·46	16·31	0·77	0·68	3880	3500	80	54

	Theoretical Figures .	4·2	23·07	20·40	0·78	0·69	3825	3450	100	100

fully applied of the energy theoretically necessary. The relatively low efficiency of the Hulin (dry) process is, to some extent, compensated for by the high current-density used, and by consequent rapidity of working.

It is obvious that electrolytic *iodine* and *bromine*, and oxygen compounds of these elements, may be produced by methods similar to those last described, and Kellner and others have patented processes with this end in view.

Hydrogen and *oxygen* may also be produced electrolytically as gases, and their respective reducing and oxidizing powers at the moment of deposition on the electrode are frequently used in the laboratory, and to some extent industrially, chiefly in the field of organic chemistry. Similarly, the formation of organic halogen products may be effected by electrolytic chlorine, as, for example, in the production of *chloral* by the gradual introduction of alcohol into an anode cell in which the electrolyte is a strong solution of potassium chloride. Again, anode reactions, such as are observed in the electrolysis of the fatty acids, may be utilized, as, for example, when the radical CH_3CO_2O—deposited at the anode in the electrolysis of acetic acid—is dissociated, two of the groups react to give one molecule of *ethane*, C_2H_6, and two of carbon dioxide. This, which has long been recognized as a class-reaction, is obviously capable of endless variation. Many electrolytic methods have been proposed for the purification of *sugar*; in some of them soluble anodes are used for a few minutes in weak alkaline solutions, so that the caustic alkali from the cathode reaction may precipitate chemically the hydroxide of the anode metal dissolved in the liquid, the precipitate carrying with it mechanically some of the impurities present, and thus clarifying the solution. In others the current is applied for a longer time to the original sugar-solution with insoluble (*e.g.*, carbon) anodes. Peters has found that with these methods the best results are obtained when ozone is employed in addition to electrolytic oxygen. Use has been made of electrolysis in *tanning* operations, the current being passed through the tan-liquors containing the hides. The current, by endosmosis, favours the passage of the solution into the hide-substance, and at the same time appears to assist the chemical combinations there occurring; hence a great reduction in the time required for the completion of the process. Many patents have been taken out in this direction, one of the best known being that of Groth, experimented upon by Rideal and Trotter (*Journ. Soc. Chem. Indust.*, 1891, vol. x. p. 425), who employed copper anodes, 4 sq. ft. in area, with current-densities of 0·375 to 1 (ranging in some cases to 7·5) ampere per sq. ft., the best results being obtained with the smaller current-densities. Electro-chemical processes are often indirectly used, as for example in the Villon process (*Elec. Rev.*, New York, 1899, vol. xxxv. p. 375) applied in Russia to the manufacture of *alcohol*, by a series of chemical reactions starting from the production of acetylene by the action of water upon calcium carbide. The production of *ozone* in small quantities during electrolysis, and by the so-called silent discharge, has long been known, and the Siemens induction tube has been devoloped for use industrially. The Siemens and Halske ozonizer, in form somewhat resembling the old laboratory instrument, is largely used in Germany; working with an alternating current transformed up to 6500 volts, it has been found to give 280 grains or more of ozone per E.H.P. hour. Andreoli (whose first British ozone-patent was No. 17,426 of 1891) uses flat aluminium plates and points, and working with an alternating current of 3000 volts is said to have obtained 1440 grains per E.H.P. hour. Yarnold's process, using corrugated glass plates coated on one side with gold or other metal leaf, is stated to have yielded as much as 2700 grains per E.H.P. hour. The ozone so prepared has numerous uses, as, for example, in bleaching oils, waxes, fabrics, &c., sterilizing drinking-water, maturing wines, cleansing foul beer-casks, oxidizing oil, and in the manufacture of vanillin.

Other electro-chemical processes.

(W. G. M.)

Electromagnet.—The technical applications of electricity and magnetism depend to a very large extent upon the employment of electromagnets.

Iron and other ferromagnetic materials, such as steel, cobalt, nickel, and some of their mixtures, alloys, and oxides, can be thrown into a state in which they are said to be magnetized (see Magnetism). This magnetization may be more or less permanent, as in the case of an ordinary hardened steel magnet or the natural magnetized material *Magnetite*, or it may be temporary and due to the continual action on the iron or ferromagnetic material of magnetic force arising from the proximity of a conductor conveying an electric current. The term electromagnet is generally employed to describe an arrangement in which a core of iron of some kind is surrounded with coils of insulated wire which create in and around it a magnetic force when they are traversed by an electric current.

Magnetic force is defined as the cause, whatever its nature, which produces or changes the state called *magnetization*. In the neighbourhood of every polar magnet, and also every conductor conveying an electric current, there is a distribution of magnetic force. If a piece of soft iron or any ferromagnetic substance is placed in this region it becomes magnetized, and its magnetization may be in part or entirely retained when the magnetizing force is withdrawn. If the magnetizing force arises from the presence of an electric current in the neighbourhood, and if the ferromagnetic material which is in its field is a piece of annealed or wrought-iron, then the persistence of the magnetization of the iron will be largely dependent upon the presence of the current in the conductor. If the iron is of such a form that the lines of magnetization are entirely closed lines, the arrangement constitutes a poleless electromagnet. Such a magnet may be realised in practice by closely winding insulated copper wire uniformly round an iron ring. If, on the other hand, the coils embrace an iron bar not forming a closed circuit, then the arrangement will constitute a polar electromagnet.

Magnetization.

It is essential to distinguish between the mere retentivity and the power of preserving magnetization against demagnetizing influences, called the coercivity. Pure annealed or soft iron can retain 90 per cent. or more of the magnetization it acquires under the influence of a strong magnetizing force when the force is removed, but the magnetization so retained is held very lightly, and even a slight knock or twist or any form of mechanical shock is sufficient to deprive the iron of nearly all its magnetization if it is in the form of a short bar. On the other hand, hardened high carbon steel, though not able to acquire such a high degree of magnetization under the action of a given magnetizing force, retains it with much greater tenacity, and a much stronger reverse magnetized force is required to demagnetize the steel than is the case with soft iron. Steel containing tungsten possesses a large coercivity.

Whatever may be the material which is thrown into a state of magnetization, if the lines of magnetization terminate anywhere on the surface they give rise to magnetic poles. These points or regions are themselves sources of magnetic force. If a uniformly magnetized magnetic filament has everywhere a section S, and if its magnetization is denoted by I, the product IS is called the *magnetic strength* of the filament, and this product is also a measure of the *strength of the pole* of the filament. If a ferromagnetic body is magnetized so that its lines of magnetization are self-closed lines, it is also said to form a complete or *closed magnetic circuit.* If, on the other hand, they are not self-closed, the magnetic circuit is called an *open magnetic circuit.* Abrupt or gradual changes in the magnetization along the circuit create in the magnetic circuit (even if closed) polar regions from which magnetic force proceeds.

The most simple and direct method of estimating the condition of a substance as regards magnetization in the case of open magnet circuits or linear magnets is to measure the magnetic force at some assigned position outside the magnetic body, where in virtue of the presence of free poles a production of magnetic force takes place. The magnetic force at any point can be estimated as regards magnitude by its mechanical action on another movable magnetic pole or polar magnet. This is called the magnetometric method.

So far we have directed consideration only to two magnetic quantities, namely, magnetization and magnetic force, but at this stage a third magnetic vector claims attention. If in front of the pole of a polar magnet a loop of insulated wire of one turn, and connected to a galvanometer, is held with its plane normal to the field, and the loop then snatched away, this circuit becomes the seat of an electromotive force which creates an induced electric current in the loop. The induced electromotive force is proportional to the time-rate of change of the surface integral of the magnetic force integrated all over the area of the loop, and hence the time-integral of the induced current, multiplied by the value of the resistance of the loop circuit, must be equal to the value of this surface integral of the normal magnetic force. The quantity so measured is now generally called the *magnetic flux*, but also denominated the *total magnetic induction*, or *total number of lines of force perforating through the loop.* We find that if a loop is held in front of the pole of a polar magnet and snatched away, the electromotive force set up in it is in the same direction as if the loop were placed like a girdle closely round the centre of the bar magnet and then suddenly drawn off, all other circumstances remaining the same. This experiment is sufficient to show that the vector with which we are here concerned is not identical with that properly called the magnetic force, since in a permanent straight steel bar magnet, when not in the neighbourhood of other magnets or electric currents, the magnetic force in the interior of the bar is in the opposite direction to the magnetic force just outside either of its poles.

Magnetic flux.

The quantity, therefore, measured by the time-integral of this induced current is a definite physical quantity, and in this article will be called *the magnetic flux.* The flux, through a unit of surface normal to the direction of the flux, is called *the flux density*, and is denoted by B. It is called by Maxwell and other writers following him the *induction*, or the *number of lines of force per square centimetre.* It is essential, however, to notice that the exploring loop used in the above manner measures a magnetic vector quantity which is not to be confused with the magnetic force. In the region outside the polar magnet the flux in the space and the magnetic force have the same direction, and as there is nothing to distinguish them they may be assumed to have the same magnitude. Inside the magnet, however, the flux and the force have not the same magnitude, and not always the same direction. The flux through any area may, however, always be evaluated by the time-integral of the current set up in a conducting loop placed in that locality with its plane normal to the direction of the flux when the flux is suppressed, or the loop suddenly removed. The flux is a quantity which, mathematically considered, is circuital. Its direction may be delineated by lines of flux, and every line of flux is a self-closed line.

The quantity called B is more important than I from an electro-technical point of view, because the chief practical use of magnets or electromagnets is to create in conductive circuits an electromotive force by varying the magnetic flux linked with them. This effect depends upon the variation of the total flux linked with the conductive circuit. The ratio of B to H is denoted by μ, and is called the magnetic *permeability* of the material corresponding to that particular flux density. The permeability is a function of the flux density, and varies with it. Corresponding to a certain value of the flux density, μ has a maximum value. The relation of B and H and B and μ are best represented by two curves called respectively the *flux-density curve* and the *permeability curve* (see Figs. 2 and 3). We may also in the same manner set out in the form of a curve the relation of the magnetization I to the magnetizing force H, and the ratio of I to H, which is called the susceptibility (k) of the material.

An immense number of observations have been carried out of late years on the permeability and susceptibility of different forms of iron and steel, and in the following tables are given some typical results, mostly from experiments made by Ewing (see *Proc. Inst. C. E.* vol. cxxvi.), in which the ballistic method has been employed to determine the flux density corresponding to various magnetizing forces acting upon samples of iron and steel in the form of rings. The samples were prepared and furnished by various manufacturers of iron and steel, and may be taken as typical of the materials which are at present (1899) in demand for the construction of cores of electromagnets of different kinds.

TABLE I.—*Magnetic Flux Density corresponding to various Magnetizing Forces in the case of certain Samples of Iron and Steel (Ewing).*

Magnetizing Force H (C.G.S. Units).	Magnetic Flux Density B (C.G.S. units).

The figures under heading I. are values given in a paper by Messrs Lydall and Pocklington (*Proc. Roy. Soc.* vol. ii. p. 228) as the results of a magnetic test of an exceptionally pure iron supplied for the purpose of experiment by Colonel Dyer, of the Elswick Works. The substances other than iron in this sample were stated to be: carbon, *trace;* silicon, *trace;* phosphorus, *none;* sulphur, 0·013 per cent.; manganese, 0·1 per cent. The other five specimens, II. to VI., are samples of commercial iron or steel. No. II. is a sample of Low Moor bar iron forged into a ring, annealed, and turned. No. III. is a steel forging furnished by Mr R. Jenkins as a sample of forged ingot-metal for dynamo magnets. No. IV. is a steel casting for dynamo magnets, unforged, made by Messrs Edgar Allen and Company by a special pneumatic process under the patents of Mr A. Tropenas. No. V. is also an unforged steel casting for dynamo magnets, made by Messrs Samuel Osborne and Company by the Siemens process. No. VI. is also an unforged steel casting for dynamo magnets, made by Messrs Fried. Krupp, of Essen.

It will be seen from the figures and the description of the materials that the steel forgings and castings have a remarkably high permeability under small magnetizing force.

Table II. shows the magnetic qualities of some of these materials as found by Ewing when tested with small magnetizing forces.

The numbers I., III., and VI. in the above table refer to the samples mentioned in connexion with Table I.

It is a remarkable fact that certain varieties of low carbon steel (commonly called mild steel), have a higher permeability than even annealed Swedish wrought iron under large magnetizing forces. The term *steel*, however, here used has reference rather to the mode of production than the final chemical nature of the material. In some of the mild-steel castings used for dynamo electromagnets, it appears that the total foreign matter, including carbon, manganese, and silicon, is not more than 0·3 per cent. of the whole, the material being 99·7 per cent. pure iron.

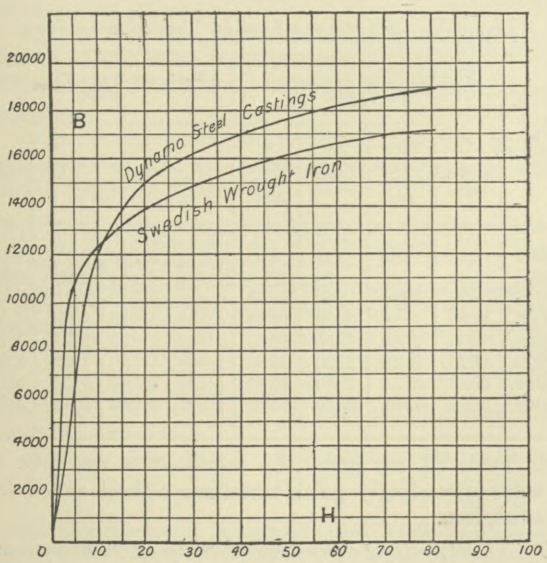

Fig. 1.

This valuable magnetic property of steel capable of being cast is, however, of great utility in modern dynamo building, as it enables field magnets of very high permeability to be constructed, which can be fashioned into shape by casting instead of being built up as formerly out of masses of forged wrought iron. The curves in Fig. 1 illustrate the manner in which the flux density or, as it is usually called, the magnetization curve of this mild cast steel crosses that of Swedish wrought iron, and enables us to obtain a higher flux density corresponding to a given magnetizing force with the steel than with the iron.

From the same paper by Ewing we extract a number of results relating to permeability tests of thin sheet iron and sheet steel, such as is used in the construction of dynamo armatures and transformer cores.

No. VII. is a specimen of good transformer-plate, 0·301 millimetre thick, rolled from Swedish iron by Messrs Sankey of Bilston. No. VIII. is a specimen of specially thin transformer-plate rolled from scrap iron. No. IX. is a specimen of transformer-plate rolled from ingot-steel. No. X. is a specimen of the wire which was used by Mr Swinburne some years ago to form the core of his "hedgehog" transformers. Its diameter was 0·602 millimetre. All these samples were tested in the form of rings by the ballistic method, the rings of sheet-metal being stamped or turned in the flat. The wire ring No. X. was coiled and annealed after coiling.

Some typical flux-density curves of iron and steel as used in dynamo and transformer building are given in Fig. 2.

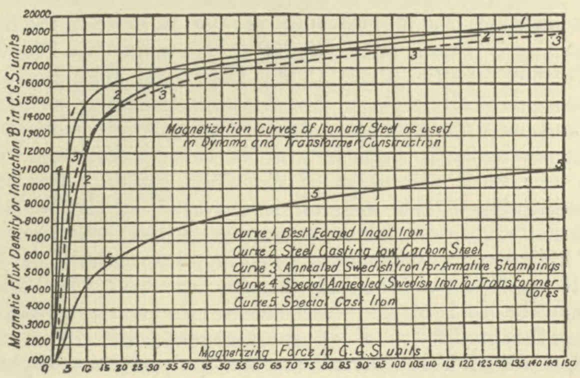

Fig. 2.

The numbers in Table III. well illustrate the statement already made that the permeability $\mu = B/H$ has a maximum value corresponding to a certain flux density. The tables also are explanatory of the fact that steel has gradually replaced iron in the manufacture of dynamo electromagnets and transformer-cores.

Materials for cores.

Broadly speaking, the materials which are now employed in the manufacture of the cores of electromagnets for technical purposes of various kinds may be said to fall into three classes, namely, forgings, castings, and stampings. In some cases the iron or steel core which is to be magnetized is simply a mass of iron hammered or pressed into shape by hydraulic pressure;

in other cases it has to be fused and cast; and for certain other purposes it must be rolled first into thin sheets, which are subsequently stamped out into the required forms.

For particular purposes it is necessary to obtain the highest possible magnetic permeability corresponding to a high, or the highest attainable flux density. This is generally the case in the electromagnets which are employed as the field magnets in dynamo machines. It may generally be said that whilst the best wrought iron, such as annealed Low Moor or Swedish iron, is more permeable for low flux densities than steel castings, the cast steel may surpass the wrought metal for high flux density. For most electro-technical purposes the best magnetic results are given by the employment of forged ingot-iron. This material is probably the most permeable throughout the whole scale of attainable flux densities.

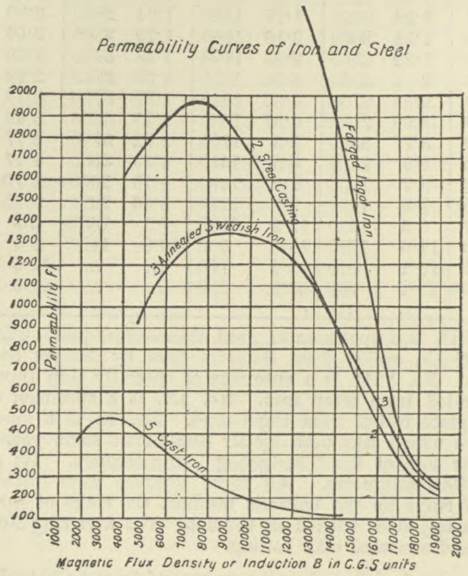

Fig. 3.

It is slightly superior to wrought iron, and it only becomes inferior to the highest class of cast steel when the flux density is pressed above 18,000 C.G.S. units (see Fig. 3). For flux densities above 13,000 the forged ingot-iron has now practically replaced for electric engineering purposes the Low Moor or Swedish iron. Owing to the method of its production it might in truth be called a soft steel with a very small percentage of combined carbon. The best description of this material is conveyed by the German term "Flusseisen," but its nearest British equivalent is "ingot-iron." Chemically speaking, the material is for all practical purposes very nearly pure iron. The same may be said of the cast steels now much employed for the production of dynamo magnet-cores. The cast steel which is in demand for this purpose has a slightly lower permeability than the ingot-iron for low flux densities, but for flux densities above 16,000 the required result may be more cheaply obtained with a steel casting than with a forging. When high tensile strength is required in addition to considerable magnetic permeability, it has been found advantageous to employ a steel containing 5 per cent. of nickel. The rolled sheet iron and sheet steel which is in request for the construction of magnet cores, especially those in which the exciting current is an alternating current, are, generally speaking, produced from Swedish iron. Owing to the mechanical treatment necessary to reduce the material to a thin sheet, the permeability at low flux densities is rather higher than, although at high flux densities it is inferior to, the same iron and steel when tested in bulk. For most purposes, however, where a laminated iron magnet-core is required, the flux density is not pressed up above 6000 units, and it is then more important to secure small hysteresis loss than high permeability. The magnetic permeability of cast iron is much inferior to that of wrought or ingot-iron, or the mild steels taken at the same flux densities.

The following Table IV. gives the flux density and permeability of a typical cast iron taken by Fleming by the ballistic method.

The metal, of which the tests are given in Table IV., contained 2 per cent. of silicon, 2·85 per cent. of total carbon, and 0·5 per cent. of manganese. It will be seen that a magnetizing force of about 5 C.G.S. units is sufficient to impart to a wrought-iron ring a flux density of 18,000 C.G.S. units, but the same force hardly produces more than one-tenth of this flux density in cast iron.

The testing of sheet iron and steel for magnetic hysteresis loss has developed into an important factory process, giving as it does a means of ascertaining the suitability of the metal for use in the manufacture of transformers and alternating-current electromagnets.

In Table V. are given the results of hysteresis tests by Ewing on samples of commercial sheet iron and steel. The numbers VII., VIII., IX., and X. refer to the same samples as those for which permeability results are given in Table III.

V.	8930	13,423	8·658

For most practical purposes the constructor of electromagnetic machinery requires his iron or steel to have some one of the following characteristics. If for dynamo or magnet making it should have the highest possible permeability at a flux density corresponding to practically maximum magnetization. If for transformer or alternating-current magnet building it should have the smallest possible hysteresis loss at a maximum flux density of 2500 C.G.S. units during the cycle. If required for permanent magnet making it should have the highest possible coercivity combined with a high retentivity. Manufacturers of iron and steel have been able to meet these demands in a very remarkable manner, during the last few years, by the commercial production of material of a quality which at one time would have been considered a scientific curiosity.

It is usual now to specify iron and steel for the first purpose by naming the minimum permeability it should possess corresponding to a flux density of 18,000 C.G.S. units; for the second, by stating the hysteresis loss in watts per lb, per 100 cycles, per second, corresponding to a maximum flux density of 2500 C.G.S. units during the cycle; and for the third, by mentioning the coercive force required to reduce to zero magnetization a sample of the metal in the form of a long bar magnetized to a stated magnetization.

In dealing with problems involving the use of an electromagnet, we are confronted with the notion and laws of the magnetic circuit.

Consider in the first instance the simple case of a ring of iron magnetized by an endless solenoid. Let the section of the ring be S and the mean perimeter L.

Let H be the magnetizing force to which the iron is subjected. In the interior of the solenoid this force is equal to $4\pi/10$ times the exciting ampere-turns per unit length of perimeter. The product HL is called the line integral of magnetic force, or the magnetomotive force (M.M.F.). It is obviously measured by $0{\cdot}4\pi$ times the exciting ampere-turns (A.T.)

Hence since $\mu H = B$ if we write ρ^{-1} for μ and call ρ the *reluctivity* of the material, we have—

$$BS = \frac{HL}{\frac{\rho L}{S}} = \frac{\text{M.M.F.}}{R} = \frac{0{\cdot}4\pi\,\text{A.T.}}{R}$$

or the total magnetic flux is numerically equal to the quotient of the magnetomotive force by a quantity (R) called the magnetic reluctance of the circuit.

Hence if the reluctivity (ρ) of the material or its reciprocal the permeability (μ) corresponding to a given flux density (B) is known, we can calculate the ampere-turns (A.T.) required to produce a given total flux in the iron core.

The value of μ corresponding to any given flux density can always be obtained from the permeability curve of the material (see Fig. 3).

Hence the ampere-turns (A.T.) necessary to produce a required total flux in a magnetic circuit of length L and section S can be calculated from the expression

$$\text{A.T.} = 0{\cdot}8\,(BS) \times R = 0{\cdot}8 \times (BS) \times \frac{L}{S\mu}$$

where BS is the total flux and R is the reluctance of the circuit. This last is equal to $i/\mu S$ where μ is the permeability corresponding to B. (For all practical purposes $0{\cdot}8 = 10/4\pi$.)

The fundamental law of the non-homogeneous magnetic circuit traversed by one and the same total magnetic flux is that the sum of all the magnetomotive forces acting on the circuit is numerically equal to the product of 0·8 times the total flux in the circuit, and the sum of all the reluctances of the various parts of the circuit. If then the circuit consists of materials of different permeability, and it is desired to know the ampere-turns required to produce a given total of flux round the circuit, we have to calculate from the magnetization curves of each part the necessary magnetomotive forces and add these forces together. The practical application of this principle to the predetermination of the field windings of dynamo magnets was first made by Drs J. and E. Hopkinson (see *Phil. Trans. Roy. Soc.* vol. clxxvii. p. 331).

We may illustrate the principles of this predetermination by a simple example. Suppose a ring of iron has a mean diameter of 10 cms. and a cross section of 2 square cms. and a transverse cut or air gap made in it one millimetre wide, required the ampere-turns to be put upon the ring to create in it a total flux of 24,000 C.G.S. units. The total length of the iron part of the circuit is $(10\pi - 0{\cdot}1)$ cms., and its section is 2 sq. cms., and the flux density in it is to be 12,000. From Table II. we see that the permeability of pure iron corresponding to a flux density of 12,000 is 2760. Hence the reluctance of the iron circuit is equal to $\frac{10\pi - 0{\cdot}1}{2760 \times 2} = \frac{220}{38640}$ C.G.S. units.

The length of the air gap is 0·1 cm., its section 2 sq. cms., and its permeability is unity. Hence the reluctance of the air gap is

$$\frac{0{\cdot}1}{1 \times 2} = \frac{1}{20}\ \text{C.G.S.}$$

Accordingly the magnetomotive force in ampere-turns required to produce the required flux is equal to

$$0{\cdot}8(24{,}000)\left(\frac{1}{20} + \frac{220}{38640}\right) = 1070 \text{ nearly.}$$

It will be seen that the part of the magnetomotive force required to overcome the reluctance of the narrow air gap is about nine times that required for the iron alone.

In the above example we have for simplicity assumed that the flux in passing across the air gap does not spread out at all. In dealing with dynamo designing we have to take into consideration this spreading as well as the leakage of flux across the circuit (see DYNAMO).

It will be seen, therefore, that in order that we may predict the effect of a certain kind of iron or steel when used as the core of an electromagnet we must be provided with tables or curves showing the reluctivity corresponding to given flux densities or —which comes to the same thing—with (B, H) curves for the sample.

The commercial testing of iron for electro-technical purposes has of late years become a very important matter. The electrical engineer is now enabled to specify the particular kind of iron or steel required for his purpose with the same accuracy and definiteness that a mechanical engineer specifies for certain mechanical qualities in the materials he employs. The process for obtaining hysteresis loops and permeability curves from the series of observations made with the ballistic galvanometer to determine a (B, H) curve or (B, H) cycle is a tedious operation, yet at the same time it is the most accurate and trustworthy method. In order to shorten the process many instruments have been devised of late years for use in the workshop. Instruments of this kind for determining the flux density corresponding to a given magnetizing force in a complete magnetic circuit formed in part or in whole of a particular material are called permeameters (see MAGNETISM).

The measurement of hysteresis losses in samples of sheet iron is facilitated by the employment of various forms of hysteresis meter. The principle on which some of these instruments depend for their operation is the fact that if a mass of laminated iron or steel is caused to revolve in a magnetic field, or suspended in a revolving magnetic field with the plane of the laminations parallel to the direction of the field, forces will be brought to bear tending to create a rotation either of the magnet or of the mass of laminated metal. In order that sources of error may be eliminated it is necessary that the specimen tested should be so well laminated as to destroy all electric eddy-currents in its mass. A simple yet convenient instrument of this kind has been devised by Ewing, and is shown in Fig. 4. The instrument consists of a curved permanent steel magnet, nicely balanced on knife edges, and having attached to it a long index needle. The specimen of iron to be tested for hysteresis is prepared in the form of thin sheets of a rectangular shape, 3 inches long and $\frac{5}{8}$ of an inch wide. Seven of these little sheets are fixed together and attached to a shaft which can be caused to revolve between the poles of the magnet. The user of the instrument by rotating the handle causes the specimen to revolve rapidly between the poles of the balanced magnet with the plane of its laminations parallel to the direction of the interpolar field. In consequence of the waste of energy in the sample due to hysteresis a torque is brought into existence which displaces the magnet through a certain angle depending upon the counter-balance attached

Hysteresis meters.

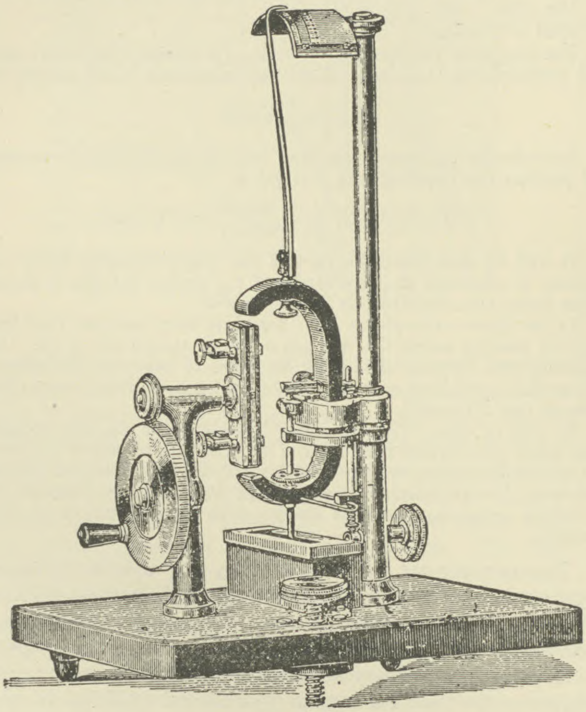

Fig. 4.

to the magnet, which tends to bring it back into a vertical position. The instrument is provided with certain samples of iron plate cut to the proper size, the hysteresis loss in which is accurately known. By comparing the deflexions of the permanent magnet given by these standard specimens with that produced by the specimen under test, the hysteresis loss in the specimen can be at once obtained. The assumptions made in the construction of the instrument are that for samples of iron not differing very much in magnetic quality the hysteresis losses at different induction densities are in the same ratio; also that slight differences in permeability do not affect the result by causing the magnetic forces on the two specimens to be very different.

One objection which has been raised to the employment of such a rotating hysteresis meter is, that the character of the cyclic change of the magnetizing force is quite different in this case from that which it is when the magnetic force undergoes the periodic change without any alteration in this direction. These two cases are clearly different. In the first case, which is that of the alternating transformer, the magnetic force passes through a cycle of values, the iron remaining stationary, and the direction of the magnetic force being always the same. In the other case, the direction of the magnetic force in the iron is constantly changing, and at the same time undergoing a change in magnitude.

It has been shown by F. G. Baily that if a mass of laminated iron is rotating in a magnetic field, the field remaining constant in direction and magnitude in any one experiment, as the magnitude of the flux density in the iron is increased the hysteresis loss rises to a maximum, and then falls away again to nearly zero value. These observations have been confirmed by other observers. The question has been much debated whether the values of the hysteresis loss obtained by these two different methods are identical for magnetic cycles in which the flux density reaches the same maximum value. This question is also connected with another one, namely, whether the hysteresis loss per cycle is or is not a function of the speed with which the cycle is traversed. Early experiments by Steinmetz and others seemed to show that there was a difference between slow-speed and high-speed hysteresis cycles, but later experiments by Hopkinson and by Tanakadate, though not absolutely exhaustive, tend to prove that up to 400 cycles per second the hysteresis loss per cycle is practically unchanged.

Experiments made in 1896 by Fleming, Beattie, and Clinker on magnetic hysteresis in rotating fields were partly directed to determine whether the hysteresis loss at moderate flux densities, such as are employed in transformer-work, was the same as that found by measurements made with alternating-current fields on the same iron and steel specimens. These experiments showed that over moderate ranges of induction, such as may be expected in electro-technical work, the hysteresis loss per cycle per cubic centimetre was practically the same when the iron was tested in an alternating field with a periodicity of 100, the field remaining constant in direction, and when the iron was tested in a rotating field giving the same maximum flux density.

In the hysteresis tester of Ewing the field magnet is arranged to give a mean flux density of about 4000 C. G. S. units on the specimen under test. Hence the hysteresis loss in the standard specimens is determined for that value. If the loss is required at any other flux density, it is determined by means of a series of factors which show the ratio of hysteresis losses at various flux densities. The factors are as follows:—

Maximum Flux Density in C.G.S. Units.	Relative Amount of Hysteresis Loss.
2000	0·33
2500	0·47
3000	0·63
4000	1·00
5000	1·41
6000	1·89
7000	2·41
8000	3·00

With respect to the variation of hysteresis loss in magnetic cycles having different maximum values for the flux density, Steinmetz found that the hysteresis loss (W) as measured by the area of the complete (B, H) cycle and expressed in ergs per centimetre-cube per cycle, varies proportionately to a constant called the *hysteretic constant*, and to the 1·6th power of the maximum flux density (B), or $W = \eta B^{1 \cdot 6}$.

The hysteretic constants for various kinds of iron and steel are given in the table below:—

Metal.	Hysteretic Constant.
Swedish wrought iron, well annealed .	·0010 to ·0017
Annealed cast steel of good quality; small percentage of carbon	·0017 to ·0029
Cast Siemens-Martin steel . . .	·0019 to ·0028
Cast ingot-iron	·0021 to ·0026
Cast steel, with higher percentages of carbon, or inferior qualities of wrought iron	·0031 to ·0054

Steinmetz's law, though not strictly true for very low or very high maximum flux densities, is yet a convenient empirical rule for obtaining approximately the hysteresis loss at any one maximum flux density, knowing it at another, provided these values fall within a range varying say from 1 to 9000 C.G.S. units. (See also MAGNETISM.)

The standard maximum flux density which is adopted in electro-technical work is 2500, hence in the construction of the cores of alternating-current electromagnets and transformers iron has to be employed having a known hysteretic constant at the standard flux density. It is generally expressed by stating the number of watts per ℔ of metal which would be dissipated for a frequency of 100 cycles, and a maximum flux density (B max.) during the cycle of 2500. In the case of good iron or steel for transformer-core making, it should not exceed 1·25 watt per ℔ per 100 cycles per 2500 B (maximum value).

It has been found that if the sheet iron employed for cores of alternating electromagnets or transformers is heated to a temperature somewhere in the neighbourhood of 200° C. the hysteresis loss is very greatly increased. It was noticed in 1894 by Partridge that alternating-current transformers which had been in use some time had a very considerably augmented core loss when compared with their initial condition. Bláthy and Mordey in 1895 showed that this augmentation in hysteresis loss in iron was due to heating. Parshall investigated the effect up to moderate temperatures, such as 140° C., and an extensive series of experiments was made in 1898 by Roget (*Proc. Roy. Soc.*, May and Dec. 1898). Roget found that below 40° C. a rise in temperature did not produce any augmentation in the hysteresis loss in iron, but if it is heated to between 40° C. and 135° C. the hysteresis loss increases continuously with time, and this increase is now called "ageing" of the iron. It proceeds more slowly as the temperature is higher. If heated to above 135° C., the hysteresis loss soon attains a maximum, but then begins to decrease. Certain specimens heated to 160° C. were found to have their hysteresis loss doubled in a few days. The effect seems to come to a maximum at about 180° C. or 200° C. Mere lapse of time does not remove the increase, but if the iron is re-annealed the augmentation in hysteresis disappears. If the iron is heated to a higher temperature, say between 300° C. and 700° C., Roget found the initial rise of hysteresis happens more quickly, but that the metal soon settles down into a state in which the hysteresis loss has a small but still augmented constant value. The augmentation in value, however, becomes more nearly zero as the temperature approaches 700° C. Brands of steel are now obtainable which do not age in this manner, but these *non-ageing* varieties of steel have not generally such low initial hysteresis values as the "Swedish Iron," commonly considered best for the cores of transformers and alternating current magnets.

The following conclusions have been reached in the matter:—(1) Iron and mild steel in the annealed state are more liable to change their hysteresis value by heating than when in the harder condition; (2) all changes are removed by re-annealing; (3) the changes thus produced by heating affect not only the amount of the hysteresis loss, but also the form of the lower part of the (B, H) curve.

The form which an electromagnet must take will greatly depend upon the purposes for which it is to be used. A design or form of electromagnet which will be very suitable for some purposes will be useless for others. Supposing it is desired to make an electromagnet which shall be capable of undergoing very rapid changes of strength, it must have such a form that the coercivity of the material is overcome by a self-demagnetizing force. This can be achieved by making the magnet in the form of a short and stout bar rather than a long thin one. It has already been explained that the ends or poles of a polar magnet exert a demagnetizing power upon the mass of the metal in the interior of the bar. If then the electromagnet has the form of a long thin bar, the length of which is several hundred times its diameter, the poles are very far removed from the centre of the bar, and the demagnetizing action will be very feeble; such a long thin electromagnet, although made of very soft iron, retains a considerable amount of magnetism after the magnetizing force is withdrawn. On the other hand, a very thick bar very quickly demagnetizes itself, because no part of the metal is far removed from the action of the free poles. Hence when, as in many telegraphic instruments, a piece of soft iron, called an armature, has to be attracted to the poles of a horseshoe-shaped electromagnet, this armature should be prevented from quite touching the polar surfaces of the magnet. If a soft iron mass does quite touch the poles, then it completes the magnetic circuit and abolishes the free poles, and the magnet is to a very large extent deprived of its self-demagnetizing power. This is the explanation of the well-known fact that after exciting the electromagnet and then stopping the current, it still requires a good pull to detach the "keeper"; but when once the keeper has been detached, the magnetism is found to have nearly disappeared.

Forms of electro-magnet.

Various forms of electromagnets used in connexion with dynamo machines are considered in another place (see DYNAMO), and there is, therefore, no necessity to refer particularly to the numerous different shapes and types employed in electro-technics.

Electro-Metallurgy.—The present article will, as explained under ELECTRO-CHEMISTRY, treat only of those processes in which electricity is applied to the production of chemical reactions or molecular changes at furnace temperatures. In many of these the application of heat is necessary to bring the substances used into the liquid state for the purpose of electrolysis, aqueous solutions being unsuitable. Among the earliest experiments in this branch of the subject were those of Davy, who in 1807

(*Phil. Trans. Roy. Soc.*, 1808, p. 1), produced the alkali metals by passing an intense current of electricity, from a platinum wire to a platinum dish, through a mass of fused caustic alkali. The action was started in the cold, the alkali being slightly moistened to render it a conductor; then, as the current passed, heat was produced, and the alkali fused, the metal being deposited in the liquid condition. Later, Matthiessen (*Quarterly Journ. Chem. Soc.* vol. viii. p. 30) obtained potassium by the electrolysis of a mixture of potassium and calcium chlorides fused over a lamp. There are here foreshadowed two types of electrolytic furnace-operations: (*a*) those in which external heating maintains the electrolyte in the fused condition, and (*b*) those in which a current-density is applied sufficiently high to develop the heat necessary to effect this object unaided. Much of the earlier electro-metallurgical work was done with furnaces of the (*a*) type, while nearly all the later developments have been with those of class (*b*). There is a third class of operations, exemplified by the manufacture of calcium carbide, in which electricity is employed solely as a heating agent; these are termed *electrothermal*, as distinguished from *electrolytic*. In certain electrothermal processes (*e.g.*, calcium carbide production) the heat from the current is employed in raising mixtures of substances to the temperature at which a desired chemical reaction will take place between them, while in others (*e.g.*, the production of graphite from coke or gas-carbon) the heat is applied solely to the production of molecular or physical changes. In ordinary electrolytic work only the continuous current may of course be used, but in electrothermal work an alternating-current is equally available.

Electric Furnaces.—Independently of the question of the application of external heating, the furnaces used in electro-metallurgy may be broadly classified into (i) arc furnaces, in which the intense heat of the electric arc is utilized, and (ii) resistance and incandescence furnaces, in which the heat is generated by an electric current overcoming the resistance of an inferior conductor.

Excepting such experimental arrangements as that of Depretz, for use on a small scale in the laboratory, Pichou in France and Johnson in England appear, in 1853, to have introduced the earliest practical form of furnace. In these arrangements, which were similar if not identical, the furnace charge was crushed to a fine powder and passed through two or more electric arcs in succession.

Arc furnaces.

When used for ore smelting, the reduced metal and the accompanying slag were to be caught, after leaving the arc and while still liquid, in a hearth fired with ordinary fuel. Although this primitive furnace could be made to act, its efficiency was low, and the use of a separate fire was disadvantageous. In 1878 Sir William Siemens patented a form of furnace [1] which is the type of a very large number of those designed by later inventors.

In the best known form a plumbago crucible was used with a hole cut in the bottom to receive a carbon rod, which was ground in so as to make a tight joint. This rod was connected with the positive pole of the dynamo or electric generator. The crucible was fitted with a cover in which were two holes; one at the side to serve at once as sight-hole and charging door, the other in the centre to allow a second carbon rod to pass freely (without touching) into the interior. This rod was connected with the negative pole of the generator, and was suspended from one arm of a balance-beam, while from the other end of the beam was suspended a vertical hollow iron cylinder, which could be moved into or out of a wire coil or solenoid joined as a shunt across the two carbon rods of the furnace. The solenoid was above the iron cylinder, the supporting rod of which passed through it as a core. When the furnace with this well-known regulating device was to be used, say, for the melting of metals or other conductors of electricity, the fragments of metal were placed in the crucible and the positive electrode was brought near them. Immediately the current passed through the solenoid it caused the iron cylinder to rise and, by means of its supporting rod, forced the end of the balance beam upwards, so depressing the other end that the negative carbon rod was forced downwards into contact with the metal in the crucible. This action completed the furnace-circuit, and current passed freely from the positive carbon through the fragments of metal to the negative carbon, thereby reducing the current through the shunt. At once the attractive force of the solenoid on the iron cylinder was automatically reduced, and the falling of the latter caused the negative carbon to rise, starting an arc between it and the metal in the crucible. A counterpoise was placed on the solenoid end of the balance beam to act against the attraction of the solenoid, the position of the counterpoise determining the length of the arc in the crucible. Any change in the resistance of the arc, either by lengthening, due to the sinking of the charge in the crucible, or by the burning of the carbon, affected the proportion of current flowing in the two shunt circuits, and so altered the position of the iron cylinder in the solenoid that the length of arc was, within limits, automatically regulated. Were it not for the use of some such device the arc would be liable to constant fluctuation and to frequent extinction. The crucible was surrounded with a bad conductor of heat to minimize loss by radiation. The positive carbon was in some cases replaced by a water-cooled metal tube, or ferrule, closed, of course, at the end inserted in the crucible. Several modifications were proposed, in one of which, intended for the heating of non-conducting substances, the electrodes were passed horizontally through perforations in the upper part of the crucible walls, and the charge in the lower part of the crucible was heated by radiation.

The furnace used by Moissan in his experiments on reactions at high temperatures, on the fusion and volatilization of refractory materials, and on the formation of carbides, silicides, and borides of various metals consisted, in its simplest form, of two superposed blocks of lime or of limestone with a central cavity cut in the lower block, and with a corresponding but much shallower inverted cavity in the upper block, which thus formed the lid of the furnace. Horizontal channels were cut on opposite walls, through which the carbon poles or electrodes were passed into the upper part of the cavity. Such a furnace, to take a current of 4 H.P. (say, of 60 amperes and 50 volts), measured externally about 6 by 6 by 7 in., and the electrodes were about 0·4 in. in diameter, while for a current of 100 H.P. (say, of 746 amperes and 100 volts) it measured about 14 by 12 by 14 in., and the electrodes were about 1·5 in. in diameter. In the latter case the crucible, which was placed in the cavity immediately beneath the arc, was about 3 in. in diameter (internally), and about 3½ in. in height. The fact that energy is being used at so high a rate as 100 H.P. on so small a charge of material sufficiently indicates that the furnace is only used for experimental work, or for the fusion of metals which, like tungsten or chromium, can only be melted at temperatures attainable by electrical means. Moissan succeeded in fusing about ¾ ℔ of either of these metals in 5 or 6 minutes in a furnace similar to that last described. He has also arranged an experimental tube-furnace by passing a carbon tube horizontally beneath the arc in the cavity of the lime blocks. When prolonged heating is required at very high temperatures it is found necessary to line the furnace-cavity with alternate layers of magnesia and carbon, taking care that the lamina next to the lime is of magnesia; if this were not done the lime in contact with the carbon crucible would form calcium carbide and would slag down, but magnesia does not yield a carbide in this way. Chaplet has patented a muffle or tube furnace, similar in principle, for use on a larger scale, with a number of electrodes placed above and below the muffle-tube. The arc furnaces now widely used in the manufacture of calcium carbide on a large scale are chiefly developments of the Siemens furnace. But whereas, from its construction, the Siemens furnace was intermittent in operation, necessitating stop-

[1] Cf. Siemens's account of the use of this furnace for experimental purposes in *British Association Report* for 1882.

page of the current while the contents of the crucible were poured out, many of the newer forms are specially designed either to minimize the time required in affecting the withdrawal of one charge and the introduction of the next, or to ensure absolute continuity of action, raw material being constantly charged in at the top and the finished substance and bye-products (slag, &c.) withdrawn either continuously or at intervals, as sufficient quantity shall have accumulated. In the King furnace, for example, the crucible, or lowest part of the furnace, is made detachable, so that when full it may be removed and an empty crucible substituted. In the United States a revolving furnace is used which is quite continuous in action.

Incandescence furnaces.

The class of furnaces heated by electrically incandescent materials has been divided by Borchers into two groups: (1) those in which the substance is heated by contact with a substance offering a high resistance to the current passing through it, and (2) those in which the substance to be heated itself affords the resistance to the passage of the current whereby electric energy is converted into heat. Practically the first of these furnaces was that of Depretz, in which the mixture to be heated was placed in a carbon tube rendered incandescent by the passage of a current through its substance from end to end. In 1880 Borchers introduced his resistance-furnace, which, in one sense, is the converse of the Depretz apparatus. A thin carbon pencil, forming a bridge between two stout carbon rods, is set in the midst of the mixture to be heated. On passing a current through the carbon the small rod is heated to incandescence, and imparts heat to the surrounding mass. On a larger scale several pencils are used to make the connexions between carbon blocks which form the end walls of the furnace, while the side walls are of fire-bricks laid upon one another without mortar. Many of the furnaces now in constant use depend mainly on this principle, a core of granular carbon fragments stamped together in the direct line between the electrodes, as in Acheson's carborundum furnace, being substituted for the carbon pencils. In other cases carbon fragments are mixed throughout the charge, as in Cowles's zinc-smelting retort. In practice, in these furnaces, it is possible for small local arcs to be temporarily set up by the shifting of the charge, and these would contribute to the heating of the mass. In the remaining class of furnace, in which the electrical resistance of the charge itself is utilized, are the continuous-current furnaces, such as are used for the smelting of aluminium, and those alternating-current furnaces (*e.g.*, for the production of calcium carbide) in which a portion of the charge is first actually fused, and then maintained in the molten condition by the current passing through it, while the reaction between further portions of the charge is proceeding.

Uses and advantages.

For ordinary metallurgical work the electric furnace, requiring as it does (excepting where waterfalls or other cheap sources of power are available) the intervention of the boiler and steam engine, or of the gas or oil engine, with a consequent loss of energy, has not usually proved so economical as an ordinary direct fired furnace. But in some cases in which the current is used for electrolysis and for the production of extremely high temperatures, for which the calorific intensity of ordinary fuel is insufficient, the electric furnace is employed with advantage. The temperature of the electric furnace, whether of the arc or incandescence type, is practically limited to that at which the least easily vaporized material available for electrodes is converted into vapour. This material is carbon, and as its vaporizing point is (estimated at) over 3500° C., and less than 4000° C., the temperature of the electric furnace cannot rise much above 3500° C. (6330° F.); but Moissan has shown that at this temperature the most stable of mineral combinations are dissociated, and the most refractory elements are converted into vapour, only certain borides, silicides, and metallic carbides having been found to resist the action of the heat. It is not necessary that all electric furnaces shall be run at these high temperatures; obviously, those of the incandescence or resistance type may be worked at any convenient temperature below the maximum. The electric furnace has several advantages as compared with some of the ordinary types of furnace, arising from the fact that the heat is generated from within the mass of material operated upon, and (unlike the blast-furnace, which presents the same advantage) without a large volume of gaseous products of combustion and atmospheric nitrogen being passed through it. In ordinary reverberatory and other heating furnaces the burning fuel is without the mass, so that the vessel containing the charge, and other parts of the plant, are raised to a higher temperature than would otherwise be necessary, in order to compensate for losses by radiation, convection, and conduction. This advantage is especially observed in some cases in which the charge of the furnace is liable to attack the containing vessel at high temperatures, as it is often possible to maintain the outer walls of the electric furnace relatively cool, and even to keep them lined with a protecting crust of unfused charge. Again, the construction of electric furnaces may often be exceedingly crude and simple; in the carborundum furnace, for example, the outer walls are of loosely piled bricks, and in one type of furnace the charge is simply heaped on the ground around the carbon resistance used for heating, without containing-walls of any kind. There is, however, one (not insuperable) drawback in the use of the electric furnace for the smelting of pure metals. Ordinarily carbon is used as the electrode material, but when carbon comes in contact at high temperatures with any metal that is capable of forming a carbide a certain amount of combination between them is inevitable, and the carbon thus introduced impairs the mechanical properties of the ultimate metallic product. Aluminium, iron, platinum, and many other metals may thus take up so much carbon as to become brittle and unforgeable. It is for this reason that Siemens, Borchers, and others substituted a hollow water-cooled metal block for the carbon cathode upon which the melted metal rests while in the furnace. Liquid metal coming in contact with such a surface forms a crust of solidified metal over it, and this crust thickens up to a certain point, namely, until the heat from within the furnace just overbalances that lost by conduction through the solidified crust and the cathode material to the flowing water. In such an arrangement, after the first instant, the melted metal in the furnace does not come in contact with the cathode material.

Electrothermal Processes.—In these processes the electric current is used solely to generate heat, either to induce chemical reactions between admixed substances, or to produce a physical (allotropic) modification of a given substance. Borchers predicted that, at the high temperatures available with the electric furnace, every oxide would prove to be reducible by the action of carbon, and this prediction has in most instances been justified. Alumina and lime, for example, which cannot be reduced at ordinary furnace temperatures, readily give up their oxygen to carbon in the electric furnace, and then combine with an excess of carbon to form metallic carbides. In 1885 the brothers Cowles patented a process for the electrothermal reduction of oxidized ores by exposure to an intense current of electricity when admixed with carbon in a retort. Later in that year they patented a process for the reduction of aluminium by carbon, and in 1886 an electric furnace with sliding carbon rods passed through the end walls to the centre of a rectangular furnace. The impossibility of working with just sufficient carbon to reduce the alumina, without using any excess which would be free to form at least so much carbide as would suffice, when diffused through the metal, to render it brittle, practically restricts the use of such processes to the production of aluminium alloys. Aluminium bronze (aluminium and copper) and ferroaluminium (aluminium and iron) have been made in this way; the latter is the more satisfactory product, because a certain proportion of carbon is expected in an alloy of this character, as in ferromanganese and cast-iron, and its presence is not objectionable. The furnace is built of fire-brick and may measure (internally) 5 ft. in length by 1 ft. 8 in. in width, and 3 ft. in height. Into each end wall is built a short iron tube sloping downwards towards the centre, and through this is passed a bundle of five 3-in. carbon rods, bound together at the outer end by being cast into a head of cast-iron for use with iron alloys, or of cast-copper for aluminium bronze. This head slides freely in the cast-iron tubes, and is connected by a copper rod with one of the terminals of the dynamo supplying the current. The carbons can thus, by the application of suitable mechanism, be withdrawn from or plunged into the furnace at will. In starting the furnace, the bottom is prepared by ramming it with charcoal-powder that has been soaked in milk of lime and dried, so that each particle is coated with a film of lime, which serves to reduce the loss of current by conduction through the lining when the furnace becomes hot. A sheet-iron case is then placed within the furnace, and the space between it and the walls rammed with limed charcoal; the interior is filled with fragments of the iron or copper to be alloyed, mixed with alumina and coarse charcoal, broken pieces of carbon being placed in position to connect the electrodes. The iron case is then removed, the whole is covered with charcoal, and a cast-iron cover with a central flue is placed above all. The current, either continuous or alternating, is then started, and continued for about 1 to 1½ hours, until the operation is complete, the carbon rods being gradually withdrawn as the action proceeds. In such a furnace a continuous current, for example, of 3000 amperes, at 50 to 60 volts, may be used at first, increasing to 5000 amperes in about half an hour. The reduction is not due to electrolysis, but to the action of carbon on alumina ($Al_2O_3 + 3C = Al_2 + 3CO$), a part of the carbon in the charge being consumed and evolved as carbon monoxide gas, which burns at the orifice in the cover so long as reduction is taking place. The reduced aluminium alloys itself immediately with the fused globules of metal in its midst, and as the charge becomes reduced the globules of alloy unite until, in the end, they are run out of the tap-hole after the current has been diverted to another furnace. It was found in practice (in 1889) that the expenditure of energy per pound of reduced aluminium was about 23 H.P.-hours, a number considerably in excess of that required at the present time for the production of pure aluminium by the electrolytic process hereafter to be described.

Aluminium alloys.

Calcium carbide.

Wöhler, in 1862, had obtained an impure calcium carbide, and Borchers had unintentionally produced some of the carbide (CaC_2) in his incandescence electric-furnace, but Willson, in America, working with an arc furnace, seems to have been the first to make the product industrially, and to have realized the possibilities of its use in the manufacture of acetylene by mere contact with water. Willson and Moissan (*Comptes Rendus*, vol. cxv. p. 558), in 1892, described the production of the carbide in their respective electric furnaces, the one commercially the other experimentally, and since then many inventors have turned their attention to its manufacture by electrothermal methods. In every case the principle is the same, the charge, consisting of pure lime and good hard coke-dust, very finely crushed and intimately mixed in the approximate proportion of 10 to 7, is introduced into a carbon-lined vessel, in the interior of which a powerful arc is passing between carbon electrodes (usually between a vertical carbon and a carbon bottom). Part of the carbon reduces the lime, whilst a further portion combines with the liberated calcium to form the carbide, thus ($CaO + 3C = CaC_2 + CO$), and the carbide fuses and sinks to the bottom. The system of treatment may be either continuous or intermittent. In the continuous process a carbon-lined furnace is commonly used, with a massive carbon electrode (made up of several blocks of carbon clamped together) within it. Sufficiently high current-density is employed to ensure that the carbide formed remains fluid, and the passage of the (alternating) current through the fluid carbide, after the furnace is once in working order, is depended upon to generate the heat necessary both to keep it molten and to continue the action. A part of the carbide is tapped out of the furnace from time to time as it accumulates. In the intermittent process the current is stopped in about 12 to 18 hours when sufficient carbide is formed, and after cooling the solidified product is removed. In the King type of furnace a movable hearth is used, so that the action of the furnace is practically continuous, the current being broken only for the few minutes necessary to effect the exchange of hearths.

Although continuous processes appeared at one time to be growing in favour, there is in many places a tendency to revert to intermittent furnaces. Carlson, in a comparison of the two types (*Zeitschrift f. Elektrochem.*, 1900, vol. vi. pp. 413–429), has pointed out that the intermittent process is more economical, mainly on account of the higher temperature necessary in the continuous furnace to maintain the carbide fluid, but partly owing to the fact that the cooling carbide to some extent continues the reaction on portions of the surrounding charge still unconverted after the current has been diverted. The reaction between lime and carbon appears to begin at a temperature not greatly above 1500° C., but fusion does not occur until 2800° C. is reached, and the product only flows freely at temperatures between 3500° and 4000° C. In order that the carbide may be tapped from the furnace, it must attain a temperature, therefore, of at least 3500° C., whereas in the intermittent process 2800° to 3000° C. (3500° to 3800° F.) suffices. This leads to a saving in many directions, too numerous here to mention in detail. In the intermittent process, using an electrode of about 100 sq. in. in cross section, a current of about 2000 amperes at 70 to 100 volts (equal to about 250 E.H.P.) has been found to give in practice about 11 cwt. of a product containing, say, 80 per cent. of pure carbide for each ton of charge. This is equivalent to a production of about 0·4 ℔ of carbide per E.H.P.-hour.

Carborundum.

Carborundum, which on account of its great hardness has assumed an important place among abrasives used for polishing, and also has possible applications in the metallurgy of iron and steel, is a silicide of carbon (SiC) formed by the action of carbon on sand (silica) at high temperatures. Its name was derived from *carbon* and *corundum* (a form of alumina), from a mistaken view as to its composition. It was first obtained accidentally in 1891 by Acheson, in America, when he was experimenting with the electric furnace in the hope of producing artificial diamonds. The experiments were followed up in an incandescence furnace, which on a larger scale is now employed for the industrial manufacture of the product. A full description of the process has been given by Kohn (*Journ. Soc. Chem. Industry*, 1897, vol. xvi. p. 863). The furnace is rectangular, about 16 ft. long and 5 ft. wide by 5 ft. high, with massive brick end-walls 2 ft. thick, through which are built the carbon poles, consisting of bundles of 60 parallel 3-in. carbon rods, each 3 ft. in length, with a copper rod let into the outer end to connect it with a copper cap, which in turn is connected with one of the terminals of the generating dynamo. The spaces between the carbons of the electrode are packed tightly with graphite. In preparing the furnace for use, transverse iron screens are placed temporarily across each end, the space between these and the end walls being rammed with fine coke, and that in the interior is filled to the level of the centre of the carbon poles with the charge, consisting of 34 parts of coke, with 54 of sand, 10 of sawdust, and 2 of salt. A longitudinal trench is then formed in the middle, and in this is arranged a cylindrical pile of fragments of coke about $\frac{1}{2}$ in. or more in diameter, so that they form a core, about 21 in. in diameter, connecting the carbon poles in the end walls. Temporary side walls are then built up, the iron screens are removed, and a further quantity of charge is heaped up about 3 ft. above the top of the furnace. An alternating current of about 1700 amperes at 190 volts is now switched on; as the mass becomes heated by the passage of the current the resistance diminishes, and the current is regulated until after about 2 hours or less from starting it is maintained constant at about 6000 amperes and 125 volts. Carbon monoxide is given off and burns freely around the sides and top of the furnace, tinged yellow after a time by the sodium in the salt mixed with the charge. Meanwhile a shrinkage takes place, which is made good by the addition of a further quantity of charge until the operation is complete, usually in about 36 hours from the commencement. The current is then switched off, and the side walls, after cooling for a day, are taken down, the comparatively unaltered charge from the top is removed, and the products are carefully extracted. These consist of the inner carbon core, which at the temperature of the furnace will have been for the most part converted into graphite, then a thin black crust of graphite mixed with carborundum, next a layer of nearly pure crystallized carborundum about a foot in thickness, then grey amorphous carbide of silicon mixed with increasing proportions of unaltered charge, and lastly, on the outside, the portion of the charge which had never reached the temperature necessary for reaction, and which is altered only by the intrusion of salt from the inner part of the furnace. Special precautions are taken in making and breaking the intense current here used (amounting at the end to about 750 kilowatts, or 1000 E.H.P.), a water-regulator consisting of removable iron plates dipped in salt water being used for the purpose. In such a furnace as that above described the charge weighs about 14 tons, the yield of carborundum is about 3 tons, and the expenditure of energy about 3·9 kilowatt-hours (5·2 H.P.-hours) per pound of finished product. The carborundum thus produced is crystalline, greenish, bluish, or brownish in colour, sometimes opaque, but often translucent, resisting the action of even the strongest acids, and the action of air or of sulphur at high temperatures. The crude product can therefore be treated with hot sulphuric acid to purify it. In hardness it nearly equals the diamond, and it is used for tool grinding in the form of vitrified wheels (mixed with powdered porcelain and iron, pressed into shape and fired in a kiln). Carborundum paper, made like emery paper, is now largely used in place of garnet paper in American shoe factories, and is rapidly finding a market in other directions. The amorphous carbide, which was at first a waste product, has been tried, it is reported, with success as a lining for steel furnaces, as it is said not to be affected by iron or iron oxide at a white heat.

Graphite. The alteration of carbon at high temperatures into a material resembling graphite has long been known. In 1893, Girard and Street patented a furnace and a process by which this transformation could be effected. Carbon powder compressed into a rod was slowly passed through a tube in which it was subjected to the action of one or more electric arcs. In this way they converted into graphite about 85 per cent. of the carbon in a $\frac{1}{2}$-in. rod, the electric conductivity being increased fourfold, and the specific gravity being raised from 1·98 to 2·6. But Acheson, in 1896, patenting an application of his carborundum process to graphite manufacture, was apparently the first to undertake the production of graphite in large quantities. Powdered coke or other form of carbon is mixed with a small proportion of an oxide or silicate, and is moulded into the desired shape with the aid of water containing a little sugar. The moulded pieces are then embedded in carbon dust, surrounded with a bad conductor of heat, such as amorphous carbide of silicon, and subjected to the action of the current. The oxides present form carbides which, in turn, are probably dissociated, the metal being volatilized. In time the whole of the carbon could be converted into graphite, but it is preferred to leave a small proportion unchanged, as the product is then somewhat stronger than if it were pure graphite. Graphite so produced is widely used for electrodes in electro-chemical operations, as well as for dynamo brushes, lead pencils, and the like.

Phosphorus. During the last few years an electrothermal process has been largely employed for the manufacture of phosphorus. Calcium phosphate, mixed with sand and carbon, is fed into an electric furnace provided with a closely fitting cover with an outlet for the vapour and gases produced during the operation; these gases are then passed through a condenser to separate the condensible portion. The furnaces are smaller than those used in carborundum production, and commonly make about $1\frac{1}{2}$ cwt. of phosphorus each per diem. At the temperature of the furnace the silica (sand) attacks the calcium phosphate, forming silicate, and setting free phosphorus pentoxide, which is attacked by the carbon of the charge, forming phosphorus and carbon monoxide gas. As phosphorus boils at 290° C. (554° F.), it is produced in the form of vapour, which, mingled with the carbon monoxide, passes to the condenser, where it is condensed. It is then cast under water into the sticks in which it is known in commerce. The calcium silicate remains in the furnace in the form of a liquid slag, which may be run off to make room for a further charge, so that the action is practically continuous. Kaolin may with advantage be used in addition to or in part substitution for sand, because the double silicate thus formed is more fusible than the single silicate of lime. The alternating current is generally used, the action not being electrolytic. One of the special advantages of the electrical over the older process is that the distilling vessels have a longer life, owing to the fact that they are not externally heated, and so subjected to a relatively high temperature when in contact with the corrosive slag formed in the process. The Readman-Parker process (see *Journ. Soc. Chem. Industry*, 1891, vol. x. p. 445) appears to be very generally adopted. Readman, experimenting with a Cowles furnace in Staffordshire in 1888, patented his process, and in the same year Parker and Robinson, working independently, patented a similar one. The two inventors then co-operated, an experimental plant was run successfully, and the patents were taken over by the leading firm of phosphorus manufacturers. With the object of obtaining a valuable bye-product in place of the slag produced in this furnace, several patentees (*e.g.*, Hilbert and Frank, Billaudot, Bradley and Jacobs, and others) have sought to combine the manufacture of calcium carbide and phosphorus by using only calcium phosphate and carbon, effecting direct reduction by carbon at a high temperature. It remains to be seen whether the result will be satisfactory industrially.

Electrolytic Processes.—Bunsen and Deville, working independently, both produced metallic aluminium on a small scale in 1854 by the electrolysis of the fused double chloride of aluminium and sodium contained in a porcelain crucible, heated externally in a gas flame, and divided into two compartments, one containing a carbon anode, the other a carbon or platinum (Deville) cathode. This process could not well be used industrially, not only because at that time there was no cheap source of electric energy, but because the double chloride employed is very hygroscopic, and is therefore liable, unless stored in a perfectly dry place, to become converted into hydrated chloride which will not fuse, but is, on heating, decomposed into alumina and hydrochloric acid. The dry chloride, too, is volatile at comparatively low temperatures, so that it is practically impossible to avoid loss by vaporization, and moreover, the use of a chloride at all is objectionable, because of the difficulty in dealing with the corrosive and suffocating chlorine evolved at the anode. The actual system adopted in these experiments involves the use of external firing, which, as already pointed out, is usually to be avoided. Attempts to deposit aluminium from aqueous solution have been unsuccessful, and the reduction of alumina (aluminium oxide) by carbon in the electric furnace cannot well be used for the production of pure aluminium, on account of the readiness with which the metal at these high temperatures combines with carbon, and is thus rendered brittle. The use of the electric arc for the reduction of aluminium compounds other than the oxide has not met with success industrially. Speaking generally, the heat of the arc is too local and too intense for use except for the production of extremely high temperatures. From 1870 to the present time numerous patents have been granted for methods of reducing aluminium. The processes by which it is now for the most part made—the Héroult, the C. M. Hall, and the Minet—are in principle practically the same, and have entirely replaced the older, purely chemical method.

Aluminium reduction.

The furnace consists of an iron or other tank lined with stamped carbon dust, the whole of the lining acting as the cathode. A stout carbon rod, or a bundle of such rods, forms an anode, which may be lowered into the tank to any required depth. A cover to the tank is provided, with apertures for the anode and for introducing the charge. In some furnaces a tap-hole, fitted with a removable plug, is placed at one side, on a level with the bottom, so that a portion of the reduced aluminium may be run into a ladle from time to time; in others, the aluminium is removed from the tank by means of a ladle or a siphon. The bath consists usually of a mixture of the fluorides of aluminium, sodium and calcium, or of cryolite (a natural double fluoride of aluminium and sodium), with or without admixture with other fluorides. The mixture chosen must be one which melts readily at a bright red heat; it is either melted, little by little, in the furnace itself, with the aid of the current, a further quantity of charge being added as required until the tank is sufficiently full, or it is melted in an ordinary furnace outside, and then run into the electric furnace when ready for use. But it is not the fluoride that is electrolysed. The mixture of fluorides has the power, when melted at a red heat, of dissolving about one-fifth of its weight of aluminium oxide (alumina), just as water will dissolve copper sulphate. The electrolysis of this solution is comparable with that of copper sulphate—it is the dissolved substance (alumina), not the solvent (fluoride), which is dissociated by the electric current. The voltage theoretically required for the reduction is therefore that necessary for the decomposition of alumina, or about 2·8 volts. But since no external heat is applied, and during the whole period loss of heat by radiation is taking place, the mass would soon cool below its fusing point, and would therefore solidify, unless a current-density were used sufficiently high to ensure that the heat lost is made good by the conversion of electric into heat energy by the current in overcoming the resistance of the bath. For this reason a high electromotive force is necessary to drive the current through the mass, and of the total energy consumed a great part employed is expended to produce heat. In practice, the pressure applied is about 4 volts. The alumina is electrolysed into aluminium, which is deposited on the bottom and side walls of the tank, and oxygen, which, being liberated on the surface of the red-hot carbon anode, combines with it to form carbonic oxide (CO). The anode thus wears away, but in so doing contributes by its combustion towards the heat necessary to maintain the fluidity of the electrolyte. The expenditure of anode carbon is, however, somewhat in excess of the amount (2 ℔ of carbon : 3 ℔ of aluminium) theoretically necessary according to the equation $Al_2O_3 + 3C = Al_2 + 3CO$, partly owing to oxidation by air, partly, no doubt, to disintegration; and in practice the consumption of carbon is often equal in weight to the aluminium reduced. The aluminium is deposited at the temperature of the bath, which is commonly about 800° C. (1,500° F.), and therefore above the fusing-point of the metal (654° C. or 1200 F.), so that it is perfectly fluid and may readily be tapped or ladled out. Fresh alumina is introduced from time to time to dissolve into the bath and take the place of that which has been electrolysed. Thus the action of the furnace is continuous. The fluorides are practically unchanged, and may remain in use for a long period. The alumina and the carbon anode, both of which are used up in the process, must be as pure as possible. As aluminium stands very high in the list of electro-positive metals, nearly every other metal, and even certain metalloids, such as silicon, if present in the bath, would be deposited more readily than it, and would therefore be co-precipitated, rendering the product impure and less marketable. The fluorides, on the other hand, need not be absolutely pure initially, because they remain in use for a long time, and any impurity they may contain at first is removed in the first batch of aluminium deposited, the solvent then remaining fairly pure. Commercial aluminium now rarely contains more than from 1 to 1½ per cent. of impurities, which consist chiefly of iron, silicon, and carbon, and the best qualities are even purer.

In the early days of the electric smelting of aluminium an expenditure of 22 electrical horse-power hours (16½ kilowatt hours) was necessary for every pound of aluminium produced; this, at a later date, was reduced to 16 E.H.P. hours (or 12 K.W. hours), and at Foyers, in Scotland, the expenditure per pound has now been reduced to 12 E.H.P. hours (or 9 K.W. hours). It may be noted that at Foyers (see *Journ. Soc. Chem. Industry*, 1898, vol. xvii. p. 308) the total current employed in each furnace is 8000 amperes, and the current-density is 35 amperes per sq. in. of anode surface, and nearly 4·8 amperes per sq. in. of cathode surface, thus indicating that the areas of anode and cathode immersed are respectively about 228 sq. in. and 11½ sq. ft. It would appear that rather more than one-third of the energy consumed, and about three-fifths of the current volume applied, are usefully employed in depositing aluminium.

Many other processes have been proposed for cheapening the process of reducing aluminium. The direction in which many inventors have worked has been to find a suitable compound of aluminium with a lower heat of formation than the oxide, as such a substance would require a lower electromotive force to effect its decomposition, and would therefore entail a smaller expenditure of energy to produce a given weight of the metal. Aluminium sulphide is such a substance, requiring only 0·9 volt theoretically for decomposition, but one of the chief difficulties is to find a sufficiently economical method of preparing it. The Aluminium Industrie Aktiengesellschaft took out a patent in Germany in 1890 for the electrolysis of this substance. Peniakoff in 1896, Blackmore in 1897, and others have also worked at sulphide processes, but there is at present no indication that any of them will displace the oxide-electrolysis process already described.

Magnesium reduction.

The problem of magnesium reduction is in many respects similar to that of aluminium extraction, but the lightness of the metal as compared, bulk for bulk, with its fused salts (its specific gravity is only 1·75 in the solid state), and the readiness with which it burns when exposed to air at high temperatures, render the problem somewhat more difficult. Moissan found that the oxide resists reduction by carbon in the electric furnace, so that electrolysis of a fusible salt of the metal must be resorted to. Bunsen, in 1852, electrolysed fused magnesium chloride in a porcelain crucible, divided into two compartments by a porcelain partition which did not quite reach the bottom. The electrodes were shaped carbon rods passing through perforations in a fire-clay lid, the cathode having inverted steps cut on the side facing the anode, so that there should be three or four ledges to intercept and retain globules of molten magnesium accumulating on the cathode surface, and tending to float upwards to the top of the bath. The separation into two compartments was necessary to prevent the passage of chlorine to the cathode side, where it would recombine with magnesium. In later processes, carnallite (a natural double chloride of magnesium and potassium) has commonly, after careful dehydration, been substituted for the single chloride. Graetzel's process, which was at one time employed, consisted in electrolysing the chloride in a metal crucible heated externally, the crucible itself forming the cathode, and the magnesium being deposited upon its inner surface. Suspended within this was a fire-clay cell closed at the top and bottom, but with large perforations around the side walls near the bottom, and with a side tube near the top to conduct away the chlorine generated on the surface of the carbon anode, which is suspended within this cell through a hole in its cover. The outer crucible was also provided with an annular cover, so that the space above the melted charge could be filled with a reducing gas, such as coal gas, to prevent oxidation of the reduced magnesium by contact with air. The apertures at the bottom of the fire-clay cell allowed the passage of melted electrolyte, and therefore of the current, but, being near the bottom, prevented the escape of chlorine into the outer cell excepting by diffusion. Following a suggestion made by Deville in the case of aluminium reduction, an attempt was made to replenish the bath with magnesium by introducing into the anode cell a compressed rod of magnesia and carbon, in the expectation that, in the presence of chlorine, the magnesia would be reduced by the carbon. The rods, however, crumbled into the bath and were unsatisfactory. Borchers also uses an externally heated metal cathode vessel as the cathode; it is provided with a supporting collar or flange a little below the top, so that the upper part of the vessel is exposed to the cooling influence of the air, in order that a crust of solidified salt may there be formed, and so prevent the creeping of the electrolyte over the top. The carbon anode passes through the cover of a porcelain cylinder, open at the bottom, and provided with a side-tube at the top to remove the chlorine formed during electrolysis. The operation is conducted at a dull red heat (about 760° C. or 1400° F.), the current density being about 0·64 amperes per sq. in. of cathode surface, and the pressure about 7 volts. The fusing-point of the metal is about 730° C. (1350° F.), and the magnesium is therefore reduced in the form of melted globules which gradually accumulate. At intervals the current is interrupted, the cover removed, and the temperature of the vessel raised considerably above the melting-point of magnesium. The metal is then removed from the walls with the aid of an iron scraper, and the whole mass poured into a sheet-iron tray, where it solidifies. The solidified chloride is then broken up, the shots and fused masses of magnesium are picked out, run together in a plumbago crucible without flux, and poured into a suitable mould. Smaller pieces are thrown into a bath of melted carnallite and pressed together with an iron rod, the bath being then heated until the globules of metal float to the top, when they may be removed in perforated iron ladles, through the holes in which the fused chloride can drain away, but through which the melted magnesium cannot pass by reason of its high surface tension. The globules are then re-melted. For some years past practically the whole of the magnesium made has been obtained electrolytically.

The isolation of the alkali metals from caustic alkalis by Davy, in 1808, was one of the earliest triumphs of electrolysis. Until quite recently, however, the whole output of these metals was obtained by a metallurgical method; but now electrolytic processes alone are used. Since 1851, when Charles Watt patented his process for the reduction of the metals from fused chlorides, many inventors have worked at the subject, most of them electrolysing pure or mixed chlorides. Among the difficulties here to be contended with are the destructive action of fused chlorides and of the reduced alkali metals upon most non-metallic substances available for the containing vessel and its partition, and also of the anode chlorine upon metals; also the low fusing-point (95° C. or 203° F. for sodium, and 62° C. or 144° F. for potassium), and the low specific gravity of the metals, so that the separated metal floats as a fused layer upon the top of the melted salt. Again, pure sodium chloride melts at about 775° C. (1427° F.), while sodium boils at about 900° C., so that the margin of safety is but small if loss by vaporization is to be prevented. Borchers (*Zeitschrift f. angewandte Chem.*, 1893, vol. xvi. p. 486) endeavours to contend against the first difficulty by employing an iron cathode vessel and a chamotte (fire-clay) anode chamber united by a specially constructed water-cooled joint. The other difficulty is to some extent met by using mixed chlorides (*e.g.*, sodium, potassium, and strontium chlorides for sodium extraction), as these melt at a lower temperature than does the pure chloride. Castner, whose sodium process (as employed at Oldbury and Niagara and in Germany) has displaced not only the old metallurgical, but the chloride method, reverted to the electrolysis of fused caustic soda. The apparatus described in the patent specification is an iron cylinder heated by gas rings below, with a narrower cylinder beneath, through which passes upwards a stout iron cathode rod cemented in place by caustic soda solidified in the narrower vessel. Iron anodes are suspended around the cathode, and between the two is a cylinder of iron gauze at the bottom with a sheet-iron continuation above, the latter being provided with a movable cover. During electrolysis, oxygen is evolved at the anode and escapes from the outer vessel, while the sodium deposited in globules on the cathode floats upwards into the iron cylinder, within which it accumulates, and from which it may be removed at intervals by means of a perforated iron ladle, the fused salt, but not the metal, being able to pass freely through the perforations. The sodium is then cast into moulds. Sodium hydroxide has certain advantages compared with chloride, although it is more costly; its fusing-point is only 320° C. (600° F.), and no anode chlorine is produced, so that both containing vessel and anode may be of iron, and no porous partition is necessary. Alloys of sodium and lead have been prepared successfully from their fused chlorides, and in the article on ELECTRO-CHEMISTRY allusion is made to their use in the production of caustic alkalis.

Reduction of sodium and potassium.

Calcium, barium, and strontium have all been produced by electro-metallurgical methods, but the processes have only a laboratory interest at present. Lead, zinc, and other metals have also been reduced in this manner, but the industrial development of these processes has yet to come.

Philadelphia, 1896.

(W. G. M.)

Elets (pronounced *Yelets*), a district town of Russia, government and 121 miles by rail east-south-east of Orel. It has grown rapidly since the development of the railway system, has gymnasia for boys and girls and other schools, and is now an important centre and depôt for trade in corn, live-stock, hides, tallow, wool, metals, and leather. The goods sent to it by rail during the year amount to an average of 171,500 tons. Population (1897), 37,455.

Eleusis.—The excavations at Eleusis have been carried on systematically by M. Philios for the Greek Archæological Society since 1882, and have laid bare the whole of the sacred precinct. It is now possible to trace its boundaries as extended at various periods, and also many successive stages in the history of the Telesterion, or Hall of Initiation. These complete excavations have shown the earlier and partial excavations to have been in some respects deceptive.

In front of the main entrance of the precinct is a large paved area, with the foundations of a temple in it, usually identified as that of Artemis Propylæa; in their present form both area and temple date from Roman times; and on each side of the Great Propylæa are the foundations of a Roman triumphal arch. Just below the steps of the Propylæa, on the left as one enters, there has been discovered, at a lower level than the Roman pavement, the curb surrounding an early well. This is almost certainly the *καλλίχορον φρέαρ* mentioned by Pausanias. The Great Propylæa is a structure of Roman Imperial date, in close imitation of the Propylæa on the Athenian Acropolis. It is, however, set in a wall of 6th-century work, though repaired in later times. This wall encloses a sort of outer court, of irregular triangular shape. The Small Propylæa is not set exactly opposite to the Great Propylæa, but at an angle to it; an inscription on the architrave records that it was built by Appius Claudius Pulcher, the contemporary of Cicero. It is also set in a later wall that occupies approximately the same position as two earlier ones, which date from the 6th and 5th centuries respectively, and must have indicated the boundary of the inner precinct. From the Small Propylæa a paved road of Roman date leads to one of the doors of the Telesterion. Above the Small Propylæa, partly set beneath the overhanging rock, is the precinct of Pluto; it has a curious natural cleft approached by rock-cut steps. Several inscriptions and other antiquities were found here, including the famous head, now in Athens, usually called Eubuleus, though the evidence for its identification is far from satisfactory. A little farther on is a rock-cut platform, with a well, approached by a broad flight of steps, which probably served for spectators of the sacred procession. Beyond this, close to the side of the Telesterion, are the foundations of a temple on higher ground; it has been conjectured that this was the temple of Demeter, but there is no evidence that such a building existed in historic times, apart from the Telesterion.

The Telesterion, or Hall of Initiation, was a large covered building, about 170 feet square. It was surrounded on all sides by steps, which must have served as seats for the mystæ, while the sacred dramas and processions took place on the floor of the hall: these seats were partly built up, partly cut in the solid rock; in later times they appear to have been cased with marble. There were two doors on each side of the hall, except the north-west, where it is cut out of the solid rock, and a rock terrace at a higher level adjoins it; this terrace may have been the station of those who were not yet admitted to the full initiation. The roof of the hall was carried by rows of columns, which were more than once renewed.

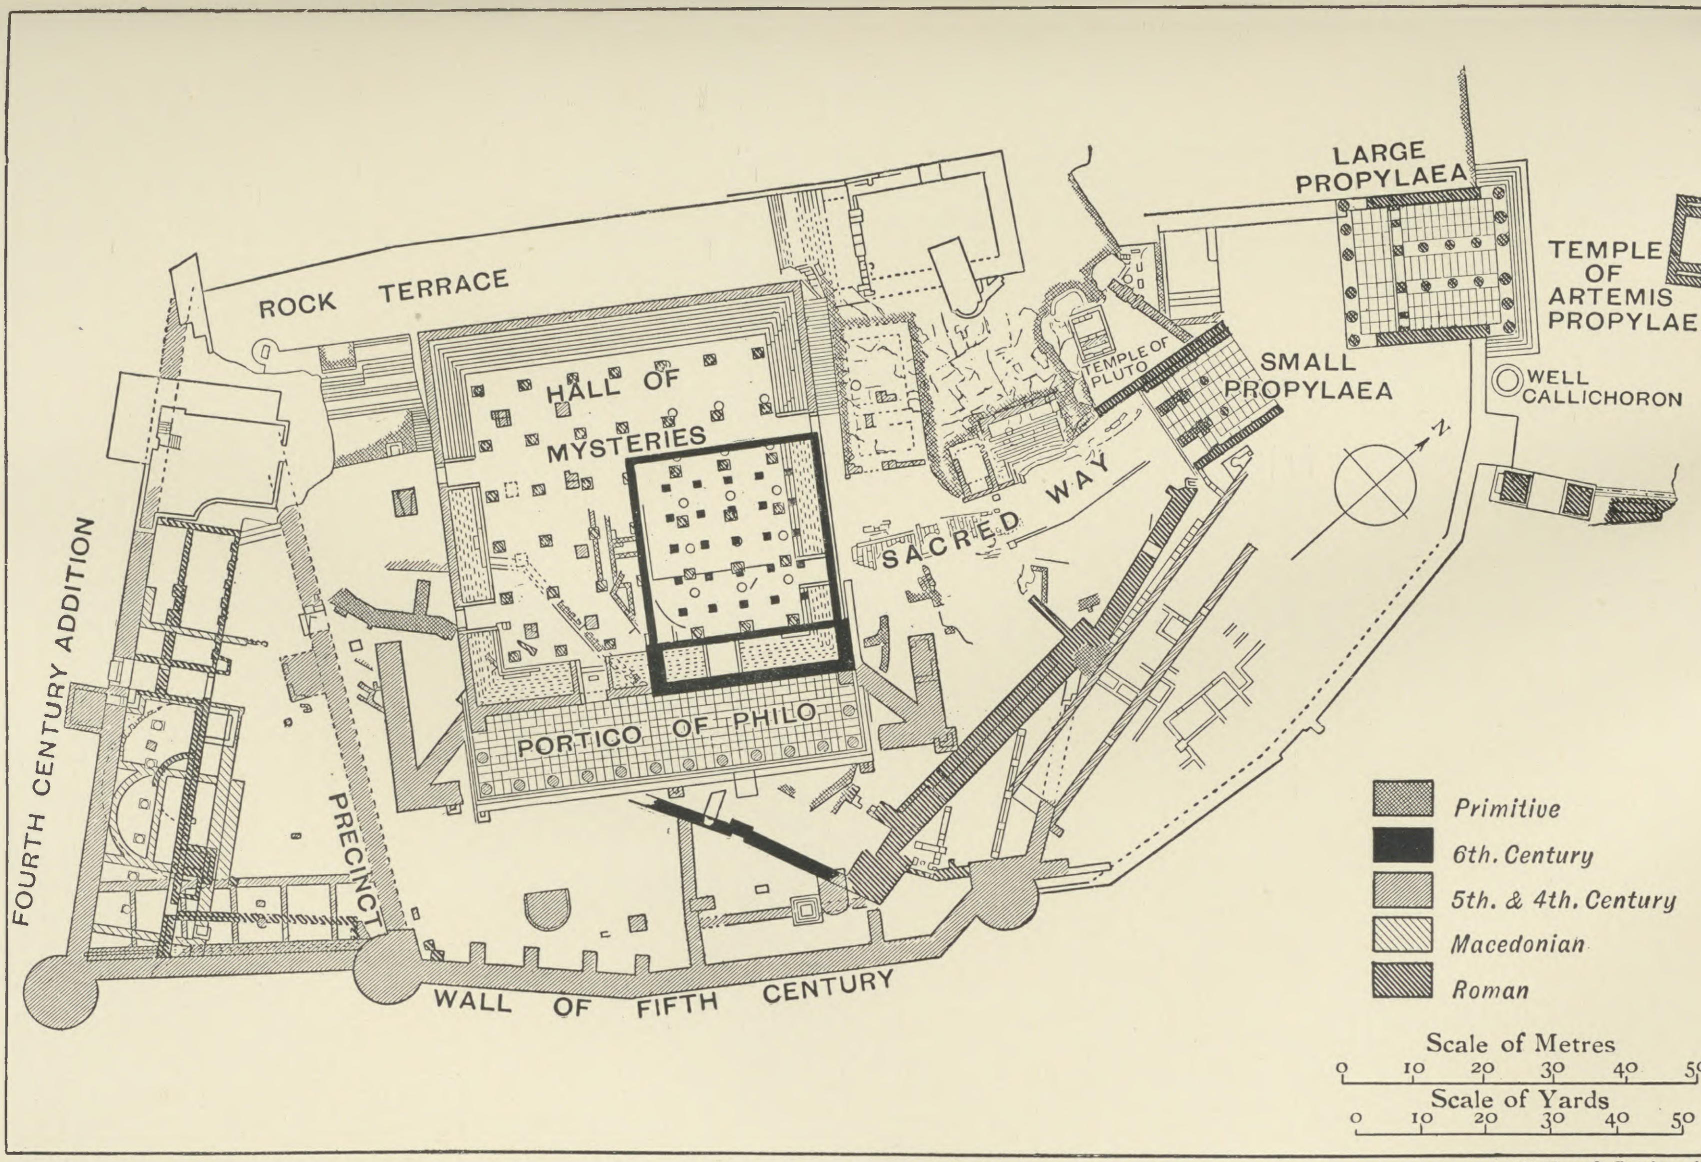
The architectural history of the hall has been traced by Professor Dörpfeld with the help of the various foundations that have been brought to light. The earliest building on the site is a small rectangular structure, with walls of polygonal masonry, built of the rock quarried on the spot. This was succeeded by a square hall, almost of the same plan as the later Telesterion, but about a quarter of the size; its eastern corner coincides with that of the later building, and it appears to have had a portico in front like that which, in the later hall, was a later addition. Its roof was carried by columns, of which the bases can still be seen. This building has with great probability been assigned to the time of Pisistratus; it was destroyed by the Persians. Between this event and the erection of the present hall, which must be substantially the one designed by Ictinus in the time of Pericles, there must have been a restoration, of which we may see the remains in a set of round sinkings to carry columns, which occur only in the north-east part of the hall; a set of bases arranged on a different system occur in the south-west part, and it is difficult to see how these two systems could be reconciled unless there were some sort of partition between the two parts of the hall. Both sets were removed to make way for the later columns, of which the bases and some of the drums still remain. These later columns are shown, by inscriptions and other fragments built into their bases, to belong to later Roman times. At the eastern and southern corners of the hall of Ictinus are projecting masses of masonry, which may be the foundation for a portico that was to be added; but perhaps they were only buttresses, intended to resist the thrust of the roof of this huge structure, which rested at its northern and western corners against the solid rock of the hill. On the south-east side the hall is faced with a portico, extending its whole width; the marble pavement of this portico is a most conspicuous feature of Eleusis at the present day. The portico was added to the hall by the architect Philo, under Demetrius Phalereus, about the end of the 4th century B.C. It was never completed, for the fluting of its columns still remains unfinished.

The Telesterion took up the greater part of the sacred precinct, which seems merely to have served to keep the profane away from the temple. The massive walls and towers of the time of Pericles, which resemble those of a fortress, are quite close in on the south and east; later, probably in the 4th century B.C., the precinct was extended farther to the south, and at its end was erected a building of considerable extent, including a curious apsidal chamber, for which a similar but larger curved structure was substituted in Roman times. This was probably the Buleuterium. The precinct was full of altars, dedications, and inscriptions; and many fragments of sculpture, pottery, and other antiquities, from the earliest to the latest days of Greece, have been discovered. It is to be noted that the subterranean passages, which some earlier explorers imagined to be connected with the celebration of the mysteries, have proved to be nothing but cisterns or water-courses.

The excavations of Eleusis, and the antiquities found in them, have been published from time to time in the Ἐφημερὶς Ἀρχαιολογική and in the Πρακτικά of the Greek Archæological Society, especially for 1887 and 1895. See also D. Philios, *Éleusis, ses mystères, ses ruines, et son Musée.* Inscriptions have also been published in the *Bulletin de Correspondance Hellénique.*

(E. GR.)

Elevators or **Lifts** are machines for raising or lowering loads, whether of people or material, from one level to another. They are operated by steam, hydraulic, or electric power, or, when small and light, by hand. Their construction varies with the magnitude of the work to be performed and the character of the motive power. In private houses, where only small weights, as coal, food, &c., have to be transferred from one floor to another, they usually consist simply of a small counter-balanced platform suspended from the roof or an upper floor by a tackle, the running part of which hangs from



Walker & Cockerell sc.

Eleusis; showing Excavations.

top to bottom and can be reached and operated at any level. If the platform is sufficiently large and strong to permit one or more persons to be carried, the hoisting is often performed by the person raised, or by an attendant, who manages the tackle from the "car" or cage. In hotels and warehouses, where great weights and numbers of people have to be lifted, or a high speed of elevation is demanded, some form of motor is necessary. This is usually, directly or indirectly, a steam engine or occasionally a gas engine; sometimes a water-pressure engine is adopted, and recently it has become more and more common to employ an electric motor deriving its energy from the general distribution of the city. Large establishments, hotels or business houses, commonly have their own source of energy, an electric or other power "plant," on the premises.

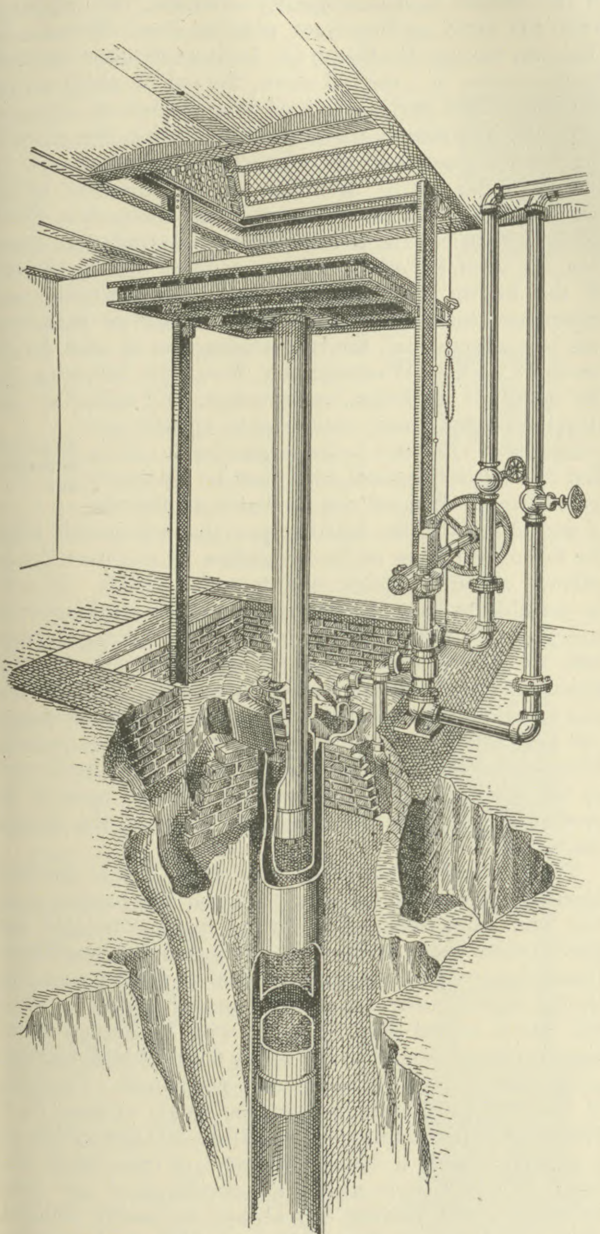


FIG. 1.—The Plunger, or Direct Lift Hydraulic Engine.

The Hydraulic Elevator is the simplest in construction of elevators proper, sometimes consisting merely of a long pipe set deeply in the ground under the cage and containing a correspondingly long plunger, which rises and falls as required and carries the elevator-cage on its upper end (Fig. 1). The "stroke" is thus necessarily equal to the height traversed by the cage, with some surplus to keep the plunger steady within its guiding-pipe. The pipe or pump chamber has a length exceeding the maximum rise and fall of the plunger, and must be strong enough to sustain safely the heavy hydraulic pressures needed to raise plunger and cage with load. The power is usually supplied by a steam pump (occasionally by a hydraulic motor), which forces water into the chamber of the great pipe as the elevator rises, a waste-cock drawing off the liquid in the process of lowering the cage. A single handle within the cage generally serves to apply the pressure when raising, and to reduce it when lowering the load. When an ample supply of water can be commanded at the top of the hoist, a still simpler mechanism is available. The cable is supported from a pulley, and the cage, which is attached to one of its ends, is nearly balanced by a water tank attached to the other. When it is desired to raise the cage and its load, the water tank, which is then at the top, is filled with water until it becomes sufficiently heavy to overbalance the weight of the cage, when it falls by the force of gravity. To reverse the motion, water is withdrawn from the tank until it becomes lighter than the cage, which then descends by virtue of its superior weight. A suitable brake regulates the speed of the cage, whether rising or falling. The most common form of this class of elevator, for important work and under usual conditions of operation, as in cities, consists of a suspended cage, carried by a tackle, the running part of which is connected with a set of pulleys at each end of a frame (Fig. 2). The rope is made fast at one end, and its intermediate part is carried round first one pulley at the farther end of the frame and then round another at the nearer end, and so on as often as is found advisable in the particular case. The two pulley shafts carrying these two sets of pulleys are made to traverse the frame in such a way as, by their separation, to haul in on the running part, or, by their approximation, to permit the weight of the cage to haul out the rope. By this alternate hauling and "rendering" of the rope the cage is raised and lowered. The use of a number of parallel and independent sets of pulleys and tackles assures safety in case of the breakage of any one, each being strong enough alone to hold the load. The movement of the pair of pulley shafts is effected by a water-pressure engine, actuating the plunger of a pump which is similar to that used in the preceding apparatus, but being relatively of short stroke and large diameter, is more satisfactory in design and construction as well as in operation. This form of construction is the usual one for elevators employed in commercial work. A steam engine, however, or electric motor, may be directly attached to the system of pulleys. The majority of the existing elevators are constructed on such a plan, being denominated steam, hydraulic, or electric, according to the form of energy employed as the primary source of power.

Hydraulic elevators.

An account of the older hydraulic elevators having been given in *Ency. Brit.* (9th ed., vol. xiv. p. 575), it is the intention here to describe the later forms in common use, especially in the United States, where, owing to the erection of tall buildings and the general adoption of such machines in great warehouses, there has been much more rapid and more extensive development than in other countries, and where enterprise, sharp competition, and exceptional ingenuity on the part of both manufacturer and artisan have combined to evolve most ingenious and most efficient systems of general construction and details. The electric elevator, particularly in the cities, has undergone remarkable development, and the commencement of the 20th century finds it in by far the most extensive use; the older

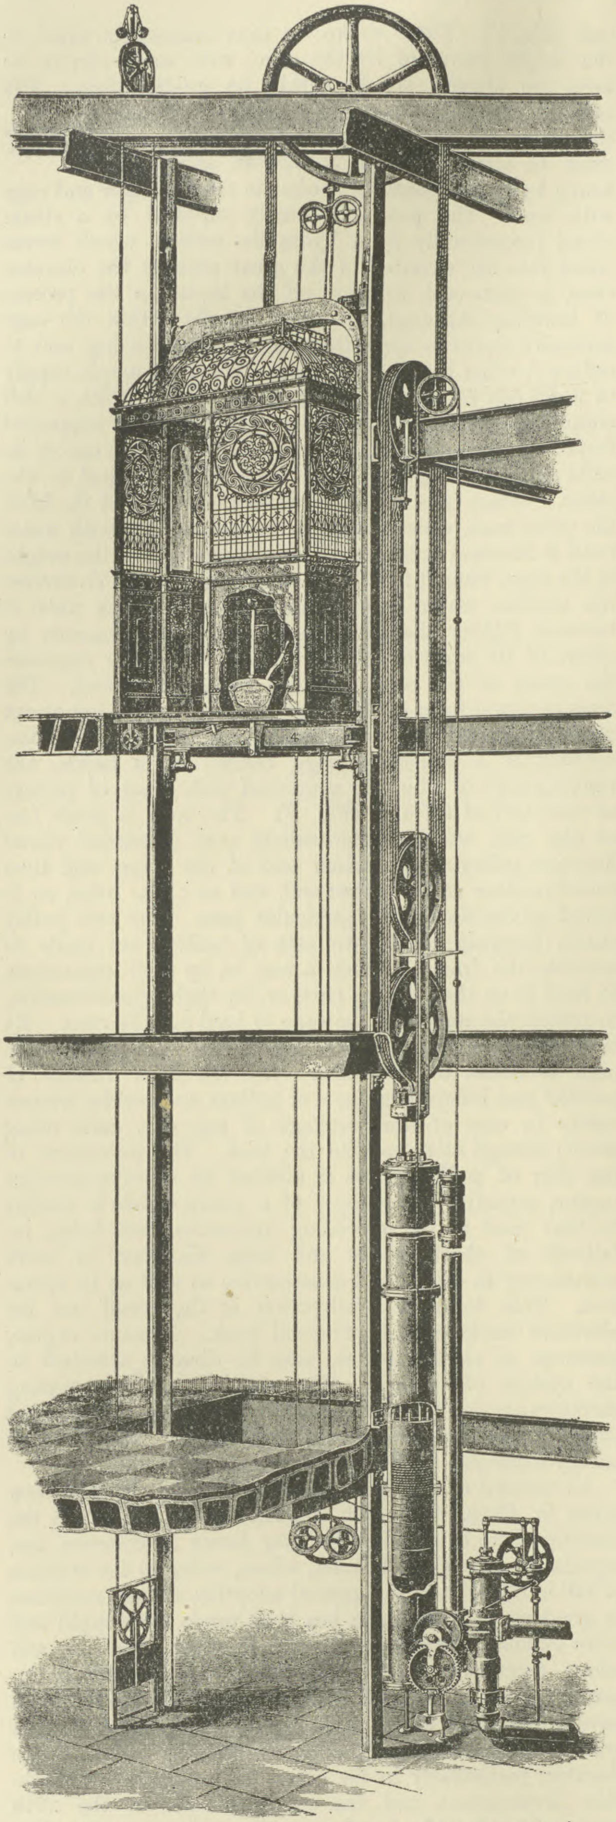

FIG. 2.—The Otis Standard Hydraulic Passenger Lift, with pilot valve and lever-operating device.

forms are rapidly disappearing, except in localities which offer special advantages for their employment. The history of the elevator is chronologically extensive, but only since 1850 has rapid or important progress been effected. In that year George H. Fox & Co. built an elevator operated by the motion of a vertical screw, the nut on which carried the cage. This device was used in a number of instances, especially in hotels in the large cities, during the succeeding twenty years, and was then generally supplanted by the hydraulic lift of the kind already described as the plunger-lift. With the increased demand for power, speed, safety, convenience of manipulation, and comfort in operation, the inventive ability of the engineer developed each of the known systems more and more perfectly, and experience gradually showed to what service each type was best adapted and the best construction of each for its peculiar work. Whatever the class, the following are the essentials of design, construction, and operation: the elevator must be safe, comfortable, speedy, and convenient; must not be too expensive in either first cost or maintenance, and must be absolutely trustworthy. It must not be liable to fracture of any element of the hoisting gear that will permit either the fall of the cage or its projection by an overweighted balance upwards against the top of its shaft. It must be possible to stop it, whether in regular working or in emergency, or when accident occurs, with sufficient promptness, yet without endangering life or property, or even very seriously inconveniencing the passengers. Acceleration and retardation in starting and stopping must be smooth and easy, the stop must be capable of being made precisely where and when intended, and no danger must be incurred by the passengers from contact with running parts of the mechanism or with the walls and doors of the elevator shaft.

Essentials of design, &c.

These requirements have been fully met in the later forms of elevator commonly employed for passenger service, and those designed for lifting heavy "freight" and merchandise have hardly less safety and trustworthiness. Usual sizes range from loads of 1000 to 5000 pounds, but special constructions are not infrequently called for which can take a loaded dray, weighing with its burden several tons, from the ground to the upper floors of high buildings at the rate of from 100 to 300 feet per minute. Capacities of 100,000 to 750,000 foot-pounds, speeds of from 80 to 250 feet a minute unloaded, and 75 to 200 feet loaded, are a standard, with a height of travel of from 50 to 200 feet. Where electric motors are employed, as now usual in cities where current can always be readily obtained, their speed ranges from 600 and 700 revolutions per minute in the larger to 1000 and 1200 in the smaller sizes, corresponding to from 20 down to 4 or 5 horse-power. Two or more counter-weights are employed, and from four to six suspension cables ensure as nearly as possible absolute safety. The electric elevators of the Central Electric Railway, London, are guaranteed to raise 17,000 pounds 65 feet, in some of its shafts, in 30 seconds from start to stop. Over 100,000 feet of $\frac{7}{8}$-inch and 17,000 feet of $\frac{3}{4}$-inch steel rope are required for its 24 shafts, and each rope carries from 16 to 22 tons without breaking. The steel used in the cables, of which there are four to six for each car and counter-weight, has a tenacity of 85 to 90 tons per square inch of section of wire. The maximum pull on each set of rope is assumed to be not over 9500 pounds, the remainder of the load being taken by the counter-balance. Oil "dash-pots" or buffers, into which enter plungers attached to the bottom of the cage, prevent too sudden a stop in case of accident, and safety-clutches with friction adjustments of ample power and fully tested before use give ample insurance against a fall even if all the cables should yield at once—an almost inconceivable contingency. The efficiency, *i.e.*, the ratio of work performed to power expended in the same time, was in these elevators found by test to be between 70 and 75 per cent.

Safety devices. Safety devices constitute perhaps the most important of the later improvements in elevator construction where passengers are carried. The simplest and, where practicable, most certain of them is the "air-cushion," a chamber into which the cage drops if detached or from any cause allowed to fall too rapidly to the bottom, compression of the air bringing it to rest without shock (Fig. 3). This chamber must be perfectly air-tight, except in so far as a purposely arranged clearance around the sides, diminishing downwards and in well-established proportion, is adjusted to permit a "dashpot" action and to prevent rebound. The air-cushion should be about one-tenth the depth of the elevator shaft; in high buildings it may be a well 20 or 30 feet deep. The Empire Building, in New York, is twenty storeys in height, and its air-cushion, at the bottom of 287 feet of travel of cage, is 50 feet deep, extending from the floor of the third storey to the bottom of the shaft. Sliding doors of great strength, and automatic in action, at the first and second floors, are the only openings. The shaft is tapered for some distance below the third floor, and then carried straight to the bottom. An inlet valve admits air freely as the cage rises, and an adjusted safety-valve provides against excess pressure. A "car," falling freely from the twentieth storey, was checked by this arrangement without injury to a basket of eggs placed on its floor, the weight being about 1 ton. The velocity of the fall attained a maximum at about 70 miles an hour, assuming retardation by friction to the extent of about 10 per cent. Other safety devices usually employed consist of catches under the floor of the cage, so arranged that they are held out of engagement by the pull on the cables. But if the strain is suddenly relieved, as by breakage of a cable or accident to the engine or motor, they instantly fly into place and, engaging strong side-struts in the shaft, hold the car until it can be once more lifted by its cables. These operate well when the cables part at or near the car, but they are apt to fail if the break occurs on the opposite side of the carrying sheaves at the top of the shaft, since the friction and inertia of the mass of the cables may in that case be sufficient to hold the pawls out of gear either entirely or until the headway is so great as to cause the smashing of all resistances when they do engage.

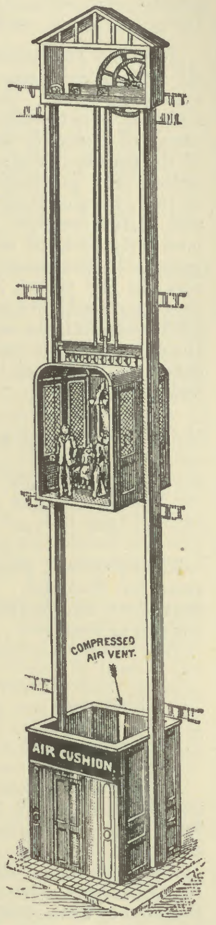

Fig. 3.—Safety Air-Cushion.

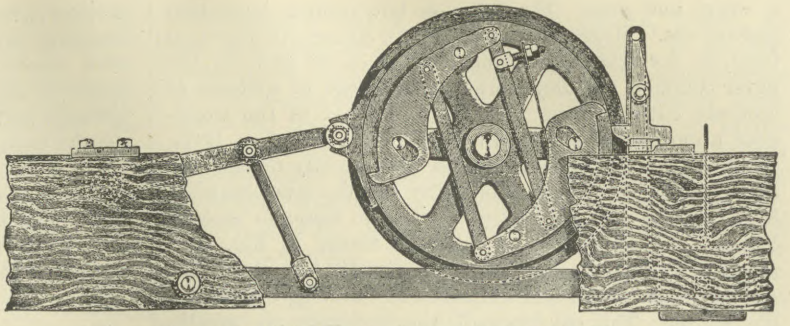

Fig. 4.—Centrifugal Elevator Governor (Stoke and Parish).

Another principle employed in safety arrangements is the action of inertia of parts properly formed and attached. Any dangerous acceleration of the cage causes the inertia of these parts to produce a retardation relative to the car which throws into action a brake or a catch, and thus controls the motion within safe limits or breaks the fall, entirely without injury. The hydraulic brake has been used in this apparatus, as have mechanical and pneumatic apparatus. This control of the speed of fall is most commonly secured by the employment of a centrifugal or other governor or regulator (Fig. 4). The governor may be on the top of the cage and driven by a stationary rope fixed between the upper and the lower ends of the shafts, or it may be placed at the top of the shaft and driven by a rope travelling with the car. Its action is usually to trip into service a set of spring grips or friction clutches, which, as a rule, grasp the guides of the cage and by their immense pressure and great resultant friction bring the cage to rest within a safe limit of speed, time, and distance. A coefficient of friction of about 15 per cent. is assumed in their design, and this estimate is confirmed by their operation. Pressures of 10 tons or more are sometimes provided in these grips to ensure the friction required. There are many different forms of safety device of these various classes, each maker having his own. The importance of absolute safety against a fall is so great that the best builders are not satisfied with any one form or principle, but combine provisions against every known danger, and often duplicate such precautions against the most common accidents.

The hoisting cables are handled by means of a winding drum driven by steam, electric, or other motor. Most commonly a system of gearing is arranged between the motor and the drum to accommodate the normal speeds of the two each to the other. This intermediate gearing consists of either a series of "spur" gears and pinions, or

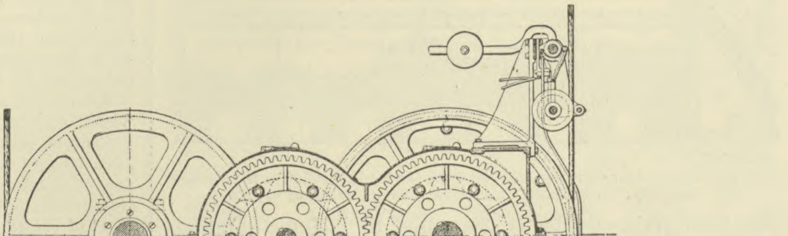

Fig. 5.—Sprague Worm-Gear.

a worm and gear. The latter is now coming more into general use. Recent improvements in construction and in form, as, for example, the introduction of the now old but never common Hindley worm, and the use of systems of accurate cutting, have made the efficiency of the worm-gear approximate closely to that of the spur-gear train, while the cost of construction has been greatly reduced by its employment, and the complexity and the space required have also been much lessened. In the Sprague electric elevator (the worm-gear of which is shown in Fig. 5) a motor of suitable design is coupled directly to a screw, the nut of which carries and displaces the moving sheaves of the cables. The efficiency of the apparatus is greatly

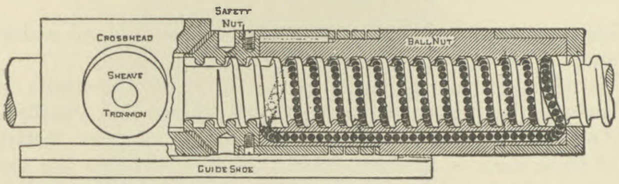

Fig. 6.—Multiple sheave type—hoisting nut at upper end of screw.

increased by the use of a ball-bearing system between the thread of the screw and that of the nut (Fig. 6).

The "Travelling Staircase" may be classed among the passenger elevators, as may be the "Travelling Platform or Sidewalk" among the "conveyors." It usually consists of a staircase so constructed that while the passenger is ascending it the whole structure is also ascending at a predetermined rate, so that the progress made is the sum of the two rates of motion. The system of "treads and risers" is carried on a long endless band of chain sustained by guides holding it in its desired line, and rendering at either end over cylinders or sprockets. The junctions between the stairway and the upper or lower floors are ingeniously arranged so as to avoid danger of injury to the passengers.

"Freight" elevators have the same general forms as the passenger elevators, but are often vastly larger and more powerful, and are not as a rule fitted up for such heights of lift, or constructed with such elaborate provision for safety or with any special finish. They are simple, strong, and durable, and should be economical in operation. Elevators raising grain, coal, earth, and similar materials, such as can be taken up by scooping into a bucket, or can be run into and out of the bucket by gravity, constitute a class by themselves, and entirely differ in construction from those just described. A set of buckets of suitable form and dimensions is fitted upon some kind of flexible carrying arrangement extending from the point of reception of the grain, fuel, or other material, to the point of delivery, with provisions for loading the bucket at the one end and discharging it at the other (Fig. 7).

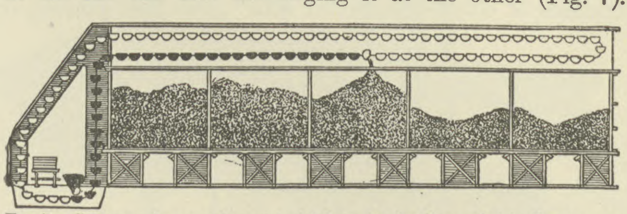

Fig. 7.—Conveyor for carrying material from the loading point to the storage bins, vertically, horizontally, or inclined, without shock or breakage.

The term grain elevator is often used to include buildings as well as machinery, and it is not unusual in Europe to hear a flour-mill, with its system of motor machinery, mills, elevator, and storage departments, spoken of as an "American elevator." The "conveyor" or bucket-chain elevator is very extensively employed where, as in transferring coal from point to point for the supply of large batteries of boilers or in excavating earthwork on large contracts, the path to be traversed has a variable direction in either a vertical or a horizontal plane, or in both. The flexibility of the system adapts it to such cases, and it often constitutes part, in this manner, of an extensive system of transportation of such materials. It is also the operative part of the apparatus often employed for dredging, the buckets acting also as scoops and taking the earth from the bottom of the channel and conveying it to the point of discharge. The bucket-and-chain dredge is sometimes built upon a large scale, as for the deepening of harbours or the cutting of canals, and somewhat similar mechanism is employed in the making of railway cuttings.

(R. H. T.)

Elgin, or Morayshire, a maritime county of North Scotland, bounded on the N. by the Moray Firth, on the E. and S.E. by Banffshire, on the S. and S.W. by Inverness-shire, and on the W. by Nairnshire.

Area and Population.—In 1891 the parish of Bellie and nearly all Rothes were placed in Elgin, and Boharm and Inveravon wholly in Banff; the Nairn portions of Dyke and Moy and Ardclach were transferred to Elgin; and the Elgin portion of the parish of Cromdale was constituted a parish of itself. The area of the county (foreshore excluded) is 308,499 acres, or 482 square miles. The population was, in 1881, 43,788; in 1891, 43,453; in 1891, on the above area, 43,471, of whom 20,368 were males and 23,103 females; in 1901, 44,808. On the old area, taking land only (304,606 acres or 475·9 square miles), the number of persons to the square mile in 1891 was 91, and the number of acres to the person 7·0. In the registration county the population decreased between 1881 and 1891 by 0·8 per cent. Between 1881 and 1891 the excess of births over deaths was 5925, and the decrease of the resident population 367. The following table gives particulars of births, deaths, and marriages in 1880, 1890, and 1899:—

Year.	Deaths.	Marriages.	Births.	Percentage of Illegitimate.
1880	812	274	1391	16·8
1890	818	233	1237	12·69
1899	760	270	1179	12·6

The birth-rate, death-rate, and marriage-rate are all below the rates for Scotland. The following table gives the birth-rate, death-rate, and marriage-rate per thousand of the population for a series of years:—

	1880.	1881–90.	1890.	1891–98.	1899.
Birth-rate . .	30·86	30·23	27·58	27·79	27·54
Death-rate . .	18·02	17·06	18·23	17·12	17·78
Marriage-rate .	6·08	5·52	5·19	6·02	6·31

In 1891 the number of Gaelic-speaking persons in the county was 2262, of whom 12 spoke Gaelic only; and there were 24 foreigners. The valuation in 1889–90 was £181,296; 1899–1900, £188,911.

Administration.—The county returns a member to Parliament in conjunction with Nairnshire. The royal burghs are Elgin, the county town (8407), and Forres (4313), the former belonging to the Elgin parliamentary group and the latter to the Inverness group. Lossiemouth (3889) is the largest police burgh. There are 19 civil parishes, 14 of which belong to the Morayshire Combination. The number of paupers and dependants in September 1899 was 1489. Elgin is included in one sheriffdom with Inverness and Nairn, and there is a resident sheriff-substitute at Elgin.

Education.—Twenty-one school boards manage 45 schools, which had in 1898–99 an average attendance of 6674; and 8 voluntary schools (one Episcopal and one Roman Catholic) had 766. There are academies at Elgin and Fochabers (Milne's Institution), and science and art and technical schools at Elgin and Grantown, and twelve other schools in the county earned grants in 1898 for giving higher education. The bulk of the "residue" grant is spent in subsidizing the agricultural department of Aberdeen University, the science schools at Elgin and Grantown, Milne's Institution, and science and art and technical classes elsewhere in the county.

Agriculture.—There has been a good deal of "improving" agriculture in Elgin of recent years, and the standard of farming is generally high. Of 1907 holdings in 1895, the average size was 53 acres. The percentage under 5 acres was 23·39, between 5 and 50 acres 44·05, and over 50 acres 32·56. The number of farms between 50 and 100 acres was 299; between 100 and

300, 282; between 300 and 500, 35; and over 500, 5. The percentage of cultivation was 32·9 in 1898. Heavy crops of barley are grown in the Laigh of Moray, and the barley acreage approximates more nearly to the oat acreage than in any other county except Haddington. In 1895 there were 46,688 acres under wood, 1936 having been planted since 1881. The following table gives the principal acreages at intervals of five years from 1880 :—

Year.	Area under Crops.	Corn Crops.	Green Crops.	Clover.	Permanent Pasture.	Fallow.
1880	104,992	40,192	20,410	39,264	4973	153
1885	106,004	40,551	19,738	39,709	5920	86
1890	102,738	39,034	18,786	39,257	5465	137
1895	101,758	36,922	17,996	37,343	9378	91
1899	101,689	36,497	17,793	38,964	8373	44

The following table gives particulars of the live-stock during the same years :—

Year.	Total Horses.	Total Cattle.	Cows or Heifers in Milk or Calf.	Sheep.	Pigs.
1880	5186	23,031	6832	52,202	2667
1885	5060	23,572	7285	60,364	3116
1890	4810	21,536	6571	55,957	3391
1895	5211	21,489	6197	61,802	2771
1899	4957	22,296	6895	72,514	2472

At the census of 1891, 4404 men and 450 women were returned as being engaged in agriculture.

Industries and Trade.—Distilling is the leading industry, there being as many as 15 distilleries in the county. There are woollen mills at Elgin and other places, and chemical works at Forres and Burghead. Extensions have been made in the harbours of Burghead (£60,000) and Hopeman (£20,000). Timber, fish, agricultural produce, and whisky are the principal articles of export, and coal and the raw materials for the chemical works are imported. Fishing is a considerable industry. To the four Morayshire ports there belonged, in 1899, 321 boats of 5429 tons, and 1004 resident fishermen and boys, and the value of the fish landed (about half herrings) was £32,575. The chief changes of recent years have been the decrease in the number of men and boys engaged, and the increase in the value of the boats and gear.

At the census of 1891, 4558 men and 1242 women were returned as being engaged in industrial pursuits. There are valuable sandstone quarries in the county; 28,348 tons of £5645 value were raised in 1895, and 37,124 tons of £8335 value in 1899. The average weight of the salmon despatched from the Spey, Lossie, and Findhorn district in the years 1894–98 was 485 tons. The railway mileage of the county was increased by 15 miles between 1875 and 1900, the longest of the new lines being one from Elgin to Garmouth (8⅝ miles).

(W. WA.)

Elgin, a city, royal and parliamentary burgh (Elgin group), and county town of Elgin, Scotland, 71¼ miles by rail north-west by west of Aberdeen. Modern structures include a new town-hall, public baths, a new academy, and the Victoria School of Science and Art. Lossie Green recreation ground was extended in 1888. Population of royal burgh (1881), 6286; (1901), 8260.

Elgin, a city of Kane county, Illinois, U.S.A., on the Fox river, at an altitude of 716 feet. It has fine water-power in the river. Amongst its large manufacturing interests is the Elgin watch factory, the products of which are widely known. One of the state hospitals for insane is situated here. Elgin is on branches of the Chicago and North-Western and the Chicago, Milwaukee, and St Paul Railways. Population (1880), 8787; (1890), 17,823; (1900), 22,433, of whom 5419 were foreign-born and 187 were negroes.

Elgon Mount, also known as Masawa, an extinct volcano in British East Africa, cut by 1° N. and 34½° E., forming a vast isolated mass over 40 miles in diameter. The outer slopes are in great measure precipitous on the north, west, and south, but fall more gradually to the east. The southern cliffs are remarkable for extensive caves, which have the appearance of water-worn caves on a coast-line and have for ages served as habitations for the natives. The higher parts slope gradually upwards to the rim of an old crater, lying somewhat north of the centre of the mass, and measuring some 8 miles in diameter. The highest point of the rim is about 14,100 feet above the sea. Steep spurs separated by narrow ravines run out from the mountain, affording the most picturesque scenery. The ravines are traversed by a great number of streams, which flow north-west and west to the Nile (through Lake Choga), south and south-east to Victoria Nyanza, and north-east to Lake Rudolf by the Turkwell, the head-stream of which rises within the crater, breaking through a deep cleft in its rim. To the north-west of the mountain a grassy plain, swampy in the rains, falls towards the chain of lakes ending in Choga; towards the north-east the country becomes more arid, while towards the south it is well wooded. The outer slopes are clothed in their upper regions with dense forest formed in part of bamboos, especially towards the south and west, in which directions the rainfall is greater than elsewhere. The lower slopes are exceptionally fertile on the west, and produce bananas in abundance. On the north-west and north the region between 6000 and 7000 feet possesses a delightful climate, and is well watered by streams of icy-cold water. The district of Save on the north is a halting-place for Arab and Swahili caravans going north. On the west the slopes are densely inhabited by small Bantu tribes, who style their country Masawa (whence the alternative name for the mountain); but on the south and north there are tribes which seem akin to the Gallas. Of these, the best known are the El-gonyi, from whom the name Elgon has been derived. They formerly lived almost entirely in the caves, but with the establishment of order most of them have descended to villages at the foot of the mountain. Elgon was first visited in 1883 by Joseph Thomson, who brought to light the cave-dwellings on the southern face. It was crossed from north to south, and its crater reached, in 1890 by Messrs Jackson and Gedge, while the first journey round it was made by Mr C. W. Hobley in 1896.

Eliot, Charles William (1834–——), president of Harvard University, U.S.A., was born in Boston, Mass., on the 20th of March 1834. He was the only son of Samuel Atkins Eliot, mayor of Boston, representative in Congress, and treasurer of Harvard College from 1842 to 1853. He attended the Latin School of Boston, and received the degree of B.A. from Harvard College in 1853. The next year he was made tutor in mathematics, and also studied chemistry. In 1857 he gave a course of lectures in chemistry in the medical college of the University, and in 1858 he was made assistant professor of mathematics and chemistry. In 1861 he was put in charge of the chemical department of Lawrence Scientific School. Two years later he went to Europe, where he spent two years in studying chemistry and the educational systems of England, France, and Germany. In 1865 he was appointed professor of analytical chemistry in the newly established Massachusetts Institute of Technology. This chair he held for four years, but in 1867–68 he was in Europe for fourteen months. In 1869 he was chosen president of Harvard University. President Eliot has laboured for increasing the unity of the educational system of the United States, for promoting the spirit of free inquiry on the part of teachers and of unrestricted choice of studies on the part of students, and for making available to the community, under wise conditions, all the resources of the university. The result has been the establishment at Harvard of a free optional system of studies, the advancement of professional and technical education, and other developments, which have given to Harvard a position in American education which it had not previously enjoyed. The university funds have increased from two and a quarter millions of dollars to twelve millions of dollars. A vast amount of money has been devoted to the erection of buildings and to the equipment of laboratories and libraries. The students have increased from about a thousand to about five thousand, and the tutorial staff from a hundred and fifty to five hundred. He has written two manuals of chemistry in collaboration with Professor F. H. Storer, and has published a few volumes of essays, largely upon educational or related subjects.

Eliot, George. See CROSS, M. A.

Elisabethgrad, or ELIZAVETGRAD, a fortress and district town of Russia, government and 152 miles north of Kherson, on Balta Kremenchug Railway, on the Ingul. It is a wealthy town, which has become an industrial centre for the region, especially on acount of its steam flour-mills, in which it is second only to Odessa, distilleries, mechanical works, &c., the aggregate annual produce of which exceeds £500,000. It is also a great centre for trade in corn and flour for export, and also in sheep, cattle, wool, leather, and timber. Five fairs are held annually. It has several gymnasia, a military school, a first-class meteorological station, and a spacious botanical garden. The population increased from 23,725 in 1860 to 61,841 in 1897.

Elisabethpol, a government of Russia, Transcaucasia, having Tiflis, Zakataly, and Daghestan on the N., Baku on the E., Persia on the S., and Erivan on the W. Area, 16,721 square miles. This vast government includes: (*a*) the southern slope of the main Caucasus range in the north-east, where the Tkhfan-dagh (13,764 ft.), Bazardyuz (14,722 ft.), and other peaks rise above the snowline; (*b*) the dry and unproductive steppes on the Kura, reaching 1000 ft. of altitude in the west and from 100 to 200 ft. only in the east, where irrigation is necessary for culture; and (*c*) the northern slopes of the Transcaucasian escarpment and portions of the Armenian plateau, which is intersected towards its western boundary, near Lake Gokcha, by chains of mountains consisting of trachytes and various crystalline rocks, and reaching from 11,000 to 12,856 ft. in Mount Kapudjikh. Elsewhere the country has the character of a plateau, 7000 to 8000 ft. high, deeply ravined by the tributaries of the Aras. All varieties of climate are found in this province, from the snowclad peaks, Alpine meadows, and stony deserts of the high levels, to the hill slopes, clothed with gardens and vineyards, and the dry Caspian steppes. Thus, at Shusha, on the plateau, at an altitude of 1368 ft., the average temperatures are: year 48°, January 26°, July 66°; yearly rainfall, 26·4 in.; while at Elisabethpol, in the valley of the Kura, they are: year 55°, January 32°·2, July 77°, and rainfall only 10·3 in. Nearly one-fifth of the surface is under forests.

The population, which was 871,557 in 1897 (only 392,124 women; 84,130 urban), consists chiefly of Azerbaijan Tatars (56 per cent.) and Armenians (35 per cent.). The remainder are Kurds (4·7 per cent.), Russians (a little over 1 per cent.), and a few Udines, Tates, &c. Peasants form the great bulk of the population, nearly two-thirds of them living on Crown lands, and the remainder on land belonging to landlords. Some of the Tatars and the Kurds still are nomadic. Wheat, Indian corn, barley, oats, and rye are grown, and the crops are estimated at 1,787,100 quarters of various cereals and 158,400 quarters of rice. Cultivation of the cotton tree has begun, but the rearing of silkworms is of old standing, especially at Nukha (32,700 cwts. of cocoons on the average are obtained every year). Nearly 8000 acres are under vine. Gardening reaches a high level of perfection. Liquorice root is obtained to the extent of about 700,000 cwts. The rearing of live-stock is largely carried on in the steppes, there being about 76,140 horses, 464,000 horned cattle, and 1,157,000 sheep. Copper (37,000 cwts.), some magnetic iron ore, cobalt ore, and a small quantity of naphtha are extracted, and nearly 9300 persons are employed in the 2200 factories and workshops. Carpet-weaving is widely spread. Owing to the Transcaucasian Railway, which crosses the province, trade, both in the interior and with Persia, is very brisk. The government is divided into 8 districts: Elisabethpol, Aresh, Jebrail, Jevanshir, Kazakh, Nukha, Shusha, and Zanglzur. The only towns, besides the capital, are Nukha (24,811 inhabitants) and Shusha (25,656).

Elisabethpol, formerly GANJA, capital of the above government, 120 miles by rail south-east of Tiflis and 3 miles from the railway. It is a very old town, which changed hands between Persians, Khozars, and Arabs even in the 7th century, and later fell into the possession of Mongols, Georgians, Persians, and Turks, until the Russians took it in 1796, and finally annexed it in 1813. It is situated in a very unhealthy locality, but has been much improved lately, a new European quarter having been built on the site of the old fortress. Population (1897), 20,706. Its inhabitants are chiefly Tatars and Armenians, famed for their excellent gardening, and also for silkworm breeding. It has a beautiful mosque, built in 1620, and a renowned "Green Mosque" amidst the ruins of old Ganja. The Persian poet Sheikh Nizam (Nizameddin) is said to have been buried close to the town.

Elizabeth, queen of Rumania ("Carmen Sylva"). See CHARLES I., king of Rumania.

Elizabeth, capital of Union county, New Jersey, U.S.A., in 40° 40′ N. lat. and 74° 13′ W. long., on Newark Bay. Its site is level, its plan regular, and it is divided into twelve wards. Its water supply is pumped from Ursine Lake. It is entered by the Pennsylvania, the Central of New Jersey, and the Lehigh Valley Railways. Though to a certain extent a residential city for business men in New York, it has commercial and manufacturing interests of its own. In 1890 the capital invested in manufactures was $7,785,553, employing 6561 persons, and turning out goods valued at $10,489,364. The principal productions were foundry and machine-shop articles, valued at about one-seventh of all the manufactures. In 1900 the assessed valuation of real and personal property was $17,492,021, the net debt $3,207,835, and the rate of taxation $29.60 per $1000. Population (1880), 28,229; (1890), 37,764; (1900), 52,130, of whom 14,770 were foreign-born and 1139 were negroes. The death-rate in 1900 was 17·5.

Elizabeth City, capital of Pasquotank county, North Carolina, U.S.A., situated on Pasquotank river and the Norfolk and Southern Railway. Being in a forest region, its industries consist largely of lumber trade and manufactures; it contains several saw and shingle mills. Population (1880), 2315; (1890), 3251; (1900), 6348, of whom 44 were foreign-born and 3164 were negroes.

Elkhart, a city of Elkhart county, Indiana, U.S.A., on the St Joseph river, at an altitude of 725 feet. It is on two railways, the Lake Shore and Michigan Southern, (the repair shops of which are here), and the Cleveland, Cincinnati, Chicago, and St Louis. It has varied manufactures. Population (1880), 6953; (1890), 11,360; (1900), 15,184, of whom 1353 were foreign-born and 35 were negroes.

Elland, a town and urban district in the Elland parliamentary division of Yorkshire, England, on the Calder, 2½ miles south of Halifax by rail. There are two endowed schools, a public recreation ground, a church house, and a town-hall and public baths. Cotton-mills, woollen factories, ironworks, flagstone quarries, and fire-clay works supply industries. Area of urban district, 1992 acres. Population (1901), 10,412.

Ellice, or LAGOON, a Polynesian archipelago, in about 9° S., nearly midway between Fiji and Gilbert, and some 700 miles north-west of Samoa. It comprises a large number of low coralline islands and atolls, which are disposed in nine clusters extending over a distance of 360 miles in the direction from north-west to south-east. Their total area is 14 square miles, and in 1900 the population was 2400. The chief groups, all yielding cocoanuts, pandanus fruit and yams, are Funafuti, Sophia (Rocky Island), Nui, Nukufetau, Vaitupu, Netherland, and Lynx. Nearly all the natives are Christians, Protestant missions having been long established in several of the islands. Those of Nui speak the language of the Gilbert Islanders, and have a tradition that they came some generations ago from that group. All the others are of Samoan speech, and their tradition that they came thirty generations back from Samoa is supported by recent research. The soundings taken at Funafuti in 1897 indicate almost beyond doubt that the whole of this Polynesian region is an area of comparatively recent subsidence.

Ellichpur, or ILICHPUR, a town and district of India, in Berar or the Haidarabad Assigned Districts. The town is on the left bank of the river Bichan. The population is about 36,000. The cantonment accommodates a battery of artillery and an infantry regiment, both of the Haidarabad Contingent. There are two steam factories for ginning cotton. The DISTRICT OF ELLICHPUR has an area of 2623 square miles, and had a population in 1881 of 313,805, and in 1901 of 295,392, the decrease being due to the famine of 1899–1900. The land revenue and rates were Rs.9,53,383, the incidence of assessment being R.1–10–4 per acre; the cultivated area in 1897–98 was 608,048 acres, of which 2971 were irrigated from wells; the number of police was 367; the death-rate in 1897 was 58·6 per 1000. There is no railway, but cotton is largely exported from Amraoti.

Ellis, Robinson (1834– ——), English classical scholar, was born at Barming, near Maidstone, on 5th September 1834. He was educated at Elizabeth College, Guernsey, Rugby, and Balliol. In 1858 he became fellow of Trinity College, Oxford. In 1870 he was appointed to the professorship of Latin at University College, London, but in 1876 he returned to Oxford, where from 1883 to 1893 he held the University readership in Latin. In 1893 he succeeded Henry Nettleship as professor. As early as 1859 he had turned his attention to Catullus, an author at that time much neglected by scholars both at home and abroad. His first *Commentary on Catullus* was published in 1876. It aroused great interest, and called forth a flood of Catullian literature and criticism. In 1889 appeared a second and enlarged edition, which summed up the results of thirty years' work and definitely placed its author in the first rank of authorities on Catullus. Professor Ellis quotes largely from the early Italian commentators, maintaining that the land where the Renaissance originated had done more for exact scholarship than was commonly recognized. He has supplemented his critical work by a translation of the poems in the metres of the originals. These were dedicated to Tennyson, whose alcaics and hendecasyllabics had paved the way for an experiment of this character. In the introduction he points out the necessity of observing the laws of position as well as accent in determining quantity. Another author to whom Robinson Ellis has devoted many years' study is Manilius, the astrological poet, whom Scaliger and Bentley edited and Goethe read and quoted, but who had fallen into complete neglect in an age which took a somewhat narrow view of the scope of classical scholarship. Manilius first engaged Mr Ellis's attention in 1862, but it was only in 1891 he published his *Noctes Manilianæ*, a series of dissertations on the *Astronomica*, with a number of happy emendations which will help to pave the way for a revised text of Manilius. Other less known writers with whom Robinson Ellis has dealt are Avianus, Velleius Paterculus, and the Christian poet Orientius, whom he edited for the Vienna Corpus Scriptorum Ecclesiasticorum. He has also edited the *Ibis* of Ovid, and contributed to the *Anecdota Oxoniensia* various unedited materials drawn from manuscripts in the Bodleian and other libraries.

Ellore, a town in British India, in the Godavari district of Madras, on the East Coast Railway, 303 miles from Madras. Population, about 28,000. The two canal systems of the Godavari and the Kistna deltas meet here. There are manufactures of cotton and saltpetre; a high school, with 214 pupils in 1896–97; and two printing-presses.

Elmira, capital of Chemung county, New York, U.S.A., in 42° 05′ N. lat. and 76° 50′ W. long., on the Chemung river, at an altitude of 863 feet. It is on four railways, the Delaware, Lackawanna, and Western, the Erie, the Lehigh Valley, and the Northern Central (a part of the Pennsylvania system). It contains the carriage works of the Erie Railway. Its manufactures had in 1890 an invested capital of $6,895,180, employed 5171 hands, and the products were valued at $8,844,936. These were varied, consisting in part of boots and shoes, flour, iron and steel goods, and lumber. Elmira College, which is situated here, is a Presbyterian institution, with, in 1900, 24 instructors and 237 students, all women, although the college is nominally for both sexes. The celebrated Elmira Reformatory for criminals is also here (see PRISON DISCIPLINE). The assessed valuation of real and personal property in 1900 was $17,615,158, the net debt of the city was $1,085,202, and the rate of taxation $24 per $1000. Population (1880), 20,541; (1890), 30,893; (1900), 35,672, of whom 5511 were foreign-born and 803 were negroes. The death-rate in 1900 was 15·4.

Elmshorn, a town of Prussia, province of Schleswig-Holstein, 19 miles by rail north-west from Altona. Amongst its chief industries are tanneries, breweries, linen and cotton mills, and shipbuilding yards. Population (1885), 8712; (1900), 13,640.

El Paso, capital of El Paso county, Texas, U.S.A., in 31° 45′ N. lat. and 106° 29′ W. long., on the east bank of the Rio Grande, at an altitude of 3710 feet. It is regularly laid out on the level bottom lands, stretching to the slopes on the east. Opposite, on the west bank of the river, is the Mexican town of Ciudad Juarez, with which El Paso is connected by bridges and by horse and steam trams. The city is entered by five railways, the Texas and Pacific, from the east; the Southern Pacific, which passes through it; the Atchison, Topeka, and Santa Fé, from the north; the Mexican Central, from Mexico; and the El Paso and North-Eastern. Its situation on the Mexican frontier gives it a large trade with that country. There are also extensive manufactures, including smelting works, to which are brought ores for treatment from Northern Mexico and Arizona. Population (1880), 736; (1890), 10,338; (1900), 15,906, of whom 6309 were foreign-born and 466 were negroes. A large proportion of the inhabitants are of Mexican descent.

Elreno, capital of Canadian county, Oklahoma, U.S.A., in 35° 32′ N. lat. and 97° 57′ W. long., on the north fork of Canadian river, at an altitude of 1372 feet. Its situation is on the level bottom lands, and the street plan is regular. It has two railways, a branch of the Chicago, Rock Island, and Pacific, and the Choctaw, Oklahoma, and Gulf. Near it is the military post of Fort Reno. Population (1890), 285; (1900), 3383, of whom 165 were foreign-born and 223 were negroes.

Elsinore (Danish, *Helsingör*), a seaport town of Denmark, co. Frederiksborg, on the west shore of the Sound, 28 miles by rail north from Copenhagen. Communication is maintained with Helsingborg by means of a steam ferry. Elsinore has shipbuilding yards, with foundry, engineering shops, &c.; it exports agricultural produce and imports iron, coal, cereals, and yarn. The port was entered by 899 vessels of 116,541 tons in 1899, and cleared by 918 of 127,040 tons. Population (1880), 8968; (1890), 11,076; (1900), 13,902.

Elssler, Fanny (1810–1884), the famous dancer, was born in Vienna on the 23rd of June 1810. From her earliest years she was trained for the ballet, and made her appearance at the Kärnther-Thor theatre in Vienna before she was seven. She almost invariably danced with her sister THERESA, who was two years her senior; and, after some years' experience together in Vienna, the two went in 1827 to Naples. Their success there (to which Fanny contributed more largely than her sister, who used to efface herself in order to heighten the effect of Fanny's more brilliant powers) led to an engagement in Berlin in 1830. This was the beginning of a series of triumphs for Fanny's personal beauty and skill in dancing. After captivating all hearts in Berlin and Vienna, she paid a visit to London, where she received much kindness at the hands of Mr and Mrs Grote, who practically adopted the little girl who was born three months after Fanny's arrival in England. This kind-hearted action subsequently cost them much distress of mind, but they eventually succeeded in removing the child from the atmosphere in which her mother lived. In September 1834 Fanny Elssler appeared at the Opera in Paris, a step to which she looked forward with much misgiving on account of Taglioni's supremacy on that stage. The result, however, was another triumph for Fanny Elssler, and the temporary eclipse of Taglioni, who, although the finer artist of the two, could not for the moment compete with the newcomer's personal fascination. It was conspicuously in her performance of the Spanish *cachuca* that Fanny Elssler outshone all rivals. In 1840 she sailed with her sister for New York, and after two years' unmixed success they returned to Europe, where during the following five years Fanny appeared in Germany, Austria, France, England, and Russia. In 1845, having amassed a large fortune, she retired from the stage and settled near Hamburg. A few years later her sister Theresa contracted a morganatic marriage with Prince Adalbert of Prussia, and was ennobled under the title of Baroness von Barnim. Fanny Elssler died at Vienna on the 27th of November 1884. Theresa was left a widow in 1873, and died at Meran, 19th November 1878. (R. F. S.)

Elster, the name of two rivers of Germany. 1. The Schwarze (Black) Elster rises in the Lausitz Mts., on the southern border of Saxony, flows north and north-west, and after a course of 112 miles enters the Elbe a little above Wittenberg. It is a sluggish stream, battling its way through sandy soil and frequently along a divided channel. 2. The Weisse (White) Elster rises in the north-western corner of Bohemia, a little north of Eger, cuts through the Vogtland in a deep and picturesque valley, passing Plauen, Greiz, Gera, and Zeitz on its way north to Leipzig, just below which city it receives its most important tributary, the Pleisse. At Leipzig it divides, the main stream turning north-west and entering the Saale from the right a little above Halle; the other arm, the Luppe, flowing parallel to the main stream and south of it, enters the Saale below Merseburg. Total length, 121 miles; total descent, 1286 feet.

Elswick. See NEWCASTLE-ON-TYNE.

Elvas, a city, episcopal see, and first-class fortress of Portugal, district Portalegre, 4½ miles from the right bank of the river Guadiana and 33 south-south-east from Portalegre. It is celebrated for its olives and its plums, the last named being exported, both fresh and dried, in large quantities. It also has distilleries and potteries. Population, about 13,000.

Elvey, Sir George Job (1816–1893), English organist and composer, was born at Canterbury on 27th March 1816. He was a chorister at Canterbury Cathedral under Highmore Skeats, the organist. Subsequently he became a pupil of his elder brother, Stephen, and then studied at the Royal Academy of Music under Cipriani Potter and Dr Crotch. In 1834 he gained the Gresham Prize Medal for an anthem, and in 1835 was appointed organist of St George's Chapel, Windsor, a post he filled for 47 years, retiring in 1882. He took the degree of Mus.B. at Oxford in 1838, and in 1840 that of Mus.D. Anthems of his were commissioned for the Three Choirs Festivals of 1853 and 1857, and in 1871 he received the honour of knighthood. He died at Windlesham in Surrey on 9th December 1893. His works, which are nearly all for the Church, include two oratorios, a great number of anthems and services, and some pieces for the organ. A memoir of him, by his widow, was published in 1894.

Elwood, a town of Madison county, Indiana, U.S.A., on Duck creek, at an altitude of 862 feet. It is on the Lake Erie and Western and the Pittsburg, Cincinnati, Chicago, and St Louis Railways. Population (1880), 751; (1890), 2284; (1900), 12,950, of whom 1386 were foreign-born.

Ely, a city and market-town in the Newmarket parliamentary division of Cambridgeshire, England, on the Ouse, 15 miles by rail north-north-east of Cambridge. The restoration of the cathedral was continued until 1884, when nearly £80,000 had been expended. Recent erections are two Established churches, a theological college, and a Roman Catholic chapel. The grammar school now occupies the room over the ancient archway to the monastery of which there are some remains; the chapel built by Prior John of Crandene has been restored and is used as a school chapel. Fruit growing and preserving are carried on. The water supply from the chalk is excellent. Area of urban district, 16,738 acres. Population (1881), 8177; (1891), 8017; (1901), 7713.

Elyria, capital of Lorain county, Ohio, U.S.A., on Black river, at an altitude of 720 feet. It is at the intersection of the Lake Shore and Michigan Southern and the Cleveland, Lorain, and Wheeling Railways. Population (1880), 4777; (1890), 5611; (1900), 8791, of whom 1397 were foreign-born and 201 were negroes.

Embroidery.—Embroidery is the enrichment of a stuff (generally woven) with the needle. It is mainly an affair of stitches, though the stitching on of other stuff (*appliqué*) or of gold thread or cord (*conching*) goes also by the name. The stitching, whether only, as it were, dipping into the stuff (*darning, chain stitch, &c.*), or distributed equally on both sides of it (*crewel stitch, satin stitch, &c.*), usually penetrates it at each ply of the needle. When it forms only a network upon the surface it belongs, strictly speaking, to lacework. Recent development of embroidery has been in the direction of domestic work. The Gothic Revival led to the study of old work, but chiefly of Church embroidery and in an antiquarian spirit. Greater attention is now being paid to the work itself and the way of doing it, than to its style and date. Moreover, we now know more about embroidery other than Gothic or Renaissance or Old English. There has been a discovery of early Coptic stuffs in Upper Egypt, which has found its way to the Victoria and Albert Museum in London, where also have been collected treasures of Persian, Indian, and other Oriental work. Much gorgeous Chinese and Japanese stitchery on silk, and more homely work from the Greek islands (Crete, &c.), has also been imported into England. Some of this is of a kind to appeal directly to the simple needlewoman, who, without pretending to be an artist, arrives by sincerity and thoroughness of work at artistic results. Schools of art needlework, patronized by royalty and assisted by artists, have done something to encourage the art of needlework. It is a mistake, however, to consider it too entirely as an art. It is essentially a handicraft. The needlework of to-day has long passed the stage of Berlin wool work; but it has yet to get over some of its high artistic pretensions, and settle down into the modest but beautiful needlework in which gentlewomen of earlier generations took honest pride. For embroidery begins and ends with the needle. In the simplest of work, where the stitch determines the character of the design, as in the most ambitious, where the design dictates the stitch, the one depends upon the other. Neatness or precision of stitch is a point of good workmanship; but its *direction* is of at least equal importance, for it is the means both of varying the shades of colour and of expressing form within the outlines of the design. A skilled worker gets accustomed to sort the varieties of sketches in her mind, according as they are available for outline, flat surfaces, shading, and so forth. Familiarity with the stitches is indispensable alike to the worker and to the designer, who must not ask of his interpreter more than needle and thread can do. A good design gives scope for the needle, and does justice to the material—to the gloss of lustrous silk, for instance. The term "Art Needlework" is commonly misused. Needlework is worthy of that title, not according to its pretensions, but as it is appropriately designed and cunningly worked, and beautiful accordingly. Good work does not mean only fine work. There is art in expressing form by the stepped outline which comes of accepting the square lines given by the mesh of a coarse canvas, no less than in following the subtle sweep of an easy brush stroke. Nor is one stitch or kind of embroidery intrinsically more artistic than another. There is no material so coarse it may not be embroidered, no stitch so mechanical it may not be employed to artistic purpose. All that is necessary is the artist, and he must understand his craft and work in sympathy with it. Great strides have been made in machine embroidery, and every year imitation is carried to further perfection. It is all the more incumbent, therefore, upon the needlewoman to avoid futile competition with loom or sewing-machine, and to do what sensitive hands alone can do. (L. F. D.)

Embryology.—The word embryo is derived from the Greek ἔμβρυον, which signified the fruit of the womb before birth. In its strict sense, therefore, embryology is the study of the intrauterine young or embryo, and can only be pursued in those animals in which the offspring are retained in the uterus of the mother until they have acquired, or nearly acquired, the form of the parent. As a matter of fact, however, the word has a much wider application than would be gathered from its derivation. All animals above the Protozoa undergo at the beginning of their existence rapid growth and considerable changes of form and structure. During these changes, which constitute the development of the animal, the young organism may be incapable of leading a free life and obtaining its own food. In such cases it is either contained in the body of the parent or it is protruded and lies quiescent within the egg membranes; or it may be capable of leading an independent life, possessing in a functional condition all the organs necessary for the maintenance of its existence. In the former case the young organism is called an *embryo*, in the latter a *larva*. It might thus be concluded that embryology would exclude the study of larvæ, in which the whole or the greater part of the development takes place outside the parent and outside the egg. But this is not the case; embryology includes not only a study of embryos as just defined, but also a study of larvæ. In this way the scope of the subject is still further widened. As long as embryology confines its attention to embryos, it is easy to fix its limits, at any rate in the higher animals. The domain of embryology ceases in the case of viviparous animals at birth, in the case of oviparous animals at hatching; it ceases as soon as the young form acquires the power of existing when separated from the parent or when removed from the protection of the egg membranes. But as soon as post-embryonic developmental changes are admitted within the scope of the subject, it becomes on close consideration difficult to limit its range. It must include all the developmental processes which take place as a result of sexual reproduction. A man at birth, when he ceases to be an embryo, has still many changes besides those of simple growth to pass through. The same remark applies to a young frog at the metamorphosis. A chick even, which can run about and feed almost immediately after hatching, possesses a plumage very different from that of the full-grown bird; a starfish at the metamorphosis is in many of its features quite different from the form with which we are familiar. It might be attempted to meet this difficulty by limiting embryology to a study of all those changes which occur in the organism before the attainment of the adult state. But this merely shifts the difficulty to another quarter, and makes it necessary to define what is meant by the adult state. At first sight this may seem easy, and no doubt it is not difficult when man and the higher animals alone are in question, for in these the adult state may be defined comparatively sharply as the stage of sexual maturity. After that period, though changes in the organism still continue, they are retrogressive changes, and as such might fairly be excluded from any account of development, which clearly implies progression, not retrogression. But, as so often happens in the study of organisms, formulæ which apply quite satisfactorily to one group require modification when others are considered.

Does sexual maturity always mark the attainment of the adult state? Is the Axolotl adult when it acquires its reproductive organs? Can a larval Ctenophore, which acquires functional reproductive glands and still possesses the power of passing into the form ordinarily described as adult in that group, be considered to have reached the end of its development? Or—to take the case of those animals, such as *Amphioxus*, *Balanoglossus*, and many segmented worms in which important developmental processes occur, *e.g.*, formation of new gill slits, of gonadial sacs, or even of whole segments of the body, long after the power of reproduction has been acquired—how is the attainment of the adult state to be defined, for it is clear that in them the attainment of sexual maturity does not correspond with the end of growth and development? If, then, embryology is to be regarded as including not only the study of embryos, but also that of larvæ, *i.e.*, if it includes the study of the whole developmental history of the individual—and it is impossible to treat the subject rationally unless it is so regarded—it becomes exceeding difficult to fix any definite limit to the period of life with which embryology concerns itself. The beginning of this period can be fixed, but not the end, unless it be the end of life itself, *i.e.*, death. The science of embryology, then, is the science of individual development, and includes within its purview all those changes of form and structure, whether embryonic, larval, or post-larval, which characterize the life of the individual. The beginning of this period is precise and definite—it is the completion of the fertilization of the ovum, in which the life of the individual has its start. The end, on the other hand, is vague and cannot be precisely defined, unless it be death, in which case the period of life with which embryology concerns itself is coincident with the life of the individual. To use the words of Huxley ("Cell Theory," *Collected Works*, vol. i. p. 267): "Development, therefore, and life are, strictly speaking, one thing, though we are accustomed to limit the former to the progressive half of life merely, and to speak of the retrogressive half as decay, considering an imaginary resting-point between the two as the adult or perfect state."

Reproduction.

There are two kinds of reproduction, the sexual and the asexual. The sexual method has for its results an increase of the number of kinds of individual or organism, whereas the asexual affords an increase in the number of individuals of the same kind. If the asexual method of reproduction alone existed, there would, so far as our knowledge at present extends, be no increase in the number of kinds of organism: no new individuality could arise. The first establishment of a new kind of individual by a sexual process is effected in a very similar manner in all Metazoa. The parent produces by a process of unequal fission, which takes place at a part of the body called the reproductive gland, a small living organism called the reproductive cell. There are always two kinds of reproductive cells, and these are generally produced by different animals called the male and female respectively (when they are produced by the same animal it is said to be hermaphrodite). The reproductive cell produced by the male is called the spermatozoon, and that produced by the female, the ovum. These two organisms agree in being small uninucleated masses of protoplasm, but differ considerably in form. They are without the organs of nutrition, &c., which characterize their parents, but the ovum nearly always possesses, stored up within its protoplasm, a greater or less quantity of vitelline matter or food-yolk, while the spermatozoon possesses in almost all cases the power of locomotion. The object with which these two minute and simple organisms are produced is to fuse with one another and give rise to one resultant uninucleated (for the nuclei fuse) organism or cell, which is called the *zygote*. This process of fusion between the two kinds of reproductive cells, which are termed *gametes*, is called conjugation: it is the process which is sometimes spoken of as the fertilization of the ovum, and its result is the establishment of a new individual. This new individual at first is simply a uninucleated mass of living matter, which always contains a certain amount of food-yolk, and is generally bounded by a delicate cuticular membrane called the vitelline membrane. In form the newly established zygote resembles the female gamete or ovum—so much so, indeed, that it is frequently called the ovum; but it must be clearly understood that although the bulk of its matter has been derived from the ovum, it consists of ovum and spermatozoon, and, as shown by its subsequent behaviour, the spermatozoon has quite as much to do with determining its vital properties as the ovum.

To the unaided eye the main difference between the newly formed zygotes of different species of animals is that of bulk, and this is due to the amount of food-yolk held in suspension in the protoplasm. The ovum of the fowl is 30 mm. in diameter, that of the frog 1·75 mm., while the ovum of the rabbit and *Amphioxus* have a diameter of ·1 mm. The food-yolk is deposited in the ovum as a result of the vital activity of its protoplasm, while the ovum is still a part of the ovary of the parent. It is an inert substance which is used as food later on by the developing embryo, and it acts as a dilutant of the living matter of the ovum. It has a profound influence on the subsequent developmental process. (For details as to what may be called the natural history of fertilization, see Reproduction.) The newly formed zygotes of different species of animals have undoubtedly, as stated above, a certain family resemblance to one another; but however great this resemblance may be, the differences must be most profound, and this fact becomes at once obvious when the properties of these remarkable masses of matter are closely investigated.

Causes of development.

As in the case of so many other forms of matter, the more important properties of the zygote do not become apparent until it is submitted to the action of external forces. These forces constitute the external conditions of existence, and the properties which are called forth by their action are called the acquired characters of the organism. The investigation of these properties, particularly of those which are called forth in the early stages of the process, constitutes the science of Embryology. With regard to the manifestation of these properties, certain points must be clearly understood at the outset:—(1) If the zygote is withheld from the appropriate external influences, *e.g.*, if a plant-seed be kept in a box free from moisture or at a low temperature, no properties are evolved, and the zygote remains unchanged and eventually dies; (2) the acquisition of the properties, which constitutes the growth and development of the organism, proceeds in a perfectly definite sequence, which, so far as is known, cannot be altered; (3) just as the features of the growing organism change under the continued action of the external conditions, so the external conditions themselves must change as the organism is progressively evolved. With regard to this last change, it may be said generally that it is usually, if not always, effected by the organism itself, making use of the properties which it has acquired at earlier stages of its growth, and acting in response to the external conditions. There is, to use a phrase of Mr Herbert Spencer, a continuous adjustment between the external and internal relations. For every organism a certain succession of conditions is necessary, if the complete and normal evolution of properties is to take place. Within certain limits these conditions may vary, without interfering with the normal evolution of the properties, though such variations are generally responded to by slight but unimportant variation of the properties (variation of acquired characters). But if the variation of the conditions is too great, the evolved properties become abnormal, and are of such a nature as to preclude the normal evolution of the organism; in other words, the action of the conditions upon the organism is injurious, causing abortions and, ultimately, death. For many organisms the conditions of existence are well known for all stages of life, and can be easily imitated, so that they can be reared artificially and kept alive and made to breed in confinement—*e.g.*, the common fowl. But in a large number of cases it is not possible, through ignorance of the proper conditions, or on account of the difficulty of imitating them, to make the organism evolve all its properties. For instance, there are many marine larvæ which have never been reared beyond a certain point, and there are some organisms which, even when nearly full-grown—a stage of life at which it is generally most easy to ascertain and imitate the natural conditions—will not live, or at any rate will not breed, in captivity. Of late years some naturalists have largely occupied themselves with experimental observation of the effects on certain organisms of marked and definite changes of the conditions, and the name of Developmental Mechanics (or *Physiology of Development*, under which title it is discussed below, p. 148) has been applied to this branch of study.

Gametogeny.

In normal fertilization, as a rule, only one spermatozoon fuses with the ovum. It has been observed in some eggs that a membrane, formed round the ovum immediately after the entrance of the spermatozoon, prevents the entrance of others. If more than one spermatozoon enters, a corresponding number of male pronuclei are formed, and the subsequent development, if it takes place at all, is abnormal and soon ceases. An egg by ill-treatment (influence of chloroform, carbonic acid, &c.) can be made to take more than one spermatozoon. In some animals it appears that several spermatozoa may normally enter the ovum (some Arthropods, Selachians, Amphibians, and Mammals), but of these only one forms a male pronucleus (see below), the rest being absorbed. Gametogeny is the name applied to the formation of the gametes, *i.e.*, of the ova and spermatozoa. The cells of the reproductive glands are the germ cells (*oögonia spermatogonia*). They undergo division and give rise to the progametes, which in the case of the female are sometimes called *oöcytes*, in the case of the male *spermatocytes*. The oöcytes are more familiarly called the ovarian ova. The nucleus of the oöcyte is called the germinal vesicle. The oöcyte (progamete) gives rise by division to the ovum or true gamete, the nucleus of which is called the *female pronucleus*. As a general rule the oöcyte divides unequally twice, giving rise to two small cells called polar bodies, and to the ovum. The first formed polar body frequently divides when the oöcyte undergoes its second and final division, so that there are three polar bodies as well as the ovum resulting from the division of the oöcyte or progamete. Sometimes the ovum arises from the oöcyte by one division only, and there is only one polar body (mouse, Sobotta, *Arch. f. mikr. Anat.*, 1895, p. 15). The polar bodies are ova, but as a rule they are so small as to be incapable of fertilization. They may therefore be regarded as abortive ova. In one case, however (see Francotte, *Bull. Acad. Belg.* (3), xxxiii., 1897, p. 278), the first formed polar body is nearly as large as the ovum, and is sometimes fertilized and develops. The spermatogonia are the cells of the testis; these produce by division the spermatocytes (progametes). These divide and produce the *spermatids*, which become the spermatozoa. The spermatocytes give rise to the young spermatozoa (spermatids) by division, but the number of divisions is more variable than in the case of the process by which the female gamete arises from the progamete. In *Ascaris* and some other forms there appear to be two binary divisions, giving rise to four equal spermatids, each of which becomes a functional spermatozoon; but in other cases, *e.g.*, *Lumbricus*, a much greater number of fissions follow each other, and many spermatids (young spermatozoa) result from one progamete (spermatocyte). The nucleus of the male gamete is not called the male pronucleus, as would be expected, that term being reserved for the second nucleus which appears in the ovum after fertilization. As this is in all probability derived entirely from the nucleus of the spermatozoon, we should be almost justified in calling the nucleus of the spermatozoon the male pronucleus. In *Ascaris* and some other forms in which the formation of the gametes from the progamete has been accurately followed, and in which the progamete of both sexes divides twice in forming the gametes, the division of the nucleus presents certain peculiarities. In the first place, between the first division and the second it does not enter into the resting state, but immediately proceeds to the second division. In the second place, the number of chromosomes which appear in the final divisions of the progametes and assist in constituting the nuclei of the gametes, is half the number which go to constitute the new nuclei in the ordinary nuclear divisions of the animal. The number of chromosomes of the nucleus of the gamete is therefore reduced, and the divisions by which the gametes arise from the progametes are called reducing divisions. It is not certain, however, that this phenomenon is of universal occurrence, or has the significance which is ordinarily attributed to it.

Fertilization.

As soon as the spermatozoon has conjugated with the ovum, a second nucleus appears in the ovum. This is undoubtedly derived from the spermatozoon, possibly from its nucleus only, and is called the male pronucleus. It possesses in the adjacent protoplasm a well-marked centrosome. The general rule appears to be that the female pronucleus is without a centrosome, and that no centrosome appears in the female in the divisions by which the gamete arises from the progamete. If this is true, the centrosome of the zygote nucleus must be entirely derived from that of the male pronucleus. This accounts for the fact, which has been often observed, that the female pronucleus is not surrounded by protoplasmic radiations, whereas such radiations are present round the male pronucleus in its approach to the female. In the mouse the subsequent events are as follow:—Both pronuclei assume the resting form, the chromatin being distributed over the nuclear network, and the nuclei come to lie side by side in the centre of the egg. A long loop of chromatin then appears in each nucleus and divides up into twelve pieces, the chromosomes. The centrosome now divides, the membranes of both nuclei disappear, and a spindle is formed. The twenty-four chromosomes arrange themselves at the centre of this spindle and split longitudinally, so that forty-eight chromosomes are formed. Twenty-four of these, twelve male and twelve female, as it is supposed, travel to each pole of the spindle and assist in giving rise to the two nuclei. At the next nuclear division twenty-four chromosomes appear in each nucleus, each of which divides longitudinally; and so in all subsequent divisions. The fusion of the two pronuclei is sometimes effected in a manner slightly different to that described for the mouse. In *Echinus*, for instance, the two pronuclei fuse, and the spindle and chromosomes are formed from the zygote nucleus, whereas in the mouse the two pronuclei retain their distinctness during the formation of the chromosomes. There appears, however, to be some variation in this respect: cases have been observed in the mouse in which fusion of the pronuclei occurs before the separation of the chromosomes.

Parthenogenesis.

Parthenogenesis, or development of the female gamete without fertilization, is known to occur in many groups of the animal kingdom. Attempts have been made to connect this phenomenon with peculiarities in the gametogeny. For instance, it has been said that parthenogenetic ova form only one polar body. But, as we have seen, this is sometimes the case in eggs which are fertilized, and parthenogenetic ova are known which form two polar bodies, *e.g.*, ova, of the honey-bee which produce drones (*Morph. Jahrb.* xv., 1889, p. 85), ova of *Rotifera* which produce males (*Zool. Anzeiger*, xx., 1897, p. 455). It is quite probable that parthenogenesis is more common than has been supposed, and it appears that there is some evidence to show that ova, which in normal conditions are incapable of developing without fertilization, may yet develop if subjected to an altered environment. For instance, it has been asserted that the addition of a certain quantity of chloride of magnesium and other substances to sea-water will cause the unfertilized ova of certain marine animals (*Arbacia, Chætopterus*) to develop (J. Loeb, *American Journal of Physiology*, ix., 1901, p. 423); but it is not known whether in such cases a previous formation of polar bodies has occurred. This experiment, if authenticated, suggests that ova have the power of development, but are not able to exercise it in their normal surroundings. There is reason to believe that the same assertion may be made of spermatozoa. Phenomena of the nature of parthenogenesis have never been observed in the male gamete, but it has been suggested by Giard (*Cinquantenaire de la Soc. de Biol.*, 1900) that the phenomenon of the so-called fertilization of an enucleated ovum which has been described by Boveri and Delage in various eggs, and which results in development up to the larval form, is in reality a case in which the male gamete, unable to undergo development in ordinary circumstances on account of its small size and specialization of structure, has obtained a nutritive environment which enables it to display its latent power of development. Moreover, Giard suggests that in some cases of apparently normal fertilization, one of the pronuclei may degenerate, the resultant embryo being the product of one pronucleus only. In this way he explains certain cases of hybridization in which the paternal (rarely the maternal) type is exclusively reproduced. For instance, in the batrachiate Amphibia, Héron Royer succeeded in 1883 in rearing, out of a vast number of attempts, a few hybrids between a female *Pelobates fuscus* and a male *Rana fusca*; the product was a *Rana fusca*. He also crossed a female *Bufo vulgaris* with a male *Bufo calamita*; in the few cases which reached maturity the product was obviously a *Bufo calamita*. Finally, Ziegler (*Arch. f. Ent.-Mech.*, 1898,

p. 249) divided the just fertilized ovum of a sea-urchin in such a way that each half had one pronucleus; the half with the male pronucleus segmented and formed a blastula, the other degenerated. It is said that in a few species of animals males do not occur, and that parthenogenesis is the sole means of reproduction (a species of *Ostracoda* among Crustacea; species of *Tenthredinidæ*, *Cynipidæ*, and *Coccidæ* among Insecta); this is the thelytoky of Siebold. The number of species in which males are unknown is constantly decreasing, and it is quite probable that the phenomenon does not exist. Parthenogenesis, however, is undoubtedly of frequent occurrence, and is of three kinds, namely, (1) that (arrhenotoky) in which males alone are produced, *e.g.*, honey-bees; (2) that in which the product is generally a female, but males occasionally occur, *e.g.*, some *Aphidæ*, Phyllopod Crustacea; (3) that in which there is an alternation of a sexual generation with a parthenogenetic generation (many *Cynipidæ*). It would appear that "parthenogenesis does not favour the production of one sex more than another, but it is clear that it decidedly favours the production of a brood that is entirely of one sex, but which sex that is differs according to circumstances" (Sharp, *Cambridge Natural History*, "Insects," pt. i. p. 498). In some Insecta and Crustacea exceptional parthenogenesis occurs: a certain proportion of the eggs laid are capable of undergoing either the whole or a part of development parthenogenetically, *e.g.*, *Bombyx mori*, &c. (Brauer, *Arch. f. mikr. Anat.*, 1893; consult also Maupas on parthenogenesis of Rotifera, *Comp. Rend.*, 1889–91, and Lauterborn, *Biol. Centralblatt*, xviii., 1898, p. 173).

Determination of sex.

The question of the determination of sex may be alluded to here. Is sex determined at the act of conjugation of the two gametes? Is it, in other words, an unalterable property of the zygote, a genetic character? Or does it depend upon the conditions to which the zygote is subjected in its development? In other words, is it an acquired character? It is impossible in the present state of knowledge to answer these questions satisfactorily, but the balance of evidence appears to favour the view that in most cases sex is an unalterable, inborn character, though in a few it may be an acquired character. Thus those twins which are believed to come from a split zygote are always of the same sex, members of the same litter which have been submitted to exactly similar conditions are of different sexes, and all attempts to determine the sex of offspring in the higher animals by treatment have failed. On the other hand, the male bee is a portion of a female zygote—the queen-bee. The same remark applies to the male Rotifer, in which the zygote always gives rise to a female, from which the male arises parthenogenetically, and parthenogenetic eggs which would ordinarily give rise to females may be made by certain treatment to become males. It is said that in human societies the number of males born increases after wars and famines, but this, if true, is probably due to an affection of the gametes and not of the young zygote. For a review of the whole subject, see Cuénot, *Bull. Sci. France et Belgique*, xxxii., 1899, pp. 462–535.

Cleavage.

The first change the zygote undergoes in all animals is what is generally called the segmentation or cleavage of the ovum. This consists essentially of the division of the nucleus into a number of nuclei, around which the protoplasm sooner or later becomes arranged in the manner ordinarily spoken of as cellular. This division of the nucleus is effected by the process called binary fission; that is to say, it first divides into two, then each of these divides simultaneously again into two, giving four nuclei; each of these after a pause again simultaneously divides into two. So the process continues for some time until the ovum becomes possessed of a large number of nuclei, all of which have proceeded from the original nucleus by a series of binary fissions. This division of the nucleus, which constitutes the essential part of the cleavage of the ovum, continues through the whole of life, but it is only in the earliest period that it is distinguished by a distinct name and used to characterize a stage of development. The nuclear division of cleavage is usually at first a rhythmical process; all the nuclei divide simultaneously, and periods of nuclear activity alternate with periods of rest. Nuclear divisions may be said to be of three kinds, according to the accompanying changes in the surrounding protoplasm: (1) accompanied by no visible change, *e.g.*, the multinucleated Protozoon *Actinosphærium;* (2) accompanied by a rearrangement of the protoplasm around each nucleus, but not by its division into two separate masses, *e.g.*, the division which results in the formation of a colony of Protozoa; (3) accompanied by the division of the protoplasm into two parts, so that two distinct cells result, *e.g.*, the divisions by which the free wandering leucocytes are produced, the reproduction of uninuclear Protozoa, &c. In the cleavage of the ovum the first two of these methods of division are found, but probably not the third. At one time it was thought that the nuclear divisions of cleavage were always of the third kind, and the result of cleavage was supposed to be a mass of isolated cells, which became reunited in the subsequent development to give rise to the later connexions between the tissues which were known to exist. But in 1885 it was noticed that in the ovum of *Peripatus capensis* (Sedgwick, *Q.J.M.S.*, xxv., 1885, p. 449) the extranuclear protoplasm did not divide in the cleavage of the ovum, but merely became rearranged round the increasing nuclei: the continuity of the protoplasm was not broken, but persisted into the later stages of growth, and gave rise to the tissue connexions which undoubtedly exist in the adult. This discovery was of some importance, because it rendered intelligible the unity of the embryo so far as its developmental processes are concerned, the maintenance of this unity being somewhat surprising on the previous view. On further inquiry and examination it was found that the ova of many other animals presented a cleavage essentially similar to that of *Peripatus.* Indeed, it was found that the nuclear divisions of cleavage were of the first two kinds just described. In some eggs, *e.g.*, the Alcyonaria, the first nuclear divisions are effected on the first plan, *i.e.*, they take place without at first producing any visible effect upon the protoplasm of the egg. But in the later stages of cleavage the protoplasm becomes arranged around each nucleus and related to it as to a centre. In the majority of eggs, however, the protoplasm, though not undergoing complete cleavage, becomes rearranged round each nucleus as it is formed. The best and clearest instance of this is afforded by many Arthropodan eggs, in which the nucleus of the just-formed zygote takes up a central position, where it undergoes its first division, subsequent divisions taking place entirely within the egg and not in any way affecting its exterior. The result is to give rise to a nucleated network or foam-work of protoplasm, ramifying through the yolk particles and containing these in its meshes.

In other Arthropodan eggs the cleavage is on the so-called centrolecithal type, in which the dividing nuclei pass to the cortex of the ovum, and the surface of the ovum becomes indented with grooves corresponding to each nucleus. In this kind of cleavage all the so-called segments are continuous with the central undivided yolk-mass. It sometimes happens that in Arthropods the egg breaks up into masses, which cannot be said to have the value of cells, as they are frequently without nuclei. In other eggs, characterized by a considerable amount of yolk, *e.g.*, the ova of Cephalopoda, and of the Vertebrata with much yolk, the first nucleus takes up an eccentric position in a small patch of protoplasm which is comparatively free from yolk particles. This patch is the germinal disc, and the nuclear divisions are confined to it and to the transitional region, where it merges into the denser yolk which makes up the bulk of the egg. At the close of segmentation the germinal disc consists of a number of nuclei, each surrounded by its own mass of protoplasm, which is, however, not separated from the protoplasm round the neighbouring nuclei, as was formerly supposed, but is continuous at the points of contact. In this manner the germinal disc has become converted into the blastoderm, which consists of a small watch-glass-shaped mass of so-called cells resting on, but continuous with, the large yolk-mass. It is characteristic of this kind of ovum that there is always a row of nuclei, called the yolk nuclei, placed in the denser yolk immediately adjacent to the blastoderm. These nuclei are continually undergoing division, one of the products of division, together with a little of the sparse yolk protoplasm, passing into the blastoderm to reinforce it. The other product of the dividing yolk nuclei remains in the yolk, in readiness for the next division. In this manner nucleated masses of protoplasm are continually being added to the periphery of the blastoderm and assisting in its growth. But it must be borne in mind that all the nucleated masses of which the blastoderm consists are in continuity with each other and with the sparse protoplasmic reticulum of the subjacent yolk.

In the great majority of eggs, then, the nuclear division of cleavage is not accompanied by a complete division of the ovum into separate cells, but only by a rearrangement of the protoplasm, which produces, indeed, the so-called cellular arrangement, and an appearance only of separate cells. But there still remain to be mentioned those small eggs in which the amount of yolk is inconsiderable, and in which the division of the nuclei does appear to be accompanied by a complete division of the surrounding protoplasm into separate unconnected cells—ova of many Annelida, Mollusca, Echinoderma, &c., and of Mammalia amongst Vertebrata. In the case of these (Andrews, *Zool. Bulletin*, ii., 1898) also, it has been shown that the apparently separate spheres are connected by a number of fine anastomosing threads of a hyaline protoplasm, which are not easy to detect and are readily destroyed by the action of reagents. It is therefore probable that the divisions of the nuclei in cleavage are in no case accompanied by complete division of the surrounding protoplasm, and the organism in the cleavage stage is a continuous whole, as it is in all the other stages of its existence.

Division of embryo.

Of late years a great number of experiments have been made to discover the effects of dividing the embryo during its cleavage, and of destroying certain portions of it. These experiments have been made with the object of testing the view, held by some authorities, that certain segments are already set apart in cleavage to give rise to certain adult organs, so that if they were destroyed the organs in question could not be developed. The results obtained have not borne out this view. Speaking generally, it may be said that they have been different according to the stage at which the separation was effected and the conditions under which the experiment was carried out. If the experiment be made at a sufficiently early stage, each part, if not too small, will develop into a normal, though small, embryo. In some cases the embryo remained imperfect for a certain time after the experiment, but the loss is eventually made good by regeneration. (For a summary of the work done on this subject, see Berg, *Zool. Centralblatt*, vii., 1900, p. 1.)

The layer-theory.

The end of cleavage is marked by the commencement of the differentiation of the organs. The first differentiation is the formation of the layers. These are three in number, being called respectively the ectoderm, endoderm, and mesoderm, or, in embryos in which at their first appearance they lie like sheets one above the other, the epiblast, hypoblast, and mesoblast. The layers are sometimes spoken of as the primary organs, and their importance lies in the fact that they are supposed to be generally homologous throughout the series of the Metazoa. This view, which is based partly on their origin and partly on their fate, had great influence on the science of comparative anatomy during the last thirty years of the 19th century, for the homology of the layers being admitted, they afforded a kind of final court of appeal in determining questions of doubtful homologies between adult organs. Great importance was therefore attached to them by embryologists, and both their mode of development and the part which they play in forming the adult organs were examined with the greatest care. It is very unusual for all the layers to be established at the same time. As a general rule the ectoderm and endoderm, which may be called the primary layers, come first, and later the mesoderm is developed from one or other of them. There are two main methods in which the first two are differentiated—invagination and delamination. The former is generally found in small eggs, in which the embryo at the close of cleavage assumes the form of a sphere, having a fluid or gelatinous material in its centre, and bounded externally by a thin layer of protoplasm, in which all the nuclei are contained. Such a sphere is called a blastosphere, and may be regarded as a spherical mass of protoplasm, of which the central portion is so much vacuolated that it seems to consist entirely of fluid. The central part of the blastosphere is called the segmentation cavity or blastocœl. The blastosphere soon gives rise, by the invagination of one part of its wall upon the other, and a consequent obliteration of the segmentation cavity, to a double-walled cup with a wide opening, which, however, soon becomes narrowed to a small pore. This cup stage is called the gastrula stage; the outer wall of the gastrula is the ectoderm, and its inner the endoderm; while its cavity is the enteron, and the opening to the exterior the blastopore. Origin of the primary layers by delamination occurs universally in eggs with large yolks (Cephalopoda and many Vertebrata), and occasionally in others. In it cleavage gives rise to a solid mass, which divides by delamination into two layers, the ectoderm and endoderm. The main difference between the two methods of development lies in the fact that in the first of them the endoderm at its first origin shows the relations which it possesses in the adult, namely, of forming the epithelial wall of the enteric space, whereas in the second method the endoderm is at first a solid mass, in which the enteric space makes its appearance later by excavation. In the delaminate method the enteric space is at first without a blastopore, and sometimes it never acquires this opening, but a blastopore is frequently formed, and the two-layered gastrula stage is reached, though by a very different route to that taken in the formation of the invaginate gastrula. According to the layer-theory, these two layers are homologous throughout the series of Metazoa; their limits can always be accurately defined, they give rise to the same organs in all cases, and the adult organs (excluding the mesodermal organs) can be traced back to one or other of them with absolute precision. Thus the ectoderm gives rise to the epidermis, to the nervous system, and to the lining of the stomodæum and proctodæum, if such parts of the alimentary canal are present. The endoderm, on the other hand, gives rise to the lining of the enteron, and of the glands which open into it.

So far as these two layers are concerned, and excluding the mesoderm, it would appear that the layer-theory does apply in a very remarkable manner to the whole of the Metazoa. But even here, when the actual facts are closely scanned, there are found to be difficulties, which appear to indicate that the theory may not perhaps be such an infallible guide as it seems at first sight. Leaving out of consideration the case of the Mammalia, in which the differentiation of the segmented ovum is not into ectoderm and endoderm, and the case of the sponges, the most important of these difficulties concern the stomodæum and proctodæum. The best case to examine is that of *Peripatus capensis*, in which the blastopore is at first a long slit, and gives rise to both the mouth and the anus of the adult, Here there is always found at the lips of the blastopore, and extending for a short distance inwards as enteric lining, a certain amount of tissue, which by its characters must be regarded as ectoderm. Now, in the closure of the blastopore between the mouth and anus, this tissue, which at the mouth and anus develops into the lining of the stomodæum and proctodæum, is left inside, and actually gives rise to the median ventral epithelium of the alimentary canal. Hence the development of *Peripatus capensis* suggests the conclusion, if we strictly apply the layer-theory, that a considerable portion of the true mesenteron is lined by ectoderm, and is not homologous with the corresponding portion of the mesenteron of other animals —a conclusion which will on all hands be admitted to be absurd. The difficulties in the application of the layer-theory become vastly greater when the origin and fate of the mesoderm is considered. The mesoderm is, if we may judge from the number of organs which are derived from it, much the most important of the three layers. It generally arises later than the others, and in its very origin presents difficulties to the theory, which are much increased when we consider its history. It is generally, though not always, developed from the endoderm, either as hollow outgrowths containing prolongations of the enteric cavity, which become the cœlom, or as solid proliferations. But in some groups the mesoderm is actually laid down in cleavage, and is present at the end of that process. In others it is entirely derived from the ectoderm (*Peripatus capensis*). In yet others it is partly derived from endoderm and partly from ectoderm (primitive streak of amniotic Vertebrates). Finally, in whatever manner the first rudiments are developed, it frequently receives considerable reinforcements from one of the primary layers. For instance, the structure known as the nerve crest of the vertebrate embryo is not, as was formerly supposed, exclusively concerned with the formation of the spinal nerves and ganglia, but contributes largely to the mesoderm of the axial region of the body. This is particularly clearly seen in the case of the anterior part of the head of Elasmobranch and probably of other vertebrate embryos, where all the mesoderm present is derived from the anterior part of the neural crest (*Q.J.M.S.* xxxvii. p. 92).

Mesoderm.

The layer-theory, then, will not bear critical examination. It is clear, both from their origin and history, that the layers or masses of cells called ectoderm, endoderm, and mesoderm have not the same value in different animals; indeed, it is misleading to speak of three layers. At the most we can only speak of two, for the mesoderm is formed after the others, has a composite origin, and has no more claim to be considered an embryonic layer than has the rudiment of the central nervous system, which in some animals, indeed, appears as soon as the mesoderm. Arguments as to homology, based on derivation or non-derivation from the same embryonic layer, have therefore in themselves but little value.

It has frequently been asserted that the reproductive cells are marked off at a very early stage of the development (*Sagitta*, certain Crustacea, *Scorpio*). Recently it has been asserted that in *Ascaris* (Boveri, *Kuppfer's Festschrift*, 1899, p. 383) the reproductive cells are set apart after the first cleavage, and that they can be traced by certain peculiarities of their nuclei into the adult reproductive glands.

Mesenchyme.

It has been already stated that the mesoderm is a composite tissue. This fact is frequently conspicuous at its first establishment. In many Cœlomata it is present under two forms from the beginning. One of these is epithelial in character, while the other has the form of a network of protoplasm, with nuclei at the nodes. The former is called simply epithelial mesoderm, the latter mesenchyme. Sometimes the epithelial mesoderm is the first formed, and what little mesenchyme there is is developed from it (*Amphioxus*, *Balanoglossus*, &c.). Sometimes the mesenchyme is the first to arise, the epithelial mesoderm developing from it (most, if not all, Vertebrates). Finally, it sometimes happens that these two kinds of tissue arise separately from one or other of the primary layers (Echinodermata). As already hinted, in *Balanoglossus* and *Amphioxus* the whole of the mesoderm of the body is at first in an epithelial condition, being developed as an outgrowth of the gut wall. In *Peripatus capensis* also, and possibly in other Arthropods, it has at first an intermediate form, being derived from a primitive streak and not from the gut wall, but it rapidly assumes an epithelial structure, from which all the mesodermal tissues are developed. In Annelids the bulk of the mesoderm has at first a modified epithelial form similar to that of Arthropods, but it is formed, not from a primitive streak, but from some peculiar cells produced in cleavage, called pole-cells. In Annelids with trochosphere larvæ a certain amount of mesenchyme is formed at an earlier stage and gives rise to the muscular bands of the young larva. In Echinodermata a certain amount of mesenchyme appears before the epithelial mesoderm, which is formed later as gut diverticula. In these forms the mesenchyme is said to arise as wandering amœboid cells, which are budded into the blastocœl by the endoderm just before and during its invagination, but the writer has reason to believe that this account of it does not quite describe what happens. It would seem to be more probable that the mesenchyme arises in these forms, as it certainly does in the case of the later-formed mesenchyme of the Vertebrate embryo, as a protoplasmic outflow from its tissue of origin, passing at first along the line of pre-existent protoplasmic strands which traverse the blastocœl, and sending out at the same time processes which branch and anastomose with neighbouring processes (see MacBride, *Proc. Camb. Phil. Soc.*, 1896, p. 153). In the Vertebrata the whole of the mesoderm has at first the mesenchyme form. Afterwards, when the body-cavity split appears, the bulk of it assumes a kind of modified epithelial condition, which later on yields, by a process of outflow very similar in its character to what has been supposed to occur in the Echinoderm blastula, a considerable mesenchyme of the reticulate character. Mesenchyme is the tissue which in Vertebrate embryology has frequently been called embryonic connective tissue. This name is no doubt due to the fact that it was supposed to consist of isolated stellate cells. It is, however, in no sense of the word connective tissue, because it gives rise to many organs having nothing whatever to do with connective tissue. For instance, in Vertebrata this tissue gives rise to nervous tissue, blood-vessels, renal tubules, smooth muscular fibres, and other structures, as well as to connective and skeletal tissues. The Vertebrata, indeed, are remarkable for the fact that the epithelial tissues of the so-called mesoderm, *e.g.*, the epithelial lining of the body-cavity, and of the renal tubules and urogenital tracts, all pass through the mesenchymatous condition, whereas in *Amphioxus*, *Balanoglossus*, and presumably *Sagitta* and the Brachiopoda, all the mesodermal tissues pass through the epithelial condition, the epithelial mesodermal tissues of the adult retaining this condition permanently. As has been implied in the above account, mesenchyme is usually formed from epithelial mesoderm or from endoderm, or from tissue destined to form endoderm. It is also sometimes formed from ectoderm, as in the Vertebrata at the nerve crest and other places. In some Cœlenterata also it appears certain that the ectoderm does furnish tissue of a mesenchymatous nature which passes into the jelly, but this phenomenon takes place comparatively late in life, at any rate after the embryonic period. In this connexion it may be interesting to point out that in many Cœlenterates all the tissues of the body retain throughout life the epithelial condition, nothing comparable to mesenchyme ever being formed.

Continuity of the layers.

Finally, before leaving this branch of the subject, the fact that the three germinal layers are continuous with one another, and not isolated masses of tissue, may be emphasized. Indeed, an embryo may be defined as a multinucleated protoplasmic mass, in which the protoplasm at any surface—whether internal or external—is in the form of a relatively dense layer, while that in the interior is much vacuolated and reduced to a more or less sparse reticulum, the nuclei either being exclusively found in the surface protoplasm, or if the embryo has any bulk and the internal reticulum is at all well developed, at the nodes of the internal reticulum as well.

The origin of some of the more important organs may now be considered. It is a remarkable fact that the mouth and anus develop in the most diverse ways in different groups, but as a rule either one or both of them can be traced into relation with the blastopore, the history of which must therefore be examined. In most, if not all, the great groups of the animal kingdom, *e.g.*, in Cœlenterata, Annelida, Mollusca, Vertebrata, and in Arthropoda, the blastopore or its representative is placed on the neural surface of the body, and, as will be shown later on, within the limits of the central nerve rudiment. Here it undergoes the most diverse fate, even in members of the same group. For instance, in *Peripatus capensis* it extends as a slit along the ventral surface, which closes up in the middle, but remains open at the two ends as the permanent mouth and anus. In other Arthropods, though full details have not yet in all cases been worked out, the following general statement may be made:—A blastopore (certain Crustacea) or its representative is formed on the neural surface of the embryo and always becomes closed, the mouth and anus arising as independent perforations later. Here no one would doubt the homology of the mouth and anus throughout the group; yet within the limits of a single genus—*Peripatus*—they show the most diverse modes of development. In Annelids the blastopore sometimes becomes the mouth (most *Chætopoda*); sometimes it becomes the anus (*Serpula*); sometimes it closes up, giving rise to neither, though in this case it may assume the form of a long slit along the ventral surface before disappearing. In Mollusca its fate presents the same variations as in Annelida. Now in these groups no zoologist would deny the homology of the mouth and anus in the different forms, and yet how very different is their history even in closely allied animals. How are these apparently diverse facts to be reconciled? The only satisfactory explanation which has been offered (Sedgwick, *Q.J.M.S.* xxiv., 1884, p. 43) is that the blastopore is homologous in all the groups mentioned, and is the representative of the original single opening into the enteric cavity, such as at present characterizes the Cœlenterata. From it the mouth and anus have been derived, as is indicated by its history in *Peripatus capensis*, and by the variability in its behaviour in closely allied forms; such variability in its subsequent history is due to its specialization as a larval organ, as a result of which it has lost its capacity to give rise to both mouth and anus, and sometimes to either.

Mouth and anus.

That the blastopore does become specialized as a larval organ is obvious in those cases in which it becomes transformed into the single opening with which some larvæ are, for a time at least, alone provided, *e.g.*, *Pilidium*, Echinoderm larvæ, &c., and that larval characters have been the principal causes of the form of embryonic characters, strong reason to believe will be adduced later on. In the Vertebrata the behaviour of the blastopore (anus of Rusconi) is also variable in a very remarkable manner. As a rule it is slit-like in form and closes completely, but in most cases one portion of it remains open longer than the rest, as the neurenteric canal. In a few forms (*e.g.*, Newt, *Lepidosiren*, &c.) the very hindermost portion of the slit-like blastopore remains permanently open as the anus, and from such cases it can be shown that the neurenteric aperture (when present) is derived from a portion of the blastopore just anterior to its hindermost end. The words "hindermost" and "anterior" are used on the assumption that the whole blastopore has retained its dorsal position; as a matter of fact the hindermost part of it—the part which persists or reopens as the anus—loses this position in the course of development and becomes shifted on to the ventral surface. This is clearly seen in *Lepidosiren* (Kerr, *Phil. Trans.* cxcii., 1900), in *Elasmobranchii*, and in *Amniota* (primitive streak). Moreover, in *Lepidosiren*, and possibly in some other forms, the anus, *i.e.*, the hind end of the blastopore, is at first contained within the medullary plate and bounded behind by the medullary folds. Later the portions of the medullary plate in the neighbourhood of the anus completely atrophy, and this relation is lost. This extension of the hind end of the blastopore on to the ventral surface, and atrophy of the portion of the medullary plate in relation with it, is a highly important phenomenon, and one to which attention will be again called when the relation of the mouth to the blastopore is being considered. The remarkable fact about the Vertebrata, a feature which that group shares in common with all other Chordata (*Amphioxus*, *Tunicata*, *Enteropneusta*) and with the Echinodermata, is that the mouth has never been traced into relation with the blastopore. For this reason, among others, it has been held by some zoologists that the mouth of the Vertebrata is not homologous with the mouth of such groups as the Annelida, Arthropoda, and Mollusca. But, as has been explained above, in face of the extraordinary variability in the history of the mouth and anus in these groups, this view cannot be regarded as in any way established. On the contrary, there are distinct reasons for thinking that the Vertebrate mouth is a derivate of the blastopore. In the first place, in *Elasmobranchii* (Sedgwick, *Q.J.M.S.* xxxiii., 1892, p. 559), and in a less conspicuous form in other groups, the mouth has at first a slit-like form, extending from the anterior end of the central nerve tube backwards along the ventral surface of the anterior part of the embryo. This slit-like rudiment, recalling as it does the form which the blastopore assumes in so many groups and in many Vertebrata, does suggest the view that possibly the mouth of the Vertebrata may in reality be derived from a portion of an originally long slit-like neural blastopore, which has become extended anteriorly on to the ventral surface and has lost its original relation to the nerve rudiment, as has undoubtedly happened with the posterior part, which persists as the anus.

Of the other organs which develop from the two primary layers, it is only possible to notice here the central nervous system. This in almost all animals develops from the ectoderm. In Cephalopods among Mollusca—the development of which is remarkable from the almost complete absence of features which, for want of a better name, we must call vestigial-ancestral—and in one or two other forms, it has been said to develop from the mesoderm; but apart from these exceptional and perhaps doubtful cases, the central nervous system of all embryos arises as thickenings of the ectoderm, and in the groups above mentioned, namely, Annelida, Mollusca, Arthropoda, and Vertebrata, and probably others, from the ectoderm of the blastoporal surface of the body. This surface generally becomes the ventral surface, but in Vertebrata it becomes the dorsal. These thickened tracts of ectoderm in *Peripatus* and a few other forms can be clearly seen to surround the blastopore. This relation is retained in the adult in *Peripatus*, some Mollusca, and some Nemertines, in which the main lateral nerve cords are united behind the anus as well as in front of the mouth; in other forms it cannot always be demonstrated, but it can, as in the case of the Vertebrata just referred to, always be inferred; only, in the Invertebrate groups the part of the nerve rudiment which has to be inferred is the posterior part behind the blastopore, whereas in Vertebrata it is the anterior part, namely, that in front of the blastopore, assuming that the mouth is a blastoporal derivate.

Central nervous system.

In the Echinodermata, Enteropneusta, and one or two other groups, it is not possible, in the present state of knowledge, to bring the mouth into relation with the blastopore, nor can the blastopore be shown to be a perforation of the neural surface. For the Echinoderms, at any rate, this fact loses some of the importance which might at first sight be attributed to it when the remarkable organization of the adult and the sharp contrast which exists between it and the larva is remembered. In some Annelids the central nervous system remains throughout life as part of the outer epidermis, but as a general rule it becomes separated from the epidermis and embedded in the mesodermal tissues. The mode in which this separation is effected varies according to the form and structure of the central nervous system. In the Vertebrata, in which this organ has the form of a tube extending along the dorsal surface of the body, it arises as a groove of the medullary plate, which becomes constricted into a canal. The lining of this canal consists of ectoderm, which at an earlier stage formed part of the outer surface of the body, and which now thickens, to give rise to the epithelial lining of the canal and to the nervous tissue which forms the bulk of the canal wall. The fact that the blastopore remains open at the hind end of the medullary plate explains to a certain extent the peculiar relation which always exists in the embryo between the hind end of the neural and alimentary canals. This communication between the hind end of the neural tube and the gut is one of the most remarkable and constant features of the Vertebrate embryo. As has been pointed out, it is not altogether unintelligible when we remember the relation of the blastopore to the medullary plate of the earlier stage, but to give a complete explanation of it is, and probably always will be, impossible. It is no doubt the impress of some remarkable larval condition of the blastopore of a stage of evolution now long past.

In *Ceratodus* the open part of the blastopore is enclosed by the medullary folds, and probably persists as the anus, the portion of the folds around the anus undergoing atrophy (Semon, *Zool. Forschungsreisen in Australien*, 1893, Bd. i. p. 39). In Urodeles the blastopore persists as anus, so far as is known, but the relation to the medullary folds has not been noticed. The same may be said of *Petromyzon* (Shipley, *Q.J.M.S.* xxviii., 1887).

Cranial flexure.

The nerve tube of the Vertebrata at a certain early stage of the embryo becomes bent ventralwards in its anterior portion, in such a manner that the anterior end, which is represented in the adult by the infundibulum, comes to project backwards beneath the mid-brain. This bend, which is called the cranial flexure, takes place through the mid-brain, so that the hind-brain is unaffected by it. The cranial flexure is not, however, confined to the brain: the anterior end of the notochord, which at first extends almost to the front end of the nerve tube (this extension, which is quite obvious in the young embryo of Elasmobranchs, becomes masked in the later stages by the extraordinary modifications which the parts undergo), is also affected by it. Moreover, it affects even other parts, as may be seen by the oblique, almost antero-posterior, direction of the anterior gill slits as compared with the transverse direction of those behind. No satisfactory explanation has ever been offered of the cranial flexure. It is found in all Vertebrates, and is effected at an early stage of the development. In the later stages and in the adult it ceases to be noticeable, on account of an alteration of the relative sizes of parts of the brain. This is due almost entirely to the enormous growth of the cerebral vesicle, which is an outgrowth of the dorsal wall of the fore-brain just short of its anterior end. The anterior end of the fore-brain remains relatively small throughout life as the infundibulum, and the junction of this part of the fore-brain with the part which is so largely developed, as the rudiment of the cerebrum, is marked by the attachment of the optic chiasma. The optic nerve, indeed, is morphologically the first cranial nerve, the olfactory being the second; both are attached to what is morphologically the dorsal side of the nerve tube. The morphological anterior end of the central nerve tube is the point of the infundibulum which is in contact with the pituitary body. While on the subject of the cranial flexure, it may be pointed out that there is a similar downward curve of the hind end of the nervous axis, which leads into the hind end of the enteron. If it be supposed that originally there was a communication between the infundibulum and pituitary body, then the ventral flexure found at both ends of the nerve axis would originally have had the same result, namely, of placing the neural and alimentary canals in communication. Moreover, the mouth would have had much the same relation to this imaginary anterior neurenteric canal that the anus has to the actual posterior one.

In *Amphioxus* and the Tunicata the early development of the central nervous system is very much like that of the Vertebrata, but the later stages are simpler, being without the cranial flexure. The Tunicata are remarkable for the fact that the nervous system, though at first hollow, becomes quite solid in the adult. In *Balanoglossus* the central nervous system is in part tubular, the canal being open at each end. It arises, however, by delamination from the ectoderm, the tube being a secondary acquisition. This is probably due to a shortening of development, for the same feature is found in some Vertebrata (*Teleosteans, Lepidosteus*, &c.), where the central canal is secondarily hollowed out in the solid keel-like mass which is separated from the ectoderm. Parts of the central nervous system arise by invagination in other groups; for instance, the cerebral ganglia of *Dentalium* are formed from the walls of two invaginations of ectoderm, which eventually disappear at the anterior end of the body (Kowalevsky, *Ann. Mus. Hist. Nat. Marseilles*, "Zoology," vol. i.). In *Peripatus* the cerebral ganglia arise in a similar way, but in this case the cavities of the invagination become separated from the skin and persist as two hollow appendages on the lower side of the cerebral ganglia. In other Arthropods the cerebral ganglia arise in a similar way, but the invaginations disappear in the adult. In Nemertines the cerebral ganglia contain a cavity which communicates with the exterior by a narrow canal.

Peripheral nervous system.

Although the central nervous system is almost always developed from the ectoderm of the embryo, the same cannot be said of the peripheral nerve trunks. These structures arise from the mesoblastic reticulum already described (Sedgwick, *Q.J.M.S.* xxxvii. p. 92). Inasmuch as this reticulum is perfectly continuous with the precisely similar though denser tissue in the ectoderm and endoderm, it may well be that a portion of the nerve trunks should be described as being ectodermal and endodermal in origin, though the bulk of them are undoubtedly formed from that portion of the reticulum commonly described as mesoblastic. But, however that may be, the tissue from which the great nerve trunks are developed is continuous on all sides with a similar tissue which pervades all the organs of the body, and in which the nuclei of these organs are contained.

In the early stages of development this tissue is very sparse and not easily seen. It would appear, indeed, that it is of a very delicate texture and readily destroyed by reagents. It is for this reason that the layers of the Vertebrate embryo are commonly represented as being quite isolated from one another, and that the medullary canal is nearly always represented as being completely isolated at certain stages from the surrounding tissues. In reality the layers are all connected together by this delicate tissue—in a sparse form, it is true—which not only extends between them, but also in a denser and more distinct form pervades them. In the germinal layers themselves, and in the organs developing from them, this tissue is in the young stages almost entirely obscured by the densely packed nuclei which it contains. For instance, in the wall of the medullary canal in the Vertebrate embryo, in the splanchnic and somatic layers of mesoderm of the same embryo, and in the developing nerve cords of the *Peripatus* embryo, the nuclei are at first so densely crowded together that it is almost impossible to see the protoplasmic framework in which they rest, but as development proceeds this extra-nuclear tissue becomes more largely developed, and the nuclei are forced apart, so that it becomes visible and receives various names according to its position. In the wall of the medullary canal of the Vertebrate embryo, on the outside of which it becomes especially conspicuous in certain places, and on the dorsal side of the developing nerve cords of the *Peripatus* embryo, it constitutes the white matter of the developing nerve cord; in the mesoblastic tissue outside, where it at the same time becomes more conspicuous (Sedgwick, "Monograph of the Development of *Peripatus capensis*," *Studies from the Morph. Lab. of the University of Cambridge*, iv., 1889, p. 131), it forms the looser network of the mesoblastic reticulum; and connecting the two, in place of the few and delicate strands of this tissue of the former stage, there are at certain places well-marked cords of a relatively dense texture, with the meshes of the reticulum elongated in the direction of the cord. This latter structure is an incipient nerve trunk. It can be traced outwards into the mesoblastic reticulum, from the strands of which it is indeed developed, and with which it is continuous not only at its free end, but also along its whole course. In this way the nerve trunks are developed—by a gathering up, so to speak, of the fibres of the reticulum into bundles. These bundles are generally marked by the possession of nuclei, especially in their cortical parts, which become no doubt the nuclei of the nerve sheath, and, in the neighbourhood of the ganglia, of nerve cells. In some parts of the body of Vertebrata (particularly in the case of the cranial nerves of *Elasmobranchii*) the course of the future nerve is at first marked by a tract of densely packed nuclei extending through a portion of the reticulum, in which the nuclei have become less closely packed. Such nerve tracts soon reveal themselves by the loosening of their nuclei, and become transformed into cords containing a core of the pale fibrous substance with a cortex of nuclei. From this account of the early development of the nerves, it is apparent that they are in their origin continuous with all the other tissues of the body, with that of the central nervous system and with that which becomes transformed into muscular tissue and connective and epithelial tissues. All these tissues are developed from the general reticulum, which in the young embryo can be seen to pervade the whole body, not being confined to the mesoderm, but extending between the nuclei of the ectoderm and endoderm, and forming the extra-nuclear, so-called cellular, protoplasm of those layers. Moreover, it must be remarked that in the stages of the embryo with which we are here concerned the so-called cellular constitution of the tissues, which is such a marked feature of the older embryo and adult, has not been arrived at. It is true, indications of it may be seen in some of the earlier-formed epithelia, but of nerve cells, muscular cells, and many kinds of gland cells no distinct signs are yet visible. This remark particularly applies to nerve cells, which do not make their appearance until a much later stage—not, indeed, until some time after the principal nerve trunks and ganglia are indicated as tracts of pale fibrous substance and aggregations of nuclei respectively. The neuroblasts of His and other authors have no existence, at any rate until long after the stages are passed in which they are described as taking part in the formation of nerves by the extension of their cell-bodies.

The embryos of Elasmobranchs—particularly of *Scyllium*—are the best objects in which to study the development of nerves. In many embryos it is difficult to make out what happens, because the various parts of the body remain so close together that the process is obscured, and the loosening of the mesoblastic nuclei is deferred until after the nerves have begun to be differentiated. The process may also be traced in the embryos of *Peripatus*, where the main features are essentially similar to those above described (*op. cit.* p. 131).

To sum up, the development of nerves is not, as has been recently urged, an outgrowth of cell processes from certain cells, but is a differentiation of a substance which was already in position, and from which all other organs of the body have been and are developed. It frequently happens that the young nerve tracts can be seen sooner near the central organ than elsewhere, but it is doubtful if any importance can be attached to this fact, since it is not constantly observed. For instance, in the case of the third nerve of *Scyllium* the differentiation appears to take place earliest near the ciliary ganglion, and to proceed from that point to the base of the mid-brain.

Cœlom. There are two main methods in which new organs are developed. In the one, which indicates the possibility of physiological continuity, the organ arises by the direct modification of a portion of a pre-existing organ; the development of the central nervous system of the Vertebrata from a groove in the embryonic ectoderm may be taken as an example of this method. In the other method there is no continuity which can be in any way interpreted as physiological; a centre of growth appears in one of the parts of the embryo, and gives rise to a mass of tissue which gradually shapes itself into the required organ. The development of the central nervous system in Teleosteans and in other similar exceptional cases may be mentioned as an example of the second plan. Such a centre of growth is frequently called a blastema, and consists of a mass of closely packed nuclei which have arisen by the growth-activity of the nuclei in the neighbourhood. The cœlom, an organ which is found in the so-called cœlomate animals, and which in the adult is usually divided up more or less completely into three parts, namely, body-cavity, renal organs, generative glands, presents in different animals both these methods of development. In certain animals it develops by the direct modification of a part of the primitive enteron, while in others it arises by the gradual shaping of a mass of tissue which consists of a compact mass of nuclei derived by nuclear proliferation from one or more of the pre-existing tissues of the body. Inasmuch as the first rudiment of the cœlom nearly always makes its appearance at an early stage, when the ectoderm and endoderm are almost the only tissues present, and as it then bulks relatively very large and frequently contains within itself the potential centres of growth of other, not allied, organs, it has come to be regarded by embryologists as being the forerunner of all the so-called mesodermal organs of the body, and has been dignified with the somewhat mysterious rank which attaches to the conception of a germinal layer. Its prominence and importance at an early stage led embryologists, as has already been explained, to overlook the fact that although some of the centres of growth for the formation of other non-cœlomic organs and tissues may be contained within it, all are not so contained; that there are centres of growth still left in the ectoderm and endoderm after its establishment; and, finally, that there are some animals in which probably no potential centres of growth, other than those connected with the formation of cœlomic organs, are contained in the cœlomic rudiment. If these considerations, and others like them, are correct, it would seem to follow that the conception implied by the word mesoderm has no objective existence, that the tissue of the embryo, called mesoderm, is mainly, sometimes exclusively, the rudiment of the cœlom, and that though this rudiment may contain within itself the potential centres of growth of other organs and tissues which are commonly ranked as mesodermal, it is not different in this respect from the rudiments of the two other organs already formed, namely, the ectoderm and endoderm; for these contain within themselves centres of growth for the production of the so-called mesodermal tissues, as witness the nerve-crest of Vertebrata, the growing-point of the pronephric duct, and the formation of blood-vessels from the hypoblast described for some members of the same group. In Echinodermata, *Amphioxus*, Enteropneusta, and a few other groups, the cœlom develops from a portion or portions of the primitive enteron, which eventually becomes separated from the rest and forms a variable number of closed sacs lying between the gut and the ectoderm. The number of these sacs varies in different animals, but the evidence at present available seems to show that the maximum number is five—an unpaired one in front and two pairs behind—and, further, that if a less number of sacs is actually separated from the enteron, the rule is for these sacs so to divide up that they give rise to five sacs arranged in the manner indicated. The Enteropneusta present us with the clearest case of the separation of five sacs from the primitive enteron (Bateson, *Q.J.M.S.* xxiv. 1884).

In *Amphioxus*, according to the important researches of MacBride (*Q.J.M.S.* xl. p. 589), it appears that a similar process occurs, though it is complicated by the fact that the sacs of the posterior pair become divided up at an early stage into many pairs. In *Phoronis* there are indications of the same phenomenon (Masterman, *Q.M.J.S.* xliii. p. 375). In the Chætognatha a single sac only is separated from the enteron, but soon becomes divided up. The exact method of this division is not known, but the facts so far observed suggest that a renewed investigation may show that the division is into five sacs arranged as in the Enteropneust embryo. In the Brachiopoda one pair of sacs is separated from the enteron, but our knowledge of their later history is not sufficient to enable us to say whether they divide up into the typically arranged five sacs. (The embryology of the Chætognatha and Brachiopoda would well repay investigation by modern methods with regard to this point.) In Echinodermata the number of sacs separated from the enteron varies from one to three; but though the history of these shows considerable differences, there are reasons to believe that the typical final arrangement is one unpaired and two paired sacs. But however many sacs may arise from the primitive enteron, and however these sacs may ultimately divide up and arrange themselves, the important point of development common to all these animals, about which there can be no dispute, is that the cœlom is a direct differentiation of a portion of the enteron.

In the majority of the Cœlomata the cœlomic rudiment does not arise by the simple differentiation of a pre-existing organ, and there is considerable variation in its method of formation. Speaking generally, it may be said to consist at first of a blastema (see above), which arises at an early stage as a nuclear proliferation from one or more growth-centres in one or both of the primary layers. When the cœlomic rudiment arises in this way, and not by the direct differentiation of a portion of a pre-existing organ, its later history always shows that it contains within itself the growth centres of a large number of non-cœlomic organs. In some cases, it is true, it receives later such important reinforcements, which become indistinguishably mingled with it, that it is possible that the number of those originally present in it may be less than is supposed (Vertebrata); but making all allowances for this, it must be admitted that there are some embryos, *e.g.*, *Peripatus capensis*, in which the cœlomic rudiment is not appreciably reinforced after its first establishment, but contains within itself the germs of practically all the organs which are not developed from the original ectoderm and endoderm. Apart from the Mollusca, in which the history of the mesoderm can only be followed with great difficulty, and is not in all cases known or understood, the mesoderm of Cœlomate animals, when once established, immediately proceeds to show its real nature by assuming the form and relations of the cœlom. In the first place it acquires a cavity or series of cœlomic cavities, which become transformed into the body-cavity (except in the Arthropoda), into the renal organs (with the possible exception, again, of some Arthropoda), and into the reproductive glands. In metamerically segmented animals the appearance of these cavities is synchronous with, and indeed determines, the appearance of metameric segmentation. In all segmented animals in which the cœlomic rudiment appears as a continuous sheet or band of tissue on each side of the body, the cœlomic cavity makes its first appearance not as a continuous space on each side, which later becomes divided up into the structures called mesoblastic somites, but as a series of paired spaces round which the cœlomic tissue arranges itself in an epithelial manner. In the Vertebrata, it is true, the ventral portion of the cœlom appears at first as a continuous space, at any rate behind the region of the two anterior pairs of somites, but in the dorsal portion the cœlomic cavity is developed in the usual way, the cœlomic tissue becoming transformed into the muscle plates and rudimentary renal tubules of the later stages. With regard to this ventral portion of the cœlom in Vertebrata, it is to be noticed that the cavity in it never becomes divided up, but always remains continuous, forming the perivisceral portion of the cœlom. The probable explanation of this peculiarity in the development of the Vertebrate cœlom, as compared with that of *Amphioxus* and other segmented animals, is that the segmented stage of the ventral portion of the cœlom is omitted. This explanation derives some support from the fact that even in animals in which the cœlom is at its first appearance wholly segmented, it frequently happens that in the adult the perivisceral portion of it is unsegmented, *i.e.*, it loses during development the segmentation which it at first possesses. This happens in many Annelida and in *Amphioxus*. The lesson, then, which the early history of the cœlom in segmented animals teaches, is that however the cœlomic cavity first makes its appearance, whether by evaginations from the primitive enteron, or by the hollowing out of a solid blastema-like tissue which has developed from one or both of the primary layers, it is in its first origin segmented, and forms the basis on which the segments of the adult are moulded. In Arthropoda the origin of the cœlom is similar to that of Annelids, but its history is not completely known in any group, with the exception of *Peripatus*. In this genus it develops no perivisceral portion, as in other groups, but gives rise solely to the nephridia and to the reproductive organs. It is probable, though not certainly proved, that the history of the cœlom in other Arthropods is essentially similar to that of *Peripatus*, allowance being made for the fact that the nephridial portion does not attain full development in those forms which are without nephridia in the adult.

With regard to the development of the vascular system, little can be said here, except that it appears to arise in all cases from the spaces of the mesoblastic reticulum. These acquire special epithelial walls, and form the main trunks and network of smaller vessels found in animals with a canalicular vascular system, or the large sinus-like spaces characteristic of animals with a hæmocœlic body-cavity.

Transient embryonic organs.

The existence of a phase at the beginning of life during which a young animal acquires its equipment by a process of growth of the germ is of course intelligible enough; such a phase is seen in the formation of buds, and in the sexual reproduction of both animals and plants. The remarkable point is that while in most cases this embryonic growth is a direct and simple process—*e.g.*, animal and plant buds, embryonic development of plant seeds—in many cases of sexual reproduction of animals it is not direct, and the embryonic phase shows stages of structure which seem to possess a meaning other than that of being merely phases of growth. The fact that these stages of structure through which the embryo passes sometimes present for a short time features which are permanent in other members of the same group, adds very largely to the interest of the phenomenon and necessitates its careful examination. This may be divided into two heads: (1) in relation to embryos, (2) in relation to larvæ. So far as embryos are concerned, we shall limit ourselves mainly to a consideration of the Vertebrata, because in them are found most instances of that remarkable phenomenon, the temporary assumption by certain organs of the embryo of stages of structure which are permanent in other members of the same group. As is well known, the embryos of the higher Vertebrata possess in the structure of the pharynx and of the heart and vascular system certain features—namely, paired pharyngeal apertures, a simple tubular heart, and a single ventral aorta giving off right and left a number of branches which pass between the pharyngeal apertures—which permanently characterize those organs in fishes. The skeleton, largely bony in the adult, passes through a stage in which it is entirely without bone, and consists mainly of cartilage—the form which it permanently possesses in certain fishes. Further, the Vertebrate embryo possesses for a time a notochord, a segmented muscular system, a continuity between the pericardium and the posterior part of the perivisceral cavity—all features which characterize certain groups of Pisces in the adult state. Instances of this kind might be multiplied, for the work of anatomists and embryologists has of late years been largely devoted to adding to them. Examples of embryonic characters which are not found in the adults of other Vertebrates, are the following:—At a certain stage of development the central nervous system has the form of a groove in the skin, there is a communication at the hind end of the body between the neural and alimentary canals, the mouth aperture has at first the form of an elongated slit, the growing end of the Wolffian duct is in some groups continuous with the ectoderm, and the retina is at one stage a portion of the wall of the medullary canal. In the embryos of the lower Vertebrates many other instances of the same interesting character might be mentioned; for instance, the presence of a cœlomic sac close to the eye, of another in the jaw, and of a third near the ear (Elasmobranchs), the opening of the Müllerian duct into the front end of the Wolffian duct, and the presence of an aperture of communication between the muscle-plate cœlom and the nephridial cœlom.

The interest attaching to these remarkable facts is much increased by the explanation which has been given of them. That explanation, which is a deduction from the theory of evolution, is to the effect that the peculiar embryonic structures and relations just mentioned are due to the retention by the embryo of features which, once possessed by the ancestor, have been lost in the course of evolution.

This explanation, which at once suggests itself when we are dealing with structures actually present in adult members of other groups, does not so obviously apply to those features which are found in no adult animal whatsoever. Nevertheless it has been extended to them, because they are of a nature which it is not impossible to suppose might have existed in a working animal. Now this explanation, which, it will be observed, can only be entertained on the assumption that the evolution theory is true, has been still further extended by embryologists in a remarkable and frequently unjustifiable manner, and has been applied to all embryonic processes, finally leading to the so-called recapitulation theory, which asserts that embryonic history is a shortened recapitulation of ancestral history, or, to use the language of modern zoology, that the ontogeny or development of the individual contains an abbreviated record of the phylogeny or development of the race. A theory so important and far-reaching as this requires very careful examination. When we come to look for the facts upon which it is based, we find that they are non-existent, for the ancestors of all living animals are dead, and we have no means of knowing what they were like. It is true there are fossil remains of animals which have lived, but these are so imperfect as to be practically useless for the present requirements. Moreover, if they were perfectly preserved, there would be no evidence to show that they were ancestors of the animals now living. They might have been animals which have become extinct and left no descendants. Thus the explanation ordinarily given of the embryonic structures referred to is purely a deduction from the evolution theory. Indeed, it is even less than this, for all that can be said is something of this kind:—if the evolution theory is true, then it is conceivable that the reason why the embryo of a bird passes through a stage in which its pharynx presents some resemblance to that of a fish is that a remote ancestor of the bird possessed a pharynx with lateral apertures such as are at present found in fishes.

Recapitulation theory.

But the explanation is sometimes pushed even farther, and it is said that these pharyngeal apertures of the ancestral bird had the same respiratory function as the corresponding structures in modern fishes. That this is going too far a little reflection will show. For if it be admitted that all so-called vestigial structures had once the same function as the homologous structures when fully developed in other animals, it becomes necessary to admit that male mammals must once have had fully developed mammary glands and suckled the young, that female mammals formerly were provided with a functional penis, and that in species in which the females have a trace of the secondary sexual characters of the male the latter were once common to both sexes. The second and more extended form of the explanation plainly introduces a considerable amount of contentious matter, and it will be advisable, in the first instance, at any rate, to confine ourselves to a critical examination of the less ambitious conception. This explanation obviously implies the view that in the course of evolution the tendency has been for structures to persist in the embryo after they have been lost in the adult. Is there any justification for this view? It is clearly impossible to get any direct evidence, because, as explained above, we have no knowledge of the ancestors of living animals; but if we assume the evolution theory to be true, there is a certain amount of indirect evidence which is distinctly opposed to the view. As is well known, living birds are without teeth, but it is generally assumed that their edentulous condition has been comparatively recently acquired, and that they are descended from animals which, at a time not very remote from the present, possessed teeth. Considering the resemblance of birds to other terrestrial vertebrates, and the fact that extinct birds, not greatly differing from birds now living, are known to have had teeth, it must be allowed that there is some warrant for the assumption. Yet in no single case has it been certainly shown that any trace of teeth has been developed in the embryo. The same remark applies to a large number of similar cases; for instance, the reduced digits of the bird's hand and foot, and the limbs of snakes. Moreover, organs which are supposed to have become recently reduced and functionless in the adult are also reduced in the embryo; for instance, digits 3 and 4 of the horse's foot, the hind limbs of whales (Guldberg and Nansen, "On the Development and Structure of Whales," *Bergen Museum*, 1894), the spiracle of Elasmobranchii. In fact, considerations of this kind distinctly point to the view that any tendency to the reduction or enlargement of an organ in the adult is shared approximately to the same extent by the embryo. But there are undoubtedly some, though not many, cases in which organs which were presumably present in an ancestral adult have persisted in the embryo of the modern form. As an instance may be mentioned the presence in whalebone whales of imperfectly formed teeth, which are absorbed comparatively early in fœtal life (Julin, *Arch. Biologie*, i., 1880, p. 75).

It therefore becomes necessary to inquire why in some cases an organ is retained by the embryo after its loss by the adult, whereas in other cases it dwindles and presumably disappears simultaneously in the embryo and the adult. The whole question is examined and discussed by the present writer in the *Q.J.M.S.* xxxvi., 1894, p. 35, and the conclusions there reached are as follow:—A disappearing adult organ is not retained in a relatively greater development by an organism in the earlier stages of its individual growth unless it is of functional importance to the young form. In cases in which the whole development is embryonic this rarely happens, because the conditions of embryonic life are so different from free life that functional embryonic organs are usually organs *sui generis*, which cannot be traced to a modification of organs previously present in the adult. It does, however, appear to have happened sometimes, and as an instance of it may be mentioned the *ductus arteriosus* of the Sauropsidan and Mammalian embryo. On the other hand, when there is a considerable period of larval life, it does appear that there is a strong case for thinking that organs which have been lost by the adult may be retained and made use of by the larva. The best-known example that can be given of this is the tadpole of the frog. Here we find organs, viz., gills and gill-slits, which are universally regarded as having been attributes of all terrestrial Vertebrata in an earlier and aquatic condition, and we also notice that their retention is due to their being useful on account of the supposed ancient conditions of life having been retained. Many other instances, more or less plausible, of a like retention of ancestral features by larvæ might be mentioned, and it must be conceded that there are strong reasons for supposing that larvæ often retain traces, more or less complete, of ancestral stages of structure. But this admission does not carry with it any obligation to accept the widely prevalent view that larval history can in any way be regarded as a recapitulation of ancestral history. Far from it, for larvæ in retaining some ancestral features are in no way different from adults; they only differ from adults in the features which they have retained. Both larvæ and adults retain ancestral features, and both have been modified by an adaptation to their respective conditions of life which has ever been becoming more perfect.

The conclusion, then, has been reached, that whereas larvæ frequently retain traces of ancestral stages of adult structure, embryos will rarely do so; and we are confronted again with the question, How are we to account for the presence in the embryo of numerous functionless organs which cannot be explained otherwise than as having been inherited from a previous condition in which they were functional? The answer is that the only organs of this kind which have been retained are organs which have been retained by the larvæ of the ancestors after they have been lost by the adult, and have become in this way impressed upon the development. As an illustration taken from current natural history of the manner in which larval characters are in actual process of becoming embryonic may be mentioned the case of the viviparous salamander (*Salamander atra*), in which the gills, &c., are all developed but never used, the animal being born without them. In other and closely allied species of salamander there is a considerable period of larval life in which the gills and gill-slits are functional, but in this species the larval stage, for the existence of which there was a distinct reason, viz., the entirely aquatic habits of life in the young state, has become at one stroke embryonic by its simple absorption into the embryonic period. The view, then, that embryonic development is essentially a recapitulation of ancestral history must be given up; it contains only a few references to ancestral history, namely, those which have been preserved probably in a much modified form by previous larvæ.

We must now pass to the consideration of another supposed law of embryology—the so-called law of v. Baer. This generalization is usually stated as follows:—

Law of v. Baer.

Embryos of different species of the same group are more alike than adults, and the resemblances are greater the younger the embryo examined. Great importance has been attached to this generalization by embryologists and naturalists, and it is very widely accepted. Nevertheless, it is open to serious criticism. If it were true, we should expect to find that embryos of closely similar species would be indistinguishable, but this is notoriously not the case. On the contrary, they often differ more than do the adults, in support of which statement the embryos of the different species of *Peripatus* may be referred to. The generalization undoubtedly had its origin in the fact that there is what may be called a family resemblance between embryos, but this resemblance, which is by no means exact, is purely superficial, and does not extend to anatomical detail. On the contrary, it may be fairly argued that in some cases embryos of widely dissimilar members of the same group present anatomical differences of a higher morphological value than do the adults (see Sedgwick, *loc. cit.*), and, as stated above, the embryos of closely allied animals are distinguishable at all stages of development, though the distinguishing features are not the same as those which distinguish the adults. To say that the development of the organism and of its component parts is a progress from the simple to the complex is to state a truism, but to state that it is also a progress from the general to the special is to go altogether beyond the facts. The bipinnaria larva of an echinoderm, the trochosphere larva of an annelid, the blastodermic vesicle of a mammal are all as highly specialized as their respective adults, but the specialization is for a different purpose, and of a different kind to that which characterizes the adult.

For an account of the history of the subject the reader is referred to the article EMBRYOLOGY in the 9th edition of this *Encyclopædia*, where he will also find under the heading REPRODUCTION information respecting the menstruation, fertilization, gestation, parental care, formation of ovum, and spermatozoon. The following books contain fuller information:—K. E. VON BAER. *Ueber Entwicklungsgeschichte der Thiere.* Königsberg, 1828, 1837.—F. M. BALFOUR. *A Monograph of the Development of Elasmobranch Fishes.* London, 1878. *A Treatise on Comparative Embryology*, vols. i. and ii. London, 1885 (still the most important work on Vertebrate Embryology).—M. DUVAL. *Atlas d'Embryologie.* Paris, 1889. —M. FOSTER and F. M. BALFOUR. *Elements of Embryology.* London, 1883.—O. HERTWIG. *Lehrbuch der Entwicklungsgeschichte des Menschen u. der Wirbelthiere*, 6th edition. Jena, 1898.—A. KÖLLIKER. *Entwicklungsgeschichte des Menschen u. der höheren Thiere.* Leipzig, 1879.—E. KORSCHELT and K. HEIDER. *Lehrbuch der vergleich. Entwicklungsgeschichte der wirbellosen Thiere.* Jena, 1890 (English translation, London, 1895–1900).—A. M. PHYSIOLOGY OF DEVELOPMENT.

Physiology of Development [in German, *Entwicklungsmechanik* (Roux), *Entwicklungsphysiologie* (Driesch), *Physiologische Morphologie* (Loeb)] is, in the broadest meaning of the word, the experimental science of morphogenesis, *i.e.*, of the laws that govern morphological differentiation. In this sense it embraces the study of regeneration and variation, and would, as a whole, best be called rational morphology. Here we shall treat of the Physiology of Development in a narrower sense, as the study of the laws that govern the development of the adult organism from the egg, REGENERATION and VARIATION forming the subjects of special articles.

After the work done by His, Goette, and Pflüger, who gave a sort of general outline and orientation of the subject, the first to study developmental problems properly in a systematical way, and with full conviction of their great importance, was Wilhelm Roux. This observer, having found by a full analysis of the facts of "development" that the first special problem to be worked out was the question when and where the first differentiation appeared, got as his main result that, when one of the two first blastomeres (cleavage cells) of the frog's egg was killed, the living one developed into a typical half-embryo, *i.e.*, an embryo that was either the right or the left part of a whole one. From that Roux concluded that the first cleavage plane determined already the median plane of the adult; and that the basis of all differentiation was given by an unequal division of the nuclear substances during karyokinesis, a result that was also attained on a purely theoretical basis by Weismann. Hans Driesch repeated Roux's fundamental experiment with a different method on the sea-urchin's egg, with a result that was absolutely contrary to that of Roux: the isolated blastomere cleaved like half the egg, but it resulted in a whole blastula and a whole embryo, which differed from a normal one only in its small size. Driesch's result was obtained in somewhat the same manner by Wilson with the egg of Amphioxus, by Zoja with the egg of Medusæ, &c. It thus became very probable that an inequality of nuclear division could not be the basis of differentiation. The following experiments were still more fatal to the theories of Roux and of Weismann. Driesch found that, even when the first eight or sixteen cells of the cleaving egg of the sea-urchin were brought into quite abnormal positions with regard to one another, still a quite normal embryo was developed; Driesch and Morgan discovered jointly that in the Ctenophore egg one isolated blastomere developed into a half-embryo, but that the same was the case if a portion of protoplasm was cut off from the fertilized egg not yet in cleavage; last, but not of least importance, in the case of the frog's egg which had been Roux's actual subject of experiment, conditions were discovered by O. Schultze and O. Hertwig under which one of the two first blastomeres of this egg developed into a whole embryo of half size. This result was made still more decisive by

Morgan, who showed that it was quite in the power of the experimenter to get either a half-embryo or a whole one of half size, the latter dependent only upon giving to the blastomere the opportunity for a rearrangement of its matter by turning it over.

Thus we may say that the general result of the introductory series of experiments in the physiology of development is the following:—In many forms, *e.g.*, Echinoderms, Amphioxus, Ascidians, Fishes, and Medusæ, the potentiality (*prospective Potenz*—Driesch) of all the blastomeres of the segmented egg is the same, *i.e.*, each of them may play any or every part in the future development; the prospective value (*prosp. Bedeutung*—D.) of each blastomere depends upon, or is a function of, its position in the whole of the segmented egg; we can term the "whole" of the egg after cleavage an "aequipotential system" (Driesch). But though aequipotential, the whole of the segmented egg is nevertheless not devoid of orientation or direction; the general law of causality compels us to assume a general orientation of the smallest parts of the egg, even in cases where we are not able to see it. It has been experimentally proved that external stimuli (light, heat, pressure, &c.) are not responsible for the first differentiation of organs in the embryo; thus, should the segmented egg be absolutely equal in itself, it would be incomprehensible that the first organs should be formed at one special point of it, and not at another. Besides this general argument, we see a sort of orientation in the typical forms of the polar or bilateral cleavage stages.

Differentiation, therefore, depends on a primary, *i.e.*, innate, orientation of the egg's plasma in those forms, the segmented eggs of which represent aequipotential systems; this orientation is capable of a sort of regulation or restoration after disturbances of any sort; in the egg of the Ctenophora such a regulation is not possible, and in the frog's egg it is facultative, *i.e.*, possible under certain conditions, but impossible under others. Should this interpretation be right, the differences between the eggs of different animals would not be so great as it seemed at first: differences with regard to the potentialities of the blastomeres would only be differences with regard to the capability of regulation or restoration of the egg's protoplasm.

The foundation of physiological embryology being laid, we now can shortly deal with the whole series of special problems offered to us by a general analysis of that science, but at present worked out only to a very small extent.

We may ask the following questions:—What are the general conditions of development? On what general factors does it depend? How do the different organs of the partly developed embryo stand with regard to their future fate? What are the stimuli (*Reize*) effecting differentiation? What is to be said about the specific character of the different formative effects? And as the most important question of all: Are all the problems offered to us in the physiology of development to be solved with the aid of the laws known hitherto in science, or do we want specifically new "vitalistic" factors?

Conditions of differentiation.

Energy in different forms is required for development, and is provided by the surrounding medium. Light, though of no influence on the cleavage (Driesch), has a great effect on the later stages of development (Young), and is also necessary for the formation of polyps in Eudendrium (Loeb). That a certain temperature is necessary for ontogeny has long been known; this was carefully studied by O. Hertwig, as was also the influence of heat on the rate of development. Oxygen is also wanted, either from a certain stage of development or from the very beginning of it, though very nearly related forms differ in this respect (Loeb). The great influence of osmotic pressure on growth was studied by Loeb, Herbst, and Davenport. In all these cases energy may be necessary for development in general, or a specific form of energy may be necessary for the formation of a specific organ; it is clear that, especially in the latter case, energy is shown to be a proper factor for morphogenesis. Besides energy, a certain chemical condition of the medium, whether offered by the water in which the egg lives or (especially in later stages) by the food, is of great importance for normal ontogeny; the only careful study in this respect was carried out by Herbst for the development of the egg of Echinids. This investigator has shown that all salts of the sea water are of great importance for development, and most of them specifically and typically; for instance, calcium is absolutely necessary for holding together the embryonic cells, and without calcium all cells will fall apart, though they do not die, but live to develop farther.

What we have dealt with may be called external factors of development; as to their complement, the internal factors, it is clear that every elementary factor of general physiology may be regarded as one of them. Chemical metamorphosis plays, of course, a great part in differentiation, especially in the form of secretions; but very little has been carefully studied in this respect. Movement of living matter, whether of cells or of intracellular substance, is another important factor (Bütschli, Dreyer, Rhumbler). Cell-division is another, its differences in direction, rate, and quantity being of great importance for differentiation. We know very little about it; a so-called law of O. Hertwig, that a cell would divide at right angles to its longest diameter, though experimentally stated in some cases, does not hold for all, and the only thing we can say is, that the unknown primary organization of the egg is here responsible. (Compare the papers on "cell-lineage" of Wilson, Lillie, Jennings, Zurstrassen, and others.) Of the inner factors of ontogeny there is another category that may be called physical, that already spoken of being physiological. The most important of these is the capillarity of the cell surfaces. Berthold was the first to call attention to its rôle in the arrangement of cell composites, and afterwards the matter was more carefully studied by Dreyer, Driesch, and especially Roux, with the result that the arrangement of cells follows the principle of surfaces *minimæ areæ* (Plateau) as much as is reconcilable with the conditions of the system.

Potentialities of embryonic cells.

It has already been shown that in many cases the embryo after cleavage, *i.e.*, the blastula, is an "aequipotential system." It was shown that in the egg of Echinids there existed such an absolute lack of determination of the cleavage cells that (*a*) the cells may be put in quite abnormal positions with reference to one another without disturbing development; (*b*) a quarter blastomere gives a quite normal little pluteus, even a sixteenth yields a gastrula; (*c*) two eggs may fuse in the early blastula stage, giving one single normal embryo of double size. Our next question concerns the distribution of potentiality, when the embryo is developed farther than the blastula stage. In this case it has been shown that the potentialities of the different embryonic organs are different: that, for instance, in Echinoderms or Amphibians the ectoderm, when isolated, is not able to form endoderm, and so on (Driesch, Barfurth); but it has been shown at the same time that the ectoderm in itself, the intestine in itself of Echinoderms (Driesch), the medullary plate in itself of Triton (Spemann), is as aequipotential as was the blastula: that any part whatever of these organs may be taken away without disturbing the development of the rest into a normal and proportional embryonic part, except for its smaller size.

If the single phases of differentiation are to be regarded as effects, we must ask for the causes, or stimuli, of these effects. For a full account of the subject we refer to Herbst, by whom also the whole botanical literature, much more important than the zoological, is critically reviewed. We have already seen that when the blastula represents an aequipotential system, there must be some sort of primary organization of the egg, recoverable after disturbances, that directs and localizes the formation of the first embryonic organs; we do not know much about this organization. Directive stimuli (*Richtungsreize*) play a great rôle in ontogeny; Herbst has analysed many cases where their existence is probable. They have been experimentally proved in two cases. The chromatic cells of the yolk sac of Fundulus are attracted by the oxygen of the arteriæ (Loeb); the mesenchyme cells of Echinus are attracted by some specific parts of the ectoderm, for they move towards them also when removed from their original positions to any point of the blastocœl by shaking (Driesch). Many directive stimuli might be discovered by a careful study of grafting experiments, such as have been made by Born, Joest, Harrison, and others, but at present these experiments have not been carried out far enough to get exact results.

Formative stimuli.

Formative stimuli in a narrower meaning of the word, *i.e.*, stimuli affecting the origin of embryonic organs, have long been known in botany; in zoology we know (especially from Loeb) a good deal about the influence of light, gravitation, contact, &c., on the formation of organs in hydroids, but these forms are very plant-like in many respects; as to free-living animals, Herbst proved that the formation of the arms of the pluteus larva depends on the existence of the calcareous tetrahedra, and made in other cases (lens of vertebrate eye, nerves and muscles, &c.) the existence of formative stimuli very probable. Many of the facts generally known as functional adaptations (*functionelle Anpassung*—Roux) in botany and zoology may also belong to this category, *i.e.*, be the effects of some external stimulus, but they are far from having been analysed in a satisfactory manner. That the structure of parts of the vertebrate skeleton is always in relation to their function, even under abnormal conditions, is well known; what is the real "cause" of differentiation in this case is difficult to say.

Specific characters.

It is obvious that we cannot answer the question why the different ontogenetic effects are just what they are. Developmental physiology takes the specific nature of form for granted, and it may be left for a really rational theory of the evolution of species in the future to answer the problem of species, as far as it is answerable at all. What we intend to do here is only to say in a few words wherein consists the specific character of embryonic organs. That embryonic parts are specific or typical in regard to their protoplasm is obvious, and is well proved by the fact that the different parts of the embryo react differently to the same chemical or other reagents (Herbst, Loeb). That they may be typical also in regard to their nuclei was shown by Boveri for the generative cells of Ascaris; we are not able at present to say anything definite about the importance of this fact. The specific nature of an embryonic organ consists to a high degree in the number of cells composing it; it was shown for many cases that this number, and also the size of cells, is constant under constant conditions, and that under inconstant conditions the number is variable, the size constant; for instance, embryos which have developed from one of the two first blastomeres show only half the normal number of cells in their organs (Morgan, Driesch).

We have learnt that the successive steps of embryonic development are to be regarded as effects, caused by stimuli, which partly exist in the embryo itself. But it must be noted that not every part of the embryo is dependent on every other one, but that there exists a great independence of the parts, to a varying degree in every case. This partial independence has been called self-differentiation (*Selbstdifferenzierung*) by Roux, and is certainly a characteristic feature of ontogeny. At the same time it must not be forgotten that the word is only relative, and that it only expresses our recognition of a negation.

Self-differentiation.

For instance, we know that the ectoderm of Echinus may develop farther if the endoderm is taken away; in other words, that it develops by self-differentiation in regard to the endoderm, that its differentiation is not dependent on the endoderm; but it would be obviously more important to know the factors on which this differentiation is actually dependent than to know one factor on which it is not. The same is true for all other experiments on "self-differentiation," whether analytical (Loeb, Schaper, Driesch) or not (grafting experiments, Born, Joest, &c.).

Vitalism.

Can we understand differentiation by means of the laws of natural phenomena offered to us by physics and chemistry? Most people would say yes, though not yet. Driesch has tried to show that we are absolutely not able to understand development, at any rate one part of it, *i.e.*, the localization of the various successive steps of differentiation. But it is impossible to give any idea of this argument in a few words, and we can only say here that it is based on the experiments upon isolated blastomeres, &c., and on an analysis of the character of aequipotential systems. In this way physiology of development would lead us straight on into Vitalism.

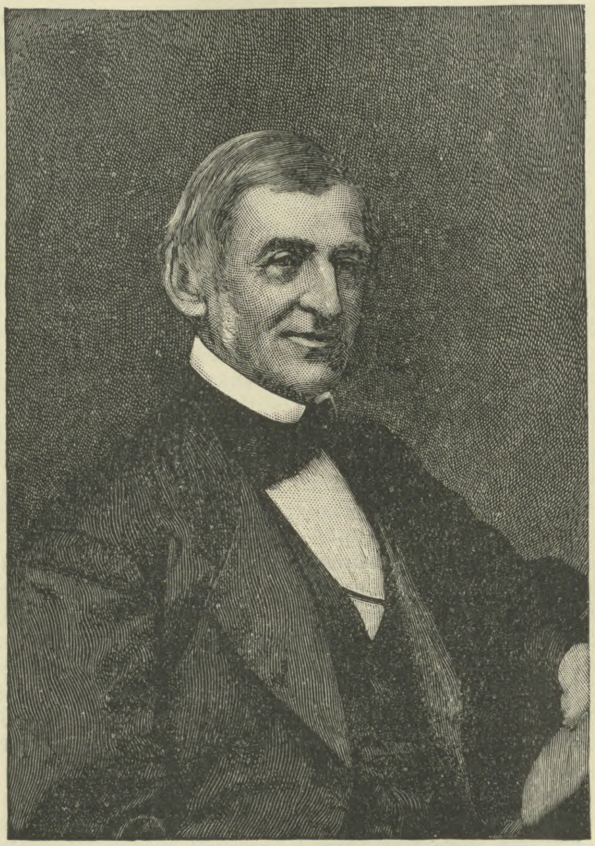
(H. A. E. D.)

Emden, a town of Prussia, province of Hanover, near the mouth of the Ems, 49 miles north-west from Oldenburg by rail. The town-hall (1574–76) possesses an exceptionally interesting collection of weapons of war. There are two other museums, one of art, coins, and Frisian antiquities, the other containing specimens of natural history. It has a school of navigation. Emden is the seat of an active trade in agricultural produce and live-stock, timber, coal, tea, wine, and fish. Cement, wire ropes, sugar, tobacco, woollens, and leather are manufactured. The harbour has been greatly improved in consequence of the construction of the Ems–Jade and the Ems–Dortmund canals; and in 1900 the Prussian Government resolved to enlarge the outer harbour and deepen it to 37 ft. 8½ in., as well as deepen the lower Ems to 32 ft. 9 in., the total cost being estimated at close upon £400,000. Population (1885), 14,019; (1900), 16,453.

Emerson, Ralph Waldo (1803–1882), American poet and essayist, was born in Boston, Massachusetts, 25th May 1803. Seven of his ancestors were ministers of New England churches. Among them were some of those men of mark who made the backbone of the American character: the sturdy Puritan, Peter Bulkeley, sometime rector of Odell in Bedfordshire, and afterward pastor of the church in the wilderness at Concord, New Hampshire; the zealous evangelist, Father Samuel Moody of Agamenticus in Maine, who pursued graceless sinners even into the alehouse; Joseph Emerson of Malden, "a heroic scholar," who prayed every night that no descendant of his might ever be rich; and William Emerson of Concord, Mass., the patriot preacher, who died while serving in the army of the Revolution. Sprung from such stock, Emerson inherited qualities of self-reliance, love of liberty, strenuous virtue, sincerity, sobriety, and fearless loyalty to ideals. The form of his ideals was modified by the metamorphic glow of Transcendentalism which passed through the region of Boston in the second quarter of the 19th century. But the spirit in which Emerson conceived the laws of life, reverenced them, and lived them out, was the Puritan spirit, elevated, enlarged, and beautified by the poetic temperament.

His father was the Rev. William Emerson, minister of the First Church (Unitarian) in Boston. Ralph Waldo was the fourth child in a family of eight, of whom at least three gave evidence of extraordinary mental powers. He was brought up in an atmosphere of hard work, of moral discipline, and (after his father's death in 1811) of that wholesome self-sacrifice which is a condition of life for those who are poor in money and rich in spirit. His aunt, Miss Mary Moody Emerson, a brilliant old maid, an eccentric saint, was a potent factor in his education. Loving him, believing in his powers, passionately desiring for him a successful career, but clinging with both hands to the old forms of faith from which he floated away, this solitary, intense woman did as much as any one to form, by action and reaction, the mind and character of the young Emerson. In 1817 he entered Harvard College, and graduated in 1821. In scholarship he ranked about the middle of his class. In literature and oratory he was more distinguished, receiving a Boylston prize for declamation, and two Bowdoin prizes for dissertations, the first essay being on "The Character of Socrates" and the second on "The Present State of Ethical Philosophy"—both rather dull, formal, didactic productions. He was fond of reading and of writing verse, and was chosen as the poet for class-day. His cheerful serenity of manner, his tranquil mirthfulness, and the steady charm of his personality, made him a favourite with his fellows, in spite of a certain reserve. His literary taste was conventional, including the standard British writers, with a preference for Shakespeare among the poets, Berkeley among the philosophers, and Montaigne (in Cotton's translation) among the essayists. His particular admiration among the college professors was the stately rhetorician, Edward Everett; and this predilection had much to do with his early ambition to be a professor of rhetoric and elocution.



RALPH WALDO EMERSON.
(From a photograph by Elliott & Fry, London.)

Immediately after graduation he became an assistant in his brother William's school for young ladies in Boston, and continued teaching, with much inward reluctance and discomfort, for three years. The routine was distasteful; he despised the superficial details which claimed so much of his time. The bonds of conventionalism were silently dissolving in the rising glow of his poetic nature. Independence, sincerity, reality, grew more and more necessary to him. His aunt urged him to seek retirement, self-reliance, friendship with nature; to be no longer "the nurseling of surrounding circumstances," but to prepare a celestial abode for the muse. The passion for spiritual leadership stirred within him. The ministry seemed to offer the fairest field for its satisfaction. In 1825 he entered the divinity school at Cambridge, to prepare himself for the Unitarian pulpit. His course was much interrupted by ill-health. His studies were irregular, and far more philosophical and literary than theological. In October 1826 he was "approbated to preach" by the Middlesex Association of Ministers. The same year a threatened consumption compelled him to take a long journey in the south. Returning in 1827, he continued his studies, preached as a candidate in various churches, and improved in health. In 1829 he married a beautiful but delicate young woman, Miss Ellen Tucker of Concord, and was installed as associate minister of the Second Church (Unitarian) in Boston. The retirement of his senior colleague soon left him the sole pastor. Emerson's early sermons were simple, direct, unconventional. He dealt freely with the things of the spirit. There was a homely elevation in his discourses, a natural freshness in his piety, a quiet enthusiasm in his manner, that charmed thoughtful hearers. In 1831 he lost his wife, a sorrow that deeply depressed him in health and spirits. In 1832, following his passion for independence and sincerity, he arrived at the conviction that the Lord's Supper was not intended by Christ to be a permanent sacrament. To him, at least, it had become an outgrown form. He was willing to continue the service only if the use of the elements should be dropped and the rite made simply an act of spiritual remembrance. Setting forth these views, candidly and calmly, in a sermon, he found his congregation, not unnaturally, reluctant to agree with him, and therefore retired, not without some disappointment, from the pastoral office. He never again took charge of a parish; but he continued to preach, as opportunity offered, until 1847. In fact, he was always a preacher, though of a singular order. His supreme task was to befriend and guide the inner life of man.

The strongest influences in his development about this time were the liberating philosophy of Coleridge, the mystical visions of Swedenborg, the intimate poetry of Wordsworth, and the stimulating essays of Carlyle. On Christmas Day 1832 he took passage in a sailing vessel for the Mediterranean. He travelled through Italy, visited Paris, spent two months in Scotland and England, and saw the four men whom he most desired to see—Landor, Coleridge, Carlyle, and Wordsworth. "The comfort of meeting such men of genius as these," he wrote, "is that they talk sincerely." But he adds that he found all four of them, in different degrees, deficient in insight into religious truth. His visit to Carlyle, in the lonely farm-house at Craigenputtock, was the memorable beginning of a lifelong friendship. Emerson published Carlyle's first books in America. Carlyle introduced Emerson's Essays into England. The two men were bound together by a mutual respect deeper than a sympathy of tastes, and a community of spirit stronger than a similarity of opinions. Emerson was a sweet-tempered Carlyle, living in the sunshine. Carlyle was a militant Emerson, moving amid thunderclouds. The things that each most admired in the other were self-reliance, directness, moral courage. A passage in Emerson's Diary, written on his homeward voyage, strikes the keynote of his remaining life. "A man contains all that is needful to his government within himself. . . . All real good or evil that can befall him must be from himself. . . . There is a correspondence between the human soul and everything that exists in the world; more properly, everything that is known to man. Instead of studying things without, the principles of them all may be penetrated into within him. . . . The purpose of life seems to be to acquaint man with himself. . . . The highest revelation is that God is in every man." Here is the essence of that intuitional philosophy, commonly called Transcendentalism. Emerson disclaimed allegiance to that philosophy. He called it "the saturnalia, or excess of faith." His practical common sense recoiled from the amazing conclusions which were drawn from it by many of its more eccentric advocates. His independence revolted against being bound to any scheme or system of doctrine, however nebulous. He said: "I wish to say what I feel and think to-day, with the proviso that to-morrow perhaps I shall contradict it all." But this very wish commits him to the doctrine of the inner light. All through his life he navigated the Transcendental sea, piloted by a clear moral sense, warned off the rocks by the saving grace of humour, and kept from capsizing by a good ballast of New England prudence.

After his return from England in 1833 he went to live with his mother at the old manse in Concord, Mass., and began his career as a lecturer in Boston. His first discourses were delivered before the Society of Natural History and the Mechanics' Institute. They were chiefly on scientific subjects, approached in a poetic spirit. In the autumn of 1835 he married Miss Lydia Jackson of Plymouth, having previously purchased a spacious old house and garden at Concord. There he spent the remainder of his life, a devoted husband, a wise and tender father, a careful householder, a virtuous villager, a friendly neighbour, and, spite of all his disclaimers, the central and luminous figure among the Transcendentalists. The doctrine which in others seemed to produce all sorts of extravagances—communistic experiments at Brook Farm and Fruitlands, weird schemes of political reform, long hair on men and short hair on women—in his sane, well-balanced nature served only to lend an ideal charm to the familiar outline of a plain, orderly New England life. Some mild departures from established routine he tranquilly tested and as tranquilly abandoned. He tried vegetarianism for a while, but gave it up when he found that it did him no particular good. An attempt to illustrate household equality by having the servants sit at table with the rest of the family was frustrated by the dislike of his two sensible domestics for such an inconvenient arrangement. His theory that manual labour should form part of the scholar's life was checked by the personal discovery that hard labour in the fields meant poor work in the study. "The writer shall not dig," was his practical conclusion. Intellectual independence was what he chiefly desired; and this, he found, could be attained in a manner of living not outwardly different from that of the average college professor or country minister. And yet it was to this property-holding, debt-paying, law-abiding, well-dressed, courteous-mannered citizen of Concord that the ardent and enthusiastic turned as the prophet of the new idealism. The influence of other Transcendental teachers, Dr Hedge, Dr Ripley, Bronson Alcott, Orestes Brownson, Theodore Parker, Margaret Fuller, Henry Thoreau, Jones Very, was narrow and parochial compared with that of Emerson. Something in his imperturbable, kindly presence, his angelic look, his musical voice, his commanding style of thought and speech, announced him as the possessor of the great secret which many were seeking—the secret of a freer, deeper, more harmonious life. More and more, as his fame spread, those who "would live in the spirit" came to listen to the voice, and to sit at the feet, of the Sage of Concord.

It was on the lecture-platform that he found his power and won his fame. The courses of lectures that he delivered at the Masonic Temple in Boston, during the winters of 1835 and 1836, on "Great Men," "English Literature," and "The Philosophy of History," were well attended and admired. They were followed by two discourses which commanded for him immediate recognition, part friendly and part hostile, as a new and potent personality. His Phi Beta Kappa oration at Harvard College in August 1837, on "The American Scholars," was an eloquent appeal for independence, sincerity, realism, in the intellectual life of America. His address before the graduating class of the divinity school at Cambridge, in 1838, was an impassioned protest against what he called "the defects of historical Christianity" (its undue reliance upon the personal authority of Jesus, and its failure to explore the moral nature of man as the fountain of established teaching), and a daring plea for absolute self-reliance and a new inspiration of religion. "In the soul," he said, "let redemption be sought. Wherever a man comes, there comes revolution. The old is for slaves. Go alone. Refuse the good models, even those which are sacred in the imagination of men. Cast conformity behind you, and acquaint men at first hand with Deity." In this address Emerson laid his hand on the sensitive point of Unitarianism, which rejected the divinity of Jesus but held fast to his supreme authority. A blaze of controversy sprang up at once. Conservatives attacked him; Radicals defended him. Emerson made no reply. But amid this somewhat fierce illumination he went forward steadily as a public lecturer. It was not his negations that made him popular; it was the eloquence with which he presented the positive side of his doctrine. Whatever the titles of his discourses, "Literary Ethics," "Man the Reformer," "The Present Age," "The Method of Nature," "Representative Men," "The Conduct of Life," their theme was always the same, namely, "the infinitude of the private man." Those who thought him astray on the subject of religion listened to him with delight when he poetized the commonplaces of art, politics, literature, or the household. His utterance was Delphic, inspirational.

There was magic in his elocution. The simplicity and symmetry of his sentences, the modulations of his thrilling voice, the radiance of his fine face, even his slight hesitations and pauses over his manuscript, lent a strange charm to his speech. For more than a generation he went about the country lecturing in cities, towns, and villages, before learned societies, rustic lyceums, and colleges; and there was no man on the platform in America who excelled him in distinction, in authority, or in stimulating eloquence.

In 1847 Emerson visited Great Britain for the second time, was welcomed by Carlyle, lectured to appreciative audiences in Manchester, Liverpool, Edinburgh, and London, made many new friends among the best English people, paid a brief visit to Paris, and returned home in July 1848. "I leave England," he wrote, "with increased respect for the Englishman. His stuff or substance seems to be the best in the world. I forgive him all his pride. My respect is the more generous that I have no sympathy with him, only an admiration." The impressions of this journey were embodied in a book called *English Traits*, published in 1856. It might be called "English Traits and American Confessions," for nowhere does Emerson's Americanism come out more strongly. But the America that he loved and admired was the ideal, the potential America. For the actual conditions of social and political life in his own time he had a fine scorn. He was an intellectual Brahmin. His principles were democratic, his tastes aristocratic. He did not like crowds, streets, hotels—"the people who fill them oppress me with their excessive civility." Humanity was his hero. He loved man, but he was not fond of men. He had grave doubts about universal suffrage. He took a sincere interest in social and political reform, but towards specific "reforms" his attitude was somewhat remote and visionary. On the subject of temperance he held aloof from the intemperate methods of the violent prohibitionists. He was a believer in woman's rights, but he was lukewarm towards conventions in favour of woman suffrage. Even in regard to slavery he had serious hesitations about the ways of the abolitionists, and for a long time refused to be identified with them. But as the irrepressible conflict drew to a head Emerson's hesitation vanished. He said in 1856, "I think we must get rid of slavery, or we must get rid of freedom." With the outbreak of the Civil War he became an ardent and powerful advocate of the cause of the Union. James Russell Lowell said, "To him more than to all other causes did the young martyrs of our Civil War owe the sustaining strength of thoughtful heroism that is so touching in every record of their lives."

Emerson the essayist was a condensation of Emerson the lecturer. His prose works, with the exception of the slender volume entitled *Nature* (1836), were collected and arranged from the manuscripts of his lectures. His method of writing was characteristic. He planted a subject in his mind, and waited for thoughts and illustrations to come to it, as birds or insects to a plant or flower. When an idea appeared, he followed it, "as a boy might hunt a butterfly"; when it was captured he pinned it in his "Thought-book." The writings of other men he used more for stimulus than for guidance. He said that books were for the scholar's idle times. "I value them," he said, "to make my top spin." His favourite reading was poetry and mystical philosophy: Shakespeare, Dante, George Herbert, Goethe, Berkeley, Coleridge, Swedenborg, Jacob Boehmen, Plato, the new Platonists, and the religious books of the East (in translation). Next to these he valued books of biography and anecdote: Plutarch, Grimm, St Simon, Varnhagen von Ense. He had some odd dislikes, and could find nothing in Aristophanes, Cervantes, Shelley, Scott, Miss Austen, Dickens. Novels he seldom read. He was a follower of none, an original borrower from all. His illustrations were drawn from near and far. The zodiac of Denderah; the Savoyards who carved their pine-forests into toys; the naked Derar, horsed on an idea, charging a troop of Roman cavalry; the long, austere Pythagorean lustrum of silence; Napoleon on the deck of the *Bellerophon*, observing the drill of the English soldiers; the Egyptian doctrine that every man has two pairs of eyes; Empedocles and his shoe; the horizontal stratification of the earth; a soft mushroom pushing its way through the hard ground;—all these allusions and a thousand more are found in the same volume. On his pages, close beside the Parthenon, the Sphinx, St Paul's, Ætna, and Vesuvius, you will find the White Mountains, Monadnock, Agiocochook, Katahdin, the pickerel-weed in bloom, the wild geese honking through the sky, the chick-a-dee braving the snow, Wall Street and State Street, cotton-mills, railroads, and Quincy granite. For an abstract thinker he was strangely in love with the concrete facts of life. Idealism, in him, assumed the form of a vivid illumination of the real. From the pages of his teeming note-books he took the material for his lectures, arranging and rearranging it under such titles as Nature, School, Home, Genius, Beauty and Manners, Self-Possession, Duty, The Superlative, Truth, The Anglo-Saxon, The Young American. When the lectures had served their purpose he rearranged the material in essays and published them. Thus appeared in succession the following volumes: *Essays* (First Series), 1841; *Essays* (Second Series), 1844; *Representative Men*, 1850; *English Traits*, 1856; *The Conduct of Life*, 1860; *Society and Solitude*, 1870; *Letters and Social Aims*, 1876. Besides these, many other lectures were printed in separate form and in various combinations.

Emerson's style is brilliant, epigrammatic, gem-like; clear in sentences, obscure in paragraphs. He was a sporadic observer. He saw by flashes. He said, "I do not know what arguments mean in reference to any expression of a thought." The coherence of his writing lies in his personality. His work is fused by a steady glow of optimism. Yet he states this optimism moderately. "The genius which preserves and guides the human race indicates itself by a small excess of good, a small balance in brute facts always favourable to the side of reason."

His verse, though in form inferior to his prose, was perhaps a truer expression of his genius. He said, "I am born a poet"; and again, writing to Carlyle, he called himself "half a bard." He had "the vision," but not "the faculty divine" which translates the vision into music. In his two volumes of verse (*Poems*, 1846; *May Day and other Pieces*, 1867) there are many passages of beautiful insight and profound feeling, some lines of surprising splendour, and a few poems, like "The Rhodora," "The Snowstorm," "Ode to Beauty," "Terminus," "The Concord Ode," and the marvellous "Threnody" on the death of his first-born boy, of beauty unmarred and penetrating truth. But the total value of his poetical work is discounted by the imperfection of metrical form, the presence of incongruous images, the predominance of the intellectual over the emotional element, and the lack of flow. It is the material of poetry not thoroughly worked out. But the genius from which it came—the swift faculty of perception, the lofty imagination, the idealizing spirit enamoured of reality—was the secret source of all Emerson's greatness as a speaker and as a writer. Whatever verdict time may pass upon the bulk of his poetry, Emerson himself must be recognized as an original and true poet of a high order.

His latter years were passed in peaceful honour at

Concord. In 1866 Harvard College conferred upon him the degree of LL.D., and in 1867 he was elected an overseer. In 1870 he delivered a course of lectures before the university on "The Natural History of the Intellect." In 1872 his house was burned down, and was rebuilt by popular subscription. In the same year he went on his third foreign journey, going as far as Egypt. About this time began a failure in his powers, especially in his memory. But his character remained serene and unshaken in dignity. Steadily, tranquilly, cheerfully, he finished the voyage of life.

I trim myself to the storm of time,
I man the rudder, reef the sail,
Obey the voice at eve obeyed at prime:
"Lowly faithful, banish fear,
Right onward drive unharmed;
The port, well worth the cruise, is near,
And every wave is charmed."

Emerson died on 27th April 1882, and his body was laid to rest in the peaceful cemetery of Sleepy Hollow, in a grove on the edge of the village of Concord.

Emery Grinding Machinery.—Emery wheels, being cleaner, safer, and more efficient than the old grindstone, have become a necessity in all iron, steel, and other metal works. An emery wheel, properly mounted, runs at a peripheral speed of 6000 feet per minute, whereas a file in the hands of the best mechanic can only travel, and that with far less cutting power, at the rate of 60 feet per minute. Moreover, the efficiency of a file lessens every hour as its teeth become duller, but the emery wheel continually presents a fresh cutting surface, and remains the same until worn down to the wrought- or cast-iron washers which generally form the mount. Emery grinding operations may be divided into four classes: (1) tool and cutter grinding, for sharpening tools which would otherwise require to be softened, filed, and then hardened again; (2) cylindrical grinding, as in a grinding lathe; (3) surface grinding, where the emery wheel does the work of a shaping or planing machine, or of files; (4) surface edge grinding, where the emery wheel takes the place of the ordinary steel tools, such as the cold chisel and files. The qualities required in an emery wheel are: (1) sufficient tenacity to withstand the centrifugal strain caused by the high speed at which it revolves; (2) ability to resist heat, inasmuch as the friction of grinding rapidly increases the temperature of the metal being operated on; and (3) uniformity of strength, density, and texture. The wheel must not be so hard as to allow the compound to project above the surface of the emery; in other words, the binding material must wear away about as fast as the emery, and also be of such a nature that it will not put a glaze on the surface of the wheel, or combine with the object operated upon. This glazing is in fact one of the most serious difficulties to be encountered in the use of emery wheels.

The fineness or coarseness of the emery used is determined by passing the crushed rock or stone through sieves or wire cloths having from 6 to 100 wires to the inch; thus emery that will pass through a sieve of 6 wires to the inch is called No. 6 grade or grit. The numbers representing the various grades run from No. 6 to No. 100, and the smoothness of surface which the wheel leaves on the article ground may be compared with that left by files as follows:—

No. 6 to 10	represents	the cut	of a	wood rasp.
,, 16 ,, 20	,,	,,	,,	coarse rough file.
,, 24 ,, 35	,,	,,	,,	bastard file.
,, 40 ,, 60	,,	,,	,,	second cut file.
,, 70 ,, 80	,,	,,	,,	smooth file.
,, 90 ,, 100	,,	,,	,,	superfine.

To obtain the best result from an emery wheel it must be perfectly true, run at a high speed, and free itself from disengaged particles of metal, so as to allow of continuous contact between itself and the work. With equal speed and proportional pressure, a wheel six inches wide ought to grind off six times as much metal from a steel or iron bar six inches wide as a wheel one inch wide would from a steel or iron bar one inch wide. Experiments show that, taking the moderate price of one shilling per pound for the emery wheel, the maximum cost of grinding one pound of cast-iron is about sixpence, whereas the cost per pound of filing cast-iron is at least one shilling and sixpence. In the case of grinding a tempered saw, where the steel resists the file, an emery wheel will remove fifty-five times more than a file in the same time.

The speed at which the wheel may be run without danger of bursting varies with its size, as well as with the quality of the binding material and the general excellence of the manufacture. The centrifugal force evolved varies as the square of the velocity; hence a wheel of any given size is subjected to four times the bursting strain at 2000 revolutions that it is at 1000. Hence a comparatively small increase in the number of revolutions adds 100 per cent. to the breaking strain. It is practically impossible for one standard speed to be maintained in the workshop, since to do so would entail the continual alteration of driving pulleys to increase the speed so as to compensate for the wear in the diameter of the emery wheel. It is a common practice, therefore, to use wheels of a certain diameter upon machines running at the appropriate speed, and to transfer them to faster ones as their size is diminished by use.

Corundum wheels are manufactured from the mineral corundum, which resembles emery, and they are made and used in the same manner as emery wheels. They are superior to the latter, both in cutting more freely and in being more durable, with less liability to glaze, but corundum is only found in limited quantities, and is consequently too expensive for the general uses for which emery wheels are equally well suited.

Emilia, a territorial division of Italy, enclosed generally between the lower Po, the Apennines, and the Adriatic, and comprising the provinces of Bologna, Ferrara, Forli, Modena, Parma, Piacenza, Ravenna, and Reggio, with an area of 7967 sq. miles, and a population (1881) of 2,183,391, and (1901) of 2,451,752. Alongside the Po and the Adriatic there are extensive marshy tracts. The principal crops are maize, wheat, vine, hemp, fruit, tobacco, flax, rice, and chestnuts. Salt and sulphur are extracted, and granite is quarried. The greatest number of people are engaged in making strawplait and chip hats in their own homes. The industries which claim the next largest numbers of workpeople are the making of mats and baskets, furniture, and cheese and butter, the manufacture of silks, tobacco, and fireworks, the production of cocoons, and ironworks. The region gets its name from the old Roman road, the Via Emilia, which traversed it from north-west to south-east. The most important towns are Bologna, Ferrara, Ravenna, Modena, Reggio, Parma, Forlì, Piacenza, Rimini, Faenza, Correggio, and Guastalla. Rimini is the only seaport. The history of Emilia is coincident with the history of the duchies of Modena, Parma, and Massa-Carrara, and of the States of the Church.

Emin Pasha [EDUARD SCHNITZER] (1840–1892), German traveller and naturalist, was the son of Ludwig Schnitzer, a merchant of Oppeln in Silesia, and was born in Oppeln, 28th March 1840. He was educated at the universities of Breslau, Berlin, and Königsberg, and took the degree of M.D. at Berlin. He displayed an early predilection for zoology and ornithology, and in later life became a skilled and enthusiastic collector, particularly of African plants and birds. When he was four and twenty he determined to seek his fortunes abroad, and made his way to Turkey, where, after practising medicine on his own account for a short time, he was appointed (in 1865) Quarantine Medical Officer at Antivari. The duties of the post were not heavy, and allowed him leisure for a diligent study of Turkish, Arabic, and Persian. From 1870 to 1874 he was in the service of the Governor of Northern Albania, had adopted a Turkish name (though not that by which he afterwards became so widely known), and was practically naturalized as a Turk. After a visit home in 1875, he went to Cairo, and then to Khartum, in the hope of an opportunity for travelling in the interior of Africa. This came to him in the following year, when General Gordon, who had recently succeeded Sir Samuel Baker as Governor of Equatorial Africa, invited Schnitzer, who was now known as "Emin Effendi," to join him at Lado. Although nominally Gordon's medical officer, Emin was soon entrusted with political missions of some importance to Uganda and Unyoro. In these he acquitted himself so well that when, in 1878, Gordon's successor in the governorship was deprived of his office on account of malpractices (Gordon himself having been made Governor-General of the Sudan), Emin was chosen to fill the post, with the title of "Bey." He proved an energetic and enterprising governor; indeed, his enterprise on more than one occasion brought him into conflict with Gordon, who eventually decided to remove Emin to Suakin. Before the change could be effected, however, Gordon resigned his post in the Sudan, and his successor revoked the order. The next three or four years were employed by Emin in various journeys through his provinces, and in the initiation of various schemes for their development, until in 1882, on his return from a visit to Khartum, he became aware that the Mahdist rebellion, which had originated in the Sudan, was spreading to Equatoria. The effect of the rebellion was, of course, more markedly felt in Emin's province after the abandonment of the Sudan by the Egyptian Government in 1884. He was obliged to give up several of his stations in face of the rebel advance, and ultimately to retire from Lado, which had been his capital, to Wadelai. This last step followed upon his receipt of a letter from Nubar Pasha, informing him that it was impossible for the Egyptian Government to send him help, and that he must stay in his province or retire towards the coast as best he could. Emin (who about this time was raised to the rank of Pasha) had some thoughts of a retreat to Zanzibar, but decided to remain where he was and endeavour to hold his own. To this end he carried on protracted negotiations with neighbouring native potentates. When, in 1887, Stanley's expedition was on its way to relieve him, it is clear from Emin's diary that he had no wish to leave his province, even if relieved. He had done good work there, and established a position which he believed himself able to maintain. He hoped, however, that the presence of Stanley's force, when it arrived, would strengthen his position; but the condition of the relieving party, when it arrived in April 1888, did not seem to Emin to promise this. Stanley's proposal to Emin, as stated in the latter's diary, was that Emin should either remain as Governor-General on behalf of the King of the Belgians, or establish himself on Victoria Nyanza on behalf of a group of English merchants who wished to start an enterprise in Africa on the model of the East India Company. After much hesitation, and prompted by a growing disaffection amongst the natives (owing, as he maintained, to his loss of prestige after the arrival of Stanley's force), Emin decided to accompany Stanley to the coast, where the expedition arrived in December 1889. Unfortunately, on the evening of a reception dinner given in his honour, Emin met with an accident which resulted in fracture of the skull. Careful nursing gradually restored him to health, and on his convalescence he resolutely maintained his decision to remain in Africa, and, if possible, to work there in future on behalf of the German Government. The seal was definitely set upon this decision by his formal engagement on behalf of his native country, early in 1890. Preparations for a new expedition into the interior were set on foot, and meanwhile Emin was honoured in various ways by learned societies in Germany and elsewhere. The object of the new expedition was (to quote Emin's instructions) "to secure on behalf of Germany the territories situated south of and along Victoria Nyanza up to Albert Nyanza," and to "make known to the population there that they were placed under German supremacy and protection, and to break or undermine Arab influence as far as possible." The force, which was well equipped, started at the end of April 1890. For a time things went well enough with the expedition, but by degrees ill-fortune clouded its prospects. Difficulties on the route; dissensions between Emin and the authorities in German East Africa, and misunderstandings on the part of both; epidemics of disease in Emin's force, followed by a growing spirit of mutiny among his native followers; an illness of a painful nature which attacked himself;—all this gradually undermined Emin's courage, and his diaries at the close of 1891 reflect a gloomy and almost hopeless spirit. The only pleasurable incident of the expedition had been his unexpected meeting with Dr Peters, who since the spring of 1888 had been at the head of a German expedition which had been sent to attempt the relief of Emin at the time when it was thought improbable that Stanley's expedition would ever reach its goal, and had itself in turn been completely lost sight of and reported annihilated. At last the hatred with which Emin had inspired the African Arabs found its vent in his treacherous murder by order of a native chief at the instigation of an Arab slave dealer, on 23rd or 24th October 1892, at Kinena in the Congo State. His journals and biography have been published since his death. (R. F. S.)

Emmaus, the name of two places in Palestine. 1. A village mentioned by St Luke (xxiv. 13), without any indication of direction, as being 60 stadia ($6\frac{9}{11}$ miles), or according to some MSS. 160 stadia, from Jerusalem. It has been identified (*a*) with Emmaus-Nicopolis, distant 176 stadia from Jerusalem; (*b*) with Kuryet el-ʿEnab, distant 66 stadia, on the carriage road to Jaffa; (*c*) with Kulónieh, distant 36 stadia, on the same road; (*d*) with el-Kubeibeh, distant 63 stadia, on the Roman road to Lydda; (*e*) with Urtas, distant 60 stadia; and (*f*) with Khurbet el-Khamasa, distant 86 stadia, on the Roman road to Eleutheropolis. Of these, el-Kubeibeh or Urtas seems the most probable. 2. Emmaus-Nicopolis, now

Amwás, a town on the maritime plain, and a place of importance during the Maccabæan and Jewish wars. Near it Judas Maccabæus defeated Lysias, 164 B.C., and Vespasian established a fortified camp A.D. 69. It was afterwards rebuilt and named Nicopolis.

Employers' Liability.—The law of England as to the liability of employers in respect of personal injuries to their servants can only be regarded as in a stage of transition. It depends upon no universal principles. It confers rights and imposes liabilities differing widely according to the employment, and even according to the accidental circumstances of the same employment. Some servants are practically insured against accident, others serve almost at their own risk, and no logical reason can be discovered for the difference. The common law, indeed, is definite enough, and in its strict limitation of a master's obligations admits of little ambiguity; but by the Employers' Liability Act, 1880, such exceptions have been grafted upon the common law, and by the Workmen's Compensation Act, 1897, principles so alien to the common law have been applied to some but not to all employments, that it is impossible now to present any view of this branch of the law as a logical whole. All that can be done is to state the nature of the liability at common law, the extension of it effected by the Employers' Liability Act, 1880, and the new liabilities introduced by the Acts of 1897 and 1900. It is necessary to bear in mind that while all servants have such rights as the common law gives them, and most may have the further rights conferred by the Act of 1880, some in certain specially favoured employments are also entitled to the peculiar benefits of the Workmen's Compensation Act.

Common law.

At common law the liability of a master is of a very limited character. There is, of course, nothing to prevent a master and servant from providing by special contract in any way they please for their mutual rights in cases of personal injury to the servant. In such cases the liability will depend upon the terms of the special contract. But apart from any special agreement, it may be broadly stated that a master is liable to his servants only for injuries caused by his own negligence. Injuries to a servant may arise from accident, from the nature of the service, or from negligence; and this negligence may be of the master, of another servant of the master, or of a stranger. If the injury is purely accidental, the loss lies where it falls. If it arises from the nature of the service, the servant must bear it himself; he has undertaken a service to which certain risks are necessarily incident; if he is injured thereby, it is the fortune of war, and no one can be made responsible. If the injury is caused by the negligence of a stranger, the servant has his ordinary remedy against the wrong-doer or any one who is responsible as a principal for the conduct of the wrong-doer. If it is caused by the negligence of a fellow-servant, he likewise has his ordinary remedy against the actual wrong-doer; but, by virtue of what is known as the doctrine of common employment, he cannot at common law make the master liable as a principal. The only case (independently of recent legislation: *see below*) in which he can recover damages from the master is where the injury has been caused by the negligence of the master himself. A master is negligent if he fails to exercise that skill and care which, in the circumstances of the particular employment, are used by employers of ordinary skill and carefulness. If he himself takes part in the work, he must act with such skill and care as may reasonably be demanded of one who takes upon himself to do work of that kind. If he entrusts the work to other servants, he must be careful in their selection, and must not negligently employ persons who are incompetent. He must take proper care so to arrange the system of work that his servants are not exposed to unnecessary danger. If tools or machinery are used, he must take proper care to provide such as are fit and proper for the work, and must either himself see that they are maintained in a fit condition or employ competent servants to do so for him. If he is bound by statute to take precautions for the safety of his servants, he must himself see that that obligation is discharged. For breach of any of these duties a master is liable to his servant who is injured thereby, but his liability extends no further.

Common employment.

That his obligations to a servant are so much less than to a stranger is chiefly due to the doctrine of common employment. As a rule a master is responsible for the negligence of his servant acting in the course of his employment; but, from about the middle of the 19th century, it became firmly rooted in the law that this principle did not apply where the person injured was himself a servant of the master and engaged in a common employment with the servant guilty of the negligence. In effect this rule protects a master as against his servant from the consequences of negligence on the part of any other of his servants; to this there is no qualification except that, for the rule to apply, both the injured and the negligent servant must be acting in pursuance of a common employment. They must both be working for a common object, though not necessarily upon the same work.

It is not easy to define precisely what constitutes a common employment in this sense, and there is peculiarly little judicial authority as to the limit at which work for the same employer ceases to be work in a common employment. It does not depend on difference in grade; all engaged in one business, from the manager to the apprentice, are within the rule. It does not depend on difference in work, if the work each is doing is part of one larger operation; all the servants of a railway company, whether employed on the trains, or at the stations, or on the line, are in a common employment. It does not necessarily depend on difference of locality; a servant who packs goods at the factory and a servant who unpacks them in the shop may well be in a common employment. On the other hand, it is not enough that the two servants are working for the same employer, if there is nothing in common between them except that they are making money for the same man; apart from special circumstances, the crews of two ships owned by the same company are probably not in common employment while navigating their respective ships. The test in each casc must be derived from the view, invented by the courts, upon which the doctrine was based, namely, that the servant by entering upon the service consented to run all the risks incidental to it, including the risk of negligence on the part of fellow-servants; if the relation between the two servants is such that the safety of the one may, in the ordinary course of things, be affected by the negligence of the other, that negligence must be taken to be one of the risks of the employment assented to by the servant, and both are engaged in a common employment. In ninety-nine cases out of a hundred it will be found that the doctrine is applicable, and the master protected from liability. It is thus seen that, in general, no action will lie against a master at the suit of his servant, unless the servant can prove personal negligence on the part of the master causing injury to the servant. And in such action the master may avail himself of those defences which he has against a stranger. He may rely upon contributory negligence, and show that the servant was himself negligent, and that, notwithstanding the negligence of the master, the injury was proximately caused by the negligence of the servant. Or (except in cases where the injury results from a breach of a statutory duty) he may prove such facts as establish the defence expressed in the maxim, *volenti non fit injuria;* that is, he may prove that the injured servant knew and appreciated the particular risk he was running, and incurred it voluntarily with full understanding of its nature. Mere knowledge on the part of the servant, or even his continuing to work with knowledge, does not necessarily establish this defence; it must be knowledge of such a kind and in such circumstances that it can be inferred that the servant contracted to take the risk upon himself. The action at common law is subject to the general rule that personal actions die with the person; except so far as the remedy for money loss caused by death by negligence has been preserved in favour of a husband or wife and certain near relatives, under Lord Campbell's Act.

Such was the law up to 1880. So long as industry was conducted on a small scale, and the master worked with his men, or was himself the manager, its hardship was perhaps little felt; his personal negligence could in many cases be established. But with the development of the factory system, and the ever-growing expansion of the scale on which all industries were conducted, it became increasingly difficult to bring home individual responsibility to the employer. As industry passed largely into the control of corporations, difficulty became almost impossibility. The employer was not liable to a servant for the negligence of a fellow-servant, and therefore, in most cases of injury, was not liable at all. It is not surprising that the condition of things thus brought about, partly by the growth of modern industry and partly by the decisions of the courts, caused grave dissatisfaction. The justice of the doctrine of common employment was vigorously called in question. In the result the Employers' Liability Act, 1880, was passed. The effect of this Act is to destroy the defence of common employment in certain specified cases. It does not abolish the doctrine altogether, nor, on the other hand, does it impose upon the master any new standard of duty which does not exist as regards strangers. All that it does is to place the servant, in certain cases, in the position of a stranger, making the master liable for the negligence of his servants notwithstanding the fact that they are in common employment with the servant injured. It is still necessary under the Act, as at common law, to prove negligence, and the master may still rely upon the defences of contributory negligence and *volenti non fit injuria.* But under the Act he cannot, as against the workmen who come within it and in the cases to which it applies, set up the defence that the negligence complained of was the negligence of a servant in a common employment. The Act does not apply to all servants. It does not apply to domestic or menial servants, or to seamen, or to any except railway servants and "any person who, being a labourer, servant in husbandry, journeyman, artificer, handicraftsman, miner, or otherwise engaged in *manual* labour . . . has entered into or works under a contract with an employer, whether the contract be oral or in writing, and be a contract of service or a contract personally to execute any work or labour." Whether a servant, not being one of those specially named, is within the Act depends on whether manual labour is the real and substantial employment, or whether it is merely incidental thereto; thus a carman who handles the goods he carries may be within the Act, but a tramcar driver or an omnibus conductor is not. The Act does not make the master liable for the negligence of all his servants, but, speaking generally, only for the negligent discharge of their duties by such as are entrusted with the supervision of machinery and plant, or with superintendence, or the power of giving orders, with the addition, in the case of a railway, of the negligence of those who are given the charge or control of signals, points, locomotive engines, or trains. The cases dealt with by the Act are five in number; in the first and fourth the words are wide enough to include negligence of the employer himself, for which, as has been seen, he is liable at common law. In such instances the workman has an alternative remedy either at common law or under the Act, but in all other respects the rights given by the Act are new, being limitations upon the defence of common employment, and can be enforced only under the Act.

The Act of 1880.

The first case is where the injury is caused by reason of any defect in the condition of the ways, works, machinery, or plant connected with or used in the business of the employer, provided that such defect arises from, or has not been discovered or remedied owing to, the negligence of the employer, or of some person in the service of the employer and entrusted by him with the duty of seeing that the ways, works, machinery, or plant are in proper condition. The second case is where the injury is caused by reason of the negligence of any person in the service of the employer who has any superintendence entrusted to him (that is, a person whose sole or principal duty is that of superintendence, and who is not ordinarily engaged in manual labour) whilst in the exercise of such superintendence. The third case is where the injury is caused by reason of the negligence of any person in the service of the employer to whose orders or directions the workman at the time of the injury is bound to conform and does conform, where such injury results from his so conforming. The fourth case is where the injury is caused by reason of the act or omission of any person in the service of the employer done or made in obedience to the rules or bye-laws of the employer, or in obedience to particular instructions given by any person delegated with the authority of the employer in that behalf, provided that the injury results from some impropriety or defect in such rules, bye-laws, or instructions. The fifth case is where the injury is caused by reason of the negligence of any person in the service of the employer who has the charge or control of any signal, points, locomotive engine, or train upon a railway.

In all these cases it is provided that the employer shall not be liable if it can be shown that the workman knew of the defect or negligence which caused his injury, and failed within a reasonable time to give, or cause to be given, information thereof to the employer or some person superior to himself in the service of the employer, unless he was aware that the employer or such superior already knew of the said defect or negligence. It was inevitable that these provisions should call for judicial interpretation, and a considerable body of authority has grown up about the Act. Where general words are used, it must always occur that, between the cases which are obviously within and those which are obviously without the words, there are many on the border line. Thus, under the Act, the courts have been called upon to determine the precise meaning of "way," "works," "machinery," "plant," and to say what is precisely meant by a "defect" in the condition of each of them. They have had to say what is included in "railway" and in "train," what is meant by having "charge" or "control," and to what extent one whose principal duty is superintendence may participate in manual labour without losing his character of superintendent, and what is the precise meaning of negligence in superintendence. These are only illustrations of many points of detail which, having called for judicial interpretation, will be found fully dealt with in the text-books on the subject. A workman who, being within the Act, is injured by such negligence of a fellow-servant as is included in one or other of the five cases mentioned above, has against his employer the remedies which the Act gives him. These are not necessarily the same as those which a stranger would have in the like circumstances; the amount of compensation is not left at large for a jury to determine, but is limited to an amount not exceeding such sum as may be found to be equivalent to the estimated earnings, during the three years preceding the injury, of a person in the same grade employed during those years in the like employment and in the district in which the workman is employed at the time of the injury. Moreover, the right to recover is hedged about with technicalities which are unknown at the common law; proceedings must be taken in the County Court, within a strictly limited time, and are maintainable only if certain elaborate provisions as to notice of injury have been complied with. Where the injury causes death the action is maintainable for the benefit of the like persons as are entitled under Lord Campbell's Act in an action at common law.

The law continued in this condition up to 1897. In the majority of cases of injury to a servant, the doctrine of common employment still protected the master; and where, under the Employers' Liability Act, it failed to do so, the liability was of a limited character and often, owing to technicalities of procedure, difficult to enforce. Moreover, there is nothing in the Act to prevent master and servant from entering into any special contract they please; and in many trades it became a common practice for contracts to be made wholly excluding the operation of the Act. In 1893 an attempt was made to alter the law by a total abolition of the defence of common employment, so as to make a master liable to a servant as to a stranger for the negligence of any of his servants acting in the course of their employment, and at the same time to prohibit any agreements to forego the rights so given to the servant. The Bill did not become law, and no further change was made until, in 1897, Parliament took the first step in what must ultimately be a complete revolution in the law of employers' liability. Up to that year, as has been seen, the foundation of a master's liability was negligence, either of the master himself, or, in certain cases, of his servants. But by the Workmen's Compensation Act, 1897,

The Act of 1897.

a new principle was introduced, whereby certain servants in certain employments were given a right to compensation for injuries, wholly irrespective of any consideration of negligence or contributory negligence. As regards such servants in such employments the master is in effect made an insurer against accidental injuries. The Act was confessedly tentative and partial; it dealt only with selected industries, and even within these industries was not of universal application. But where it does apply, it gives a right to a limited compensation in every case of injury by accident arising out of and in the course of the employment, whether that accident has been brought about by negligence or not, and whether the injured servant has or has not contributed to it by his own negligence. Owing in part to the novelty of the principles sought to be established, in part to the way in which the sections are drawn, the Act presents considerable difficulties of interpretation. In many respects, as has been said by the Court of Appeal, definition is difficult or impossible, and all that can be done is in each case, as it comes before the court, to say whether it falls within or without the Act. Many ambiguities have already been made clear by authoritative decision, but no statement of the effect of the Act can be made with any approach to finality.

The Act applies only to employment on, or in, or about certain localities where, at the same time, the employer is what the Act calls an "undertaker," that is, the person whose business is there being carried on. If we want to know whether a workman is within the Act, we must ask, first, was he employed on, or in, or about a railway, or a factory, or a mine, or a quarry, or an engineering shop, or a building of the kind mentioned in the Act; secondly, was he employed by one who was, in relation to that railway, &c., the undertaker as defined by the Act; and, thirdly, was he at the time of the accident at work on, or in, or about that railway, &c. Unless these three conditions are fulfilled the employment is not within the Act. What is included in the named localities and who are the undertakers in respect thereof will be dealt with below. But it must here be pointed out that an undertaker is in some cases liable as an employer, though he is in fact not the actual master of the workman. Section 4 of the Act in effect provides that where the undertaker has let out part of the work of his undertaking to a contractor, the workmen of such contractor shall be treated as employed by the undertaker, provided that the work so let out is part of or a process in the trade or business carried on by the undertaker; to such workmen the undertaker is made liable, whether for claims under the Act, or for claims founded on personal negligence or wilful act. The employment must be on, or in, or about the locality, and "about" means "in close propinquity to"; to this the Act makes one exception, where it provides that a workman employed in a factory which is a shipbuilding yard shall not be excluded by reason only that the accident arose outside the yard in the course of his work upon a vessel in any dock, river, or tidal water near the yard; with this exception no outworker has the benefit of the Act.

The effect of what has been said will best be seen by an illustration. A carries on business in an engineering shop, which is a factory. He employs B in the shop, and C to erect an engine in another person's mill; he also makes a contract with X whereby X undertakes part of the engineering work in the shop, X employing his own men, among whom is D; he also contracts with Y for the installation of electric light in the shop, and Y employs E to do the work. Among these workmen B and D are within the Act, C and E are without it. B is employed in a factory by the undertaker, and D is employed indirectly by the undertaker in a factory upon work which is part of the business carried on by the undertaker. C is not employed on, or in, or about a factory in relation to which his employer is an undertaker, and E, though employed about a factory and indirectly by the undertaker, is not doing work which is part of the business carried on by the undertaker.

The particular employments included in the Act are as follows:—

(1) Employment by a railway company on, in, or about a railway. A railway means the railway of any railway company to which the Regulation of Railways Act, 1873, applies, and includes a light railway made under the Light Railways Act, 1896. The "undertakers" are the railway company as defined by those Acts.

(2) Employment on, in, or about a factory by the occupier thereof. A factory means a factory within the Factory and Workshop Acts, 1878 to 1891. The "undertaker" is the occupier within the meaning of those Acts (see LABOUR LEGISLATION).

(3) Employment on, in, or about a laundry worked by steam, water, or other mechanical power, by the occupier thereof. The "undertaker" is the occupier within the meaning of the Factory and Workshop Acts, 1878 to 1895.

(4) Employment on, in, or about any dock, wharf, quay, warehouse, machinery, or plant, to which any provision of the Factory Acts is applied by the Factory and Workshop Act, 1895, by the occupier thereof within the meaning of that Act. The "undertaker" is the occupier as defined by the Act of 1895.

Docks.

Section 23 of the Factory and Workshop Act, 1895, extends certain provisions of the Factory Acts (relating to dangerous machines, notice of accidents and the like) to (*a*) every dock, wharf, quay, and warehouse, and, so far as relates to the process of loading or unloading therefrom or thereto, all machinery and plant used in that process; and (*b*) any premises on which machinery worked by steam, water, or other mechanical power, is temporarily used for the purpose of the construction of a building or any structural work in connexion with a building. The section further provides that the person having the actual use or occupation of a dock, wharf, quay, or warehouse, or of any premises within the same, or forming part thereof, and the person so using any such machinery, shall be deemed to be the occupier. This class has been the subject of much litigation, but after considerable conflict of judicial decision, most of the doubts have been set at rest. A workman engaged in an employment on, in, or about a dock, whether on the quays or on board a ship in the dock, is engaged in an employment on, in, or about a "factory" within the meaning of the Act. This does not settle the question whether the workman is within the Act, for the Act will not apply unless the employer is the "undertaker," that is to say, the occupier; and to be the occupier the employer must have the actual use or occupation of the dock, wharf, quay, or warehouse, or of premises within the same, and forming part thereof. If the workman is employed by the dock company or the warehouseman, he is clearly employed by the occupier, but if he is employed by others, say, the shipowner, or the receiver of goods, or the master stevedore who merely uses the dock or quay, or the merchant who merely stores his goods in the warehouse of another, it has to be determined whether such employer has the actual use or occupation of the dock, &c., or of premises within the same. Actual use means much more than legal occupation. On the other hand, it does not include a merely casual use. So far as the decisions go, the test seems to be whether the employer has a more or less exclusive use of something which can be defined as an area of the docks or quay. Thus a shipowner has the use of the berth in which his ship lies and of the quay on which he discharges cargo. A ship repairer has the use of the dry dock in which he is painting the ship. A merchant who merely sends a clerk across the quay has not the use of the quay. It is a question of fact to be determined according to the circumstances of each case. As to machinery or plant used in loading or discharge the question is less complicated; for, by the Factory Act, the person who, by himself, his agents or workmen, temporarily uses such machinery, is made the occupier, and is therefore an "undertaker." In general, therefore, a workman employed on or about machinery or plant used in loading or discharge will be within the Act, provided that his employer is the person who is in fact using that machinery or plant. Speaking broadly, it may be said that the majority of dock labourers are within the Act.

(5) Employment on, in, or about any mine to which the Coal Mines Regulation Act, 1887, or the Metalliferous Mines Regulation Act, 1872, applies, by the owner thereof within the meaning of those Acts. This includes all mines. The "undertaker" is the owner as defined by those Acts; that is to say, any person or body corporate who is the immediate proprietor, or lessee, or occupier of any mine, or of any part thereof; this does not include a person or body corporate who merely receives a royalty, rent, or fine from a mine, or is merely the proprietor of a mine subject to any lease, grant, or license for the working thereof, or is merely the owner of the soil, and not interested in the minerals of the mine.

(6) Employment on, in, or about any quarry under the Quarries Act, 1894, by the occupier thereof. A quarry includes every place (not being a mine) in which persons work in getting slate, stone, coprolites, or other minerals, and any part of which is more than twenty feet deep. The "undertaker" is the occupier.

(7) Employment on, in, or about an engineering work; that is to say, any work of construction, or alteration, or repair of a railroad, harbour, dock, canal, or sewer, including any other work for the construction, alteration, or repair of which machinery driven by steam, water, or other mechanical power is used. The employment must be by the person undertaking the construction, alteration, or repair, such person being the "undertaker" in respect of an engineering work.

(8) Employment on, in, or about certain buildings in course of construction, repair, or demolition, by the persons undertaking that work. The buildings included are (*a*) any building which exceeds thirty feet in height, and is being constructed or repaired by means of a scaffolding, (*b*) any building which exceeds thirty feet in height and is being demolished, and (*c*) any building on which machinery driven by steam, water, or other mechanical power is being used for the purpose of the construction, repair, or demolition thereof. The "undertaker" is the person undertaking the construction, repair, or demolition.

This class has been the subject of much litigation. What is meant by "construction," by "repair," by "scaffolding," are among the questions which have come before the courts. Questions such as these can only be determined in reference to the particular facts of each case. In practice further difficulties must arise in determining who is the undertaker. In work such as is included in classes (7) and (8), the operations are often divided among several employers who do different branches of the work. If the several contractors are indeed separate, each doing a part of the work for the building owner, each is an undertaker and liable to his own workmen. But where, as is more often the case, one contractor undertakes with the building owner to do the whole work, and then sublets portions of it to sub-contractors, such sub-contractors are not undertakers, and only the principal contractor is liable under the Act.

Given an employment to which the Act applies, all who are engaged therein are workmen within the Act, including workmen engaged in any employment (exclusive of naval or military service) by or under the Crown.

Conditions of claim.

To entitle a workman engaged in an employment to which the Act applies to compensation all the following conditions must be fulfilled:—(1) There must be personal injury by accident. This, it is submitted, will exclude (*a*) injury wilfully inflicted; (*b*) injury arising from the nature of the occupation without the occurrence of any fortuitous event, *e.g.*, lead poisoning; and (*c*) injury proximately due to a diseased condition of the workman. In the last case, where there is a diseased condition of the workman and also a fortuitous event, it will be a question of fact whether the injury was or was not proximately caused by the accident. (2) The accident must arise out of and in the course of the employment. In each case it will have to be determined whether the workman was at the time of the accident in the course of his employment, and whether the accident arose out of the employment. It will have to be considered when and where the particular employment, which, it must be remembered, must be one "on, in, or about" a particular locality, began and ended. Other difficulties have arisen and will frequently arise when the workman at the time of the accident is doing something which is no part of the work he is employed to do. So far as the decisions have gone, they indicate that if what the workman is doing is no act of service, but merely for his own pleasure, or if he is improperly meddling with that which is no part of his work, the accident does not arise out of and in the course of his employment; but if, while on his master's work, he upon an emergency acts in his master's interest, though what he does is no part of the work he is employed to do, the accident does arise out of and in the course of his employment. (3) The injury must be such as disables the workman for a period of at least two weeks from earning full wages at the work at which he was employed. (4) Notice of the accident must be given as soon as practicable after the happening thereof, and before the workman has voluntarily left the employment in which he was injured; and the claim for compensation (by which is meant notice that he claims compensation under the Act addressed by the workman to the employer) must be made within six months from the occurrence of the accident or, in case of death, from the time of death. Want of notice of the accident or defects in it are not to be a bar to proceedings, if occasioned by mistake or other reasonable cause, and the employer is not prejudiced thereby. But want of notice of a claim for compensation is a bar to proceedings, unless the employer by his conduct has estopped himself from relying upon it. (5) A workman who has given notice of an accident must, if so required by the employer, submit himself to medical examination.

When these conditions are fulfilled, an employer who is within the Act has no answer unless he can prove that the injury arose from the serious and wilful misconduct of the workman. The precise effect of these terms is not clear; but mere negligence is not within them.

Where the injury causes death, the right to compensation belongs to the workman's "dependants"; that is, such members of the workman's family specified in Lord Campbell's Act as were at the time of the death wholly or in part dependent upon the earnings of the workman for their maintenance.

Under the Act compensation is for loss of wages only, and is, as has been said, based upon the actual previous earnings of the injured workman in the employment of the employers for whom he is working at the time of the injury. In case of death, if the workman leaves dependants who were wholly dependent on his earnings, the amount recovered is a sum equal to his earnings in the employment of the same employer during the three years next preceding the injury, or the sum of £150, whichever is the larger, but not exceeding £300; if the period of his employment by the same employer has been less than three years, then the amount of his earnings during the three years is to be deemed to be 156 times his average weekly earnings during the period of his actual employment under the said employer. If the workman leaves only dependants who were not wholly dependent, the amount recovered is such sum as may be reasonable and proportionate to the injury to them, but not exceeding the amount payable in the previous case. If the workman leaves no dependants, the amount recoverable is the reasonable expenses of his medical attendance and burial, not exceeding £10. In case of total or partial incapacity for work resulting from the injury, what is recovered is a weekly payment during the incapacity after the second week not exceeding 50 per cent. of the workman's average weekly earnings during the previous twelve months, if he has been so long employed, but if not, then for any less period during which he has been in the continuous employment of the same employer; such weekly payment is not to exceed £1—and in fixing it regard is to be had to the difference between the amount of his average weekly earnings before the accident and the average amount which he is able to earn after the accident. Any payments, not being wages, made by the employer in respect of the injury must also be taken into account. If the workman is maimed, but for the time being suffers no loss, *e.g.*, if he loses a finger but continues to earn the same wages as before, no compensation can be awarded, but the Court will make a declaration of liability of the employer, leaving the amount and duration of the compensation to be fixed, upon an application to review, should the workman at any future time be unable, by reason of the injury, to earn the same wages as before the accident. The weekly payment may from time to time be reviewed at the request of either party, upon evidence of a change in the circumstances since the award was made, and after six months may be redeemed by the employer by payment of a lump sum. When the workman at the time of the injury has been in the employment for less than two weeks, so that there are no actual earnings from the same employer upon which a weekly average can be computed, the Act presents much difficulty. It has been finally decided by the House of Lords that such a workman is within the Act. But how are the average weekly earnings which he would have earned from the same employer to be estimated? The question must be determined as one of fact by reference to all the circumstances of the particular case. Suppose the workman to be engaged at six shillings a day and injured on the first day. If it can be inferred that he would have remained in such employment for a whole week, his average weekly earnings from the same employer may be taken at thirty shillings. If it can be inferred that he would have worked one day and no more, his average weekly earnings from the same employer may be taken at six shillings. The result is that the casual labourer is within the Act, but that the amount of compensation for which the casual employer is liable may be very small.

Amount.

All questions as to liability or otherwise under the Act, if not settled by agreement, are referred to arbitration in accordance with a scheme prescribed by the Act. Contracting out is not permitted, save in one event: where a scheme of compensation, benefit, or insurance for the workmen of an employer has been certified by the Registrar of Friendly Societies to be not less favourable to the general body of workmen and their dependants than the provisions of the Act, the employer and any of his workmen may contract that the provisions of the scheme shall be substituted for the Act; such certificate may not be for more than five years, and may in certain circumstances be revoked. The Act does not touch the workman's rights at common law or under the Employers' Liability Act, but the workman, if more than one remedy is open to him, can enforce only one. When the circumstances create a legal liability in some other person, *e.g.*, where the injury is caused by the negligence of a sub-contractor or of a stranger, in such cases the employer, if required to pay compensation under the Act, is entitled to be indemnified by such other person.

By the Workmen's Compensation Act, 1900, the benefits of the Act of 1897 were, after the 1st July 1901, extended to some workmen in agriculture. To come within the Act, the workman must be employed in agriculture by an employer who habitually employs one or more workmen in such employment. "Agriculture" includes horticulture, forestry, and the use of land for any purpose of husbandry, inclusive of the keeping or breeding of live stock, poultry, or bees, and the growing of fruit and vegetables. If a workman is employed by the same employer mainly in agricultural, but partly or occasionally in other work, the Act applies to the employment of the workman in such other work. The provisions of the Act of 1897, which entitle a workman employed by a contractor to recover against the undertaker whose work the contractor is doing, are limited by a provision that, where the contractor provides and uses machinery driven by mechanical power for the purpose of threshing, ploughing, or other agricultural work, he, and he alone, shall be liable to pay compensation to any workman employed by him on such work.

The Act of 1900.

Under the Factory Acts, offences, when they result in death or bodily injury to health, may be punished by fine not exceeding £100, and the whole or any part of such fine may be applied for the benefit of the injured person or his family, or otherwise as the Secretary of State determines. Similar provisions occur in the Mines Acts. Any sum so applied must be taken into account in estimating compensation under the Employers' Liability and Workmen's Compensation Acts.

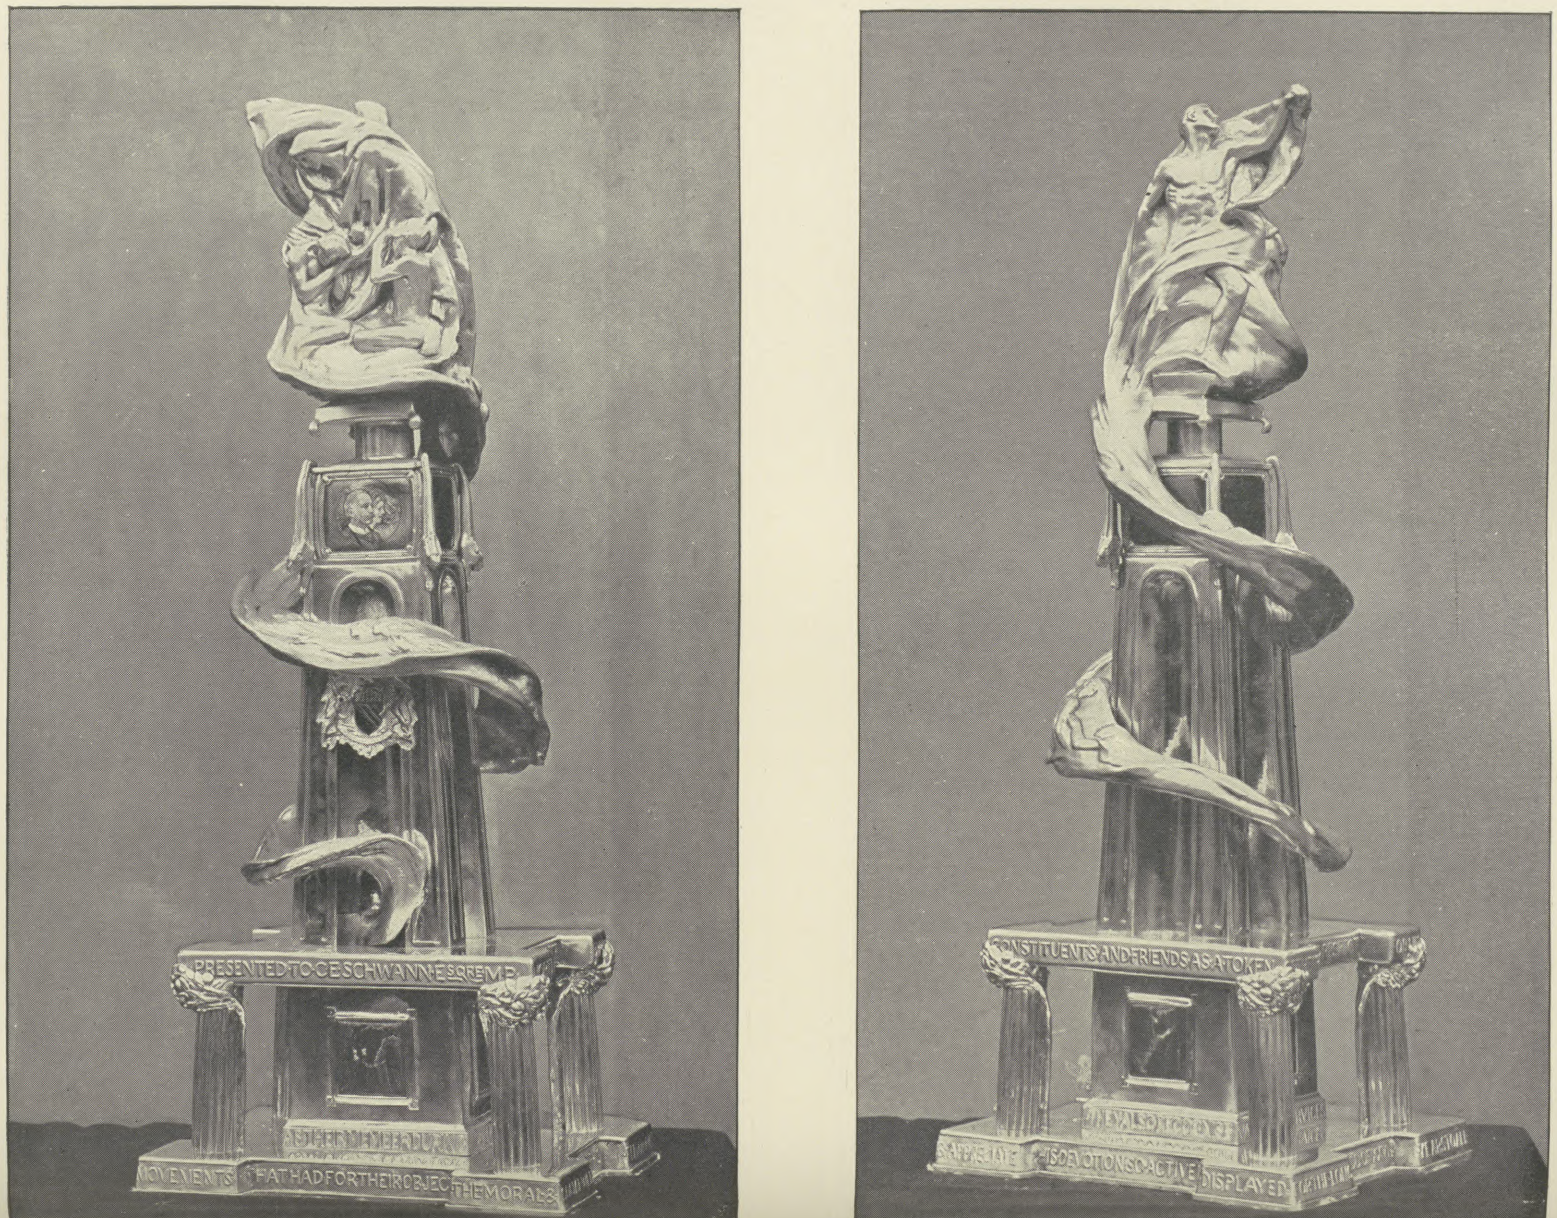
Emporia, capital of Lyon county, Kansas, U.S.A., in 38° 24′ N. lat. and 96° 10′ W. long., on the Neosho river, at an altitude of 1138 feet. It is regularly laid out on the level bottom-lands, and is divided into four wards. It has two railways, the Atchison, Topeka, and Santa Fé, and the Missouri, Kansas, and Texas. It is the seat of the College of Emporia, a Presbyterian institution, established in 1883. In 1900 the college had 12 instructors and 127 students, including those in the preparatory department. Emporia is also the seat of the State Normal School. Population (1880), 4631; (1890), 7551; (1900), 8223, of whom 686 were foreign-born and 663 were negroes.

Ems, a river of Germany, rising on the south slope of the Teutoburg Forest at an altitude of 358 ft., and flowing



A Silver and Enamel Centrepiece. Designed and made by Alexander Fisher.

generally north-west and north through Westphalia and Hanover to the east side of the Dollart, immediately south of Emden. After passing through the Dollart the navigable stream bifurcates, the eastern Ems going to the east, and the western Ems to the west, of the island of Borkum to the North Sea. Length, 205 miles.

Between 1892 and 1899 the river was canalized along its right bank for a distance of 43 miles. At the same time, and as part of the same general plan, a canal, the DORTMUND-EMS CANAL, was dug to connect the river (from Münster) with Herne in the Westphalian coal-field. At Heinrichenburg a branch from Herne (5 miles long) connects with another branch from Dortmund (10½ miles long). Another branch, from Olfen (north of Dortmund), connects with Duisburg, and so with the Rhine. There is, however, a difference in elevation of 46 ft. between the two branches first named, and vessels are transferred from the one to the other by means of a huge lift. The canal, which was constructed to carry small steamers and boats up to 220 ft. in length and 750 tons burden, measures 169 miles in length, of which 108½ miles were actually dug, and cost altogether £3,728,750. The surface width throughout is 98½ ft., the bottom width 59 ft., and the depth 8½ ft.

Ems, a town and watering-place of Prussia, province Hesse-Nassau, on the river Lahn, 11 miles by rail east from Coblenz. The hot alkaline springs (70°–135° F.), about a score in all, and on both sides of the stream, were apparently known in Roman times. A monument to the Emperor William I. was unveiled in 1893, and a stone has been set into the promenade to commemorate the spot where the emperor abruptly dismissed Benedetti, the French ambassador to Prussia. A funicular railway has been constructed to the Malberg, a favourite sanatorium. The population of 6492 (1900) is greatly increased during the summer months by visitors from all parts of the world, for whose accommodation many handsome villas have been erected.

Enamel.—The art of enamelling upon metals was practised in its simplest forms as far back in the history of man's achievements as the Assyrian and Egyptian civilizations. Since those remote ages there has been a succession of luxurious developments, followed by lapses into the decline and death of the art. In each revival there has been something added to that which was known and practised before, bearing witness to a slow progression. The last revival took place five hundred years ago, accompanying the rebirth of learning and the arts; but after flourishing for over a century, the art gradually fell into disuse, and remained so until the recent revival and further development, with which alone we are here concerned. The development consists, first, in the more complete knowledge of the technical processes, following upon the great advances which science has made; and, secondly, in a finer and more subtly artistic treatment of them. The advance in technical knowledge comprises greater facility and perfection in the production of the substance enamel, and its subsequent application to metal surfaces; more intimate knowledge of metals and their alloys to which it is applied, and greater ease in obtaining them from the metalliferous ores and reducing them to suitable dimensions and surfaces. For instance, it is now a simple matter to obtain perfectly pure copper by means of electricity. Again, formerly a flat sheet of metal was obtained by hammering, which involved an infinite amount of hard labour, whereas it is accomplished to-day with ease by means of flatting and rolling mills—*i.e.*, after the metal has been obtained from the ore in the form of an ingot, it is stretched equally to any degree of thinness by steel rollers. Further, the furnaces have been greatly improved by the introduction of gas as the heating power, instead of the wood or charcoal employed formerly.

In the manufacture of the substance enamel a much greater advance has been made, for whereas the colours, and consequently the schemes of colour, were extremely limited, we now possess an infinite gradation in the colours, as well as the transparency and opacity, the hardness and softness, of enamels. There are only two colours which cannot yet be obtained: these are opaque vermilion and lemon yellow. Many of the colours we now employ were not known by such enamellers as Leonard Limousin. Our enamels are also perfect in purity, brilliancy, and durability, qualities which are largely due to the perfect knowledge of the proportion of parts composing an enamel, and their complete combination. It is this complete combination, together with the absence of any destructible matter, which gives the enamel its lasting quality. The base of enamel is a clear, colourless, transparent, vitreous compound called flux, which is composed of silica, minium, and potash. This flux or base—termed *fondant* in France—is coloured by the addition of oxides of metals while in a state of fusion, which stain the flux throughout its mass. Enamels are either hard or soft, according to the proportion of the silica to the other parts in its composition. They are termed hard when the temperature required to fuse them is very high. The harder the enamel the less liable is it to be affected by atmospheric agencies, which in soft enamels produce a decomposition of the surface first, and ultimately of the whole enamel. It is therefore advisable to use hard enamel in all cases. This involves the employment of pure—or almost pure—metals for the plates, which are in most respects the best to receive and retain the enamel. For if there is an excess of alloy, either the metal will possibly melt before the enamel is fused, or afterwards they will part company. To the inferior quality of old silver may be attributed the fact that in all cases the enamel has flown off it; if it has not yet wholly disappeared, it will scale off in time. It is therefore essential that metals should be pure and the enamels hard. It is also noteworthy that enamels composed of a great amount of soda or potash, as compared with those wherein red lead is in greater proportion, are more liable to crack, and have less cohesion to the metal. It is better not to use silver as a basement, although it is capable of reflecting a higher and more brilliant white light than any other metal. Fine gold and pure copper, as thin as possible, are the best metals upon which to enamel. If silver is to be used, it should be fine silver, treated in the methods called *Champlevé* and *Cloisonné*.

The brilliancy of the substance enamel depends upon the perfect combination and proportion of its component parts. The intimacy of the combination depends upon an equal temperature being maintained throughout its fusion in the crucible. For this purpose it is better to obtain a flux which has been already fused and most carefully prepared, and afterwards to add the colouring oxides, which stain it dark or light according to the amount of oxide introduced. Many of the enamels are changed in colour by the difference of the proportion of the parts composing the flux, rather than by the change of oxides. For instance, turquoise blue is obtained from the black oxide of copper by using a comparatively large proportion of carbonate of soda; and a yellow green from the same oxide by increasing the proportionate amount of the red lead. All transparent enamels are made opaque by the addition of calx, which is a mixture of tin and lead calcined. White enamel is made by the addition of stannic and arsenious acids to the flux. The amount of acid regulates the density or opacity of the enamel.

To elucidate the development which has occurred, it will be necessary to describe some of the processes. After the enamel has been procured in the lump, the next stage in the process, common to all methods of enamelling, is to pulverize it. To do this properly the enamel must first be placed in an agate mortar and covered with water; next, with a wooden mallet a number of sharp blows must be given to a pestle held vertically over the enamel, to break it; then, holding the mortar firmly in the left hand, the pestle must be rotated with the right, with as much pressure as possible on the enamel, grinding it until the particles are reduced to a fine grain (Fig. 1). The powder is then subjected to a series of washings in distilled water until all the floury particles are removed. After this the metal is cleaned by immersion in acid and water. For copper, nitric acid is used; for silver, sulphuric; and for gold, hydrochloric acid. All trace of acid is then removed, first by scratching with a brush and water, and finally by drying in warm oak sawdust.

FIG. 1.—Laying enamel on a copper plate, and pulverizing enamel with a pestle and mortar.

After this the pulverized enamel is carefully and evenly spread over those parts of the metal designed to receive it, in sufficient thickness just to cover them and no more. The piece is then dried in front of the furnace, and when dry is placed gently on a fire-clay or iron *planche*, and introduced carefully into the muffle of the furnace, which is heated to a bright pale red (Fig. 2). It is now attentively watched until the enamel shines all over, when it is withdrawn from the furnace. The firing of enamel, unlike that of glass or pottery, takes only a few minutes, and in nearly all processes no annealing is required.

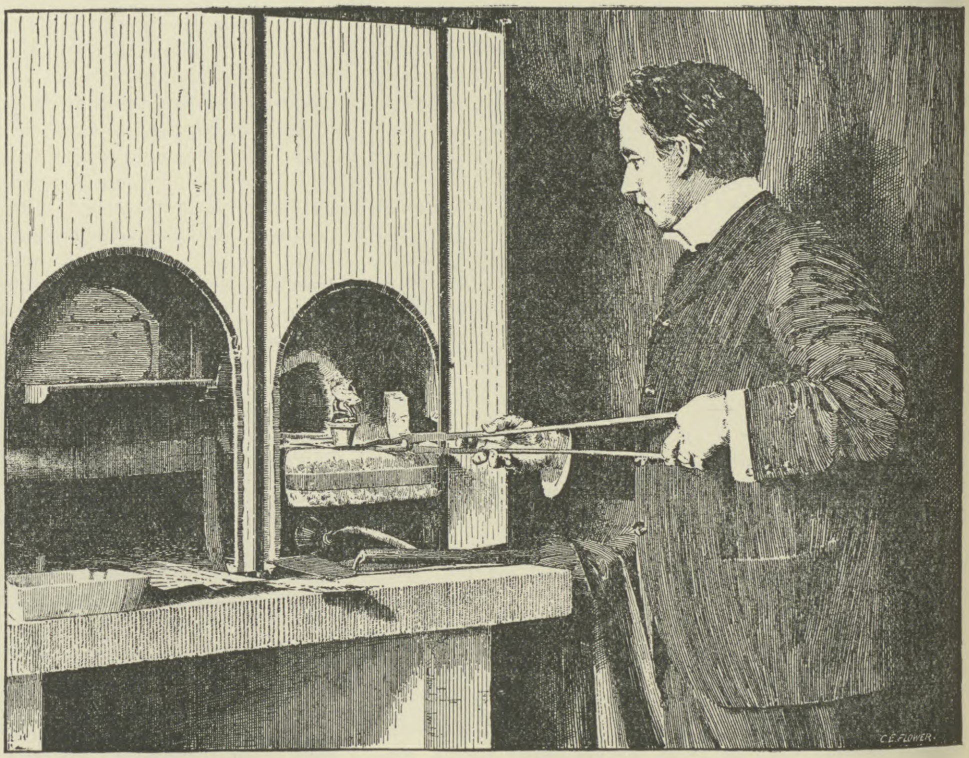

FIG. 2.—Placing an object covered with pulverized enamel into a muffle.

The following are the different modes of enamelling: Champlevé, Cloisonné, Basse-taille, Plique à jour, Painted Enamel, Encrusted, and Miniature-painted. These processes were known at successive periods of ancient art in the order in which they are named. To-day they are all known in their entirety. Each has been largely developed and improved. No new method has been discovered, although variations have been introduced into all. The most important are those connected with painted enamels, encrusted enamels, and *plique à jour*.

Champlevé enamelling is done by cutting away troughs or cells in the plate, leaving a metal line raised between them, which forms the outline of the design. In these cells the pulverized enamel is laid and then fused; afterwards it is filed with a corundum file, then smoothed with a pumice stone, and polished by means of crocus powder and rouge.

In *Cloisonné enamel* upon a metal plate or shape, thin metal strips are bent to the outline of a pattern, then fixed by silver solder or by the enamel itself. These strips form a raised outline, giving cells as in the case of *Champlevé*. The rest of the process is identical with that of *Champlevé* enamelling.

The *Basse-taille process* is also a combination of metalwork in the form of engraving, carving, and enamelling. The metal, either silver or gold, is engraved with a design and then carved into a bas-relief below the general surface of the metal, like an Egyptian bas-relief, so that when the enamel is fused it shall be level with the uncarved parts of the enamel and the design show through the transparent enamel.

Painted enamels are different from any of these processes, both in method and in result. The metal in this case is either copper, silver, or gold, but usually copper. It is cut with shears into a plate of the size required, and slightly domed with a burnisher or hammer, after which it is cleaned by acid and water. Then the enamel is laid equally over the whole surface, both back and front, and afterwards "fired." The first coat of enamel being fixed, the design is carried out, first by laying it in white enamel or any other which is opaque and most advantageous for subsequent coloration.

In the case of a *grisaille painted enamel*, the white is mixed with water or turpentine, or spike oil of lavender, or essential oil of petroleum (according to the taste of the artist), and the white is painted thickly in the light parts and thinly in the grey ones, whereby a slight sense of relief is obtained and a great degree of light and shade.

In *coloured painted enamels* the white is coloured by transparent enamels spread over the grisaille treatment, parts of which when fired are heightened by touches of gold, usually painted in lines. Other parts can be made more brilliant by the use of foil, over which the transparent enamels are placed and then fired.

Enamels by the *Plique à jour* method might be best described as *Translucent cloisonné* enamels; for they are similar to *cloisonné*, except that the ground upon which they are fired is removed, thus making them transparent, like stained glass.

Miniature enamel painting is not true enamelling, for after the white enamel is fired upon the gold plate, the colours used are not vitreous compounds—not enamels, in fact—as is the case in any other form of enamelling; but they are either raw oxides or other forms of metal, with a little flux added, not combined. These colours are painted on the white enamel, and afterwards made to adhere to the surface by partially fusing the enamel, which when in a state of partial fusion becomes viscous.

There are many of these so-called enamels to-day, which are much easier of accomplishment than the true enamel, but they possess none of the beautiful quality of the latter. It is most apparent when parts of a work are true enamels and parts are done in the manner described above. These enamel paintings—or rather paintings on enamel—are afterwards coated over with a transparent flux, which gives them a surface of enamel. Many are done in this way for the market.

All these methods were used formerly, before the present revival; but they were not so completely understood or carried so far as they are to-day, nor were the whole methods practised by any artist as they are now. The greatest advance has been in painted enamels. This process requires that both sides of the metal plate shall be covered with enamel; for this reason the plate is made convex on the top, so that the concave side does not touch the *planche* on which it is supported for firing, but rests upon its edges throughout. There are several reasons why these plates are *bombé*, the principal one being that in the firing they resist the tendency to warp and curl up at the edges, as a flat thin plate would do. Further, the enamel having been fused to both sides, is not so liable to crack or split in subsequent firings. This is most important, for otherwise the white which is placed on afterwards would be a network of cracks. The manner of firing has also to do with this, but not nearly so much as the preliminary care and mechanical perfection with which a plate is prepared. Nearly all the old enamels are seen to be cracked in the white if minutely examined. To obviate this the following points must be observed:—The plate must be of an excellent quality of metal, equal in thickness throughout and of perfectly regular shape. It must be arched equally from end to end. The first coat of enamel must be of a perfectly regular equal thickness on both sides, entirely covering the plate. Whatever the medium employed in painting the white on to the enamel, it must be completely evaporated before the plate is placed in the furnace. The furnace must be heated to a bright red heat, and the *planche* must be red-hot before being taken out for the enamel to be placed upon it, and then quickly returned to the furnace and the muffle door shut tight so as to allow no draught of cool air to enter. Then as soon as it has begun to fuse, which, if a small piece, it would do in a minute or so, the muffle door is slightly opened to afford a view of it. As soon as it shines all over its surface, it is withdrawn from the muffle.

The method of laying the white upon an enamel ground is a matter of individual taste, so far as the medium is concerned. By some, pure distilled water is preferred to any other liquid for mixing the enamel. Otherwise turpentine and the fat oil of turpentine, as well as spike oil of lavender. The oil mixture takes longer to dry, and thus gives a greater chance for modelling into fine shades, than the water. But it has several drawbacks. Firstly, there is the difficulty of drying the oil out—a process which takes some time and increases the risk of cracking in the drying process; and secondly, the enamel is not so fresh and clear after it is fired as when pure water has been employed. Besides, there is a great difference in the result: the water involves a quick, decided, direct touch and method, which carries with it its own charm. The oil medium, besides giving an effect of laborious rounded stippled surfaces, is apt partly to reduce the enamel, thus giving it a dull surface. The coloration of the white is comparatively simple, and is done by transparent enamels finely ground and evenly spread over the white after the latter has been fused. The only danger to be avoided is that of over-firing, which is produced by too great heat or a prolonged duration of firing, which causes the stannic and arsenious acids in the white to volatilize.

Plique à jour enamelling is done in the same way as *cloisonné* enamelling, except that the wires or strips of metal which enclose the enamel are not soldered to the metal basement, but are soldered to each other. Then these are simply placed upon a sheet of platinum, copper, silver, gold, or hard brass, which, after the enamel is fused and sufficiently annealed and cooled, is easily removed. For small pieces of *plique à jour* there is no necessity to apply any metallic basement, as the particles of enamel quickly fuse, become viscous, and when drawn set quite hard. Neither is there any need for annealing, as would be the case in larger work.

Commercially there has lately been an activity in enamels such as has never before occurred. This has been the case throughout Europe, Japan, and the United States of America. In London there has been a demand for a cheap form of gaudy coloured enamel, fused into sunk spaces of metal obtained by stamping with a steel dye; this has been applied to small objects of cheap jewellery, in the form of brooches, bracelets, and the like. There has also been a great demand for enamel watch-cases and small pendants, done mainly by hand, of a better class of work. Many of these have been produced in Birmingham, Berlin, Paris, and London. In Paris copies of pictures in black and white enamel, with a little gold paint in the draperies and background, have been manufactured in very large quantities and sometimes of great dimensions. Another curious demand, followed by as astonishing a production, is that of the imitations (a harder name for which is "forgeries") of old enamels, made with much skill, giving all the technical excellence of the originals, even to the cracks and scratches incidental to age. These are duly signed, and will deceive the most expert. They are copies of enamels by Nardon and Jean Pénicaud, Léonard Limousin, Pierre Reymond, Courtois, and others. The same artificers also produce copies of old Chinese *cloisonné* and *champlevé* enamels, as well as old Battersea enamel snuff-boxes, patch-boxes, and indeed every kind of enamelling formerly practised. It is advisable for the collector never to purchase any piece of enamelling as the work of an old master without having a pedigree extending at least over thirty years. From Japan there has been a continuous flow of *cloisonné* enamelled vases, boxes, and plates, either entirely covered with enamel or applied in parts. Compared with this enormous output, only a few small pieces of jewellery have come from Jaipur and other towns in India. There has also been a great quantity of *plique à jour* enamelling manufactured in Russia, Norway, and Sweden. And finally, it has been used in an unprecedented manner in large pieces upon iron and copper for purposes of advertisement.

Amongst the chief workers in the revival of this art are Claudius Popelin, Alfred Meyer, M. Grandhomme, Fernand Thesmar, Professor von Herkomer, and Mr Alexander Fisher. The work of Claudius Popelin is characterized by good technical skill, correctness, and a careful copying of the work of the old masters. Consequently it suffers from a lack of invention and individuality. His work was devoted to the rendering of mythological subjects and fanciful portraits of historical people. M. Alfred Meyer and M. Grandhomme are both accomplished and careful enamellers; the former is a painter-enameller and the author of a book dealing technically with enamelling. M. Grandhomme paints mythological subjects and portraits in a very tender manner, with considerably more artistic feeling than either Meyer or Popelin. There is a specimen of his work in the Luxembourg Museum. M. Fernand Thesmar is the great reviver of *plique à jour* enamelling in France. Specimens of his work are possessed by the Art Museums throughout Europe, and one is to be seen in the Victoria and Albert Museum, London. They are principally valued on account of their perfect technical achievement. Lucien Falize was an employer of artists and craftsmen, and to him we are indebted for the production of specimens of *Basse-taille* enamel upon silver and gold, as well as for a book reviewing the revival of the art in France, bearing particularly upon the work of Claudius Popelin. Until within the last few years there was a clear division between the art and the crafts in the system of producing art objects. The artist was one person and the workman another. It is now acknowledged that the artist must also be the craftsman, especially in the higher branches of enamelling. M. Falize initiated the production of a gold cup which was enamelled in the *Basse-taille* manner. The band of figures was designed by M. Luc Olivier Merson, the painter, and carved by a metal carver and enamelled by an enameller, both able craftsmen employed by M. Falize. Other pieces of enamelling in *Champlevé* and *Cloisonné* were also produced under his supervision and on this system; therefore lacking the one quality which would make them complete as an expression of artistic emotion by the artist's own hands. M. René Lalique is among the jewellers who have applied enamelling to their work in a peculiarly technically perfect manner. In England, Professor Hubert von Herkomer has produced painted enamels of considerable dimensions, aiming at the execution of pictures in enamel, such as have been generally regarded as peculiar to the province of oil or water-colour painting. Among numerous works is a large shield, into which plaques of enamel were inserted, as well as several portraits, one of which, made in several pieces, is 6 feet high—a portrait of the Emperor William II. of Germany. The present writer rediscovered the making of many enamels, the secrets of which had been jealously guarded. He has worked in all these processes, developing them from the Art side, and helping to make enamelling not only a decorative adjunct to metal-work, but raising it to a Fine Art. His work may be seen in the Victoria and Albert Museum, Brussels Museum, and the Chicago Art Galleries. Others who have been enamelling with success in various branches, and who have shown individuality in their work, are Messrs John Eyre, George Frampton, Nelson Dawson, and William Colton.

Energetics.—The most fundamental result attained by the progress of physical science in the 19th century was the definite enunciation and development of the doctrine of energy. Ever since physical speculation began in the atomic theories of the Greeks, its main problem has been that of unravelling the nature of the underlying correlation which binds together the various natural agencies. But it is only in recent times that scientific investigation has definitely established that there is a quantitative relation of simple equivalence between them, whereby each is expressible in terms of heat or mechanical power; that there is a certain measurable quantity associated with each type of physical action which is always numerically identical with a corresponding quantity belonging to the new type into which it is transformed, so that the energy, as it is called, is conserved in unaltered amount. The main obstacle in the way of an earlier recognition and development of this principle had been the doctrine of caloric, which was suggested by the principles and practice of calorimetry, and taught that heat is a substance that can be transferred from one body to another but cannot be created or destroyed, though it may become latent. So long as this idea maintained itself, there was no possible compensation for the destruction of mechanical power by friction; it appeared that mechanical effect had there definitely been lost. The idea that heat is itself convertible into power, and is in fact energy of motion of the minute invisible parts of bodies, had been held by Newton and in a vaguer sense by Bacon, and indeed long before their time; but it dropped out of the ordinary creed of science in the following century. It held a place, like many other anticipations of subsequent discovery, in the system of Natural Philosophy of Young (1804); and the discrepancies attending current explanations on the caloric theory were insisted on, about the same time, by Count Rumford and Sir H. Davy. But it was not till the actual experiments of Joule verified the same exact equivalence between heat produced and mechanical energy destroyed, by whatever process that was accomplished, that the idea of caloric had to be definitely abandoned. Some time previously R. Mayer, physician, of Heilbronn, had founded a weighty theoretical argument on the production of mechanical power in the animal system from the food consumed; he had, moreover, even calculated the value of a unit of heat, in terms of its equivalent in power, from the data afforded by Regnault's determinations of the specific heats of air at constant pressure and at constant volume, the former being the greater on Mayer's hypothesis (of which his calculation in fact constituted the verification) solely on account of the power required for the work of expansion of the gas against the surrounding constant pressure. About the same time Helmholtz, in his early memoir on the Conservation of Energy, constructed a cumulative argument by tracing in a highly original manner the ramifications of the principle throughout the whole range of physical science.

Mechanical and Thermal Energy.—The amount of energy, defined in this sense by convertibility with mechanical work, which is contained in a material system, must be a function of its physical state and chemical constitution and of its temperature. The change in this amount, arising from a given transformation in the system, is usually measured by degrading the energy that leaves the system into heat; for it is always possible to do this, while the conversion of heat back again into other forms of energy is impossible without assistance, taking the form of compensating degradation elsewhere. If we adopt the provisional view which is the basis of abstract physics, that all these other forms of energy are in their essence mechanical, that is, arise from the motion or strain of material or æthereal media, their distinction from heat will lie in the fact that these motions or strains are simply co-ordinated, so that they can be traced and controlled or manipulated in detail, while the thermal energy consists in irregular motions of the molecules or smallest portions of matter, which we cannot analyse on account of the bluntness of our sensual perceptions, but can only measure as regards their total amount.

Historical: Abstract Dynamics.—Even in the case of a purely mechanical system, capable only of a finite number of definite types of disturbance, the principle of the conservation of energy is very far from giving a complete account of its motions; it is only one among the equations that are required to determine their course. In its application to the kinetics of invariable systems, the principle was first emphasized as fundamental by Leibnitz, was then improved and generalized by the Bernoullis and by Euler, and was ultimately expressed in its widest form by Lagrange. It is recorded by Helmholtz that it was largely his acquaintance in early years with the works of those mathematical physicists of the previous century, who had formulated and generalized the principle as a help towards the theoretical dynamics of complex systems of masses, that started him on the track of extending the principle throughout the whole range of natural phenomena. On the other hand, the ascertained validity of this extension to new types of phenomena, such as those of electrodynamics, now forms a main foundation of our belief in a mechanical basis for these sciences.

In the hands of Lagrange the mathematical expression for the manner in which the energy is connected with the geometrical constitution of the material system became a sufficient basis for a complete knowledge of its dynamical phenomena. So far as statics was concerned, this doctrine took its rise as far back as Galileo, who recognized in the simpler cases that the work expended in the steady driving of a frictionless mechanical system is equal to its output. The expression of this fact was generalized in a brief statement by Newton in the *Principia*, and more in detail by the Bernoullis, until, in the analytical guise of the so-called principle of "virtual velocities" or virtual work, it finally became the basis of Lagrange's general formulation of dynamics. In its application to kinetics a purely physical principle, also indicated by Newton but developed long after with masterly applications by d'Alembert, that the reactions of the infinitesimal parts of the system against the accelerations of their motions statically equilibrate the forces applied to the system as a whole, was required in order to form a sufficient basis, and one which Lagrange soon afterwards condensed into the single relation of Least Action. As a matter of history, however, the complete formulation of the subject of abstract dynamics actually arose (in 1758) from Lagrange's precise demonstration of the principle of Least Action for a particle, and its immediate extension, on the basis of his new Calculus of Variations, to a system of connected particles such as might be taken as a representation of any material system; but here too the same physical as distinct from mechanical considerations come into play as in d'Alembert's principle. (See DYNAMICS, ANALYTICAL.)

It is in the cases of systems whose state is changing so slowly that kinetic reactions can be neglected, that the conditions are by far the simplest. In such systems, whether stationary or in a state of steady motion, the energy depends on the configuration alone, and its mathematical expression can be determined from measurement of the work required for a sufficient number of simple transformations; once it is thus found, all the statical relations of the system are implicitly determined along with it, and the results of all other transformations can be predicted. Thus the complete specification of a mechanical system as regards statical change is involved in its geometrical configuration and the function expressing its mechanical energy in terms thereof. Systems which have statical energy-functions of the same analytical form behave in corresponding ways, and can serve as models or representations of one another.

Extension to Thermal and Chemical Systems.—This dominant position of the principle of energy, in ordinary statical problems, has in modern times been extended to transformations involving change of physical state or chemical constitution as well as change of geometrical configuration. In this wider field we cannot assert that mechanical (or available) energy is never lost, for it may be degraded into thermal energy; but we can use the principle that on the other hand it can never spontaneously increase. If this were not so, cyclic processes might theoretically be arranged which would continue to supply mechanical power so long as energy of any kind remained in the system; whereas the irregular and uncontrollable character of the molecular motions and strains which constitute thermal energy, in combination with the vast number of the molecules, places an effectual bar on their unlimited co-ordination. In order, therefore, to establish a doctrine of *energetics* that shall form a sufficient foundation for a theory of the trend of chemical and physical change, we have to impart precision to this notion of available energy.

Carnot's Principle: Entropy.—The whole subject is involved in the new principle contributed to theoretical physics by Sadi Carnot in 1824, in which the far-reaching modern conception of cyclic processes was first scientifically developed. It was shown by Carnot, on the basis of certain axioms, whose theoretical foundations were subsequently corrected and strengthened by Clausius and Lord Kelvin, that a reversible mechanical process, working in a cycle and involving thermal changes, which takes heat, say H_1, into the material system at a given temperature T_1, and delivers the part of it not utilized, say H_2, at a lower given temperature T_2, is more efficient, considered as a working engine, than any other such process, operating between the same two temperatures but not reversible, could be. This relation of inequality involves a definite law of equality, that the efficiencies of all reversible cyclic processes are the same, whatever be the nature of their action or the material substances involved in them; that in fact the efficiency is a function solely of the temperatures at which the cyclically working system takes in and gives out heat. These considerations constitute a fundamental general principle to which all possible slow reversible processes, so far as they concern matter in bulk, must conform in all their stages; its application is almost coextensive with the scope of general physics, special kinetic theories excepted. (See THERMODYNAMICS.) If the system is an ideal gas-engine, in which a perfect gas (known from experience to be a possible state of matter) is passed through the cycle, and if temperature is measured from the absolute zero by the expansion of this gas, then simple direct calculation on the basis of the laws of ideal gases shows that $H_1/T_1 = H_2/T_2$; and as by the conservation of energy the work done is $H_1 - H_2$, it follows that the efficiency is $1 - T_2/T_1$. If we change the sign of H_2, and thus consider heat as positive when it is taken in by the system, the equation becomes $H_1/T_1 + H_2/T_2 = 0$; and as any complex reversible working system may be considered as compounded in various ways of elementary systems of this type, *whose effects are additive*, the general proposition follows, that in any reversible complete cyclic change which involves the taking in of heat by the system of amount δH_r when its temperature is between T_r and $T_r + \delta T$, the equation $\Sigma \delta H_r/T_r = 0$ holds good. Moreover, if the changes are not reversible, the proportion of the heat supply that is utilized for mechanical work will be smaller, so that $\Sigma \delta H_r/T_r$ or, as it may be expressed, $\int dH/T$, must have a smaller value, and must thus be negative. The first statement involves further, that for all reversible paths of change of the system from one state C to another state D, the value of $\int dH/T$ must be the same, because any one of these paths and any other one reversed would form a cycle; whereas for any irreversible path of change between the same states this integral must be less. The quantity represented by this integral was introduced by Clausius, and was named by him the increase of the *entropy* of the system in passing from the state C to the state D. This increase, being thus the same for the unlimited number of possible reversible paths involving independent variation of all its finite co-ordinates, along which the system can pass, can depend only on the terminal states. The entropy belonging to a given state is therefore a function of that state alone, irrespective of the manner in which it has been reached; and this is the justification of the assignment to it of a special name, connoting a property of the system depending on its actual condition and not on its previous history. Every reversible change in an isolated system thus maintains the entropy of that system unaltered; no possible spontaneous change can involve decrease of the entropy; while any defect of reversibility, arising from diffusion of matter or motion in the system, necessarily produces an increase of entropy. For a physical or chemical system with given total energy, only those changes are spontaneously possible which would increase the entropy; if the entropy is already a maximum, and so incapable of further continuous increase, there must be stable equilibrium.

This definite quantity belonging to a material system, its entropy ϕ, is thus concomitant with its energy E, which is also a definite function of its actual state by the law of conservation of energy, its temperature T, and the various co-ordinates expressing its geometrical configuration and its physical and chemical constitution; these are the quantities with which the thermodynamics of the system deals. That science develops the consequences involved in just two principles, (i) that the energy of every isolated system is constant, and (ii) that its entropy can never diminish; any complication that may be involved arises from complexity in the systems to which these two laws have to be applied.

The General Thermodynamic Equation.—When the physical or chemical system undergoes an infinitesimal change of state, we have $\delta E = \delta H + \delta U$, where δH is the heat that has been acquired from sources extraneous to the system during the change, and δU may be called the change in the internal energy of the system. It is, however, not possible to distinguish between heat acquired and internal energy, for neither δH nor δU is the exact differential of a function of the constitution of the system and independent of its previous history, although their sum is such; but δH is equal to $T\delta\phi$ where $\delta\phi$ is such, as has just been seen. Thus E and ϕ are properties of the system which, along with temperature, pressure, and other independent data specifying its constitution, must form the variables of an analytical argument. We have therefore to substitute $T\delta\phi$ for δH; also we have

$$\delta U = -p\delta v + \delta W + \mu_1\delta m_1 + \mu_2\delta m_2 + \cdots + \mu_n\delta m_n,$$

when the system consists of an intimate mixture (solution) of masses $m_1, m_2, \cdots m_n$ of given constituents, which differ physically or chemically but may be partially transformable into each other by chemical or physical action during the changes under consideration, the whole being of volume v and under extraneous pressure p, while W is potential energy arising from physical forces such as those of gravity, capillarity, &c. The variables $m_1, m_2, \cdots\cdots m_n$ may not be all independent; for example, if the system were chloride of ammonium gas existing along with its gaseous products of dissociation, hydrochloric acid and ammonia, only one of the three masses would be independently variable. The sufficient number of these variables together with two other variables, which may be v and T, or v and ϕ, specifies and determines the state of the system, considered as matter in bulk, at each instant. It is usual to include δW in $\mu_1\delta m_1 + \cdots$; in all cases where this is possible the single equation

$$\delta E = T\delta\phi - p\delta v + \mu_1\delta m_1 + \mu_2\delta m_2 + \cdots + \mu_n\delta m_n \cdots\cdots (1)$$

thus expresses the complete variation of the energy-function E arising from change of state; and when the part involving the n constitutive differentials has been expressed in terms of the number of them that are really independent, this equation by itself is the unique expression of *all* the thermodynamic relations of the system. These are in fact the various relations ensuring that the right-hand side is an exact differential, and are of type $d\mu_r/d\phi = dT/dm_r$.

The condition that the state of the system be one of stable equilibrium is that $\delta\phi$, the variation of entropy, be negative for all formally possible infinitesimal transformations which make δE vanish; for as $\delta\phi$ cannot actually be negative for any spontaneous variation, none of these transformations can then occur. From the form of the equation, this condition is the same as that $\delta E - T\delta\phi$ must be positive for *all possible* variations of state of the system without restriction.

We can change one of the independent variables expressing the state of the system from ϕ to T by subtracting $\delta(\phi T)$ from both sides of the equation of variation: then

$$\delta(E - T\phi) = -\phi\delta T - p\delta v + \mu_1\delta m_1 + \cdots + \mu_n\delta m_n.$$

It follows that for isothermal changes, *i.e.*, those for which δT is null, the condition of stable equilibrium is that the function $E - T\phi$ shall be a minimum. If the system is subject to an external pressure p, which as well as the temperature is imposed constant from without and thus incapable of variation through internal changes, the condition of stable equilibrium is similarly that $E - T\phi + pv$ shall be a minimum.

A chemical system maintained at constant temperature may thus have several states of stable equilibrium corresponding to different minima of the function here considered, just as there may be several minima of elevation on a landscape, one at the bottom of each depression; in fact, this analogy, when extended to space of n dimensions, exactly fits the case. If the system is sufficiently disturbed, for example, by electric shock, it may pass over from a higher to a lower minimum, but never (without compensation from outside) in the opposite direction. The former passage is often effected by introducing a new substance into the system; sometimes that substance is recovered unaltered at the end of the process, and then its action is said to be purely *catalytic*; its presence modifies the form of the function $E - T\phi$ so as to obliterate the ridge between the two equilibrium states in the geometrical representation. There are systems in which the equilibrium states are but very slightly dependent on temperature and pressure within wide limits, outside which reaction takes place. Thus while there are cases in which a state of mobile dissociation exists in the system which changes continuously as a function of these variables, there are others in which change does not sensibly occur at all until a certain temperature of reaction is attained, after which it proceeds very rapidly owing to the heat developed, and the system again becomes sensibly permanent in a transformed phase by completion of the reaction. In some cases of this latter type the cause of the delay in starting lies probably in passive resistance to change, of the nature of viscosity or hysteresis; but in many such reactions there seems to be no exact equilibrium at any temperature, short of the ultimate state of dissipated energy in which the reaction is completed, although the velocity of reaction is found to diminish exponentially with change of temperature, and thus becomes insignificant at a small interval from the temperature of pronounced activity.

Free Energy.—The quantity $E - T\phi$ thus plays the same fundamental part in the thermal statics of general chemical systems at uniform temperature that the potential energy plays in the statics of mechanical systems of unchanging constitution. It is a function of the geometrical co-ordinates, the physical and chemical constitution, and the temperature of the system, which determines the conditions of stable equilibrium at each temperature; it is, in fact, the potential energy generalized so as to include temperature, and thus be a single function available at each temperature and connecting the properties of the system at different temperatures. It has been called the *free energy* of the system by Helmholtz, for it is the part of the energy whose variation is connected with changes in the bodily structure of the system represented by the variables $m_1, m_2, \cdots m_n$, and not with the irregular molecular energy represented by heat, so that it can take part freely in physical transformations. Yet this holds good only subject to the condition that the temperature is not varied; it has been seen above that for the more general variation neither δH nor δU is an exact differential, and no line of separation can be drawn between thermal and mechanical energies.

Available Energy.—The same quantity ϕ arose in the early development of the subject, in the train of ideas of Rankine and Kelvin, in the expression of the *available energy* A of the material system. Suppose there were accessible an auxiliary system containing an unlimited quantity of heat at absolute temperature T_o, forming a condenser into which heat can be discharged from the working system, or from which it may be recovered at that temperature: we proceed to find how much of the heat of our system is available for transformation into mechanical work in a process which reduces the whole system to the temperature of this condenser. Provided the process of reduction is performed reversibly, it is immaterial, by Carnot's principle, in what manner it is effected: thus in following it out in detail we can consider each elementary quantity of heat δH removed from the system as set aside at its actual temperature between T and $T + \delta T$ for the production of mechanical work δW, and the residue of it δH_o as directly discharged into the condenser at T_o; the principle of Carnot gives $\delta H/T = \delta H_o/T_o$, so that the portion of the heat δH that is not available for work is δH_o, equal to $T_o \delta H/T$. In the whole process the part not available in connexion with the condenser at T_o is therefore $T_o \int dH/T$. This quantity must be the same whatever reversible process is employed: thus, for example, we may first transform the system reversibly from the state C to the state D, and then from the state D to the final state of uniform temperature T_o. It follows that the value of $T_o \int dH/T$, representing the heat degraded, is the same along all reversible paths of transformation from the state C to the state D; so that the function $\int dH/T$ is the excess of a definite quantitative property ϕ of the system in the former state as compared with the latter. It is usual to change the law of sign of δH so that gain of heat by the system is reckoned positive; then, relative to a condenser of unlimited capacity at T_o, the state C contains more mechanically *available energy* than the state D by the amount $E_C - E_D + T_o \int dH/T$, that is, by $E_C - E_D - T_o(\phi_C - \phi_D)$. In this way the existence of an entropy function with a definite value for each state of the system is again seen to be the direct analytical equivalent of Carnot's axiom that no process can be more efficient than a reversible process between the same initial and final states. The name *motivity* was proposed by Lord Kelvin in 1879 for this conception of available energy. It is here relative to a condenser of unlimited capacity at an assigned temperature T_o: the latter specification is necessary to the definition; in fact, if T_o were the absolute zero all the energy would be mechanically available.

But we can obtain an intrinsically different and more definite comparison of the available energies in a system in two different states at different temperatures, by ascertaining how much energy is dissipated in each in a reduction to the *same* standard state of the system at a standard temperature T_o. We have only to reverse the operation, and change back this standard state to each of the others in turn. This will involve abstractions of heat δH_o from the separate portions in the standard state, and returns of δH to the state at T; if this return were $\delta H_o \cdot T/T_o$ there would be no loss of availability in the direct process; hence there is actual dissipation $\delta H - \delta H_o \cdot T/T_o$, that is $T(\delta\phi - \delta\phi_o)$. On passing from state 1 to state 2 through state 0 the difference of these dissipations will represent the energy of the system that has become unavailable. Thus in this sense $E - T\phi + T\phi_o +$ const. represents for each state the amount of energy that is available; but instead of implying an unlimited source of heat at the standard temperature T_o, it implies that there is no such source. The available energy thus defined differs from $E - T\phi$, the *free energy* of Helmholtz, which involves no reference to any standard state, by a simple linear function of the temperature alone which is immaterial as regards its applications.

The determination of the available mechanical energy arising from differences of temperature between the parts of a system is a more complex problem, because it involves a determination of the common temperature to which reversible processes will ultimately reduce them; for the simple case in which no changes of state occur the solution was given by Lord Kelvin in 1853, in connexion with the above train of ideas (cf. Tait's *Thermodynamics*, § 179). In the present exposition the chemical system is in equilibrium, so that its temperature T is always uniform throughout; isolated portions at different temperatures would be treated as different systems.

Thermodynamic Potentials.—We have now to develop the relations involved in the general equation (1) of thermodynamics. Suppose the system includes two coexistent states or phases, with opportunity for free interchange of constituents—for example, a salt solution and the aqueous vapour in equilibrium above—it may be included in the material system. Then in equilibrium a slight transfer δm of the water-substance of mass m_r existing in the vapour, into the water-substance of mass m_s existing in the solution, should not produce any alteration of the first order in $\delta E - T\delta\phi$; therefore μ_r must be equal to μ_s. The quantity μ_r is called by Willard Gibbs the potential of the corresponding substance of mass m_r; it may be defined as its marginal available energy per unit mass at constant temperature. If then a system involves in this way coexistent phases which remain permanently separate, the potentials of any constituent must be the same in all of them in which that constituent exists, for otherwise it would tend to pass from the phases in which its potential is higher to those in which it is lower. If the constituent is non-existent in any phase, its potential when in that phase would have to be higher than in the others in which it is actually present; but as the potential increases logarithmically when the density of the constituent is indefinitely diminished, this condition is automatically satisfied. When the action of the force of gravity is taken into account, the potential of each constituent must include the gravitational potential gh; and in the equilibrium state the total potential of each constituent must be the same throughout all parts of the system into which it is freely mobile. A similar statement applies to other forms of mechanical potential energy arising from actions at a distance.

When a slight constitutive change occurs in a galvanic element at given temperature, producing available energy of electric current in a reversible manner and isothermally at the expense of chemical energy, it is the free energy of the system $E - T\phi$, not its total intrinsic energy, whose value must be conserved during the process. Thus the electromotive force is equal to the change of this free energy per electro-chemical equivalent of reaction in the cell. This proposition, developed by Gibbs and later by Helmholtz, modifies the earlier one of Kelvin — which tacitly assumed all the energy of reaction to be available —except in the cases in which the magnitude of the electromotive force does not depend sensibly on the temperature.

The effects produced on electromotive forces by difference of concentrations in dilute solutions can thus be accounted for and traced out, from the knowledge of the form of the free energy for such cases; as also the effects of pressure in the case of gas batteries. The free energy does not sensibly depend on whether the substance is solid or fused, though the total energy differs in these two cases by the heat of fusion; for this reason, as Gibbs has pointed out, voltaic potential differences are the same for the fused as for the solid state.

Relations involving Constitution only.—The potential of a component in a given solution can depend only on the temperature and pressure of the solution, and the densities of the various components, including itself; as no distance-actions are usually involved in chemical physics, it will not depend on the aggregate masses present. The example above mentioned, of two coexistent phases liquid and vapour, indicates that there may be relations between the constitutions of the phases present in a chemical system which do not involve their total masses. These are developed in a very direct manner in Willard Gibbs's original procedure. In so far as attractions at a distance (a uniform force such as gravity being excepted) and capillary actions at the interfaces between the phases are inoperative, the fundamental equation (1) can be integrated. Increasing the volume k times, and all the masses to the same extent —in fact, placing alongside each other k identical systems at the same temperature and pressure—will increase ϕ and E in the same ratio k; thus E must be a homogeneous function of the first degree of the independent variables ϕ, v, $m_1, \ldots, m_n$, and therefore by Euler's theorem relating to such functions

$$E = T\phi - pv + \mu_1 m_1 + \cdots + \mu_n m_n.$$

This integral equation merely expresses the additive character of the energies and entropies of adjacent portions of the system at uniform temperature, and thus depends only on the absence of sensible physical action directly across finite distances. If we form from it the expression for the complete differential δE, and subtract (1), there remains the relation

$$0 = \phi\delta T - v\delta p + m_1\delta\mu_1 + \cdots + m_n\delta\mu_n. \quad . \quad . \quad (2)$$

This implies that in each phase the change of pressure depends on and is determined by the changes in T, $\mu_1, \cdots \mu_n$; as we know beforehand that a physical property like pressure is an analytical function of the state of the system, it is therefore a function of these $n+1$ quantities. When they are all independently variable, the densities of the various constituents and of the entropy in the phase are expressed by the partial fluxions of p with respect to them: thus

$$\frac{\phi}{v} = \frac{dp}{dT}, \qquad \frac{m_r}{v} = \frac{dp}{d\mu_r}.$$

When, as in the case above referred to of chloride of ammonium gas existing partially dissociated along with its constituents, the masses are not independent, necessary linear relations, furnished by the laws of definite combining proportions, subsist between the partial fluxions, and the form of the function which expresses p is thus restricted in a manner which is easily expressible in each special case.

This proposition, that the pressure in any phase is a function of the temperature and of the potentials of the independent constituents, is a consequence of Carnot's axiom combined with the energy principle and the absence of effective actions at a distance. It shows that at a given temperature and pressure the potentials are not all independent, that there is a necessary relation connecting them, an equation of state or constitution of the phase, whose existence forms one mode of expression of Carnot's principle, and from which all the properties of the phase can be derived by simple differentiation.

The Phase Rule.—When the material system contains only a single phase, the number of independent variations that can spontaneously occur in its constitution is thus one less than the number of its independent components; in addition, the temperature and pressure can change. But where several phases coexist in the same system, the number of possible independent variations may be much smaller. The present independent variables $\mu_1, \cdots, \mu_n$ are specially appropriate in this problem, because each of them has the same value in all the phases. Now each phase has its own characteristic equation, giving a relation between δp, δT, and $\delta\mu_1, \cdots \delta\mu_n$, or such of the latter as are independent; if r phases coexist, there are r such relations; hence the number of possible independent variations, including those of v and T, is reduced to $m - r + 2$, where m is the number of independently variable chemical constituents the system contains. This number of degrees of constitutive freedom cannot be negative; therefore the number of possible phases that can coexist alongside each other cannot exceed $m + 2$. If $m + 2$ phases actually coexist, there is no variable quantity in the system, thus the temperature and pressure and constitutions of the phases are all determined; such is the triple point at which ice, water, and vapour exist in presence of each other. If there are $m+1$ coexistent phases, the system can vary in one respect only; for example, at any temperature of water-substance different from the triple point two phases only, say liquid and vapour, coexist, and the pressure is definite, as also are the densities and potentials of the components. Finally, when but one phase, say water, is present, both pressure and temperature can vary independently. The first example illustrates the case of systems, physical or chemical, in which there is only one possible state of equilibrium, forming a point of transition between different constitutions; in the second type each temperature has its own completely determined state of equilibrium; in other cases the constitution in the equilibrium state is indeterminate as regards the corresponding number of degrees of freedom. By aid of this phase rule of Gibbs the number of different chemical substances existing in a given complex system can be determined from observation of the degree of spontaneous variation which it exhibits; the rule thus lies at the foundation of the modern subject of chemical equilibrium and continuous chemical change in mixtures or alloys, and in this connexion it has been widely applied and developed in the experimental investigations of Roozeboom and van 't Hoff and other physical chemists, mainly of the Dutch school.

Cases in which the Theory can be practically developed.—It is only in systems in which the number of independent variables is small that the forms of the various potentials,—or the form of the fundamental characteristic equation expressing the energy of the system in terms of its entropy and constitution, or the pressure in terms of the temperature and the potentials,—which includes them all, can be readily approximated to by experimental determinations. Even in the case of the simple system water-vapour, which is fundamental for the theory of the steam engine, this has not yet been completely accomplished. The general theory is thus largely confined, as above, to defining the restrictions on the degree of variability of a complex chemical system which the principle of Carnot imposes. The tracing out of these general relations of continuity is much facilitated by geometrical diagrams, such as James Thomson first introduced in order to exhibit and explain Andrews's results as to the range of coexistent phases in carbonic acid. Gibbs's earliest thermodynamic surface had for its co-ordinates volume, entropy, and energy; it was constructed to scale by Maxwell for water-substance, and is fully explained in later editions of the *Theory of Heat* (1875); it forms a relief map which, by simple inspection, reveals the course of the transformations of water, with the corresponding mechanical and thermal changes, in its three coexistent states of solid, liquid, and gas. In the general case, when the substance has more than one independently variable constituent, there are more than three variables to be represented; but Gibbs has shown the utility of surfaces representing, for instance, the entropy in terms of the constitutive variables when temperature and pressure are maintained constant. Such graphical methods are now of fundamental utility in connexion with the phase rule, for the experimental exploration of the trend of the changes of constitution of complex mixtures with interacting components, as the physical conditions are altered. The study of the phenomena of condensation in a mixture of two gases or vapours, initiated by Andrews and developed in this manner by van der Waals and his pupils, forms a case in point. (See CONDENSATION OF GASES.)

There are, however, two simple limiting cases, in which the theory can be completed by a determination of the functions involved in it, which throw much light on the phenomena of actual systems not far removed from these ideal limits. They are the cases of mixtures of perfect gases, and of very dilute solutions.

If, following Gibbs, we apply his equation (2), expressing the pressure in terms of the temperature and the potentials, to a very dilute solution of substances $m_2, m_3, \cdots m_n$ in a substance m_1, and vary the co-ordinate m_r alone, p and T remaining unvaried, we have in the equilibrium state

$$m_r\frac{d\mu_r}{dm_r}+m_1\frac{d\mu_1}{dm_r}+\cdots+m_n\frac{d\mu_n}{dm_r}=0,$$

in which every m except m_1 is very small, while $d\mu_1/dm_r$ is presumably finite. This requires (when applied, for example, to the case where only two components are present) that the total potential of each component m_r, which is $m_r d\mu_r/dm_r$, shall be finite, say k_r, in the limit when m_r is null. Thus for very small concentrations the potential μ_r of a dilute component must be of the form $k_r \log m_r/v$, being proportional to the logarithm of the density of that component; it thus tends to an infinite value at evanescent concentrations, showing that removal of the last traces of any impurity would demand infinite expenditure of available energy.

The value of this logarithmic expression can be readily determined for the case of a perfect gas from its known properties, and can be thence extended to other dilute forms of matter. We have $pv=\mathrm{R}/m\cdot\mathrm{T}$ for unit mass of the gas, where m is the molecular weight being 2 for hydrogen, and R is a constant equal to $8{\cdot}2\times10^6$ in C.G.S. dynamical units, the same for all gases because they have all the same number of molecules per unit volume. The increment of heat received by the unit mass of the gas is $\delta\mathrm{H}=p\delta v+\kappa\delta\mathrm{T}$, where κ is the specific heat at constant volume, which can be a function only of the temperature. Thus

$$\phi=\int d\mathrm{H}/\mathrm{T}=\mathrm{R}/m.\ \log v\ +\int\kappa\mathrm{T}^{-1}d\mathrm{T};$$

and the available energy A per unit mass is $\mathrm{E}-\mathrm{T}\phi+\mathrm{T}\phi_o$ where $\mathrm{E}=\epsilon+\int\kappa d\mathrm{T}$, ϵ being intrinsic energy of chemical constitution, so that

$$\mathrm{A}=\epsilon+\phi_o\mathrm{T}+\int\kappa d\mathrm{T}-\mathrm{T}\int\kappa\mathrm{T}^{-1}d\mathrm{T}-\mathrm{R}/m.\ \mathrm{T}\log v.$$

If there are ν molecules in the unit mass, and N per unit volume, we have $m\nu=\mathrm{N}mv$, each being $2\nu'$ where ν' is the number of molecules per unit mass in hydrogen; thus the free energy per molecule is $a'+\mathrm{R}'\mathrm{T}\log b\mathrm{N}$, where $b=m/2\nu'$, $\mathrm{R}'=\mathrm{R}/2\nu'$, and a' is a function of T alone. In thermal energy units (calories) the gas-constant R is very approximately equal to 2. It is customary to avoid introducing the unknown molecular constant ν' by expressing the available energy per "gramme-molecule," that is, for a number of grammes equal to the molecular weight of the substance; this is a constant multiple of the available energy per molecule, and is $a+\mathrm{R}\mathrm{T}\log\rho$, ρ being the density, equal to $b\mathrm{N}$ where $b=m/2\nu'$. This formula may now be extended by simple summation to a mixture of gases, on the ground of Dalton's experimental principle that each of the components behaves in presence of the others as it would do in a vacuum. The components are actually separable wholly or partially in reversible ways which may be combined into cycles; for example, either (i) by diffusion through a porous partition, taking account of the work of the pressures, or (ii) by utilizing the modified constitution towards the top of a long column of the mixture arising from the action of gravity, or (iii) by reversible absorption of a single component. If we employ in place of available energy the form of characteristic equation which gives the pressure in terms of the temperature and potentials, the pressure of the mixture is expressed as the sum of those belonging to its components; this equation was made by Gibbs the basis of his analytical theory of gas mixtures, which he tested by its application to the only data then available, those of the mobile dissociation of nitric oxide vapour.

Van 't Hoff's Osmotic Principle: Theoretical Explanation.—We proceed to examine how far the same formulæ as hold for gases apply to the available energy of matter in solution which is so dilute that each molecule of the dissolved substance, though possibly the centre of a complex of molecules of the solvent, is nearly all the time beyond the sphere of direct influence of the other molecules of the dissolved substance. The available energy is a function only of the co-ordinates of the matter in bulk and the temperature; its change on further dilution, with which alone we are concerned in the transformations of dilute solutions, can depend only on the further separation of these molecular complexes that is thereby produced, as no one of them is in itself altered. The change is therefore a function only of the number N of the dissolved molecules per unit volume, and of the temperature, and is, per molecule, entirely independent of their constitution and of that of the medium in which they are dissolved. This suggests that the expression for the change is the same as the known one for a gas in which the same molecules would exist free and in the main outside each others' spheres of influence; which confirms and is verified by the experimental principle of van 't Hoff, that osmotic pressure obeys the laws of gaseous pressure with the same physical constants as those of gases. It can be held, in fact, that this suggestion does not fall short of a demonstration, on the basis of Carnot's principle, and independent of special molecular theory, that in all cases where the molecules of a component, whether it be of a gas or of a solution, are outside each others' spheres of influence, the available energy, so far as regards dilution, must have a common form, and the physical constants must therefore be the known gas-constants.

The single new element that thermodynamics introduces into the ordinary dynamical specification of a material system is temperature. This conception is akin to that of potential, except that it is given to us directly by our sense of heat. But if that were not so, we could still demonstrate, on the basis of Carnot's principle, that there is a definite function of the state of a body which must be the same for all of a series of connected bodies, when thermal equilibrium has become established so that there is no tendency for heat to flow from one to another. For we can by geometrical displacement change the order of the bodies so as to bring different ones into direct contact. If this disturbed the thermal equilibrium, we could construct cyclic processes to take advantage of the resulting flow of heat to do mechanical work, and such processes might be carried on without limit. This argument can be applied, by aid of adiabatic partitions, even when the bodies are in a field of force so that mechanical work is required to change their order; it has, in fact, been employed by Maxwell to extend from the case of a gas to that of any other system the proposition that the temperature is the same all along a vertical column in equilibrium under gravity. It had been shown from the kinetic theory by Maxwell that in a gas-column the mean kinetic energy of the molecules is the same at all heights. If the only test of equality of temperature consisted in bringing the bodies into contact, this would be rather a proof that thermal temperature is of the same physical nature in all parts of the field of force; but temperature can also be equalized across a distance by radiation, so that this law for gases is itself already necessitated by Carnot's general principle, and is merely confirmed by the special gas-theory.

Chemical Equilibrium based on Available Energy.—The complete theory of chemical and physical equilibrium in gaseous mixtures and in very dilute solutions may readily be developed in terms of available energy (cf. *Phil. Trans.*, 1897, A, pp. 266–280), which forms perhaps the most vivid and most direct procedure. The available energy per molecule of any kind, in a mixture of perfect gases in which there are N molecules of that kind per unit volume, has been found to be $a' + R'T \log bN$. This expression represents the marginal increase of available energy due to the introduction of one more molecule of that kind into the system as actually constituted. The same formula also applies, by what has already been stated, to substances in dilute solution in any given solvent. In any isolated system in a mobile state of reaction or of internal dissociation, the condition of chemical equilibrium is that the available energy at constant temperature is a minimum, so that it is stationary and slight change arising from fresh reaction would not sensibly alter it. Suppose that this reaction, per molecule, is equivalent to introducing n_1 molecules of type N_1, n_2 of type N_2, &c., into the system, $n_1, n_2, \cdots$ being the numbers of molecules of the different types that take part in the reaction, as shown by its chemical equation, reckoned positive when they appear negative when they disappear. Then in the state of equilibrium

$$n_1(a'_1 + R'T \log b_1N_1) + n_2(a'_2 + R'T \log b_2N_2) + \cdots$$

must vanish. Therefore $N_1^{n_1} N_2^{n_2} \cdots$ must be equal to K, a function of the temperature alone. This law, originally based by Guldberg and Waage on direct molecular statistics, expresses for each temperature the relation connecting the densities of the interacting substances, in dilution comparable as regards density with the perfect gaseous state, when the reaction has come to the state of mobile equilibrium.

All properties of any system, including the heat of reaction, are expressible in terms of its available energy A, equal to $E - T\phi + \phi_o T$. Thus as the constitution of the system changes with the temperature, we have

$$\frac{dA}{dT} = \frac{dE}{dT} - T\frac{d\phi}{dT} - (\phi - \phi_o)$$

where $dE = dH + dW$, $dH = Td\phi$, dH being heat and dW mechanical and chemical energy imparted to the system; hence $\phi - \phi_o = -\frac{d(A-W)}{dT}$, so that $A = E + T\frac{d(A-W)}{dT}$, leading to $E - W = -T^2\frac{d}{dT}\left(\frac{A-W}{T}\right)$. This general formula, applied differentially, expresses the heat $\delta E - \delta W$ absorbed by a reaction in terms of δA, the change produced by it in the available energy of the system, and of δW, the mechanical and electrical work done on the system during its progress.

In the problem of reaction in gaseous systems or in very dilute solution, the change of available energy per molecule of reaction has already been found to be

$$\delta A = \delta A_o + R'T \log K', \text{ where } K' = b_1^{n_1} b_2^{n_2} \cdots K;$$

thus, when the reaction is spontaneous without external work, the heat absorbed per molecule of reaction is $-T^2\frac{d}{dT}\frac{\delta A_o}{T}$, or $R'T^2\frac{d}{dT}\log K$. This formula has been utilized by van 't Hoff to determine, in terms of the heat of reaction, the displacement of equilibrium in various systems arising from change of temperature, K being the reaction-parameter through which alone the temperature enters into the law of chemical equilibrium.

Interfacial Phenomena: Liquid Films.—The characteristic equation hitherto developed refers to the state of an element of mass in the interior of a homogeneous substance: it does not apply to matter in the neighbourhood of an interface between two adjacent phases. A remarkable analysis has been developed by Gibbs in which the present methods concerning matter in bulk are extended to the phenomena at an interface, without the introduction of any molecular theory; it forms the thermodynamic completion of Gauss's purely mechanical theory of capillarity, based on the principle of energy. The validity of the fundamental doctrine of available energy, so far as regards all mechanical actions in bulk such as surface tensions, is postulated, even when applied to interfacial layers so thin as to be beyond our means of measurement; the argument from perpetual motions being available here also as soon as we have experimentally ascertained that the said tensions are definite physical properties of the state of the interface and not merely accidental. The procedure will then consist in assuming a definite excess of energy, of entropy, and of the masses of the various components, each per unit surface, at the interface, the potential of each component being, in equilibrium, the same as it is in the adjacent masses. The interfacial transition layer thus provides in a sense a new phase coexistent with those on each side of it and having its own characteristic equation. It is only the extent of the interface and not its curvatures that practically enters into this relation, because any slight influence of the latter can be eliminated from the equation by slightly displacing the position of the surface which is taken to represent the interface geometrically. By an argument similar to one given above it is shown that one of the forms of the characteristic equation is a relation expressing the surface tension as a function of the temperature and the potentials of the various components present on the two sides of the interface, from the differentiation of which the surface densities of the superficial distributions of these components (as above defined) can be obtained. The conditions that a given new phase may become developed when two other given ones are brought into contact, *i.e.*, that a chemical reaction may start at the interface, are thence formally expressed in terms of the surface tensions of the three transition layers and the pressures in the three phases. In the case of a thin soap-film, sudden extension of any part reduces the interfacial density of each component at each surface of the film, and so alters the surface tension, which requires time to recover by the very slow diffusion of dissolved material from other parts of the film; the system being stable, this change must be an increase of tension, and constitutes a species of elasticity in the film. Thus in a vertical film the surface tension must be greater in the higher parts, as they have to sustain the weight of the lower parts; the upper parts, in fact, stretch until the superficial densities of the components there situated are reduced to the amounts that correspond to the tension required for this purpose. Such a film could not therefore consist of pure water. But there is a limit to these processes: if the film becomes so thin that there is no water in bulk between its surfaces, the tensions cannot adjust themselves in this slow way by migration of components from one part of the film to another; if the film can survive at all after it has become of molecular thickness, it must be as a definite molecular structure all across its thickness. Of such type are the black spots that break out in soap-films, as has been suggested by Gibbs and proved by the measures of Reinold and Rücker: the spots increase in size because their tension is less than that of the surrounding film, but their indefinite increase is presumably stopped in practice by some clogging or viscous agency at their boundary.

Transition to Molecular Theory.—The subject of energetics, based on the doctrine of available energy, deals with matter in bulk and is not concerned with its molecular constitution. This analysis of the phenomena of surface tension shows how far the principle of negation of perpetual motions can carry us into regions which at first sight might be classed as molecular. But, as in other cases, it is limited to pointing out the general scheme of relations within which the phenomena can have their play. There is now a considerable body of knowledge correlating surface tension with chemical constitution, especially to a certain extent with the numerical density of the distribution of molecules; this takes us into the sphere of molecular science, and at present we have only somewhat vague indications largely derived from experiment, if we except the mere notion of interatomic forces of unknown character on which the older theories of capillarity, those of Laplace and Poisson, were constructed.

In other topics the same restrictions on the scope of the simple statical theory of energy appear. From the ascertained behaviour in certain respects of gaseous media we are able to construct their characteristic equation, and correlate their remaining relations by means of its consequences. Part of the experimental knowledge required for this purpose are the values of the gas-constants, which prove to be the same for all nearly perfect gases. The doctrine of energetics can give no clue as to why this should be so; it can only construct a scheme for each simple or complex medium on the basis of its own experimentally determined characteristic equation. The explanation of uniformities in the intrinsic constitutions of various media belongs to molecular theory, which is a distinct and in the main more complex and more speculative department of knowledge. When we proceed further and find, with van 't Hoff, that these same universal gas-constants reappear in the relations of very dilute solutions, our demand for an explanation such as can only be provided by molecular theory (as *supra*) is intensely stimulated. But except in these respects the doctrine of energetics gives a complete synthesis of the course and relations of the chemical reactions of matter in bulk, from which we can eliminate atomism altogether by restating the merely numerical atomic theory of Dalton as a principle of equivalent combining proportions. Of recent years there has been a considerable school of chemists who insist on this procedure as a purification of their science from the hypothetical ideas as to atoms and molecules in terms of which its experimental facts have come to be expressed. A complete system of doctrine can be developed in this manner, but its scope will be limited. It makes use of one principle of correlation, the doctrine of available energy, and discards another such principle, the atomic theory. Nor can it be said that the one principle is really more certain and definite than the other. This may be illustrated by what has sometimes in Germany been called Gibbs's paradox: the energy that is available for mechanical effect in the inter-diffusion of given volumes of two gases depends only on these volumes and their pressures, and is independent of what the gases are; if the gases differed only infinitesimally in constitution it would still be the same, and the question arises where we are to stop, for we cannot suppose the inter-diffusion of two identical gases to be a source of power. This then looks like a real failure, or rather limitation, of the principle; and there are other such, that can only be satisfactorily explained by aid of the complementary doctrine of molecular theory. That theory, in fact, shows that the more nearly identical the gases are, the slower will be the process of inter-diffusion, so that the mechanical energy will indeed be available, but only after a time that becomes indefinitely prolonged. It is a case in which the simple doctrine of energetics becomes inadequate before the limit is reached. The phenomena of highly rarefied gases provide other cases. And in fact the only reason hitherto thought of for the invariable tendency of available energy to diminish, is that it represents the general principle that in the kinetic play of a vast assemblage of independent molecules individually beyond our control the tendency is for the regularities to diminish and the motions to become less correlated: short of some such reason, it is an unexplained empirical principle. In the special departments of theoretical physics on the other hand, the molecular theory, there dynamical and therefore much more difficult and less definite, is an indispensable part of the framework of science; and even experimental chemistry now leans more and more on new physical methods and instruments. Without molecular theory the clue which has developed into spectrum analysis, bringing with it stellar chemistry and a new physical astronomy, would not have been available; nor would the laws of diffusion and conduction in gases have attained more than an empirical form; nor would it have been possible to weave the phenomena of electrodynamics and radiation into an entirely rational theory, as is now being done.

The doctrine of available energy, as the expression of thermodynamic theory, is directly implied in Carnot's *Essai* of 1824, and constitutes, in fact, its main theme; it took a fresh start, in the light of fuller experimental knowledge regarding the nature of heat, in the early memoirs of Rankine and Lord Kelvin, which may be found in their collected scientific papers; a subsequent exposition occurs in Maxwell's *Theory of Heat;* its most familiar form of statement is Lord Kelvin's principle of the dissipation of available energy. Its principles were very early applied by James Thomson to a physico-chemical problem, that of the influence of stress on the growth of crystals in their mother liquor. The "thermodynamic function" introduced by Rankine into its development is the same as the "entropy" of the material system, independently defined by Clausius about the same time. Clausius's form of the principle, that in an adiabatic system the entropy tends continually to increase, has been placed by Professor Willard Gibbs, of Yale University, at the foundation of his magnificent but complex and difficult development of the theory, "On the Equilibrium of Heterogeneous Substances," *Trans. Connecticut Academy*, 1876–78, pp. 320, abstracted by its author in the *American Journal of Science*, vol. xvi., which has been translated into German by Ostwald, and into French (as regards the more purely chemical part) by Le Chatelier. This monumental memoir made a clean sweep of the subject; and workers in the modern experimental science of physical chemistry have returned to it again and again to find their empirical principles forecasted in the light of pure theory, and to derive fresh inspiration for new departures. As specially preparatory to Gibbs may be mentioned Lord Rayleigh's memoir on the thermodynamics of gaseous diffusion (*Phil. Mag.*, 1876), which has been expounded by Maxwell in the 9th edition of the *Ency. Brit.* (vol. vii. p. 214, art. DIFFUSION). The fundamental importance of the doctrine of dissipation of energy for the theory of chemical reaction had already been insisted on in general terms by Rayleigh; subsequent to, but independently of, Gibbs's work it had been elaborated by von Helmholtz (*Gesamm. Abhandl.* ii. and iii.) in connexion with the thermodynamics of voltaic cells, and more particularly in the calculation of the free or available energy of solutions from data of vapour-pressure, with a view to the application to the theory of concentration cells, therein also coming close to the doctrine of osmotic pressure. Expositions and developments on various lines will be found in papers by Riecke and by Planck in *Annalen der Physik* between 1890 and 1900, in the course of a memoir by Larmor, *Phil. Trans.*, 1897, A, in Voigt's *Compendium der Physik*, in Planck's *Vorlesungen über Thermodynamik*, and in Duhem's elaborate *Traité de Mécanique Chimique* and *Le Potentiel Thermodynamique.* Numerous actual applications are expounded in van 't Hoff's *Lectures on Chemical Physics*, translated by Lehfeldt.

See also THERMODYNAMICS. (J. L*.)

Enfield, a township in the Enfield parliamentary division of Middlesex, England, 10 miles north of London by rail. There are nine Established churches (one containing ancient memorials); also Roman Catholic and various Nonconformist chapels. Recent erections are a church institute, parish hall, and public library. Associated with Enfield by residence have been Charles Lamb, Isaac D'Israeli (born here in 1766), Babbage the mathematician, Captain Marryat the novelist, and Keats the poet, who were educated within the parish. Area of township (an urban district), 12,600 acres. Population (1881), 18,944; (1901), 42,738.

Enfield, a town of Hartford county, Connecticut, U.S.A., on the east bank of the Connecticut river, and traversed by the New York, New Haven, and Hartford Railways. It includes an area of 35 square miles, containing a considerable rural population, together with the villages of Enfield, Thompsonville, and Hazardville. It is mainly known from its manufacture of gunpowder. Population of the town (1880), 6755; (1890), 7199; (1900), 6699.

Engadine, the upper or Swiss portion of the Valley of the Inn. Its length from the Maloja to Martinsbruck, by an excellent high road, is 59½ miles, of which 26¾ miles are in the Upper Engadine and the rest in the Lower Engadine. The *Upper Engadine* is now best known as one of the great "air cures" of Europe, especially in winter, though the mineral waters of St Moritz are also much employed in the summer time. Many good carriage roads lead to the Upper Engadine over the Maloja, Julier, Albula, and Bernina Passes, all built between 1820 and 1865. A railway is now being constructed by the Albula (tunnel beneath the pass). The *Lower Engadine* begins at the Punt 'Ota, close to the hamlet of Brail. It is far more picturesque and more romantic than the flat, level valley of the Upper Engadine, but is not so well known to tourists, though the waters of Tarasp have long been celebrated. The Lower Engadine is poor in carriage roads over the side passes, there being but two —over the Flüela Pass to Davos, and over the Ofen Pass to Mals, the former built in 1867, and the latter in 1871–72. Since 1282 the Lower Engadine has been separated from Tirol by the wild and savage gorge of Finstermünz, passable only on foot, the carriage road from Martinsbruck to Pfunds making a great ascent to Nauders, and then a great descent. In 1900 the population of the Upper Engadine (capital, Samaden, 1028 souls) was 5498, and that of the Lower Engadine (capital, Schuls, 1116 souls) 6275. Practically the whole population speaks the quaint Romance dialect known as Ladin.

Engels, Friederich (1820–1896), German Socialist. See MARX.

Engineers, Military.—Military engineers first came to England with William of Normandy in 1066, and until the 18th century all engineers were military. They were the builders of castles and defensible strongholds, as well as the inventors, manufacturers, and directors in action of engines of war with which to attack or defend them. By the middle of the 13th century there existed an organized body of skilled workmen employed under a "chief engineer." At the siege of Calais in 1347 this corps consisted of masons, carpenters, smiths, tentmakers, miners, armourers, gunners, and artillerymen. At the siege of Harfleur in 1415, the chief engineer was designated Master of the King's Works, Guns, and Ordnance, and the corps under him numbered 500 men, including 21 foot-archers. Headquarters of engineers existed at the Tower of London before 1350, and a century later developed into the Office of Ordnance (afterwards the Board of Ordnance), whose duty was to administer all matters connected with fortifications, artillery, and ordnance stores.

Henry VIII. employed many engineers (of whom Sir Richard Lee is the best known) in constructing coast defences from Penzance to the Thames and thence to Berwick-on-Tweed, and in strengthening the fortresses of Calais and Guisne in France. He also added to the organization a body of pioneers under trenchmasters and a master trenchmaster. Charles II. increased the peace establishment of engineers and formed a separate one for Ireland, with a chief engineer who was also Surveyor-General of the King's Works. In both countries only a small permanent establishment was maintained, a special ordnance train being enrolled in war-time for each expedition and disbanded on its termination. The commander of an ordnance train was frequently, but not necessarily, an engineer, but there was always a chief engineer of each train. At the battle of Blenheim in 1704 Marlborough's ordnance train was commanded by Holcroft Blood, a distinguished engineer, who brought up the guns and placed them in position. But after the rebellion of 1715 it was decided to separate the artillery from the engineers, and the royal warrant of 26th May 1716 established two companies of artillery as a separate regiment, and an engineer corps composed of 1 chief engineer, 3 directors, 6 engineers-in-ordinary, 6 engineers extraordinary, 6 sub-engineers, and 6 practitioner engineers. From this warrant the Royal Artillery date their birth and the Royal Engineers their release from artillery duties.

Until 14th May 1757 officers of engineers frequently held, in addition to their military rank in the corps of engineers, commissions in foot regiments; but on and after that date all engineer officers were gazetted to army as well as engineer rank—the chief engineer as colonel of foot, directors as lieutenant-colonel, and so forth down to practitioners as ensigns. On 18th November 1782 engineer grades, except that of chief engineer, were abolished, and the establishment was fixed at: 1 chief engineer and colonel, 6 colonels commandant, 6 lieutenant-colonels, 9 captains, 9 captain lieutenants (afterwards second captains), 22 first lieutenants, and 22 second lieutenants. Ten years later a small invalid corps was formed. On 25th April 1787 the designation "Royal" was conferred upon the engineers, and its precedence settled to be on the right of the army, with the royal artillery.

In 1802 the title of Chief Engineer was changed to Inspector-General of Fortifications. From this time to the conclusion of the Crimean War various augmentations took place, consequent on the increasing and widely extending duties thrown upon the officers. These, in addition to ordinary military duties, comprised the construction and maintenance of fortifications, barrack and ordnance store buildings, and all engineering services connected with them. The cadastral survey of the United Kingdom (called the "Ordnance Survey") had been entrusted to the engineers as far back as 1784, and absorbed many officers in its execution. Officers were also selected for various important civil positions, such as permanent under-secretaries of State, colonial governors, railway inspectors, mint-masters, consuls-general, international boundary and other commissioners, colonial engineers and surveyors-general, directors of Admiralty works, and so on.

On 6th March 1772 the formation at Gibraltar of "The Company of Soldier Artificers," officered by Royal Engineers, was authorized, and a second company was added soon afterwards. By royal warrant of 10th October 1787 "The Corps of Royal Military Artificers" was established at home, consisting of six companies, with which the Gibraltar companies were amalgamated. In 1806 this corps was doubled, and in 1811 increased to 32 companies. In 1813 its title was changed to "The Royal Sappers and Miners." On 12th October 1856, at the close of the Crimean War, it was incorporated with "The Corps of Royal Engineers," by whom it had always been officered. At that date the corps numbered about 340 officers and 4000 non-commissioned officers and men, comprised in 1 troop and 32 companies.

In 1770 the East India Company reorganized the engineer corps of the three Presidencies, composed of officers only. Native corps of sappers or pioneers were formed later, and officered principally by engineers. The officers of engineers were employed in peace-time on the public works of the country, their services when required being placed at the disposal of the military authorities. The Indian Engineers have not only distinguished themselves in the operations of war, but have left monuments of engineering skill in the irrigation works, railways, surveys, roads, bridges, public buildings, and defences of the country. When Indian administration was transferred to the Crown (1862) the Indian Engineers became "Royal," and have since almost died out, so that there now exists but one corps, the Royal Engineers.

The corps is composed of about 1000 officers of all ranks, and 7700 warrant and non-commissioned officers and men. Of the officers some 220 are attached to units, about 400 are employed either at home or in the colonies on engineering duties in military commands, on the staff, or on special duty, and about 370 are on the Indian establishment.

The head of the corps at the War Office is the Inspector-General of Fortifications, who is assisted by two deputy inspectors-general of fortifications, one in charge of the fortification subdivision and the other of the barrack subdivision. Each of these deputies has two assistant inspectors-general with a staff of officers, warrant officers, civil surveyors, clerks, and draughtsmen. There is at the present time a third deputy inspector-general with his staff, forming a special barrack subdivision for the administration of the loans for the construction of new barracks. In the fortifications subdivision the deputy inspector-general has under him inspectors of submarine mining defences and of iron structure with their staffs. A post-captain of the Royal Navy and a field officer of artillery are attached to the office of the Inspector-General of Fortifications as expert advisers. A deputy adjutant-general and an assistant adjutant-general of Royal Engineers, under the adjutant-general to the forces and in consultation with the Inspector-General of Fortifications, deal with all questions of *personnel* of the corps and the armament and equipment in its possession.

The officer commanding the Royal Engineers in a military district or command is called the District Commanding Royal Engineer, and is the staff officer of the general or other officer commanding for engineer services. A district is generally divided into subdistricts, to each of which is appointed a Subdistrict Commanding Royal Engineer, who carries out the engineer services in the subdistrict by means of a staff of officers of Royal Engineers, military foremen of works, and other subordinates, and is responsible to the District Commanding Royal Engineer. The senior officer of Royal Engineers in Ireland is called the Chief Engineer.

(R. H. V.)

ENGINES.

1. Steam Engines.

Recent developments in steam engineering have been directed, for the most part, towards improving the efficiency of the engine as a thermodynamic machine. Increase in speed, with consequent increase in the power developed by an engine of given weight, has also been aimed at, and the mechanical problems involved in high-speed running have received much attention. Reduction of weight is in some cases a matter of primary importance, but much more generally the chief consideration is that the engine may convert into work as large as possible a fraction of the heat which is supplied to it. The early progress of steam engineering was largely empirical; in the most recent developments the influence of theory is apparent. Recognizing that thermodynamic principles establish a limit of efficiency which in given conditions cannot be surpassed, engineers have directed their attention to tracing, and as far as possible removing, the causes which make the real performance fall short of this ideal. Any scientific criticism of the actual steam engine requires that we should in the first place consider what is the ideal which may fairly be set up as a standard with which the real performance is to be compared.

Theoretical limits of efficiency.

In the sketch of thermodynamics as applied to heat engines which was given in the article STEAM ENGINES in the ninth edition of this *Encyclopædia*, it was shown that the action of a heat engine depends on its receiving heat at a temperature higher than that at which it is capable of rejecting heat to surrounding objects. The working substance in the engine must necessarily pass from an upper temperature, at which it takes in heat, to a lower temperature, at which it rejects heat, the difference between the heat taken in and the heat rejected being the thermal equivalent of the work done. It was further shown that when the conditions are such as to make this difference as great as possible,—in other words, to make the efficiency reach its ideal limit,—the ratio of the heat taken in to the heat rejected depends only on the temperature at which reception and rejection of heat occur. Calling τ_1 and τ_2 the absolute temperatures at which heat is taken in and rejected respectively, and Q_1 and Q_2 the quantities of heat taken in and rejected, the limit of efficiency is reached when

$$\frac{Q_1}{Q_2}=\frac{\tau_1}{\tau_2},$$

and the efficiency then has the value

$$\frac{Q_1-Q_2}{Q_1}=\frac{\tau_1-\tau_2}{\tau_1}.$$

In the ideal engine imagined by Carnot the action is of this simple character. The working substance is brought by adiabatic compression from the lower to the upper extreme of temperature. It then takes in heat, without changing in temperature. It then expands adiabatically until its temperature falls to the lower extreme, and at that temperature it rejects enough heat to restore it to its initial state, thereby completing a cycle of operations. The ideal cycle of Carnot is not, however, an appropriate standard with which to compare the action of a steam engine, for the steam engine makes no attempt to restore the working substance to its upper limit of temperature by adiabatic compression. Taking the case of a condensing engine, the working substance passes through a cycle of operations which, except for practical imperfections, has three stages corresponding to three of the stages in the Carnot process. At the boiler temperature it takes in heat; it then expands, doing work and falling in temperature towards the lower limit, at which condensation is to occur. It then gives out heat at this lower temperature by being condensed, and if the expansion were adiabatic the correspondence would so far be exact. But the stage of adiabatic compression is wanting, and its place is taken by the direct return of the condensed water to the boiler, a process which involves the heating of the water by its taking in heat at a varying temperature, which ranges from the lower to the upper limit. The chief part of the heat which the working substance receives is still taken in at the upper limit of temperature, during the process of evaporation, but a certain part has been taken in before this, namely, during the heating of the feed water, while the water had a lower temperature. Any heat so taken in loses something of its availability for conversion into work, because it is taken in at a temperature below the top of the range, and consequently the ideal efficiency of the cycle is reduced.

To determine the theoretical limit in the amount of work obtainable from a given quantity of heat in a cycle in which heat is taken in at various temperatures, let δQ represent that portion of the whole heat which is taken in at any temperature τ. The temperature of rejection of heat will be represented, as before, by τ_2. Then the amount of work which may be obtained under ideally favourable conditions from this portion of the heat is, by Carnot's principle,

$$\frac{\delta Q(\tau-\tau_2)}{\tau},$$

and the whole amount of work ideally obtainable in the complete process is to be found by calculating

$$\Sigma\frac{\delta Q(\tau-\tau_2)}{\tau},$$

where the summation includes all the heat that is taken in. In a steam engine using saturated steam the principal item in this sum is the latent heat L_1, which is taken in at constant temperature τ_1, during the change of state from water to steam. But there is, in addition, the heat taken in by the feed-water before it reaches the temperature at which steam is formed, and this may be represented as the sum of a series of elements $\sigma\delta\tau$ taken in at varying temperatures τ, where σ is the specific heat of water. Thus if W represents the thermal equivalent of the work theoretically obtainable per ℔ of steam, under ideally favourable conditions,

$$W=\Sigma\frac{\sigma\delta\tau(\tau-\tau_2)}{\tau}+\frac{L_1(\tau_1-\tau_2)}{\tau_1}.$$

The experiments of Regnault show that σ, within the limits of temperature that obtain in boilers, is a nearly constant quantity, and no serious error will be introduced in this integration by treating it as a constant, with a value equal to the mean value, as determined by Regnault, between the limits of τ_1 and τ_2. On this basis

$$W=\sigma(\tau_1-\tau_2)-\sigma\tau_2\log_\epsilon\frac{\tau_1}{\tau_2}+\frac{L_1(\tau_1-\tau_2)}{\tau_1}.$$

This expresses the greatest amount of work which a ℔ of steam can yield when the temperature τ_1 at which it reaches the engine and the temperature τ_2 at which it leaves the engine are assigned. It consequently serves as a standard with which the actual performance may usefully be compared. The actual yield per ℔ of steam is always considerably less, chiefly because the ideal condition of adiabatic expansion from the higher to the lower extreme of temperature is never satisfied.

In practice the lower limit of temperature, in a condensing engine, is in favourable cases about 100° Fahr., which corresponds to a pressure in the exhaust pipe of nearly 1 ℔ per square inch. Taking this as a fairly representative figure, the following table of values of W has been calculated for various pressures of admission. The table also gives the number of ℔ of steam which would be required per horse-power-hour under the same ideally favourable conditions. Taking the thermal unit to be equivalent to 778 foot-pounds, one horse-power-hour is equivalent to 2545 thermal units, and the ideal number of ℔ of steam per horse-power-hour is therefore got by dividing 2545 by W:—

Ideal Performance of Saturated Steam, assuming the Lower Limit of Temperature to be 100° *Fahr.*

Absolute Pressure of Supply in ℔ per Square Inch.	W Thermal Units.	Number of ℔ of Steam per Horse-Power-hour.
50	248	10·26
60	259½	9·81
70	269	9·46
80	277½	9·17
90	285	8·93
100	292	8·72
110	298	8·54
120	303½	8·39
130	308½	8·25
140	313	8·12
150	318	8·00
160	322	7·90
170	326	7·81
180	329½	7·73
190	333	7·66
200	335½	7·59
210	338½	7·53

The performance of the ideal engine may be exhibited graphically by drawing the pressure-volume curve or "indicator diagram" of the process, but a more interesting construction is to draw the diagram of entropy and temperature. The study of this diagram has contributed materially to the elucidation of steam-engine problems. Entropy is a condition of the working substance defined by the statement that when a substance takes in or rejects any quantity of heat δQ at the (absolute) temperature τ, its entropy is increased or reduced by the amount $\frac{\delta Q}{\tau}$. Thus $\Sigma\frac{\delta Q}{\tau}$ measures the whole change of entropy in a process which involves the taking in or rejection of heat at more than one temperature. We shall denote entropy by ϕ, and consider it as reckoned per unit of mass of the substance.

Entropy-temperature diagrams.

Since by definition of entropy $\delta\phi = \delta Q/\tau$, $\tau\delta\phi = \delta Q$, and hence if a curve be drawn with τ and ϕ for ordinates to exhibit the action of a working substance, the area under the curve, or $\int \tau d\phi$, being equal to $\Sigma\delta Q$, measures the heat which the substance has received or rejected during the operation which the curve represents.

In a reversible cycle of operations Carnot's principle shows that $\Sigma\frac{\delta Q}{\tau}=0$, and it is obvious in such a case that the entropy returns at the end of the cycle to its primitive value. The same result may be extended to a cycle which includes any non-reversible step, by taking account of the heat generated within the substance by such a step, as if it were heat communicated from outside, in the reckoning of entropy. Thus, for example, if at one stage in the cycle the substance passes through a throttle-valve, which lowers its pressure without letting it do work, the action is equivalent in effect to an adiabatic expansion, together with the communication to the substance, as heat, of the work which is lost in consequence of the irreversible expansion through the throttle-valve taking the place of adiabatic expansion against a piston. If this heat be included in the reckoning, $\Sigma\frac{\delta Q}{\tau}=0$ for the complete cycle.

The entropy-temperature diagram for any complete cyclic process is a closed curve, and the area it encloses, being the excess of the heat received over the heat rejected, measures the work done. The entropy-temperature diagram shares this useful characteristic with the pressure-volume diagram, but in addition it shows directly the heat received and the heat rejected by the areas under the forward and backward limbs of the curve. To draw the entropy-temperature diagram for the ideal steam engine, we have to reckon first the entropy which water acquires in being heated, and next the entropy $\frac{L_1}{\tau_1}$ which is acquired when the conversion into steam has taken place. Reckoning from any standard temperature τ_o, in the heating of the feed-water up to any temperature τ, the entropy acquired is

$$\phi_w = \int_{\tau_o}^{\tau} \frac{\sigma d\tau}{\tau},$$

and taking σ as sensibly constant,

$$\phi_w = \sigma(\log_\epsilon \tau - \log_\epsilon \tau_o).$$

During evaporation at τ_1 a quantity of heat L_1 is taken in at temperature τ_1, and hence the entropy of the steam

$$\phi_s = \phi_w + \frac{L_1}{\tau_1} = \sigma(\log_\epsilon \tau_1 - \log_\epsilon \tau_o) + \frac{L_1}{\tau_1}.$$

There results the diagram illustrated in Fig. 1, where ab, a

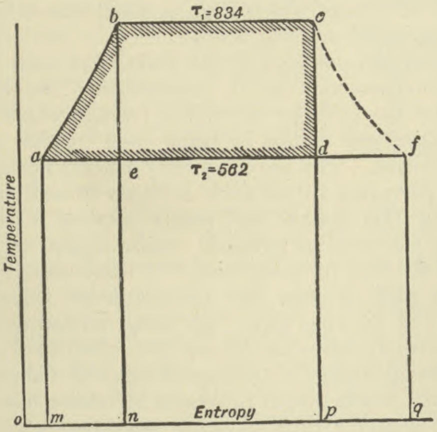

Fig. 1.

logarithmic curve, represents the process of heating the feed-water, and bc the passage from the state of water into that of steam. The diagram is drawn to scale for a case in which steam is formed at a pressure of 180 ℔ per square inch, and condensed at a pressure of 1 ℔ per square inch. After the formation of the steam, the next step in the ideal process is adiabatic expansion from the higher to the lower limit of temperature, which is represented by the vertical straight line cd, an adiabatic process being also isentropic. Finally, the cycle is completed by da, which represents the condensation of the steam after its temperature has been reduced by adiabatic expansion to the lower limit of temperature. The area $abcd$ represents the work done, and its value per ℔ of steam is identical with W as reckoned above. The area $mabcp$ is the whole heat taken in, and the area $madp$ is the heat rejected.

Further, let a curve cf be drawn to show the values of the entropy of steam for various temperatures of saturation: then if ad be produced to meet the curve in f, the ratio $\frac{fd}{fa}$ represents the fraction of the steam which was condensed during adiabatic expansion. For the point f represents the state of 1 ℔ of saturated steam, and in the condensation of 1 ℔ of saturated steam the heat given out would be the area under fa, whereas the heat actually given out in the condensation from d was the area under da. Thus the state at d is that of a wet mixture in which $\frac{da}{fa}$ represents the fraction present as steam, and $\frac{fd}{fa}$ the fraction present as water. It obviously follows that by drawing horizontal lines at intermediate temperatures the development of wetness in the expanding steam can be readily traced. Again, if the steam is not dry when expansion begins, its state may be represented by making the expansion line begin at a point in the line bc, such that the segments into which the line is divided are proportional to the constituents of the wet mixture. In this way the ideal process may be exhibited for steam with any assumed degree of initial wetness. Further, the entropy-temperature diagram admits of ready application to the case of incomplete expansion. Suppose, for example, that after adiabatic expansion from c to c' (Fig. 2) the steam is

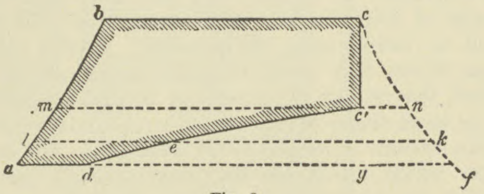

Fig. 2

directly cooled to the lower-limit temperature by the application of cooling water instead of by continued expansion. This process is represented by the line $c'ed$, which is a curve of constant volume. Its form is determined by the consideration that at any point e the proportion of steam still uncondensed, or $\frac{le}{lk}$, is such that the mixture fills the same volume as was filled at c'.

In the above calculation of ideal performance, and in the diagrams which have been sketched, it has been assumed that the steam is supplied to the engine in a saturated state. To extend the same treatment to the case of superheated steam, we have to take account of the supplementary supply of heat which the steam receives after the point c is reached, and before expansion begins. When superheating is resorted to, as is now often the case in practice, the superheat is given at constant pressure. If κ represent the specific heat of steam at constant pressure, the addition of entropy during the process of superheating from τ_1 to τ' is $\kappa(\tau' - \tau_1)$. In the absence of precise knowledge regarding the value of κ it is usually treated as a constant, and the addition to the entropy may then be written as $\kappa(\log \tau' - \log \tau_1)$. This gives a line such as cr on the entropy diagram (Fig. 3), and increases the value of W by the amount $\int_{\tau_1}^{\tau'} \frac{\kappa d\tau(\tau-\tau_2)}{\tau}$, which is represented on the diagram by the area $dcrs$. During adiabatic expansion from r the steam remains superheated until it reaches the state t,

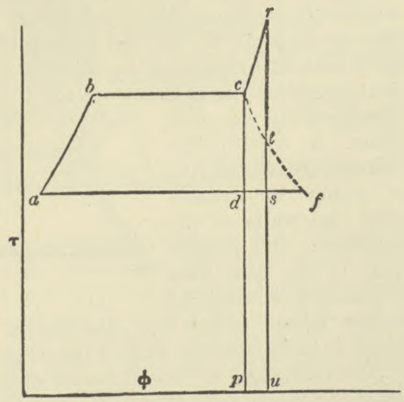

Fig. 3.

when it is just saturated, and further expansion results in the condition of wetness indicated by *s*. The extra work *d c r s* is done at the expense of the extra supply of heat *p c r u*, and an inspection of the diagram suffices to show that the efficiency of the ideal cycle is only very slightly increased by even a large amount of superheating. In practice, however, superheating does much to promote efficiency, because it materially reduces the amount by which the actual performance of an engine falls short of the ideal performance, by keeping the steam comparatively dry in its passage through the engine, and thereby reducing exchanges of heat between the steam and the metal.

Actual performance.

Trials of engines using saturated steam show that in the most favourable cases from 60 to 65 per cent. of the ideally possible amount of work is realized as "indicated" work. One of the causes of loss is that the expansion is incomplete. In practice the steam is allowed to escape to the condenser, while its pressure is still considerably higher than the pressure at which condensation is to take place. When the pressure of steam in the cylinder has been so far reduced by expansion that it can only overcome the friction of the piston, there is no advantage in going on further; the indicated work due to any additional expansion would add nothing to the output of the engine, when allowance is made for the work spent on friction within the mechanism itself. Considerations of bulk often lead to an even earlier release of the expanding steam; and another consideration which points the same way is that when expansion is carried very far, the losses due to exchange of heat between the cylinder and the steam, referred to below, tend to increase. Again, since experience shows that the most efficient engines are those in which the process of expansion is divided into two, three, or more stages by the use of compounded cylinders, a certain amount of loss is to be ascribed to the drops in pressure which are liable to occur through unresisted expansion in the transfer of steam from one vessel to another. But the chief cause of loss is to be found in the exchanges of heat which take place between the steam and the metal. In each cylinder there is a process of alternate condensation and re-evaporation—condensation during the period of admission, when the steam finds itself brought into contact with metal which has been chilled by evaporation during the preceding exhaust stroke, and then evaporation, when the pressure has fallen sufficiently, during the later stage of expansion as well as during exhaust. The consequence is that the steam, though supplied in a dry state, may contain some 20 or 30 per cent. of moisture when admission to the cylinder is complete, and the entropy diagram for the real process of expansion takes a form such as is indicated by the line c' c'' in Fig. 4. The heat supplied is still measured by the area under *a b c*. The condensation from *c* to c' occurs by contact with the walls of the cylinder; and though part of the heat thus abstracted is restored before release occurs at c'', the general result is to make a large reduction in the area of the diagram.

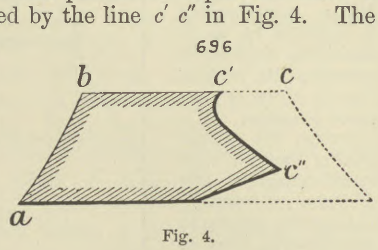

Fig. 4.

The exchanges of heat between steam and metal in the engine cylinder have been made the subject of an elaborate experimental examination by Professors Callendar and Nicolson (see *Min. Proc. Inst. C.E.* vol. cxxxi. p. 147), who studied the cyclic variations of temperature throughout the metal by means of thermo-electric junctions set at various depths. They found that the range of temperature through which the surface of the metal fluctuates is much less than the range of temperature passed through by the steam; the processes of condensation and re-evaporation are slow, and the time is too short to bring the surface of the metal into anything like equilibrium with the steam. The amount of condensation up to the point of cut-off, as inferred from the heat which the metal takes up, is also much less than the "missing quantity" or difference between the steam supplied per stroke and the dry steam then present. According to their experiments, the discrepancy is accounted for by leakage of steam past the valve, direct from the steam chest to the exhaust, and they suggest that this source of error may have been present in many estimates of initial condensation based on determinations of the missing quantity. This may explain cases in which the initial condensation has apparently been excessive, but large amounts of initial condensation certainly do occur, and constitute the most potent factor in making the real performance of the engine fall short of the ideal standard.

In the alternate condensation and re-evaporation of steam in the cylinder more heat is given to the metal by each pound of steam that is condensed than is taken from the metal by each pound of steam that is re-evaporated, the temperature of condensation being higher than that of re-evaporation. The quantity $H_1 - H_2$, namely, the difference of total heat at the two temperatures, represents this excess of heat. Unless this is in some way abstracted from the metal, the process cannot occur. Hence the action of the cylinder walls in causing alternate condensation and re-evaporation to occur may be limited by imposing conditions which prevent or reduce the abstraction of heat. By the use of a steam jacket the metal may be prevented from losing heat externally, and may even be made to take up heat. Under these conditions the action depends on the fact that more water is re-evaporated than is condensed. To some extent this is a necessary result of the work done during expansion, which (in an adiabatic process) would make the steam become wetter as expansion proceeds, and would therefore leave more water to be evaporated than is initially condensed by the action of the cylinder walls. But it is important to notice that any water which is introduced into the cylinder along with the steam will be an important factor in supplying the means by which this thermal balance is maintained. With steam that is perfectly dry before admission the action of the walls takes its limit from the condensation which expansion brings about; with steam that is wet before admission no such limit applies. Hence the importance of having steam that is initially dry. To secure this, no method is so certain as to give some initial superheat to the steam, and hence the practical advantage which even a small amount of superheating is found to bring about.

To a considerable extent the slide-valve itself promotes initial condensation, for it requires that the hot steam shall enter the cylinder through a passage which, immediately before, was chilled by being used for the escape of exhaust steam. The use of entirely distinct admission and exhaust ports and valves tends towards economy of steam, partly for this reason and partly because it allows the clearance spaces to be reduced. Accordingly, we find that many of the best recorded results of tests relate to engines in which each cylinder has four separate valves of the Corliss or of the drop type. By using horizontal cylinders with admission valves on the top and exhaust valves below, the further advantage of drainage through the exhaust valves is secured. Water which is present at release has then the chance of escaping without being re-evaporated, a circumstance which contributes largely to reduce the exchange of heat between the working substance and the metal. Thus a horizontal triple-expansion engine with drop valves, by Messrs Sulzer, using saturated steam at an absolute pressure of 160 ℔ per square inch, and indicating not much more than 200 horse-power, is reported, in a test by Professor Stodola, to have used only 11·52 ℔ of steam per indicated horse-power-hour (see *Engineer*, 1st July 1898; also summary of trials by B. Donkin, *Ibid.*, 13th October 1899). By the table given above it will be seen that the ideal consumption for the same pressure of supply will be 7·9 ℔. The performance in the test is therefore equivalent to nearly 69 per cent. of the ideal, an exceptionally high figure. In other particularly favourable records of trials the consumption of steam with triple-expansion engines has been found to lie between 12 and 13 ℔ per indicated horse-power-hour. Some of the best results relate to slow-running pumping engines fitted with steam jackets on the barrels and on the covers of the cylinders, and may be taken as showing how influential, in a long-period engine, the jacket may prove in reducing the evils of initial condensation. In the mean of several apparently authoritative trials by different observers on different engines, the consumption of steam was 12·2 ℔ per horse-power-hour, at an absolute pressure of about 140 ℔ per square inch, which corresponds to 66 per cent. of the ideal performance. It should be added that these figures are exceptional. A consumption of 13 or 14 ℔ of steam per horse-power-hour is much more usual even in large and well-designed triple-expansion engines; and with two-cylinder compound engines, using steam with an absolute pressure of 100 or 120 ℔ per square inch, anything from 14 to 15 ℔ may be reckoned a good performance.

Experimental results as to efficiency.

Willans engine.

Amongst comparatively recent developments in steam-engine practice a conspicuous place must be given to the work of the late Mr P. W. Willans, who, both by his design and manufacture of engines and by his published trials, did much to introduce a highly successful type of engine, the characteristic of which is great frequency of stroke. The quicker the period of the engine, the less time is there given for exchanges of heat to take place between the working substance and the metal, and consequently the more near is the approach towards adiabatic action. Thus high frequency tends to reduce the deleterious action of the cylinder walls, and in this respect to cause a close approximation to the condition of the ideal engine. As a partial set off, however, it augments to some extent the losses by throttling in admission and exhaust and in transfer from one cylinder to another, and it presents to the designer what is in several respects a more difficult mechanical problem than he has to face in dealing with low speeds. The comparatively high speed of rotation required in the driving of dynamo-electric machinery has been an important factor in stimulating the use of high-frequency engines, which admit of being directly coupled to high-speed dynamos without the intervention of gearing. Most, though by no means all, of such high-speed engines are of the single-acting class, of which the Willans engine is a conspicuous example. In this the piston-rods are vertical, and steam is admitted to the upper side only of each piston, with the result that the rods are kept in a state of thrust throughout the action, and no reversal of stress is allowed to occur at the joints. Notwithstanding the admission of steam to one side only, reversal of thrust would occur, as a consequence of the inertia of the reciprocating parts, if special means were not taken to prevent it. This is done by introducing a cushion cylinder in which air is compressed during the up-stroke of the piston, so that the energy which the reciprocating masses have to part with during the second half of their up-stroke is absorbed in compressing air, and is restored during the down-stroke. In the compound and triple expansion forms of this engine the two or three compounded cylinders are set in tandem, and the space below the upper piston serves as an intermediate receiver. In some of the smaller engines a single crank is used, but generally two or three sets of cylinders are grouped in parallel vertical lines, each set acting on one crank. The piston-rod of each set is hollow, and within it there is a valve-rod furnished with piston-valves for the admission and release of the steam. The valve-rod is worked by an eccentric on the crank-pin, so that it may have the proper relative movement with respect to the hollow piston-rod in which it works. The cross-head takes the form of a piston, which acts as the air-buffer to produce the cushioning referred to above. These features will be better understood by reference to Fig. 5, which

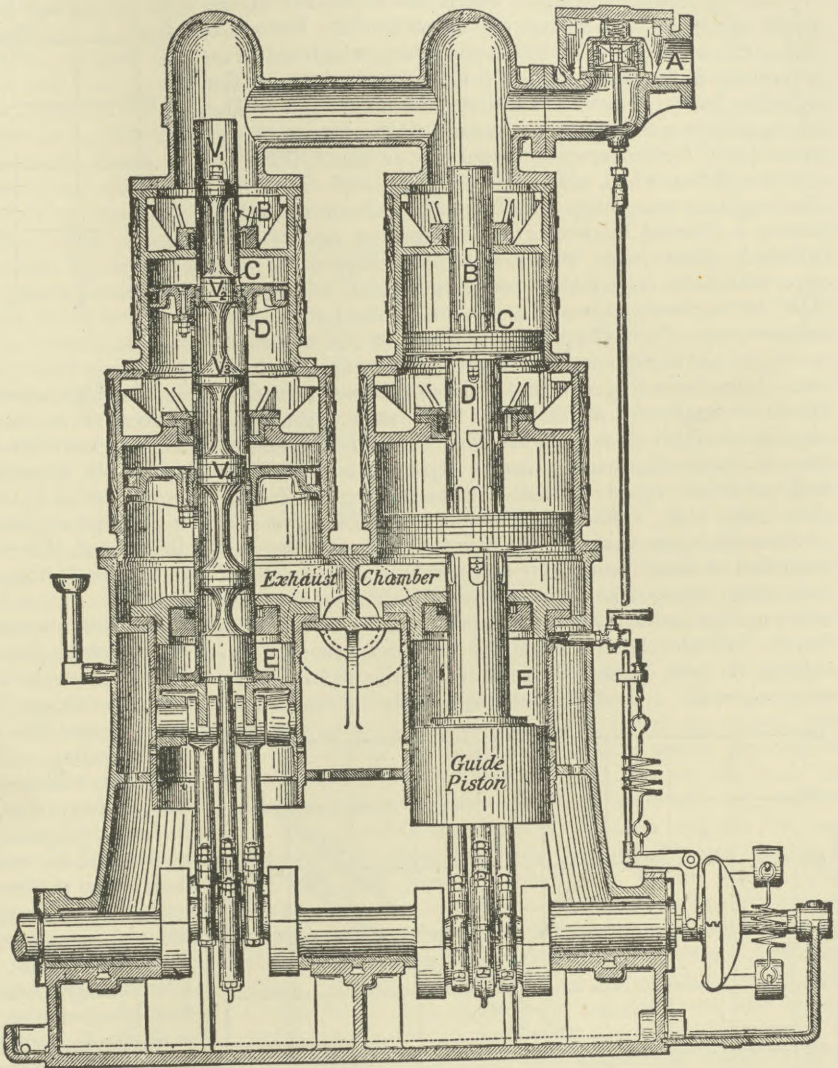

Fig. 5.

gives a section through the two lines of cylinders in a two-crank compound engine. The two lines are alike, but in the drawing the pistons and piston-rod of one line are shown in section, so that the piston-valves may be seen. Steam enters at A through a throttle valve which is controlled by a shaft governor, and is admitted to the topmost cylinder through the ports B and C in the hollow piston-rod. Cut-off occurs when the ports B are covered by disappearing into the gland of the top cylinder cover as the rod descends. Subsequently the relative motion of the valve-rod within makes the valve V_2 cover the port C, and near the end of the down-stroke the ports C and D are put in communication with each other between the valves V_2 and V_3, so that the steam which has expanded in the upper cylinder passes during the up-stroke into the space below the upper piston. From this space, which serves as a receiver, it is admitted in the next down-stroke to the cylinder below, where it continues its expansion. The air-cushion which prevents reversal of the thrust at the crank-pin is formed by compressing air in the cylinder E above a piston, which also serves as guide and cross-head. The engine is completely encased, and much of the lubrication is effected by letting the cranks dip into oil and splash it about freely within the case. Engines of this type with three cranks have been built which work up to 2400 horse-power, and engines of 1200 horse-power are in common use. In the larger sizes a speed of 200 or 250 revolutions per minute is usual; with small engines of the same type indicating one or two hundred horse-power the speed is commonly about 450. That such engines are capable of highly economical working was demonstrated by the remarkably thorough series of experiments carried out and published by Mr Willans ("Steam Engine Trials," *Proc. Inst. C.E.*, 1888 and 1893). An important feature of these trials was that they dealt not simply with the consumption of steam under the favourable conditions which hold when the engine is fully loaded, but also with the consumption under various amounts of light load, including the extreme case in which the engine is merely overcoming its own frictional resistance without doing any external work. To represent the results of such tests

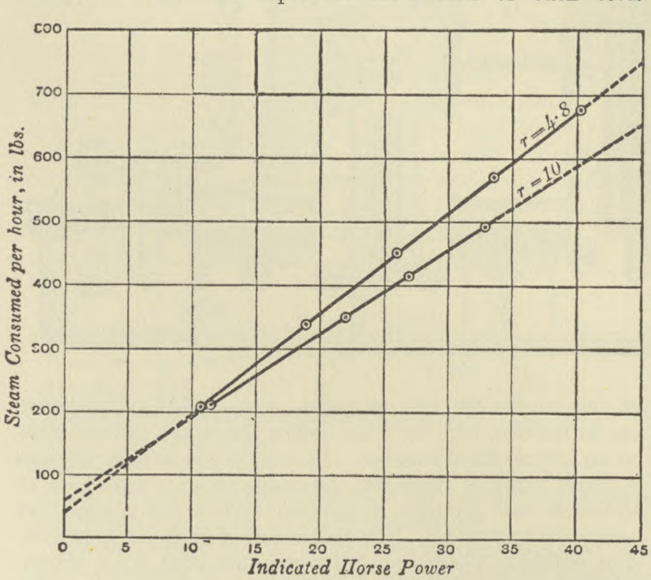

Fig. 6.

Willans introduced the practice of drawing curves which show the total consumption of steam per hour in relation to the horse-power. He found that the Willans line, as such a curve is now generally called, is sensibly straight when the reduction of power from full load to lighter load or to no load is effected by throttling the steam, while the point of cut-off remains unchanged. Examples of two such lines are given in Fig. 6, which shows the results of two tests by Willans of the same engine, using two different ratios of total expansion, namely, 4·8 and 10. Another useful curve is drawn by plotting the relation between the horse-power and the steam used per horse-power-hour; the same trials are exhibited in this way in Fig. 7.

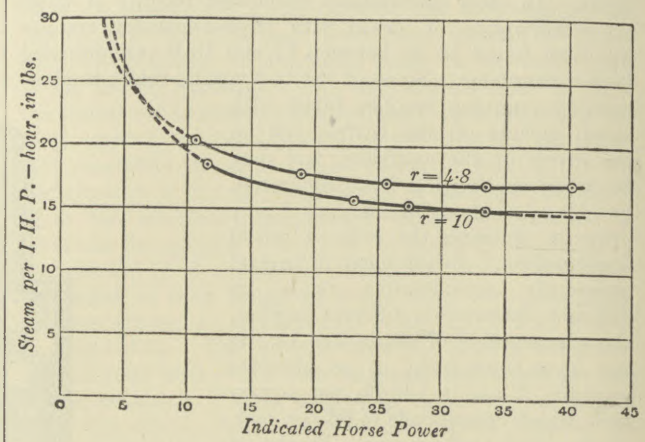

Fig. 7.

The high speed single-acting type of engine has been successful in the hands of more than one maker, and success has also attended efforts which have been made to secure the advantages of high speed without the sacrifice of power which is involved in single-action. Of double-acting high speed engines an interesting form is that of Messrs Belliss and Morcom, the chief distinctive feature of which is the use of forced lubrication at the pin-joints and shaft-bearings. In a double-acting engine, where the thrust acts alternately on one and the other side of the crank-pins and cross-head pins, high frequency of stroke tends to produce much knocking and wear unless the brasses are very closely adjusted, and in that case the pins are liable to get hot, and to "seize" by expanding sufficiently to fill the small clearance. This difficulty, which exists when lubrication is carried out in the ordinary way, is overcome in the Belliss engine by feeding the bearings with a continuous supply of oil, which is pumped in under a pressure of about 15 ℔ per square inch. The presence of a film of oil is thereby continuously secured, and knocking is prevented although the brasses are not set very close (see Dales, "High-Speed Engines," *Proc. Inst. C.E.*, 1899; and Morcom "High-Speed Self-Lubricating Steam Engines," *Proc. Inst. Mech. Eng.*, 1898). Notable examples in which double action is combined with a relatively high frequency of stroke are found in naval engineering practice, especially in the engines of high-speed cruisers and torpedo-boat destroyers. As a rule these engines employ triple expansion, with four cranks and four cylinders, the third stage of the expansion being performed in two cylinders, which divide the steam between them. The steam is supplied from water-tube boilers at a pressure of about 250 ℔ per square inch. The engines of the *Powerful*, which develop nearly 26,000 horse-power under forced draught, have cylinders 45 inches, 70 inches, and two of 76 inches in diameter, with a stroke of 4 feet. The cylinder ratio is therefore 1 : 2·4 : 5·7. At 114 revolutions per minute the piston speed is 915 feet per minute, and the total weight of machinery per indicated horse-power is made up of 93 ℔ in the engine and 101 ℔ in the boilers, which are of the Belleville water-tube type. In recent torpedo-boat destroyers the mean piston

Other high-speed engines.

speed approaches 1200 feet per minute, with nearly 400 revolutions per minute and an 18-inch stroke, and the horse-power developed is about 6000. In some instances this is accomplished with a total weight of 50 lb per indicated horse-power, which is nearly equally divided between the engines and the boilers (Durston and Oram, "The Machinery of Warships," *Proc. Inst. C.E.*, 1899).

Balancing. In such engines, and in other cases where quickly reciprocating masses have to be dealt with, the problem of balancing the forces due to inertia assumes great importance. This is especially true of marine engines, on account of the absence of massive foundations; but even in land engines a want of balance may, at high speeds, cause enough vibration to constitute a serious nuisance. In considering the question of balance, the system of excentrically revolving masses and the system of reciprocating masses have to be considered separately. A reciprocating mass such as a piston cannot be balanced by the use of revolving masses, for the forces which are due to the inertia of the piston necessarily act along the line of its stroke, while those due to revolving masses are continually changing their direction. The inertia of each connecting-rod may be approximately treated by resolving its mass into two constituents, one of which moves with the crank-pin, and is therefore an addition to the revolving system, while the other moves with the cross-head, and is therefore an addition to the reciprocating system. The mass of the rod may be divided for this purpose into parts which are inversely proportional to the distances of its centre of gravity from the crank-pin and the cross-head respectively. Let M_1, M_2, M_3, &c., represent the various revolving masses, r_1, r_2, r_3, &c., their effective radii of rotation, and a_1, a_2, a_3, &c., their distances from any assumed plane of reference taken perpendicular to the shaft. Then the conditions necessary for balance amongst them are that the vector sum of $M r$ shall vanish, and also that the vector sum of $M a r$ shall vanish, this latter quantity being the resultant of the moments of the centrifugal forces with respect to the plane of reference. In a four-crank engine there is no serious difficulty in arranging the revolving masses in such a manner that these conditions shall be satisfied, so far as those masses are concerned. The problem, as Professor Dalby has shown, lends itself readily to graphical treatment (see "Balancing of Engines," *Trans. Inst. Naval Architects*, 1899). With respect to the reciprocating masses, a first approximation towards balance is attained by satisfying the conditions which would secure balance if the motions were simply harmonic. These conditions are identical with those which have just been stated for the revolving masses, when r is interpreted as the semi-amplitude of the harmonic motion. When the conditions in question are satisfied, the only remaining source of disturbance is that which comes from the fact that the reciprocating masses are connected to the cranks by rods of finite length; in other words, that the motions are not simply harmonic. For this reason the force required to accelerate each piston is greater when the piston is at the end of the stroke farthest from the shaft than when it is at the other end, and consequently the balance, which would be perfect if the connecting-rods were indefinitely long, is disturbed by the presence of forces which vary periodically with a frequency twice that of the rotation. When three cranks, 120° apart, are employed, it will be found that the effect of the shortness of the connecting-rods in causing forces to act in the line of the stroke is almost completely eliminated; or rather the effect is reduced to a couple tending to tilt the engine in a fore and aft direction, which may in its turn be balanced by using a second set of three cranks on the same shaft, the second set being so arranged that the couple to which it gives rise neutralizes the couple due to the first set. A six-crank engine may be arranged in this way to secure an extremely close approximation to perfect balance, and the same state of balance can be secured when the number of cranks is reduced to five (see Robinson, "Single Acting High-Speed Engines," *Journ. Inst. Elec. Eng.*, 1895).

Superheated steam. The advantage of superheated steam, which arises mainly from its influence in reducing the exchange of heat between the steam and cylinder walls, was demonstrated by the experiments of Hirn, and as early as 1860 it was not unusual to supply superheaters with marine engines. But the practice of superheating was soon abandoned, chiefly on account of difficulties in regard to lubrication. By the introduction of heavy mineral oils this objection has been removed, and a revival in the use of superheating has recently taken place, with striking effect on the thermodynamic economy of engines. Experiments made in 1892 by the Alsatian Society of Steam Users on a large number of engines, showed that superheating effected an average saving in coal to the extent of about 20 per cent. when the superheater was simply placed in the boiler flue, so that it utilized what would otherwise be waste heat, and about 12 per cent. when the superheater was separately fired. In those cases the steam was superheated only about 60° or 80° Fahr. above the temperature of saturation, but in more recent practice much greater amounts of superheat have been successfully applied. Professor Schröter has tested a factory engine of 1000 horse-power, using steam superheated by some 93° Fahr., and has shown that this amount of superheat is not sufficient to prevent some of the steam from becoming condensed on the walls during admission to the cylinder (*Zeitschrift der Vereins deutscher Ingenieure*, vol. xl., 1896). It follows that still larger amounts of superheat will be thermodynamically advantageous. That this is the case has been demonstrated by the remarkable results which have been obtained with very highly superheated steam by Mr W. Schmidt. Using engines of somewhat special design, Mr Schmidt has shown that it is perfectly practicable to employ steam superheated by as much as 300° Fahr., and that an efficiency not attainable from steam in any other way is thereby reached. In several authentic trials of Schmidt engines the consumption of steam has been considerably less than 10 lb per indicated horse-power-hour,—a figure which, after allowance is made for the heat taken up during the process of superheating, represents a better performance than that of the best engines using saturated or slightly superheated steam. It has been found that the consumption of coal, in the boiler and superheater together, need not exceed $1\frac{1}{3}$ lb per indicated horse-power even with engines of small power. To attain this remarkable result it is of course necessary that, after the hot gases have passed the superheater, a further extraction of heat from them should take place. This is done by an economizer or feed-water heater of peculiar form, consisting of a long coil of small pipes which maintain a circulation of hot distilled water through a closed system containing an external coil, which forms the heater of a tank through which the feed-water passes on its way to the boiler. Some of the Schmidt engines adopt the principle of single action, to escape the necessity of having a piston-rod and gland on the side which is exposed to contact with high-temperature steam; but it is found that this precaution is not essential, and that with glands of suitable design a double-acting piston may be used without inconvenience, and without risk of undue wear. In some instances Mr

Schmidt transfers to the partially expanded steam in the intermediate receiver a portion of the heat which is conveyed to the engine by the highly superheated steam; and when this is done, the steam may properly receive a still higher degree of initial superheat. In tests by the present writer of a Schmidt plant indicating 180 horse-power, in which this device was employed, the initial superheat was as much as 385° Fahr., namely, from 360° Fahr., the temperature of saturation, to 745° Fahr. In this trial the temperature of the chimney gases was reduced, by the use of Mr Schmidt's feed-water, to 347° Fahr., and the consumption of coal was 1·31 ℔ per indicated horse-power-hour.

Steam turbines. The most interesting, and without doubt also the most important, feature of modern steam practice is the development of the steam turbine. In the hands of Mr C. A. Parsons the steam turbine has reached a degree of efficiency which equals, even if it does not surpass, that of the best engines of the piston and cylinder type. The mechanical problems to be solved before this result could be attained were of a high order of difficulty, but the success with which they have been overcome is not more conspicuous than the simplicity of the means by which it has been achieved. The central idea in the Parsons steam turbine has been to make the action compound; the steam is allowed to fall in pressure by a long series of steps, each step so small that the steam acquires comparatively little velocity through its drop in pressure. This enables the kinetic energy which is acquired in each step to be given up with a good degree of efficiency to turbine blades running at a moderate speed, before the steam passes on to acquire more velocity before it encounters the next series of moving blades. The whole turbine is made up of a long series of rings of moving blades, sandwiched between which there are rings of fixed blades, forming guides to deliver the steam with proper direction and velocity against the moving blades. The latter are mounted on a drum, from which they project radially outwards; the fixed blades project radially inwards from a casing, within which the drum revolves. The arrangement of guide

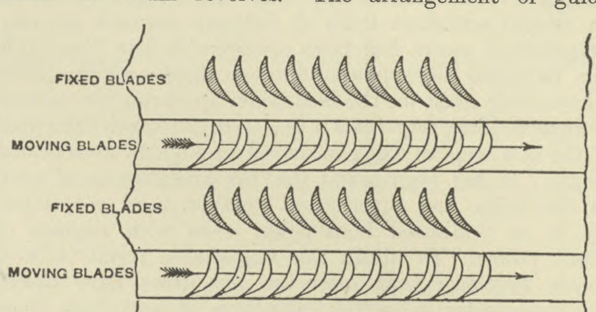

Fig. 8.

blades and moving blades is illustrated in Fig. 8, where the guide blades are shown in section. Fig. 9 shows a portion of the drum, with the moving blades projecting from it as they appear when part of the cover is removed. The general direction taken by the steam is parallel to the axis as it passes from ring to ring of blades. In its passage the energy of the steam is gradually extracted as it expands from a pressure which is in some cases as much as 200 or 250 ℔ per square inch, down to 1 ℔ per square inch. With a condenser it is practicable in the steam turbine to utilize pressures as low as can be reached; there is no such lower limit, as friction and other considerations impose in engines of the ordinary

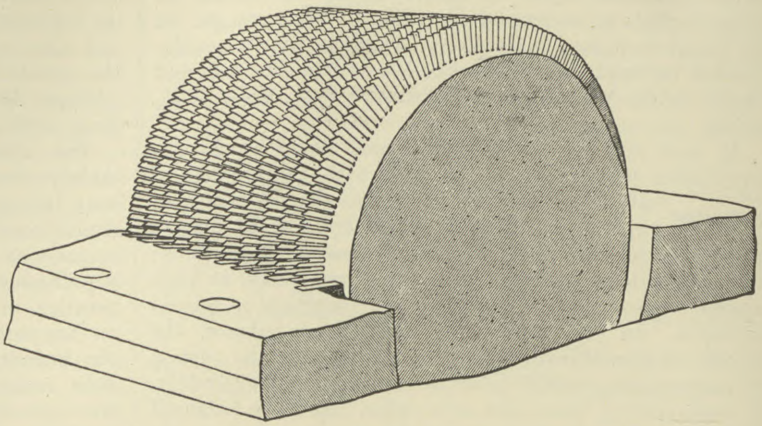

Fig. 9.

type. Even with this division of the whole expansion into many steps the speed of the turbine blades has to be fairly high; and to permit the shaft to revolve smoothly at a high speed the bearings are of a special design, which is shown in section in Fig. 10. In each bearing a number of coaxial cylindrical sleeves are slipped over the shaft to form the bush in which the shaft revolves, and oil is continuously pumped in under pressure. The result is that a film of oil is maintained round the shaft and between each sleeve and the one outside it. This gives the shaft some freedom to adjust itself by lateral displacement, but at the same time the viscosity of the oil films effectively damps out any oscillations which may tend to become set up. The general arrangement of a Parsons steam turbine is shown in Fig. 11, which is a section through a turbine with some eighty successive rings of moving blades. Steam is admitted to the turbine rings at A, and passes through them to the right, passing first through short and closely spaced blades, and then through blades which are longer and of coarser pitch, to give a greater area of passage as the pressure falls and the volume increases. It finally escapes to the condenser at B. The moving blades are grouped in three sets, on three drums of different diameters. Owing to the one-sided action of the steam, each of these drums is forced to the right; and to balance this pressure there are sets of "dummies" or balance-discs of corresponding diameter, which are forced with equal pressure to the left. These are shown at C, D, and E. Each dummy consists of a group of discs revolving in close juxtaposition to rings which project inwardly between the discs from the casing; and between each dummy and the corresponding portion of the turbine drum there is a channel, which secures that both shall be subjected to the same pressure of steam. Finally, a thrust block at F serves to take up any longitudinal force that may remain unbalanced. A worm on the turbine shaft at G gives a comparatively slow motion of rotation to the worm-wheel H, from the axis of which the air-pump and oil-pump are driven. Admission of steam takes place through the valve J, which is periodically lifted to let the steam enter in a series of gusts; and the speed of the turbine is regulated by adjusting the duration of each gust. The

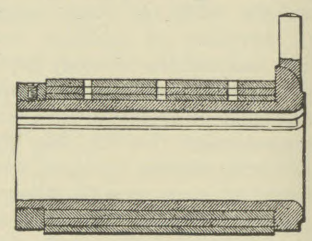

Fig. 10.

valve J is opened by the action of steam admitted through a small relay-valve K to the spring piston L. The duration of each gust depends on the amplitude of motion of the relay-valve K; and this is controlled by the governor, which acts by varying the position of the fulcrum of a rocking-lever M, by which the relay-valve is actuated. This lever is caused to rock periodically by a connexion between it and the worm-wheel H. When the turbine has only a light load, the rocking of the lever barely suffices to open the relay-valve, and each gust of steam is accordingly of very brief duration. When the load is heavy, the gusts are so long as to become blended into a nearly continuous blast. In turbines used for electric lighting, the control of the rocking-lever is usually effected by an electro-magnetic solenoid with the result that the speed is so regulated as to keep the volts constant; in

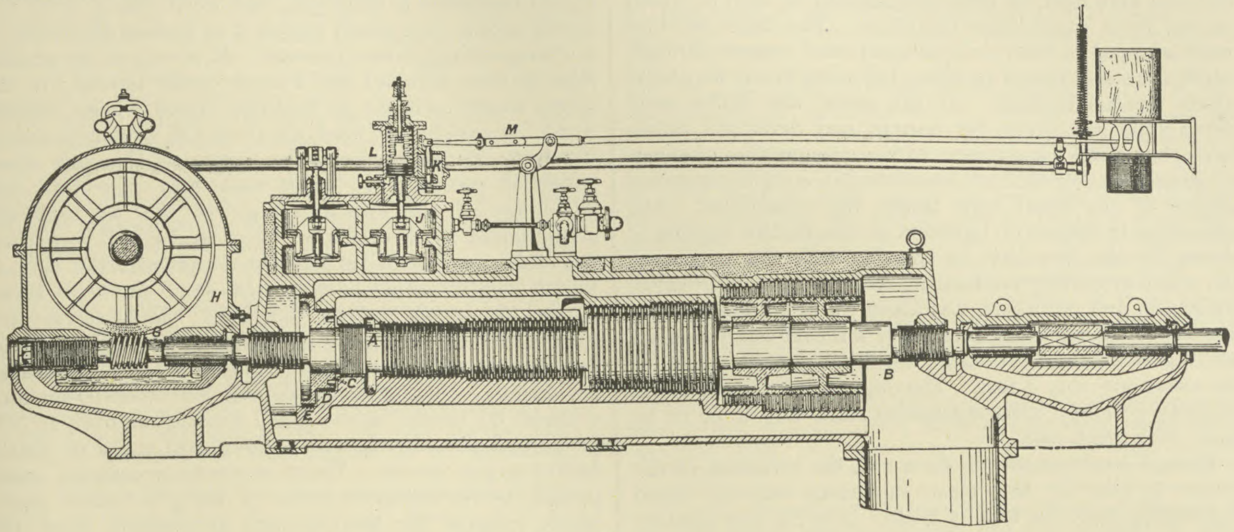

Fig. 11.

other cases the control is supplied by a centrifugal governor, which acts so as to preserve a uniform speed. This governor is remarkably effective; and a conspicuous merit of the steam turbine is that nearly the whole of the load may be suddenly thrown on or off without causing more than a trifling variation in the speed, and without in any way straining the machine. Another important mechanical advantage is the perfect balance of the moving parts,—a balance much more perfect than is attainable in any reciprocating engine,—which allows the steam turbine to be used with practically no foundations. Other points to be noted are the small internal friction of the turbine as a mechanism, its small weight and small size in relation to the power it develops, the extreme simplicity of its working parts, and the fact that as there are no rubbing surfaces exposed to the action of the steam, the steam can be kept free from oil, a matter of considerable moment in engines which condense the steam and return it to the boiler.

Efficiency.

The compound steam turbine dates from 1885, but it was not till 1891 that the introduction of the condensing type demonstrated that the turbine is capable of yielding results which are on a par, as regards efficiency, with those given by piston and cylinder engines. In the turbine one great source of loss is avoided which is present in the piston engine, namely, the periodic give and take of heat between the steam and the cylinder walls. On the other hand, the turbine suffers losses through leakage of steam in the clearance spaces round the blades and round the "dummies," as well as from the imperfect utilization of the kinetic energy acquired by the steam in each step of the expansion. The ideal return which the steam is capable of giving is the same in both types of engine; and though the sources of loss are very different in the two, it appears that their total effect in making the actual performance fall short of the ideal performance is, in the best cases, much alike. Large steam turbines succeed in utilizing between 60 and 70 per cent. of the energy which the steam is ideally capable of giving out, which is fully as high a fraction as is reached in the most favourable tests of large piston engines. With small turbines the results are less favourable, the losses due to clearance leakage being relatively greater. Trials made in April 1900 by the present writer of a Parsons turbine of about 2000 horse-power, running at 1500 revolutions per minute, directly coupled to a dynamo, gave striking evidence of the high degree of efficiency to which this type of engine has been brought. Electrical measurements were used to determine the effective output. In one of the trials, with steam at 155 ℔ per square inch, superheated 84° Fahr., the useful electrical output was 1435 kilowatts and the consumption of steam was 18¼ ℔ per kilowatt-hour. Since 1 kilowatt is 1·34 horse-power, this consumption is equal to 13·6 ℔ per electrical horse-power-hour. Trials of the best piston engines, driving dynamos, show that under the most favourable conditions about 84 per cent. of the indicated power may take the form of useful electrical output. Accordingly, the above result is equivalent to the performance of an engine using 11·4 ℔ of steam per indicated horse-power-hour. This represents about 68 per cent. of the work theoretically obtainable from the steam. An important characteristic of the steam turbine is that it maintains its efficiency while working under lighter loads. The table below illustrates this by giving the result of a series of trials of the same machine under various conditions as to load:—

Load in Kilowatts.	Consumption of Steam per Kilowatt-hour in ℔.
1450	18·1
1250	18·5
1000	19·2
750	20·3
500	22·6
250	34·0

The most considerable application of the steam turbine has hitherto been to the driving of dynamo-electric machinery, but Mr Parsons has demonstrated its suitability for the propulsion of steamships, and it may confidently be expected to come widely into use for this purpose. The *Turbinia*, a vessel of the dimensions of a torpedo-boat, fitted with Parsons steam turbines adapted to use steam with a pressure of fully 200 ℔ per square inch, achieved in 1897 the then unprecedented speed of $32\frac{3}{4}$ knots in trials on the measured mile; and more recently the *Viper*, a torpedo-boat destroyer with turbine engines of about 10,000 horse-power, built to the order of the British Admiralty, reached a speed of $35\frac{1}{2}$ knots. In the *Turbinia* three steam turbines were used, on three separate shafts, each of which carried three small screw propellers. The three turbines were arranged to form a single compound system through which the steam passed in series, becoming finally expanded about two-hundredfold. At full speed the shafts made about 2200 revolutions per minute, and developed rather more than 2000 horse-power, with a consumption of steam no greater than would have been found in a triple-expansion engine of the usual type under like conditions. The advantage in respect of lightness of the turbine engines is shown by the fact that in the *Turbinia* the weight of the whole propelling mechanism, including engines, boiler, condenser, and propellers, was about 22 ℔ per horse-power developed. The running machinery was completely encased and was well below the water-line, although the draught of the vessel was only 3 feet. The engines were found to be remarkably handy, allowing sudden starts and stops to be made with great ease.

Applications.

Enough has been said to show that the invention of the steam turbine is the most important step in steam engineering since the time of Watt. It is the first solution of the problem of using steam efficiently in an engine without reciprocating parts. The object in most steam engines is to deliver power to revolving machinery, and much ingenuity has been expended in attempts to devise engines which will produce rotation directly, instead of by conversion of reciprocating motion. No rotary engine, however, was permanently successful until the steam turbine took a practical form. The direct impact of a jet of steam on moving vanes was used by Hero of Alexandria in a philosophical toy, which may be described as the very earliest steam engine. Attempts were made in the 17th century by Giovanni Branca to turn this method to practical account, but no success was achieved until the compound system of working a turbine was developed by Parsons.

De Laval's turbine.

Subsequently to his invention, the simpler type of steam turbine, which utilizes the direct impact of a steam jet against a single ring of revolving blades, has been brought to a remarkable degree of efficiency by De Laval. In De Laval's turbine the steam expands at one step from the full pressure of the supply to the pressure of the exhaust by discharge in the form of a jet from a conical orifice, and the jet acquires a corresponding amount of kinetic energy. It then acts on a ring of blades in much the same way as the jet of water acts on the blades of a Pelton wheel or other form of pure impulse turbine. To utilize this impact of steam the blades have to run at an enormous velocity, and the speed of the shaft which carries them is so great that gearing down is resorted to before the motion is applied to useful purposes. The general arrangement of the steam nozzle and turbine blades is illustrated in Fig. 12. The blades project from the circumference of a disc-shaped wheel and form a complete ring round it, only a few of the blades being shown in the sketch. The nozzle has a divergent form, which causes the steam to expand before it leaves the mouth, and so causes the pressure energy to be used in giving kinetic energy to the jet before it is projected against the blades. The jet impinges at one side, and escapes at the other after having had its direction of motion nearly reversed. The expansion in the nozzle is carried to atmospheric pressure, or near it, if the turbine is to be used without a condenser; but in many cases an ejector condenser is employed, and when that is done the nozzle is of a form which adapts it to expand the steam to a correspondingly lower pressure. It is only in the smaller sizes of these turbines that a single nozzle is used; in the larger steam turbines, as in large Pelton wheels, several nozzles are applied at intervals along the circumference of the disc. To permit the blades to run at the high speed which is necessary in order that they may take full advantage of the kinetic energy of the jet, they are strengthened by shrinking a ring of steel round their tips; and this also serves as a cover to prevent the ring of blades from acting as a centrifugal fan. In a 50 horse-power De Laval turbine the shaft which carries the turbine disc makes 16,000 revolutions per minute; in the 5 horse-power size it makes as many as 30,000 revolutions per minute. A turbine developing 300 horse-power uses a wheel 30 inches in diameter, running at over 10,000 revolutions per minute, with a peripheral speed of nearly 1400 feet per second. These enormous speeds are made possible by the ingenious device of using a flexible shaft, which protects the bearings and foundations from the vibration which any want of balance would otherwise produce. The elasticity of the shaft is such that its period of vibration is much longer than the time taken to complete a revolution. The high-speed shaft which carries the turbine disc is geared, by means of double helical wheels with teeth of specially fine pitch, to a second-motion shaft, which runs at one-tenth of the speed of the first; and from this the motion is taken, by direct coupling or otherwise, to the machine which the turbine is to drive. Turbines of this class are now in extensive use for driving dynamos, fans, and centrifugal pumps. Compared with the Parsons turbine, De Laval's lends itself well to work where comparatively small amounts of power are wanted, and there it achieves a higher efficiency, though in large sizes the Parsons turbine is the more efficient of the two. Trials of a De Laval turbine used with a condenser, and developing about 63 horse-power, have shown an average steam consumption at the rate of about 20 ℔ per brake-horse-power hour, and even better results are reported in turbines of a larger size. (J. A. E.)

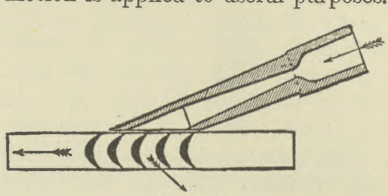

Fig. 12

2. Gas Engines.

A gas engine is a heat engine in which the working fluid is atmospheric air and the fuel an inflammable gas or vapour. It differs from a hot air or a steam engine in that the heat is given to the working fluid by combustion within the motive power cylinder. In most gas engines—in fact, in all those at present on the market—the working fluid and the fuel that supplies it with heat are mixed with each other before the combustion of the fuel. The fuel—which in the steam and in most hot air engines is burned in a separate furnace—is, in the gas engine, introduced directly to the motor cylinder and burned there; it is, indeed, part of the working fluid. A gas engine, therefore, is an internal combustion engine using gaseous or vapour fuel.

The commercial history of the gas engine dates from 1876, when the late Dr Otto patented the well-known engine now in extensive use, but long before that year inventors had been at work, attempting to utilize gas for producing motive power. The first proposal made in Great Britain is found in Street's Patent

No. 1983 of 1794, where an explosion engine is suggested, the explosion to be caused by vaporizing spirits of turpentine on a heated metal surface, mixing the vapour with air in a cylinder, firing the mixture, and driving a piston by the explosion produced. Most of the early engines were suggested by the fact that a mixture of an inflammable gas and atmospheric air gives an explosion when ignited—that is, produces pressure which can be applied in a cylinder to propel a piston. Lebon, in France, proposed a gas engine in which the gas and air were raised to a pressure above that of the atmosphere before use in the cylinder, but he did not appear to be clear in his ideas. Samuel Brown, in patents dated 1823 and 1826, proposed to fill a closed chamber with a gas flame, and so expel the air; then he condensed the flame by injecting water, and operated an air engine by exhausting into the partial vacuum so obtained. The idea was evidently suggested by Watt's condensing steam engine, flame being employed instead of steam to obtain a vacuum. Brown's engine is said to have been actually employed to pump water, drive a boat on the Thames, and propel a road carriage. L. W. Wright in 1833 described an explosion engine working at atmospheric pressure and exploding on both sides of the piston. The cylinder is shown as water-jacketed. In William Barnett's engine of 1838 two great advances were made. The engine was so constructed that the mixture of gas and air was compressed to a considerable extent in the motor cylinder before ignition. The method of igniting the compressed charge was also effective. The problem of transferring a flame to the interior of a cylinder when the pressure is much in excess of that of the external air was solved by means of a hollow plug cock having a gas jet burning within the hollow. In one position the hollow was opened to the atmosphere, and a gas jet issuing within it was lit by an external flame, so that it burned within the hollow. The plug was then quickly rotated, so that it closed to the external air and opened to the engine cylinder; the flame continued to burn with the air contained in the cock, until the compressed inflammable mixture rushed into the space from the cylinder and ignited at the flame. This mode of ignition is in essentials the one adopted by Otto about thirty years later. To Barnett belongs the credit of being the first to realize clearly the great idea of compression before explosion in gas engines, and to show one way of carrying out the idea in practice. Barnett appears to have constructed an engine, but he attained no commercial success. Several attempts to produce gas engines were made between 1838 and 1860, but they were all failures. Several valuable ideas were published in 1855. Drake, an American, described a mode of igniting a combustible gaseous mixture by raising a thimble-shaped piece of metal to incandescence. In 1857 Barsanti and Matteucci proposed a free-piston engine, in which the explosion propelled a free piston against the atmosphere, and the work was done on the return stroke by the atmospheric pressure, a partial vacuum being produced under the piston. The engine never came into commercial use, although the fundamental idea was good.

Previous to 1860 the gas engine was entirely in the experimental stage, and in spite of many attempts no practical success was attained. Lenoir, whose patent is dated 1860, was the inventor of the first gas engine that was brought into general use. The piston, moving forward for a portion of its stroke by the energy stored in the fly-wheel, drew into the cylinder a charge of gas and air at the ordinary atmospheric pressure. At about half stroke the valves closed, and an explosion, caused by the electric spark, propelled the piston to the end of its stroke. On the return stroke the burnt gases were discharged, just as a steam engine exhausts. These operations were repeated on both sides of the piston, and the engine was thus double-acting. Four hundred of these engines were said to be at work in Paris in 1865, and the Reading Iron Works Company Limited built and sold one hundred of them in Great Britain. They were quiet, and smooth in running; the gas consumption, however, was excessive, amounting to about 100 cubic feet per indicated horse-power per hour. The electrical ignition also gave trouble. Hugon improved on the engine in 1865 by the introduction of a flame ignition, but no real commercial success was attained till 1867, when Otto and Langen exhibited their free-piston engine in the Paris Exhibition of that year. This engine was identical in principle with the Barsanti and Matteucci, but Otto succeeded where those inventors failed. He worked out the engine in a very perfect manner, used flame ignition, and designed a practical clutch, which allowed the piston free movement in one direction but engaged with the fly-wheel shaft when moved in the other; it consisted of rollers and wedge-shaped pockets—the same clutch, in fact, as has since been so much used in free-wheel bicycles. This engine consumed about 40 cubic feet of gas per brake horse-power per hour—less than half as much as the Lenoir. Several thousands were made and sold, but its strange appearance and unmechanical operation raised many objections. Several inventors meanwhile advocated compression of the gaseous mixture before ignition, among them being Schmidt, a German, and Million, a Frenchman, both in 1861.

To a Frenchman, M. Alph. Beau de Rochas, belongs the credit of proposing, with perfect clearness, the cycle of operations now widely used in compression gas engines. In a pamphlet published in Paris in 1862, he stated that to obtain economy with an explosion engine four conditions are requisite: (1) The greatest possible cylinder volume with the least possible cooling surface; (2) the greatest possible rapidity of explosion; (3) the greatest possible expansion; and (4) the greatest possible pressure at the beginning of the expansion. The sole arrangement capable of satisfying these conditions he stated would be found in an engine operating as follows: (1) Suction during an entire outstroke of the piston; (2) compression during the following instroke; (3) ignition at the dead point, and expansion during the third stroke; (4) forcing out of the burnt gases from the cylinder on the fourth and last return stroke. Beau de Rochas thus exactly contemplated, in theory at least, the engine produced by Dr Otto fourteen years later. He did not, however, put his engine into practice, and probably had no idea of the practical difficulties to be overcome before realizing his conception in iron and steel. To the late Dr Otto belongs the honour of independently inventing the same cycle, now correctly known as the Otto cycle, and at the same time overcoming all practical difficulties and making the gas engine of world-wide application. This he did in 1876, and his type of engine very rapidly surpassed all others, so that now the Otto cycle engine is manufactured over the whole world by hundreds of makers. In 1876 Dr Otto used low compression only about 30 ℔ per square inch above atmosphere. Year by year compression was increased and greater power and economy were obtained, and at present compressions of 100 ℔ per square inch are commonly used with most satisfactory results.

The history of the subject since 1876 is one of gradual improvement in detail of construction, enabling higher compressions to be used with safety. Attempts have also been made to produce gas engines giving an impulse at every revolution instead of one at every two revolutions, but these attempts so far have not been commercially successful. Perhaps the best known of this type is the Clerk engine, produced in 1881, and since followed by many designers.

Gas engines may be divided, so far as concerns their working process, into three well-defined types:—

(1) Engines igniting at constant volume, but without previous compression;

(2) Engines igniting at constant pressure, with previous compression;

(3) Engines igniting at constant volume, with previous compression.

For practical purposes engines of the first and second types may be disregarded. Gas engines without compression are now considered to be much too wasteful of gas to be of commercial importance. Those of the second type have never really reached the stage of commercial application; they are scientifically interesting, however, and may take an important place in the future development of the gas engine. The expectations of the late Sir William Siemens with regard to them have not been realized, although he spent many years in experiments. Of other engineers who also devoted much thought and work to this second type may be mentioned Brayton, 1872; Foulis, 1878; Crowe, 1883; Hargreaves, 1888; Clerk, 1889; and Diesel, 1892. All the gas and oil engines now in commercial use are of the third type.

The working cycles of the three types are as follows:—

First Type.—Four operations.
- (a) Charging the cylinder with explosive mixture at atmospheric pressure.
- (b) Exploding the charge.
- (c) Expanding after explosion.
- (d) Expelling the burnt gases.

Second Type.—Five operations.
- (a) Charging the pump cylinder with gas and air mixture at atmospheric pressure.
- (b) Compressing the charge into an intermediate receiver.
- (c) Admitting the charge to the motor cylinder, in a state of flame, at the pressure of compression.
- (d) Expanding after admission.
- (e) Expelling the burnt gases.

Third Type.—Five operations.
- (a) Charging the cylinder with gas and air mixture at atmospheric pressure.
- (b) Compressing the charge into a combustion space.

(*c*) Exploding the charge.
(*d*) Expanding after explosion.
(*e*) Expelling the burnt gases.

In all these types the heating of the working fluid is accomplished by the rapid method of combustion within the cylinder, and for the cooling necessary in all heat engines is substituted the complete rejection of the working fluid with the heat it contains, and its replacement by a fresh portion taken from the atmosphere at atmospheric temperature. This is the reason why those cycles can be repeated with almost indefinite rapidity, while the old hot-air engines had to run slowly in order to give time for the working fluid to heat or cool through metal surfaces.

Otto cycle engines belong to the third type, being explosion engines in which the combustible mixture is compressed previous to explosion. Fig. 1 is a side elevation, Fig. 2 is a plan, and Fig. 3 is an end elevation of an engine

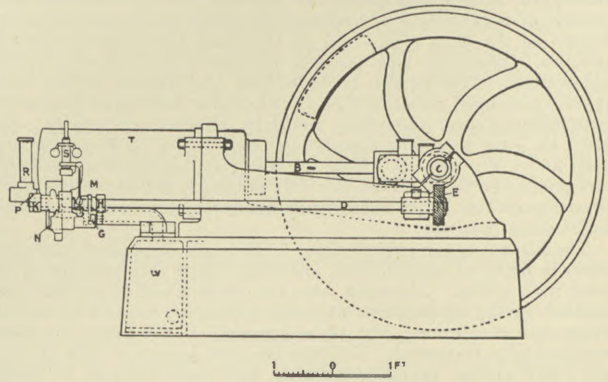

Fig. 1.—Side elevation of Otto Cycle Engine.

built by Messrs Crossley of Manchester, who were the original makers of Otto engines in Great Britain. In external appearance it somewhat resembles a modern high-pressure steam engine, of which the working parts are excessively strong. In its motor and only cylinder, which is horizontal and open-ended, works a long trunk piston, the front end of which carries the crosshead pin. The crank shaft is heavy, and the fly-wheel large, considerable stored energy being required to carry the piston through the negative part of the cycle. The cylinder is considerably longer than the stroke, so that the piston when full in leaves a space into which it does not enter. This is the combustion space, in which the charge is first compressed and then burned. On the forward stroke, the piston A (Fig. 2) takes into the cylinder a charge of mixed gas and air at atmospheric

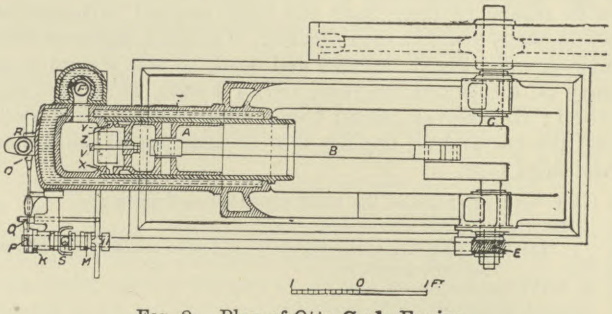

Fig. 2.—Plan of Otto Cycle Engine.

pressure, which is compressed by a backward stroke into the space Z at the end of the cylinder. The compressed charge is then ignited, and so the charge is exploded with production of a high pressure. The piston now makes a forward stroke under the pressure of the explosion, and on its return, after the exhaust valve is opened, discharges the products of combustion. The engine is then ready to go through the same cycle of operations. It thus takes four strokes or two revolutions of the shaft to complete the Otto cycle, the cylinder being used alternately as a pump and a motor, and the engine, when working at full load, thus gives one impulse for every two revolutions. The valves, which are all of the conical-seated lift type, are four in number—charge inlet valve, gas inlet valve, igniting valve, and exhaust valve. The igniting valve is usually termed the timing valve, because it determines the time of the explosion. Since the valves have each to act once in every two revolutions, they cannot be operated by cams or eccentrics placed directly on the crank shaft. The valve shaft D is driven at half the rate of revolution of the crank shaft C by means of the skew or worm gear E, one wheel of which is mounted on the crank shaft and the other on the valve shaft. Ignition is accomplished by means of a metal tube heated to incandescence by a Bunsen burner. At the proper moment the ignition or timing valve is opened, and the mixed gas and air under pressure being admitted to the interior of the tube, the inflammable gases come into contact with the incandescent metal surface and ignite; the flame at once spreads back to the cylinder and fires its contents, thus producing the motive explosion.

The working parts are as follows:—A the piston, B the connecting rod, C the crank shaft, D the side or valve shaft, E the skew gearing, F the exhaust valve, G the exhaust valve lever, H the exhaust valve cam, I the charge inlet valve, J the charge inlet valve lever, K the charging valve cam, L the gas inlet valve, M the gas valve cam, N lever and link operating gas valve, O igniting or timing valve, P timing valve cam, Q timing valve lever or tumbler, R igniting tube, S governor, T water jacket and cylinder, U Bunsen burner for heating ignition tube. On the first forward or charging stroke the charge of gas and air is admitted by the inlet valve I, which is operated by the lever J from the cam K, on the valve shaft D. The gas supply is admitted to the inlet valve I by the lift valve L, which is also operated by the lever and link N from the cam M, controlled, however, by the centrifugal governor S. The governor operates either to admit gas wholly, or to cut it off completely, so that the variation in power is obtained by varying the

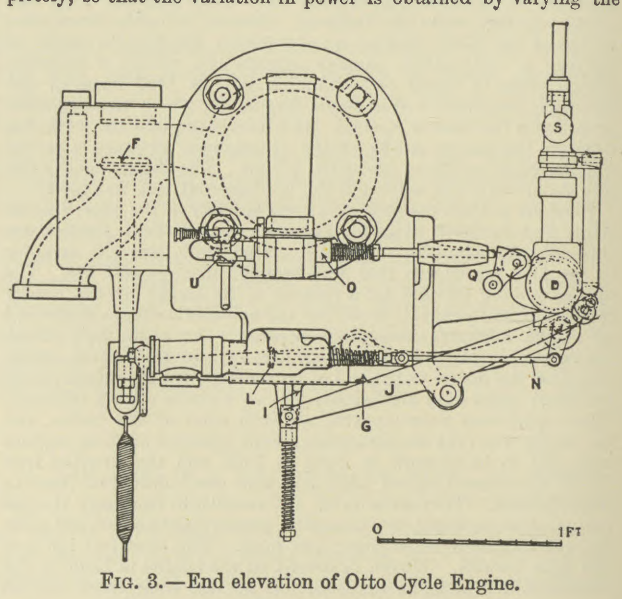

Fig. 3.—End elevation of Otto Cycle Engine.

number of the explosions. The exhaust valve F is actuated by the lever G and cam H. The ignition is produced by admitting a portion of the compressed inflammable charge from the compression space to the metal tube R, rendered incandescent by the Bunsen flame. The passage to the incandescent tube is controlled by the timing valve O, operated by the lever Q and cam P. The valve O is double-seated, and during the compression period of the engine the face nearest the compression space is kept up against the seat by a powerful spring. The incandescent tube is thus kept open to the atmosphere, and notwithstanding any leak which may occur from the cylinder, the tube remains empty until the moment when it is required for ignition. When the valve is lifted from one seat, a small portion of the compressed mixture is discharged through a small port to the air, and this clears out the burnt gases from the passages between the cylinder and the igniting tube; these burnt gases would otherwise render the ignition irregular. By this device a pure combustible mixture at once reaches the incandescent interior surface of the igniting tube, when the outer valve closes on its seat and the charge at once ignites.

The adoption of lift valves for the admission and discharge of gases to and from the engine cylinder is an important advance on the slide valve employed in the earlier engines, for it renders possible the use of much higher compressions. So long as slide valves were used it was difficult to provide a sufficiently large inlet area, as the area of the port determined the pressure necessary to hold the slide valve up against the cylinder face; hence a large port necessitated a heavy pressure, and a slide pressed up by a heavy pressure against a port carrying flame at a temperature of at least 1600° C. was easily overheated, and cut on the surface. Slide valves therefore made it practically impossible to use either large ports or high explosion pressures. The slide valve, too, with its flame igniter, proved more troublesome in practice than the tube igniter. With lift valves and tube ignition the difficulties are removed. In Great Britain slide valves and flame igniters have quite disappeared, and all designs of Otto cycle engines use lift valves and tube ignition in various forms. In the older Otto engines also the side shaft was driven by bevel or spur gear from the crank shaft. In recent engines the skew or worm gear is generally adopted. It is found to produce a more sightly engine, and also to operate much more smoothly than the old arrangement.

Since the engine shown in Figs. 1 to 3 was built further modifications have been made, principally in the direction of dispensing with or diminishing port space, that is, so arranging the ports that the compression space is not broken up into several separate chambers. In this way the cooling surface in contact with the intensely hot gases is reduced to a minimum. This is especially important when high compressions are used, as then the compression space being small, the port spaces form a large proportion of the total space. For maximum economy it is necessary to get rid of port space altogether; this is done by making the lift valves open directly into the compression space. This arrangement can be readily made in small and medium-sized engines, but in the larger engines it becomes necessary to provide ports, so as to allow the valves to be more easily removed for cleaning. Fig. 4 is an external view of a modern Crossley Otto engine, arranged with its valves opening directly into the combustion chamber, as made for engines of moderate powers. Fig. 5 is an external view of one of the largest gas engines built by Messrs Crossley. It is a double cylinder engine, with the cylinders facing each other; the opposing connecting rods engage the same crank pin. The valve arrangements involve the use of short ports, but the port space is relatively very small. The cylinders are each of 26 inches diameter, and the stroke is 3 feet. The speed is 150 revolutions per minute, and the maximum indicated horse-power 530. The engine was built for Messrs Brunner, Mond, and Co. of Northwich, to work with Mond producer gas.

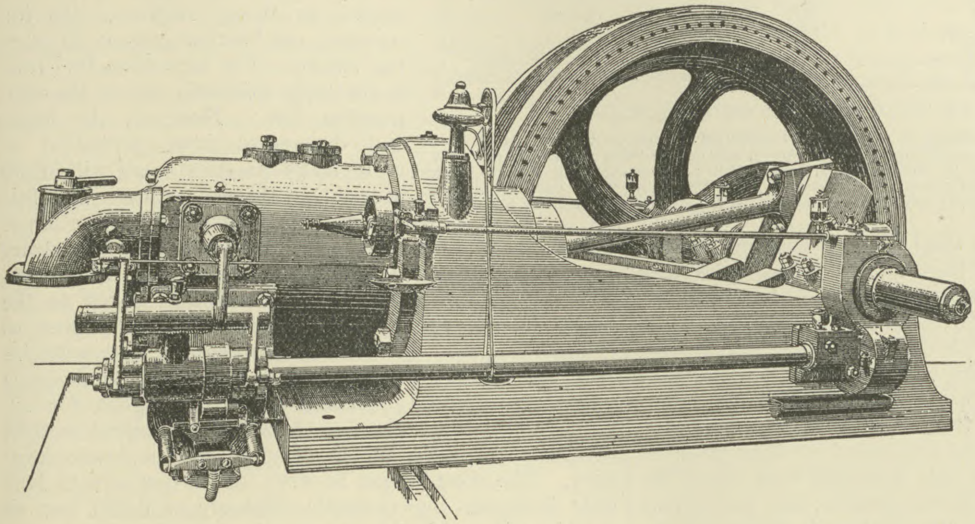

FIG. 4.—Crossley Otto Engine.

Otto cycle engines, with slight variations from the type described above, are made by a number of British firms. The minor points in which they differ often display considerable ingenuity.

Fig. 6 is an indicator diagram from a Crossley Otto gas engine. A B is the atmospheric line, B C the compression line, C D the explosion line, D E the expansion line, and E B A the exhaust line. The scale of this diagram is small because of the heavy pressures to be registered, and accordingly the suction line and the exhaust lines are not distinguishable from the atmospheric line. Fig. 7 is an indicator diagram taken from the same engine by means of a light spring in the indicator; it gives only part of the compression and part of the fall of pressure, because the movement of the indicator piston was limited. It shows clearly, however, the different course of the exhaust line and the suction line. As before, A B is the atmospheric line, F G H is the exhaust line, during which the piston is moving in the direction of the arrow 1. At G this line crosses below the atmospheric line, and remains below till the end of the stroke at I. The suction line is I H K. It remains slightly below atmospheric pressure during the whole time the piston is moving in the direction of the arrow 2. In both Figs. 6 and 7 the arrows indicate the direction of the movement of the piston of the engine while the particular curve is being traced. It will be seen from Fig. 6 that the gas consumption is 14·8 cubic feet per indicated horse-power per hour, and 17 cubic feet per brake horse-power hour, the engine being a small one, with cylinder 7 inches diameter and 15 inches stroke, giving practically 12 brake horse-power. Larger engines recently made by Messrs Crossley give one brake horse-power hour on so low a consumption as 13·5 feet of the same gas. Manchester coal gas used in these tests has a heating value of 530,000 foot pounds per cubic foot, so that the latter result gives a conversion of 27·6 per cent. of the whole heat of the gas into brake, that is, effective, horse-power. It may now be taken that a modern Otto cycle

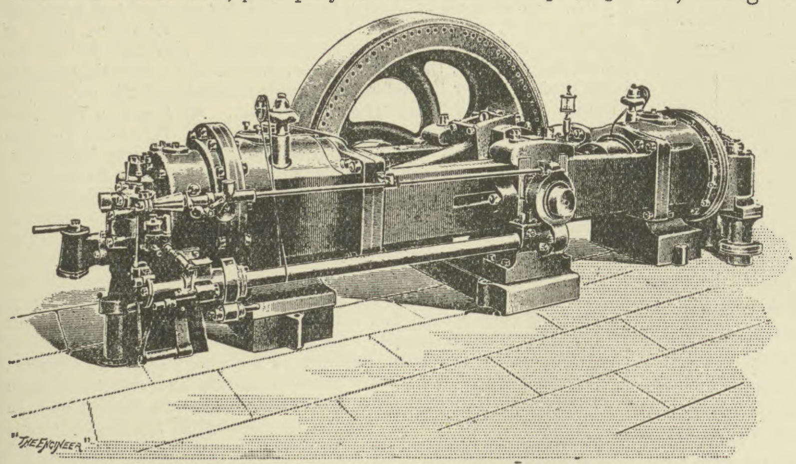

FIG. 5.—530 I.H.P. Crossley Otto Engine.

gas engine by a standard maker will consume in ordinary work, if of large size, about 17 cubic feet of gas per brake horse-power hour, and about 25 cubic feet per brake horse-power hour if of small size.

It was first pointed out by the present writer that the theoretic efficiency of an Otto cycle engine depends on the compression, and that it is constant for any given compression and independent of the maximum temperature of the explosion. Assume an ideal Otto cycle engine, operating with pure air; assume the compression line to be truly adiabatic, the explosion to take place at constant volume, and the expansion from the maximum temperature to be adiabatic—*i.e.*, assume an air engine in which the air does not lose heat to the enclosing walls of the cylinder, or gain it from these walls; further, suppose that the air is admitted to and discharged from the cylinder without loss. Then on such an engine the proportion of heat given to the engine, and converted into indicated work upon the piston, depends only on the compression, and is constant for any given compression. The indicated efficiency is the proportion of heat given to the engine which is converted into work, and it may be expressed in terms of the volume of the air before and after compression as

$$E = 1 - \left(\frac{V_c}{V_o}\right)^{\gamma - 1}$$

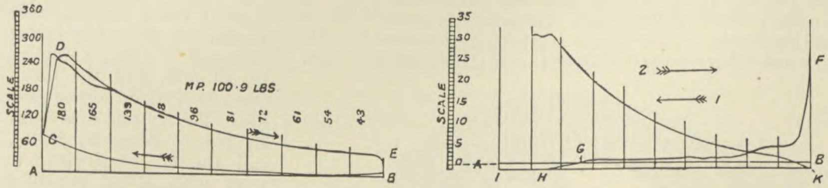
When V_o is the total volume of gases in the cylinder and compression space before compression, and V_c is the volume at maximum compression, $\gamma = 1{\cdot}408$, a constant for the ratio between the specific heat of air at constant pressure and constant volume, and E is the efficiency. Working out the theoretic efficiencies for different pressures of compression in an Otto cycle engine, the following values are found for certain selected compressions:—

	Pressure in lb per Square Inch above Atmosphere.	Theoretic Efficiency for Corresponding Pressure.
1	38	0·33
2	67	0·40
3	87	0·43
4	210	0·55

The first three pressures have been chosen as pressures which have been used at different times in the Otto cycle engine. The fourth is chosen as a probable limit for Otto cycle engines without added compounding. It is now universally accepted that the theoretic efficiency depends absolutely on the compression. Hence, since the introduction of the Otto cycle engine, the history is one of gradually increasing compression and gradually increasing economy. The following figures give the actual indicated efficiency found in practice from 1882 to 1894 in engines using different degrees of compression:—

	Years.	Efficiency.	Pressure of Compression above Atmosphere.
1	1882–88	0·16	38 lb per square inch.
2	1888–94	0·19	67 lb per square inch.
3	1894	0·25	87 lb per square inch.

The pressures correspond to the pressures in the preceding table, and the actual efficiency steadily rises with increased compression, and practically in proportion to the increased theoretic efficiency. In each case, in fact, the actual efficiency is equal, roughly, to half the theoretic efficiency. The actual engine, of course, has losses of heat to the cylinder; with the flame within the cylinder at the temperature of a blast-furnace these could not be avoided.



FIGS. 6, 7.—4 N.H.P. Crossley Otto Scavenging Engine.

Diameter of cylinder, 7 inches; stroke, 15 inches; revolutions per minute, 200; I.H.P., 14 at 100 lb per square inch mean pressure (average of three cards); gas consumption per I.H.P. per hour, 14·8 cubic feet (Openshaw gas, 20 candle-power); B.H.P. 11·97: gas consumption per B.H.P. per hour, 17 cubic feet; maximum pressure of explosion, 275 lb per square inch; pressure of compression, 87·5 lb per square inch; compression space, 34 per cent. of volume swept by piston.

There are other losses, too, from imperfection in carrying out the conditions of the cycle. The heat is not all added at the beginning of the stroke, as theory requires. On the contrary, combustion goes on through the stroke. The expansion line thus is not truly adiabatic, nor is the compression line. However, the losses and departures from perfection of cycle make practice come within 50 per cent. of theory, and even with this the gas engine converts a far larger proportion of heat given to it into work than any steam engine and boiler. In steam engines of moderate dimensions only 12 per cent. of the total heat given to the boiler in the form of coal appears in the engine as indicated work. It is found in practice that with increased compression the percentage of actual to theoretic efficiency increases. Taking the third figure, for example, 0·25, the highest of the actual efficiencies is 0·58 of the theory, while 0·16 is only 0·45 of the lower efficiency. The compression to over 200 lb per square inch only increases the theoretic efficiency to 0·55; but an actual engine with this compression would probably give an efficiency of 0·38. The engine, however, would have a maximum pressure of about 700 lb per square inch, with a usual explosion temperature of about 1700° C. This would make it too heavy in proportion to its power to be commercially successful.

Some 50,000 Otto cycle engines have been made and sold in the British Isles alone, and 35,000 on the Continent. About the year 1880 most of the engines were of small dimensions; the largest size was known as 16 horse-power nominal, and the most popular engine was the 3 horse-power size. Gradually the power of the engines increased, and engines have since been built with two cylinders indicating over 500 horse-power. The whole gas engine power now at work in Britain cannot fall far short of half a million horse-power, nor can the Continental power be much short of 300,000 horse-power. The work performed is multifarious—all the stationary work of the steam engine, in fact. An interesting inquiry has been made by Schaefer into the distribution of the gas engine among the various industries in Germany. He found in 1894 that of 2300 gas engines distributed throughout thirty-six German cities, 65·6 per cent. were distributed among the following industries: printing, pumping water, textile, electric lighting, machine shops, joiners and cabinetmakers, butchers, locksmiths, coffee-roasters, cutlery, elevators. Of these the number used in the printing industry was in excess of the others by 14·4 per cent.; next came pumping with 8·6 per cent., and so on. The remaining 34·4 per cent. was scattered through 140 more industries. One-half the engines were used in large factories. In England the average power per engine used has been stated by Mr Dowson to be about 12 horse-power per engine. So far the substantial application of the gas engine has been confined to stationary engines. Several attempts have been made to propel tramcars and cars running in Germany, and between Blackpool and St Anne's in England, in which the motive power is given by gas engines supplied with gas compressed and carried in reservoirs. Compressed gas, too, has been used in one barge in France to operate gas engines driving a screw propeller, but no important application has been made in this direction. The light oil engines, now largely used for motor-cars, are practically gas engines, and will be described later.

The unit of heat supplied to a gas engine in the form of coal gas is more costly than the unit of heat supplied to the steam engine in the form of coal, so that the gas engine using town's gas is at a disadvantage. So long as coal gas alone was used, only the smaller powers really competed with steam, their lower cost of attendance and the wastefulness of the small steam engine giving them the advantage. The disadvantage of the more expensive heat unit is not felt in such cases, because the governing of the engine (so far as fuel consumption is concerned) and the heat efficiency are so much superior to any small steam engine, that the gas engine is more economical even in actual expense of fuel. Accordingly it is quite unnecessary to trouble about gas other than town's gas for engines under 20 horse-power, but larger engines working at or near full load require cheaper gas to compete. They are therefore supplied with gas by a Dowson or some similar producer. Good results are thus obtained. With an engine indicating, for example, 100 horse-power, a consumption of 1 ℔ of anthracite per indicated horse-power is usual, and even lower consumptions have been recorded. (See GAS PLANTS FOR POWER PURPOSES.)

Blast-furnace gases are now used to a limited extent on the Continent for the purpose of producing motive power by gas engines. Although the experiments were first made in Great Britain, yet Continental engineers have been first in the field commercially. Mr B. H. Thwaite in 1895 started an experimental plant at the Glasgow Iron Works, Wishaw, arranging an apparatus which took gas from the blast-furnace main, purified it by scrubbing and passed it into a gas-holder. A 20 horse-power gas engine, supplied from the holder, drove a dynamo for electric lighting with good results. Mr Thwaite considered that one brake horse-power per hour could be obtained for every $1\frac{1}{4}$ ℔ of fuel fed into the blast-furnace, and he further calculated that each blast-furnace of ordinary dimensions would provide sufficient gas to give a spare power by gas engine of about 2500 horse-power. This opens up a great field for the saving of fuel and the cheap production of power. The blast-furnaces of the United States of America, Mr W. H. Booth calculated, could produce 2,000,000 horse-power continuously by gas engine. Mr Thwaite's plant has also been set up at Frodingham, near Doncaster. Simultaneously with Mr Thwaite's experiments, the Société Cockerill at Seraing, in Belgium, also attacked the problem. They have established at their Seraing works two engines each of 200 horse-power, and one engine of 600 horse-power, operated by blast-furnace gas. The three engines were working well when inspected by the present writer in 1901. Several engines of 1200 horse-power have been constructed at the same works. The Cockerill engines operate on the Otto cycle. Two engines, each of 600 horse-power, have been set up at the Hoerde Iron Works in Westphalia. These engines are of the impulse every revolution type, somewhat after the Clerk cycle, and are the invention of Mr Oechelhauser. The Gas Motoren Fabric Deutz have built large engines for this purpose, among them being one with two cylinders, each giving 300 horse-power; this has been erected at Oberhausen. English makers are also constructing large gas engines for blast-furnace gases, and an interesting advance in the power of the engines may be expected. The largest English gas engine constructed so far is one by Messrs Crossley Brothers of 700 horse-power for Sir Alfred Hickman's works, to be operated with blast-furnace gas. Other large gas engines have been constructed by the Premier Company, 500 horse-power; Stockport engine, 300 horse-power; Tangye engine, 100 horse-power; Fielding engine, 100 horse-power; Campbell engine, 100 horse-power; and Westinghouse engine, 650 horse-power. The last of these was built in America, but the new works of the British Westinghouse Electric Company at Manchester have been built to undertake their manufacture in Great Britain. The Westinghouse gas engine is of the enclosed crank, vertical cylinder type; electrical ignition is used, and there is an interesting system of mixing the gas and air before admission to the engine cylinder. The engine is governed by throttling the gas and air charge after mixing. The Otto cycle is followed, and in the large gas engines the piston is supplied with a forced water circulation. All the large gas engines of both English and Continental makers now water-jacket the pistons.

3. OIL ENGINES.

Oil engines resemble gas engines in that the power is generated by the explosion of a compressed inflammable gaseous mixture in an engine operating according to the Otto cycle. In the earlier forms, and in those used on motor cars, where very light inflammable oils of the gasoline or petrol kind are consumed, the problem of vaporizing the oil is comparatively simple. It is only necessary to draw air over a surface saturated with gasoline or some lighter oil to produce a mixture of vapour and air which, when taken into the cylinder, readily supplies the place of coal gas, and gives explosions under compression closely resembling those obtained with coal gas. The earliest proposal to use oil as a means of producing motive power by explosion was made by Street in 1791, but the first practical petroleum engine was that of Julius Hock of Vienna, produced in 1870. It was of the non-compression kind, like Lenoir's; it took in a charge of air and light petroleum spray during part of the forward stroke of the piston, ignited the charge by a flame jet, and so produced a low-pressure explosion. In 1873 Brayton, an American engineer, produced an oil engine using light oil on the constant-pressure system. The engine was a flame engine, operating without explosion, and it was the earliest compression engine to use oil fuel instead of gas. Shortly after the introduction of the Otto gas engine in 1876, air charged with inflammable vapour by being passed through gasoline was drawn into the engine cylinder with a further supply of air to form an explosive mixture, which was compressed and ignited in the usual way. The Spiel petroleum engine was the first Otto cycle engine introduced into practice which dispensed with an independent vaporizing apparatus. Light oil, of specific gravity not greater than ·725, was injected directly into the cylinder on the suction stroke. It mixed with the air and was vaporized, and on compression an explosion was obtained, just as with a gas engine. Many engines consuming light oil are used in America for stationary work, but in Great Britain they are confined almost entirely to motor-cars, motor-cycles, and motor vehicles generally.

The first aud the most successful of all the light oil road carriage motors is the Daimler. Many other ingenious motors are in use, but if the peculiarities of this form be understood, it is not difficult to follow the others. Fig. 8 is a diagrammatic section of the Daimler motor. A is the cylinder, B the piston, C the connecting rod, and D the crank, which is entirely enclosed in a casing. A small fly-wheel is carried by the crank shaft, and it serves the double purpose of a fly-wheel and a clutch. *a* is the combustion space, E the single port, which serves both for inlet and charge and for discharge of exhaust. W is the exhaust valve, F the charge inlet valve, which is automatic in its action, and is held closed by a spring *f*, G the vaporizer, H the igniter tube, I the igniter tube lamp, K the air charge inlet passage, L the air filter chamber, and M an adjustable air inlet cap for regulating the air inlet area. The light oil—or petrol, as it is commonly called—is supplied to the float chamber N of the vaporizer by means of the valve O. So long as the level of the petrol is high, the float *n*, acting by levers above it, holds the valve O closed against oil forced by air pressure along the pipe P. When the level falls, however, the valve opens and more oil is admitted. When the piston B makes its suction stroke, air passes from the atmosphere by the passage K through the valve F, which it opens automatically. The pressure falls within the passage K, and a spurt of petrol passes by the jet G^1, separate air at the same time passing by the passage K^1 round the jet. The petrol breaks up into spray by impact against the walls of the passage K, and then it vaporizes and passes into the cylinder A as an inflammable mixture. When the piston B returns it compresses the charge into *a*, and upon compression the incandescent igniter tube H fires the charge. H is a short platinum tube, which is always open to the compression space. It is rendered incandescent by the burner I, fed with petrol from the pipe supplying the vaporizer. The open incan-

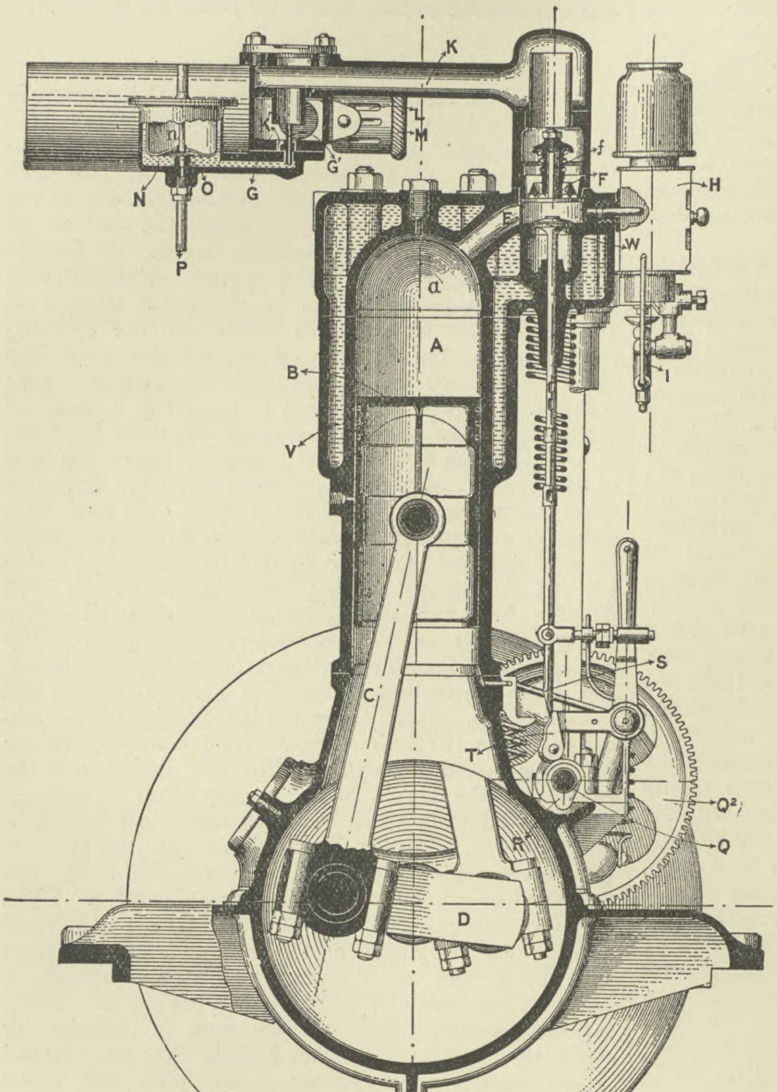


FIG. 8.—Diagrammatic section of Daimler Motor.

descent tube is found to act well for small engines, and it does not ignite the charge until compression takes place, because the inflammable mixture cannot come into contact with the hot part till it is forced up the tube by the compression. The engine is started by giving the crank shaft a smart turn round by means of a detachable handle. The exhaust valve is alone actuated from the valve shaft. The shaft Q is operated by pinion and a spur wheel Q^2 at half the rate of the crank shaft. The governing is accomplished by cutting out explosions as with the gas engine, but the governor operates by preventing the exhaust valve from opening, so that no charge is discharged from the cylinder, and therefore no charge is drawn in. The cam R operates the exhaust valve, the levers shown are so controlled by the governor (not shown) that the knife edge S is pressed out when speed is too high, and cannot engage the recess T until it falls. The engine has a water jacket V, through which water is circulated. Cooling devices are used to economize water.

Most of the motor-car engines resemble the Daimler. For the smaller vehicles, however, such as cycles, the cylinders are not water-jacketed, but are provided with ribs to radiate away the heat. Some engines also use electric spark ignition generated by battery and coil, or by magneto-electric devices. The application of oil engines to motor carriages has led to a multitude of most ingenious details, which cannot here be dealt with. The Daimler engine and similar engines have been extensively applied to small marine work, such as launches and dinghies.

Heavy oil engines are those which consume oil having a flashing point above 73° F.—the minimum at present allowed by Act of Parliament in Great Britain for oils to be consumed in ordinary illuminating lamps. Such oils are American and Russian petroleums and Scottish paraffins. They vary in specific gravity from ·78 to ·825, and in flashing point from 75° to 152° F. Engines burning such oils may be divided into three distinct classes :—

1st. Engines in which the oil is subjected to a spraying operation before vaporization.

2nd. Engines in which the oil is injected into the cylinder and vaporized within the cylinder.

3rd. Engines in which the oil is vaporized in a device external to the cylinder, and introduced into the cylinder in the state of vapour.

The method of ignition might also be used to divide the engines into those igniting by the electric spark, by an incandescent tube, or by the heat of the internal surfaces of the combustion space. Spiel's engine was ignited by a flame-igniting device similar to that used in Clerk's gas engine, and it was the only one introduced into Great Britain in which this method was adopted, though on the Continent flame igniters were not uncommon. Recently, however, electrically-operated igniters have come into extensive use on the Continent. In Great Britain all other methods of ignition both in gas and oil engines have for practical purposes been displaced by hot-tube and hot-surface igniters.

The engines at present in use in Great Britain which fall under the first head are the Priestman and the Samuelson, the oil being sprayed before being vaporized in both. The principle of the spray producer used is that so well and so widely known in connexion with the atomizers or spray producers used by perfumers. Fig. 9 shows such a spray producer in section. An air blast passing from the small jet A crosses the top of the tube B, and creates within it a partial vacuum. The liquid contained in C flows up the tube B, and issuing at the top of the tube through a small orifice is at once blown into very fine spray by the action of the air jet. If such a scent distributor be filled with petroleum oil, such as Royal Daylight or Russoline, the oil will be blown into fine spray, which can be ignited by a flame and will burn, if the jets be properly proportioned, with an intense blue non-luminous flame. The earlier inventors often expressed the idea that an explosive mixture could be prepared without any vaporization whatever, by simply producing an atmosphere containing inflammable liquid in extremely small particles distributed throughout the air in such proportion as to allow of complete combustion. The familiar explosive combustion of lycopodium, and the disastrous explosions caused in the exhausting rooms of flour mills by the presence of finely-divided flour in the air, have also suggested to inventors the idea of producing explosions for power purposes from combustible solids. Although, doubtless, explosions could be produced in that way, yet in oil engines the production of spray is only a preliminary to the vaporization of the oil. If a sample of oil be sprayed in the manner just described, and injected in a hot chamber also filled with hot air, it at once passes into a state of vapour within that chamber, even though the air be at a temperature far below the boiling point of the oil. The spray producer, in fact, furnishes a ready means of saturating any volume of air with heavy petroleum oil

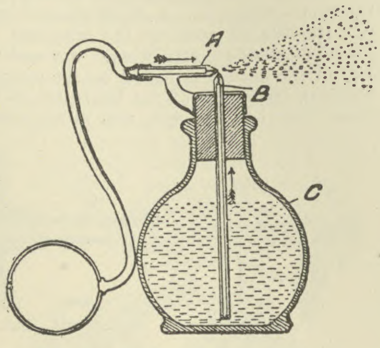

Fig. 9.—Perfume Spray Producer.

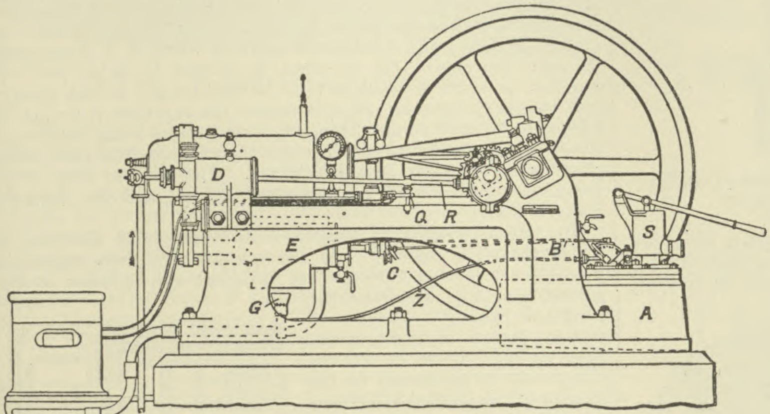

Fig. 10.—Priestman Oil Engine (general arrangement).

to the full extent possible from the vapour tension of the oil at that particular temperature. The oil engines described below are in reality explosion gas engines of the ordinary Otto type, with special arrangements to enable them to vaporize the oil to be used. Only such parts of them as are necessary for the treatment and ignition of the oil will, therefore, be described.

In Fig. 10 is shown the general arrangement of the Priestman engine, which was the first capable of using heavy safe oils. Fig. 11 is a vertical section through the cylinder and vaporizer, and Fig. 12 is a section on a larger scale, showing the vaporizing jet and the air admission and regulation valve leading to the vaporizer. Oil is forced by means of air pressure from the reservoir A through the pipe B to the spraying nozzle C, and air passes from the air-pump D by way of the annular channel *b* into the sprayer *c*, and there meets the oil jet issuing from *a*. The oil is thus broken up into spray, and the air charged with spray flows into the vaporizer E, which is heated up in the first place on starting the engine by means of a lamp G. In the vaporizer the oil spray becomes oil vapour, saturating the air within the hot walls. On the out-charging stroke of the piston the mixture passes by way of the inlet valve H into the cylinder, air flowing into the vaporizer to replace it through the valve I (Fig. 12). The cylinder K is thus charged with a mixture of air and hydrocarbon vapour, some of which may exist in the form of very fine spray. The piston L then returns and compresses the mixture, and when the compression is quite complete an electric spark is passed between the points M, and a compression explosion is obtained precisely similar to that obtained in the gas engine. The piston moves out, and on its return stroke the exhaust valve N is opened and the exhaust gases discharged by way of the pipe O, round the jacket P, enclosing the vaporizing chamber. The latter is thus kept hot by the exhaust gases when the engine is at work, and it remains sufficiently hot without the use of the lamp G. To obtain the electric spark a bichromate

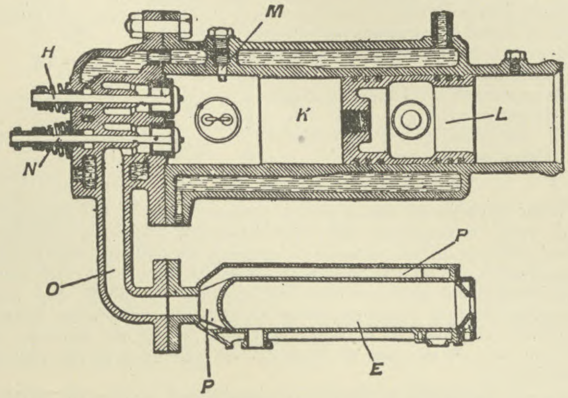

Fig. 11.—Priestman Oil Engine (vertical section through cylinder and vaporizer).

battery with an induction coil is used. The spark is timed by contact pieces Q, operated from the eccentric rod R, used to actuate the exhaust valve and the air-pump for supplying the oil chamber and the spraying jet. To start the engine the hand pump is worked until the pressure is sufficient to force the oil through the spraying nozzle, and oil spray is formed in the lamp G; the spray and air mixed produce a blue flame which heats the vaporizer. The fly-wheel is then rotated by hand, and the engine moves away. The eccentric shaft is driven from the crank shaft by means of toothed wheels, which reduce the speed to one-half the revolutions of the crank shaft. The charging inlet valve is automatic. Governing is effected by throttling the oil and air supply. The governor operates on the butterfly valve T (Fig. 12), and on the plug-cock *t* connected to it, by means of the spindle t^1. The air and oil are thus simultaneously reduced, and the attempt is made to maintain the charge entering the cylinder at a constant proportion by weight of oil and air, while reducing the total weight, and therefore volume, of the charge entering. The Priestman engine thus gives an explosion on every second revolution in all circumstances, whether the engine be running light or loaded. The compression pressure of the mixture before admission is, however, steadily reduced as the load is reduced, and at very light loads the engine is running practically as a non-compression engine. This is a grave disadvantage, as the fuel consumption per indicated horse-power rises rapidly with the reduction of compression.

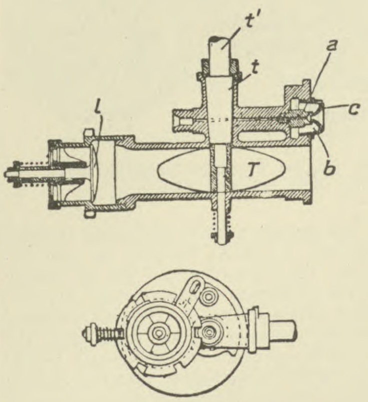

Fig. 12.—Priestman Oil Engine (section on a larger scale).

A test by Professor Unwin of a 4½ nominal horse-power Priestman engine, cylinder 8·5 inches diameter, 12 inches stroke, normal speed 180 revolutions per minute, showed the consumption of oil per indicated horse-power hour to be 1·066 lb, and per brake horse-power hour 1·243 lb. The oil used was that known as Broxburn Lighthouse, a Scottish paraffin oil produced by the destructive distillation of shale, having a density of ·81, and a flashing point about 152° F. With a 5 horse-power engine of the same dimensions, the volume swept by the piston per stroke being ·395 cubic feet, and the clearance space in the cylinder at the end of the stroke ·210 cubic feet, the principal results were :—

	Daylight Oil.	Russoline Oil.
Indicated Horse-Power . . .	9·369	7·408
Brake Horse-Power . . .	7·722	6·765
Mean Speed (revolutions per minute)	204·33	207·73
Mean available Pressure (revolutions per minute) . .	53·2	41·38
Oil consumed per Indicated Horse-Power per Hour . . .	·694 lb	·864 lb
Oil consumed per Brake Horse-Power per Hour . . .	·842 lb	·946 lb

With Daylight oil the explosion pressure was 151·4 lb per square inch above atmosphere, and with Russoline 134·3 lb. The terminal pressure at the moment of opening the exhaust valve with Daylight oil was 35·4 lb, and with Russoline 33·7 per square inch. The compression pressure with Daylight oil was 35 lb, and with Russoline 27·6 lb pressure above atmosphere. Professor Unwin calculated the amount of heat accounted for by the indicator as 18·8 per cent. in the case of Daylight oil and 15·2 in the case of Russoline oil.

Messrs Samuelson's engine is constructed under the Griffin patents, and it resembles Priestman's in subjecting the oil to the preliminary process of spraying before vaporizing; the vaporizer also is heated during the running of the engine by the exhaust gases. It differs, however, from the Priestman engine in the methods of igniting and governing. The tube igniter is used, and the governing device, instead of reducing the power of the explosions, so operates that when speed becomes too high the air supply is entirely cut off and the exhaust valve closed, after the combustion products of the last explosion have been discharged from the cylinder. The piston consequently moves out, expanding the contents of the compression space, while the oil valve is simultaneously shut off in the sprayer, so that no oil is injected. Fig. 13 is a section of the Griffin patent oil sprayer.

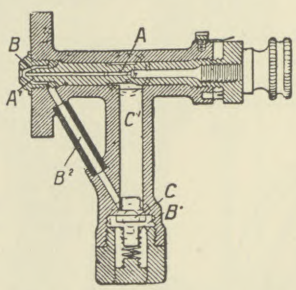

FIG. 13.—Section of Griffin Oil Sprayer.

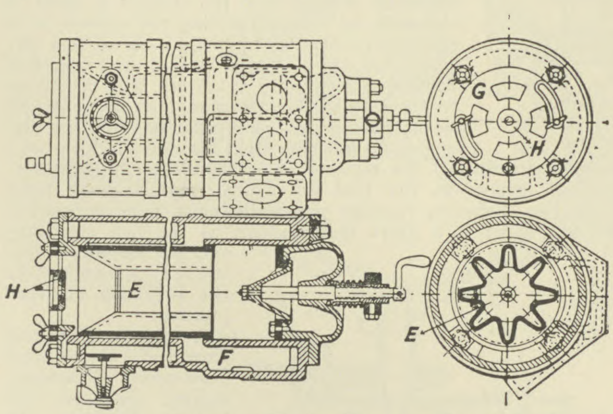

FIG. 14.—Samuelson Engine Vaporizer (longitudinal transverse section, plan and end elevation).

The air enters by way of the passage A, and discharges through the nozzle A^1, thereby causing a partial vacuum in the annular space B formed between the air nozzle and the oil nozzle. The passage B^2 connects to the oil-supply chamber B^1 by way of a spraying valve C attached to a plunger stem C^1. The air pressure, when admitted, forces down the plunger C^1, and thus opens the valve C against the pressure of the spring. Oil thus passes up the passage B^2 from the chamber B^1, and is discharged with the air from the nozzle A^1 in a state of fine spray. Whenever the air-pressure is removed from the plunger C^1, the spring forces the valve to its seat and cuts off the oil supply. The air pressure is maintained at from 12 to 15 lb above atmosphere by a pump driven from an eccentric on the valve shaft. The vaporizer is shown in longitudinal transverse section, plan and end elevation, in Fig. 14. The vaporizer E, corrugated in outline, is surrounded by the exhaust jacket F. The air is admitted from the atmosphere by the adjustable perforated plate G, and the spray nozzle, attached at a point H, discharges the spray into the centre of the vaporizer. Instead of the electric spark for igniting, an incandescent tube is adopted, heated and kept hot by an ingenious lamp shown in Fig. 15. In this lamp oil is admitted to the chamber J by the pipe K, and it is maintained at a constant level there by means of the overflow pipe L. A short piece of wire M is immersed in the oil, and the oil runs up the wire and covers the bent part by reason of capillary attraction. Air under pressure is admitted by way of the pipe N adjusted by the screw N^1, and it passes to the nozzle O, striking upon the bent part of the wire M. The air thus blows the oil off the wire, and at the same time the jet sucks in a

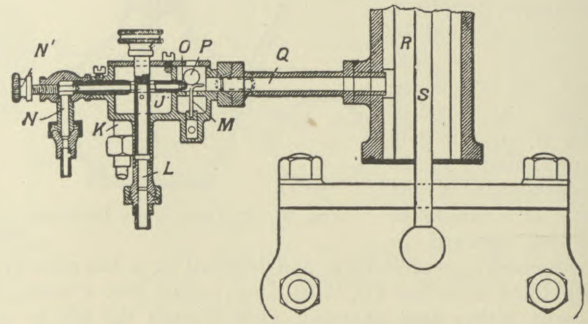

FIG. 15.—Samuelson Engine Spray Lamp.

further supply of air through holes P, and the mixed air and oil spray pass through the tube Q to the asbestos-lined funnel R. The mixture, on being ignited within this funnel, burns with a fierce blue flame, and heats up the igniter tube S; this opens into the engine cylinder, and ignites the mixture when it is compressed. To start the engine the air-pump is worked by hand until the required pressure is obtained; air is then turned on the sprayer, and the spray lighted. By this means the vaporizer is heated for about ten minutes from within, the burnt gases being discharged through a special valve opening into the exhaust, this valve being closed when sufficient heat is attained. The heating lamp of the incandescent tube is in the meantime lighted, and the engine is ready to start.

The Hornsby-Ackroyd engine is an example of the class in which the oil is injected into the cylinder and there vaporized. Fig. 16 is a section through the vaporizer and cylinder of this engine, and Fig. 17 shows the inlet and exhaust valves also in section placed in front of the vaporizer and cylinder section. Vaporizing is conducted in the interior of the combustion chamber, which is so arranged that the heat of each explosion maintains it at a temperature sufficiently high to enable the oil to be vaporized by mere injection upon the hot surfaces. The vaporizer A is heated up by a separate lamp, the oil is injected at the oil inlet B, and the engine is rotated by hand. The piston then takes in a charge of air by the air inlet valve into the cylinder, the air passing by the port directly into the cylinder without passing through the vaporizer chamber. While the piston is moving forward, taking in the charge of air, the oil thrown into the vaporizer is vaporizing and diffusing itself through the vaporizer chamber, mixing, however, only with the hot products of combustion left by the preceding explosion. During the charging stroke the air enters through the cylinder, and the vapour formed from the oil is almost entirely confined to the combustion chamber. On the return stroke of the piston air is forced through the somewhat narrow neck *a* into the combustion chamber, and is there mixed with the vapour contained in it. At first, however, the mixture is too rich in inflammable vapour to be capable of ignition. As the compression proceeds, however, more and more air is forced into the vaporizer chamber, and just as compression is completed the mixture attains proper explosive proportions. The sides of the chamber are sufficiently hot to cause explosion, under the pressure

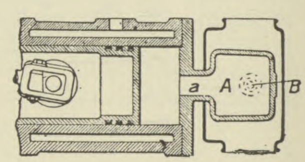

FIG. 16.—Hornsby-Ackroyd Engine (section through vaporizer and cylinder).

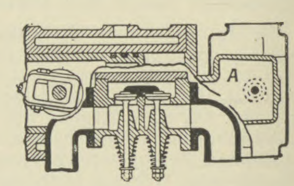

FIG. 17.—Hornsby-Ackroyd Engine (section through valves, vaporizer, and cylinder).

of which the piston moves forward. As the vaporizer A is not water-jacketed, and is connected to the metal of the back cover only by the small section or area of cast iron forming the metal neck *a*, the heat given to the surface by each explosion is sufficient to keep its temperature at about 700–800° C. Oil vapour mixed with air will explode by contact with a metal surface at a comparatively low temperature; this accounts for the explosion of the compressed mixture in the combustion chamber A, which is never really raised to a red heat. It has long been known that under certain conditions of internal surface a gas engine may be made to run with very great regularity, without incandescent tube or any other form of igniter, if some portion of the interior surfaces of the cylinder or combustion space be so arranged that the temperature can rise moderately; then, although the temperature may be too low to ignite the mixture at atmospheric pressure, yet when compression is completed the mixture will often ignite in a perfectly regular manner. It is a curious fact that with heavy oils ignition is more easily accomplished at a low temperature than with light

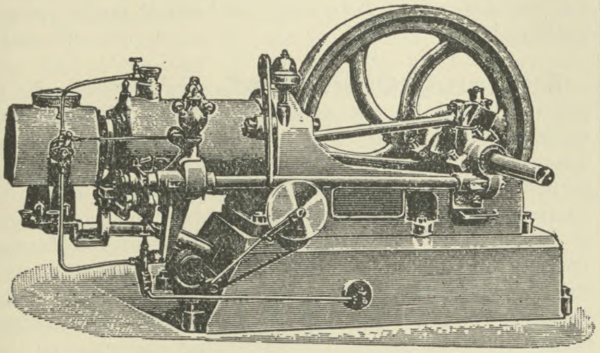

FIG. 18.—Hornsby-Ackroyd Oil Engine.

oils. The explanation seems to be that while in the case of light oils the hydrocarbon vapours formed are tolerably stable from a chemical point of view, the heavy oils very easily decompose by heat, and separate out their carbon, liberating the combined hydrogen, and at the moment of liberation the hydrogen, being in what chemists know as the *nascent* state, very readily enters into combination with the oxygen beside it. To start the engine the vaporizer is heated by a separate heating lamp, which is supplied with an air blast by means of a hand-operated fan. This operation should take about nine minutes. The engine is then moved round by hand, and starts in the usual manner. The oil tank is placed in the bed plate of the engine. The air and exhaust valves are driven by cams on a valve shaft. Fig. 18 is a general view of the external appearance of the engine, from which it will be seen that the governing is effected by a centrifugal governor. This governor

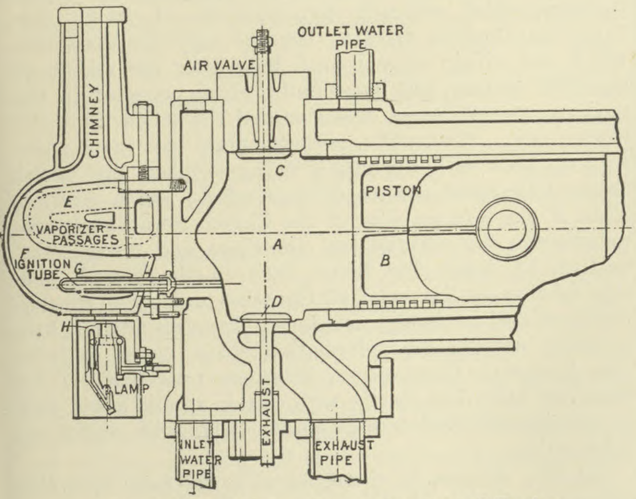

FIG. 19.—Vertical section of Crossley Oil Engine.

operates a bye-pass valve, which opens when the speed is too high, and causes the oil pump to return the oil to the oil tank. The fan and starting lamp will be seen in the lower part of the illustration. At a test of one of these engines, which weighed 40 cwts. and was given as of 8 brake horse-power, with cylinder 10 inches in diameter and 15 inches stroke, according to Professor Capper's report, the revolutions were very constant, and the power developed did not vary one quarter of a brake horse-power from day to day. The oil consumed, reckoned on the average of the three days over which the trial extended, was ·919 ℔ per brake horse-power per hour, the mean power exerted being 8·35 brake horse. At another full-power trial of the same engine a brake horse-power of 8·57 was obtained, the mean speed being 239·66 revolutions per minute, and

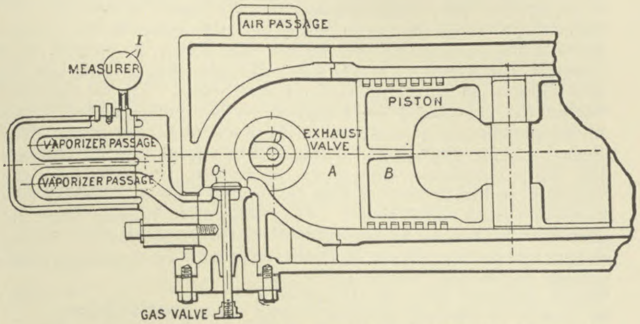

FIG. 20.—Sectional plan of Crossley Oil Engine.

the test lasting for two hours; the indicated power was 10·3 horse, the explosions per minute 119·83, the mean effective pressure 28·9 ℔ per square inch, the oil used per indicated horse-power per hour was ·81 ℔, and per brake horse-power per hour ·977 ℔. In a test at half power, the brake horse-power developed was 4·57 at 235·9 revolutions per minute, and the oil used per brake horse-power per hour was 1·48 ℔. On a four hours' test, without a load, at 240 revolutions per minute, the consumption of oil was 4·23 ℔ per hour.

Other engines of this class are those manufactured by Messrs Robey & Co. and one, a German engine, known as the Capitaine.

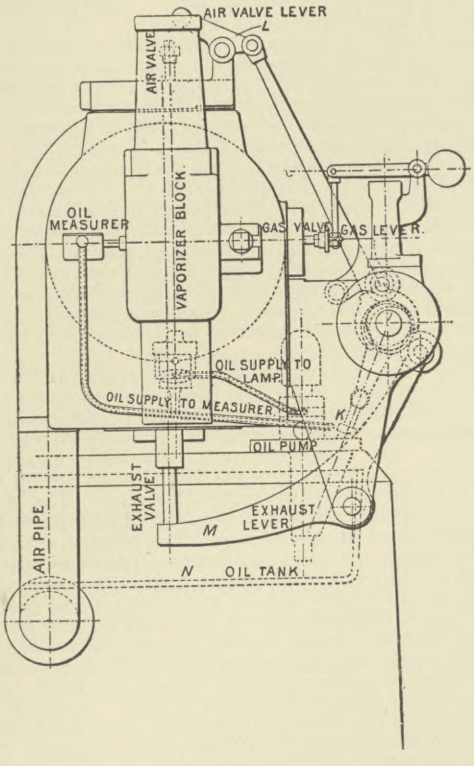

FIG. 21.—End elevation of Crossley Oil Engine.

The former vaporizes its charge by the injection of the oil against the heated walls of the combustion chamber, and ignition is accomplished also by contact with these hot walls. The Capitaine engine has a vaporizer and igniter placed within the combustion space of a cylinder; the oil is vaporized by injection upon the hot surfaces of the vaporizer, and ignition also takes place when compression is completed by contact with these hot surfaces. The late Mr Brayton also proposed and experimented with an engine somewhat of this type.

As a type of the engines in which the oil is vaporized in a device external to the cylinder, and introduced into the cylinder in a state of vapour, the Crossley oil engine may be described. Figs. 19, 20, and 21 show respectively vertical section, sectional plan, and end elevation of the combustion chamber and cylinder. Fig. 22 shows in elevation the oil pump on a larger scale. A is the combustion space, B the piston, C the air inlet valve, D the exhaust valve, E the vaporizer, F the vaporizer and igniter casing, G the igniter tube, H the heating lamp, I the oil measurer, J the valve shaft, K the oil pump, L the air valve lever, M the exhaust valve lever, and N the oil tank. The lamp H consists of a chamber into which oil is pumped. This chamber is heated in the first instance by burning a little oil upon waste. The oil vaporizes within the chamber when forced in by the pump, and it issues under pressure at a small nozzle at the foot of the lamp. The flame sucks air with it, and burns within a space passing through the lamp chamber. The flame so formed proceeds into the vaporizer casing F, heating first the igniter tube G, which is surrounded with a metal shield. The flame, after passing from the igniter tube, heats the vaporizer E, which consists of a casting having one passage within it, made continuous by a corresponding passage in the face shown in Fig. 20. Oil is pumped into the measurer I by means of the oil pump K. The measurer passes only a certain fixed volume at each stroke, the excess volume being sent back to the oil reservoir. The oil vaporizes in the vaporizer passage, and it is admitted to the engine by the oil valve O, which is operated by governor from the cam shaft J, as shown in Fig. 22. The advance of the piston B draws in a charge of air through the valve C. At the same time the oil valve O is opened, and the vapour of oil passes into the cylinder from the vaporizer passage. A small quantity of air is at the same time sucked through the passage. A vaporized charge of oil is thus passed into the cylinder with the air charge, and the piston B on its return stroke compresses the charge into the combustion space A. There it is ignited by the igniter tube G, and the engine makes its explosion or power stroke. This operation is repeated so long as power is required. When the speed of the engine exceeds the limit, the governor prevents the vapour valve O from opening, and no oil charge finds its way through the measurer to the vaporizer passage. One of these engines declared of 7½ brake horse-power developed on the brake 6·28 horse-power, and consumed ·90 lb of Russoline oil per brake horse-power per hour. The Tangye oil engine made under Pinkney's patents has also an external vaporizer, but all the air charge is dragged through the vaporizer to the cylinder, and the vaporizer is always opened to the cylinder, so that the port space is somewhat excessive. Many other oil engines are now upon the market, but all appear to be constructed in accordance with the types described.

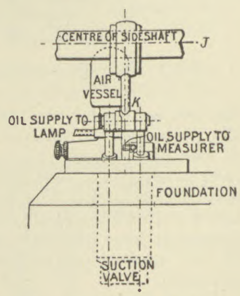

FIG. 22.—Oil Pump for Crossley Oil Engine (elevation).

Mr Diesel has, however, produced an engine which departs somewhat from other types. In it air alone is drawn into the cylinder on the charging stroke. The air is compressed on the return stroke to a very high pressure, generally over 700 lb per square inch. This compression raises the air to incandescence, and then oil is injected into the incandescent air by a small portion of air compressed to a still higher point. The oil ignites at once as it enters the combustion space, and so a power impulse is obtained, but without explosion. The pressure does not rise above the pressure of air and oil injection. The Diesel engine thus embodies two very original features: it operates at pressures very much higher than those used on any other internal combustion engines, and it dispenses with all the usual igniting devices by rendering the air charge incandescent by compression. The engine has been built both as an Otto cycle engine and as an impulse-every-revolution engine. One of the latter type was exhibited at the Glasgow Exhibition of 1901. So far the engine has not attained any commercial position. Although economical, it appears to be a heavy engine for the power developed.

The oil engine is at present in the development stage. Large alterations are continually being made, and in a few years great extensions may be looked for in the applications of oil engines to industrial purposes. At present, so far as dimensions are concerned, they are in the stage which the gas engine had attained about 1880. The difficulties have not been so thoroughly overcome as in gas engines, and especially the difficulties of constructing them of large size. An oil engine giving about 50 brake horse-power would at present be regarded as a large one, whereas now a large gas engine would be one giving about 300 brake horse-power. Great future developments may be expected both in gas and oil engines. So far as economy of heat is concerned, both have considerably surpassed the best steam engines, but much remains to be done before they equal the latter in frequency of impulses, in absolute steadiness of governing, and in power of control for cases where, for instance, reversing is required. As yet the applications of gas and oil to any but fixed engines have been limited, but ultimately they will be used with great advantage for propelling ships and for driving locomotives. Many engineers are now at work on the subject, and when the problem is further solved it will aid much in economizing fuel for all purposes where both large and small motive powers are required. (D. CL.)

England, Church of.—Subsequently to the period covered by the article in the 9th edition of this work, there has only been one material change in the constitutional status of the English Church. As a consequence of the disestablishment of the Irish Church, the "union created by Act of Parliament between the Churches of England and Ireland" was dissolved from 1st January 1871, although the Churches remain in full communion with one another. The projected disestablishment and disendowment of the four Welsh dioceses in 1893 would, if carried out, have had far more sweeping consequences; but it was rejected on an appeal to the country (see ESTABLISHMENT). There are other events, however, which must be recorded, both as being more important in themselves and as likely to lead to far-reaching consequences in the future. The so-called Catholic revival, of which the Oxford Movement was the most prominent feature, has, on the one hand, entirely remodelled the popular conception of the Church, and profoundly affected every side of its work; whilst, on the other hand, many of its developments have been stigmatized as popish, and have called forth strenuous opposition on this account. A more liberal cast of thought and a revival of exact scholarship have done much to assuage the apprehension with which natural science and Biblical criticism were formerly alike regarded; and a sounder and deeper theology, chief amongst the pioneers of which was Frederick Denison Maurice, has not only displaced that which was widely current until long after the middle of the 19th century, but has found a strong support in the modern conceptions of evolution and the solidarity of the human race. Meanwhile, resolute efforts have been made to keep pace with the ever-growing religious and social needs of the great centres of population; and a growing sense of the responsibility of the Church towards her own members in the colonies and elsewhere, and towards the heathen at large, has borne fruit in the growth and organization of the colonial Churches and in a greatly increased zeal for foreign missions. Recourse must be had to other articles for information upon these subjects (see ANGLICAN COMMUNION, MISSIONS); all that can be done here is to deal shortly with certain special heads, and to supplement what is said under these with statistical information.

(1) The changes in ritual, based in the main upon the express provisions of the Ornaments Rubric, or else upon an interpretation of it, as referring to the year before the introduction of the First Prayer-Book of Edward VI., have given rise to frequent legislation, the more important early cases being those of Westerton *v.* Liddell (1855–57), Martin *v.* Mackonochie (1867–68), and Elphinstone (afterwards Hebbert) *v.* Purchas (1869–70). Each

of these was carried to the Privy Council, the judgments of which not only varied in different cases, but showed no signs of being based upon an adequate knowledge of the facts under review. A Royal Commission on Ritual (1867–70) put forth valuable material, but did nothing to set matters at rest; and several unsuccessful efforts at legislation culminated at length, in 1874, in the passing of the Public Worship Regulation Act, in spite of strong opposition. This only made things worse, by constituting a new civil court in place of the ancient Court of Arches (see ARCHES, COURT OF), and facilitating litigation, without in any way conducing to a better interpretation or administration of the law. In the Folkestone case (1875–76) the defendant, the Rev. C. J. Ridsdale, only conformed to its judgment under a formal dispensation from his diocesan, Dr Tait, from the observance of the rubric as he interpreted it; and in six other cases, the last being that of the Rev. J. Bell Cox in 1887, clergymen went to prison for contempt of court rather than obey its monitions. Public opinion declared itself very strongly against this, however, and largely owing to the influence of Archbishop Tait (who bore witness that nothing of the kind had been intended by the promoters of the Act), it gradually came to an end. An entirely new departure was marked by the case of the Bishop of Lincoln, in which a purely spiritual judgment was given (LINCOLN JUDGMENT), which was very widely accepted by Churchmen. From 1898 there has been renewed agitation on the subject of ritual excesses, but the temper of Parliament was opposed to any introduction of legislation which should overrule the power of the bishops. The question of the meaning of the Ornaments Rubric was again raised in 1899, in regard to the ceremonial use of incense and the reservation of the Eucharist. At the request of the bishops concerned, the two Archbishops heard counsel and received evidence on both subjects (the Archbishop of York acting as assessor only as regards the former), and gave it as their opinion that both were forbidden (see INCENSE; RESERVATION). The directions of the bishops in accordance with these opinions have been very generally, but by no means universally, obeyed by the clergy; and an attempted prosecution of some of those who had not done so (by a non-parishioner) was stopped by the veto of the Bishop of London in December 1900. It was generally felt that action of some kind was desirable, but that it should be remedial rather than penal. Something has been done already by the restoration of the old Court of Arches; but the recommendations of the Ecclesiastical Courts Commission (1881–83) have not yet borne fruit, and nothing has yet been done to adapt to modern conditions the rigidity of an order of service which was largely moulded by the conditions of the 16th and 17th centuries.

(2) Closely connected with the subject of ritual is that of doctrine, of which it is in general the outward expression. As regards this, two things are noteworthy: on the one hand a tendency to permit the largest possible liberty of opinion, and on the other a fuller realization of the ancient doctrine of the Church as expressed in its formularies. The judgment of the Privy Council in the Gorham case (1847–50), to the effect that Mr Gorham's views were "not contrary or repugnant to the declared doctrine of the Church of England," is almost a dead letter excepting from the former point of view. Although the *Essays and Reviews*, published in 1860, caused a great sensation at the time of their publication, the condemnation of two of the essayists in the Court of Arches was reversed by the Privy Council, and a third became Archbishop of Canterbury in the person of Dr Temple. And whilst many of the views advanced would now be repudiated as contrary to sound learning, others are now on all hands accepted. Again, the Colenso controversy, if it showed that there was a rooted objection to the use of modern critical methods in the interpretation of Scripture, showed also that there was no Socinianism in the Church as a whole. Turning to the other side, the case of the Rev. W. J. E. Bennett (1870–72) vindicated for English Churchmen the right to hold and to teach the ancient doctrine of the Real Presence in the Eucharist. Naturally, changes such as these have not come about without much party feeling. The opposing tendencies are represented by (for the High Church party) the English Church Union, founded in 1859 "to defend and maintain unimpaired the doctrine, discipline, and ritual of the Church of England," and (for the Low Church party) the Church Association, founded in 1865 "to counteract the efforts now being made to pervert the teaching of the Church of England." The more aggressive spirits in the Low Church party (with whom the name of Mr Kensit was associated in their more violent outbreaks) have been active in making public protests against what they regarded as Roman tendencies; while similar tactics have been pursued by Father Black and others against the marriage of divorced persons in church, and other practices objectionable to the advanced High Church section.

(3) As regards corporate action, considerable advances have been made. The revival of the meeting of Convocation for business, if it has not given autonomy to the Church, has at least supplied it with a mouthpiece. In 1885 there was inaugurated a House of Laymen for the province by vote of both Houses of the Convocation of Canterbury. The Convocation of York followed suit in 1892, and the Houses of Laymen, although purely consultative bodies, have already done notable service. The Diocesan Synod is now a real bishop's council in some dioceses. A more popular element is supplied by the Church Congresses, held annually since 1861 at some selected centre, and presided over by the Bishop of the diocese, and by the various diocesan conferences; and the Lambeth Conferences (*q.v.*) have done very valuable work in keeping the Church at home in touch with its daughter Churches abroad. A widely felt need is being supplied by the Church House, proposed by Bishop Harvey Goodwin in 1886, founded as the Church's memorial of Queen Victoria's jubilee, and inaugurated by royal charter in 1888, to be a place of meeting for the Convocation of Canterbury, a home for Church organizations of all kinds, and a centre of operations for the whole Anglican communion.

(4) Nor can it be doubted that this enlarged corporate action has been accompanied by increased activity of the whole body. Without going into details here, one or two points may be noticed. A number of theological colleges have been founded which aim at supplying training for candidates for holy orders. New agencies for work of various kinds are supplied by brotherhoods and sisterhoods, and by institutions of deaconesses. The missionary activities of the Church of England are greater to-day than ever before. New interests are represented or stimulated by such societies as the Christian Social Union, the Church Historical Society, and the Church Reform League.

(W. E. CO.)

CHURCH WORK.

In summarized form the work and progress of the Church of England during the period 1875–1900 is treated on the next page from a statistical standpoint.

Home Missions.—The abnormal growth of population during the last quarter of the 19th century was met by the maintenance of exceptional agencies for ministering to the spiritual wants of the people. Bishops' Funds were established for creating new districts, building churches, and for the increase of parochial clergy, at a cost averaging not less than £80,000 a year. The Additional Curates Society, the Church Pastoral Aid, and kindred societies also provide for additional clergy, and otherwise assist in the extension and maintenance of Home Mission work, raising annually for this purpose about £275,000. To bring wealth and intellectual culture into closer touch with the needs of the masses, the late Bishop Walsham How took the initiative in the formation of Universities and Public Schools' Missions. Eight colleges and twenty-four public schools maintain such missions in populous centres. The Oxford House in Bethnal Green, the Cambridge House in South London, with the Inns of Court Mission in Drury Lane, have become permanent and active centres for the advancement of the religious and social welfare of the people. For the maintenance of these missions and settlements at least £35,000 is annually contributed. (See also CHURCH ARMY.) To supplement the work of the parochial clergy, systematic provision has been made for the holding of parochial missions. This work mainly originated with the Aitken Memorial Mission, now employing a staff of experienced preachers. In eighteen dioceses provision of a similar kind has been made by the appointment of diocesan missioners, or the creation of societies of mission clergy. The spiritual needs of the seafaring population have been vigorously ministered to by the missions to seamen and kindred societies. The increased activity of the military chaplains has been greatly aided by the work of the Soldiers' Institutes Association in establishing institutes at eight of the principal military depôts. At least £65,000 is annually contributed for the work of the Church among soldiers and sailors.

Foreign Missions.—The total sum contributed in voluntary offerings at home for the support of foreign missions in the year ending Easter 1900 was £831,093, 14s. 9d. To further corporate action, a Board of Missions has been established for the Provinces of Canterbury and York, and works in systematic connexion with the Houses of Convocation, collecting information, presenting reports upon the operations of various agencies, and organizing missionary unions and festivals. Associations of junior clergy have now been formed in almost every diocese: there are 91 such associations, representing a membership of 4921; they seek to promote an interest in missions by means of conferences, lectures, and services of intercession. (See also the article on MISSIONS.)

The Episcopate.—Since 1877 the sum of £533,909, 17s. 10d. has been contributed in voluntary offerings for the endowment of seven new sees, this sum being entirely independent of any assistance from the relieved dioceses or any sources of ecclesiastical income. These sees, with the date of creation and the amount contributed, are as follows:—Truro, 1877, £70,948; St Albans, 1877, £55,073; Liverpool, 1880, £94,676; Newcastle, 1882, £88,866; Southwell, 1884, £65,834; Wakefield, 1888, £83,510; Bristol, 1897, £75,000. The following suffragan bishops have been appointed since 1879: Bedford, 1879; Colchester, 1882; Marlborough, Shrewsbury, and Leicester, 1888; Richmond, Beverley, Reading, Derby, and Barrow-in-Furness, 1889; Swansea, 1890; Hull, Southwark, and Coventry, 1891; Thetford, 1894; Stepney and Southampton, 1895; Crediton, 1897; Islington, 1898; Ipswich, 1899; Kensington and Barking, 1901.

Colonial and Missionary Bishoprics.—There are now 99 Colonial and Missionary sees, and of these the following have been created since 1875:—

Asia.—Lahore and Rangoon in 1877; Travancore and Cochin, 1879; North China, 1880; South Tôkyô, 1883; Korea, 1889; Chhota Nagpur, 1890; Lucknow, 1893, Kiushiu, 1894; Western China, 1895; Tinnevelly, Osaka, and Hokkaido, 1896.

Africa.—Pretoria, 1878; Uganda, 1884; Lebombo and Mashonaland, 1891; Likoma, 1892.

Australia.—Ballarat, 1875; North Queensland, 1878; Riverina, 1883; Rockhampton, 1892; New Guinea, 1897; Carpentaria, 1899.

British North America.—Niagara, 1875; Athabasca and Qu' Appelle, 1884; Calgary, 1887; Selkirk, 1890; Ottawa, 1896; Keewatin, 1899; Kootenay, 1899; West Indies and South America, Windward Isles, 1878; Honduras, 1883.

The Clergy.—The number of deacons ordained 1875–1900 was 17,904; regarding these as additions to the ranks of the clergy, this will represent an average of 716 for each year. According to the official returns for the year ending Easter 1900, the parochial clergy numbered 21,750, representing 13,873 incumbents and 7877 assistant clergy. To these figures should be added the cathedral clergy, and a considerable number attached to the universities, public schools, hospitals, prisons, workhouses, and other institutions; with the army and navy chaplains. The official returns of the bishops for 1899–1900 report that there were 4625 clergy working in the Colonies, India, and the Missionary Dioceses.

Statistics of Parochial Work.—The following figures have been carefully registered in exact detail from the official returns of the clergy for the year ending Easter 1900:—Baptisms, infants 578,489, adults 12,244; communicants, 1,974,629; communicants' classes, 227,268; celebrations of the holy communion (monthly), before midday 32,293, at midday 23,045, after midday 2142; church accommodation, parish churches, appropriated 1,342,980, free 4,333,913; chapels of ease, appropriated 67,295, free 532,503; mission rooms, 609,307; other buildings systematically used for service, 114,377; total accommodation, appropriated 1,410,275, free 5,590,100; churches open for daily prayer, 4848; for private prayer, 6838; Sunday schools, infants 647,313, boys 805,453, girls 934,914; teachers, male 55,453, female 148,449; Bible classes, male 220,655, female 233,527; guilds, male 122,501, female 322,322; temperance work, adult abstainers 117,851, adult non-abstainers 45,798, juvenile abstainers 437,046; lay-help: district visitors, male 3406, female 67,376; lay-readers, licensed 2280, unlicensed 1959; sisters, 641; deaconesses, 379; nurses, 2030; mission women, 980; choir, male 251,192, female 86,278. With regard to confirmation, the number of candidates for 1900 were: males 79,058, females 116,511, total 195,569.

Church Extension.—During the last quarter of the 19th century 1712 churches were built or rebuilt, and 6325 churches restored; the cost of such work in the year 1899 was £1,183,739, practically representing the annual expenditure. Taking a period of sixteen years (1884–99), the following sums were contributed in purely voluntary offerings for these specific branches of Church extension: church building, £17,531,626; endowment of benefices, £2,348,611; burial-grounds, £410,572; parsonage houses, £1,567,739: making a total of £21,858,548. A parliamentary return shows that from 1868 to 1896, 1461 new parishes were constituted under Church Building Acts, providing for a population of 4,926,243.

Education.—The Church has vigorously maintained her voluntary schools. The accommodation increased from 2,011,434 in 1875 to 2,794,791 in 1899; the average attendance from 1,175,289 to 1,895,569; the number of assistant and certificated teachers from 15,763 to 45,823; the average cost per scholar was £1, 11s. 11d., increasing to £2, 4s. 11d. in 1899. In that year the sum of £42,880 was spent upon the maintenance of thirty training colleges for masters and mistresses, and the diocesan religious inspection of schools. For the year 1899, £996,808 was voluntarily contributed for the general maintenance of elementary schools, and the enlargement of school buildings. The total amount of voluntary expenditure on church schools and training colleges since 1870 was £27,352,967. The educational work of the Church has been immensely aided by the *National Society*, through its liberal grants for the building and maintenance of Church training colleges, the religious inspection of schools, and by the assistance it has given in grants of books and fittings. In the *Sunday Schools* of the Church of England there are now 2,387,680 children receiving instruction from 203,892 teachers. In adult Bible classes, more or less connected with Sunday schools, there are 454,182 members. The Sunday-school work is voluntarily maintained at an annual cost of about £150,000. For the instruction of children and adults of the higher and middle classes in the principles and teaching of the Church of England, reading societies have been formed in sixteen dioceses; by this provision courses of lectures are given at certain fixed centres, and examinations annually held. Seven schools have been established since 1875 in development of the Woodard scheme, making in all thirteen. Considerably over £500,000 has been voluntarily contributed for the foundation and maintenance of these schools. For the education of children above the class attending elementary schools, the Church Schools Company was formed in 1883, and in 1900 had 27 schools, educating about 2500. The *Society for Promoting Christian Knowledge* has, to a most valuable extent, advanced the higher education of the people by its publications and circulation of pure and popular literature, and its generous grants of books and tracts. In the British colonies and dependencies the work of the society has much assisted the bishops and clergy.

Philanthropic Work.—The extent of the efforts of the Church in this direction may be inferred from the following records of voluntary contributions during 1900: for industrial schools, penitentiaries, and preventive homes, £208,279, 18s.; orphanages, £124,792, 10s. 3d.; nursing institutions, convalescent homes, and cottage hospitals, £189,757, 0s. 5d.; making a total of £522,829, 8s. 8d. The figures relating to the Metropolitan Hospital Sunday Fund are especially instructive; the contributions between 1872 and 1900 represented a total of £922,116, 13s.; of this the Church of England contributed £715,552, 7s. in 24,282 separate collections out of a total of 41,199.

Clerical Incomes and Support of the Clergy.—The official returns for the year ending Easter 1900 represented the gross income of the clergy arising from all sources to be £4,386,451, 4s. 11d., the total deductions £973,611, 19s. 6d., leaving a net income of £3,412,839, 4s. 5d. This will give the average income of a benefice as £241, and to this figure should be generally added the value of the parsonage-house. Owing to the serious diminution in the value of tithe, with the consequent prevalence of poverty it has created, it has become necessary to organize provision for subsidizing diminished clerical incomes; this has been made by the inauguration of the Queen Victoria Clergy Fund, incorporated by Royal Charter in 1897; working in co-operation with this Fund, each diocese has its own distinct organization, and by this union of effort a sum averaging about £30,000 is annually raised. A large number of educational and charitable societies also exist for the assistance of the poorer clergy, their widows and orphans, representing an expenditure of about £140,000.

Voluntary Offerings.—The Church of England raised during the year ending Easter 1900 a sum total of £7,770,992, 15s. 1d. by purely voluntary effort and gifts, completely exclusive of any grants from the Ecclesiastical Commissioners, Queen Anne's Bounty, or anything in the nature of Government aid; nor does this amount embrace the contributions to societies supported by the co-operation of Churchmen and Nonconformists.

Brotherhoods.—There has been a growing recognition of the value of Brotherhoods, and of their work and life in the Church of England. Several new societies have been founded. The Society of Mission Priests of St John the Evangelist, otherwise known as the *Cowley Fathers*, was founded by the Rev. R. M. Benson in 1865 at Cowley St John, for the cultivation of a life dedicated to God, upon the principles of poverty, chastity, and obedience. It works by missionary and educational efforts for the advancement of Christ's kingdom at home and abroad; lay brothers are united with the clergy in dedication to the religious life, and generally assist in carrying out the aims of the society. The society has extended its labours to Bombay and Poonah in India, Cape Town in South Africa, and Boston in the United States.—The *Community of the Resurrection* had its origin in 1892 at Pusey House, Oxford, its founder being the Rev. Charles Gore. Subsequently it removed to Radley, then to Westminster, and it is now permanently located at Mirfield, in Yorkshire. The society consists of celibate clergy living under rule and with a common purse. As a condition of membership each priest must serve a period of probation with the intention of permanent association with the community, without binding himself, however, by any life vow. Taking the basis of study and prayer, each member is pledged to occupy himself in various works for the edification of the Church, pastoral, evangelistic, literary, and educational.—The *Society of the Sacred Mission* originated in the widely felt necessity for an agency which should train working-men and others who might be deterred by want of means or education for the foreign mission field. The work was begun in 1891, at the desire of Bishop Corfe of Korea, by the Rev. H. Kelly. The house is now located at Mildenhall, in Suffolk, and is recognized by the Bishop of Ely as a theological and missionary college. Each applicant for admission declares his intention (1) to serve for his whole life unpaid, receiving only the necessaries of life; (2) to remain unmarried; (3) not to seek ordination or undertake any work not assigned to him. The training varies from one to eight years; the life is of the simplest, the discipline that of a religious house.—The *Order of St Paul* is a community for priests and laymen "dedicated to God and our merchant seamen in holy religion." The house is at Alton, in Hampshire.—There is also a community, consisting of clerical and lay members, which has its headquarters in the mission district of St Philip's, Plaistow, E. The members are engaged in the work of the mission. (See also SISTERHOODS.) (F. BU.)

ENGLAND AND WALES.[1]

I. GEOGRAPHY.

THE object of this section is to give a physical description of England and Wales according to natural regions, which usually follow the geology of the country very closely. The lines of division thus do not correspond with the political or official divisions used for other purposes, and the general description which follows is intended to be supplemented by the statistics of the separate counties and towns, which will be found in separate articles. The southern portion of the island of Great Britain, to which alone the name of England is properly applied, extends from the mouth of the Tweed in 55° 48′ N. lat. to Lizard Head in 49° 58′ N., in a roughly triangular form. The base of the triangle runs from the South Foreland to Land's End W. by S., a distance of 316 miles in a straight line, but 545 miles following the larger curves of the coast. The east coast runs N.N.W. from the South Foreland to Berwick, a distance of 348 miles, or, following the coast, 640 miles. The west coast runs N.N.E. from Land's End to the head of Solway Firth, a distance of 354 miles, or, following the much-indented coast, 1225 miles. The total length of the coast-line may be put down as 2350 miles.[2] The most easterly point is at Lowestoft, 1° 46′ E., the most westerly is Land's End, in 5° 43′ W. The total area is given officially as 58,309 square miles, of which 50,867 square miles are assigned to England and 7442 square miles to Wales. The coasts are nowhere washed directly by the ocean, except in the extreme south-west; the south coast faces the English Channel, which is bounded on the southern side by the coast of France, converging from 100 miles apart at the Lizard to 21 at Dover. The east coast faces the shallow North Sea, which widens from the point where it joins the Channel to 375 miles off the mouth of the Tweed, the opposite shores being occupied in succession by France, Belgium, Holland, Germany, and Denmark. The west coast faces the Irish Sea, with a width varying from 45 to 130 miles. Except along the centre of the Irish Sea, at one point off the Tweed, and one between Devon and Normandy, the depth of water between England and the nearest land nowhere exceeds 50 fathoms. The east and south coasts show considerable stretches of uniform uninflected coast-line, and except for the Farne Islands and Holy Island in the extreme north, and the Isle of Wight in the south, they are without islands. The west coast, on the other hand, is minutely fretted into capes and bays, headlands and inlets of every size, and an island-group lies off every great headland. The coast-line, both on the west and east, is curved into numerous large inlets, which may be grouped in pairs—the Thames and Severn, the Wash and Cardigan Bay, the Humber and Mersey, the Tyne and Solway. In this way the land is so deeply penetrated by the water that no part is more than 75 miles from the sea.[3]

General Configuration and Geology.[4]—In their broad lines the configuration and geology of the country are

[1] See also UNITED KINGDOM, THE.

[2] Measurements made on a map on the scale of 12½ miles to 1 inch, the coast being assumed to run up estuaries until the breadth became 1 mile, and no bays or headlands of less than one mile across being reckoned. The coast-line of Anglesea and the Isle of Wight, but of no other islands, is included.

[3] Buckingham appears to be the most inland town in England, being 75 miles from the estuaries of the Severn, Thames, and Wash; Coleshill, near Birmingham, is also almost exactly 75 miles from the Mersey, Severn, and Wash.

[4] The work of the Ordnance Survey, the Geological Survey, and the Hydrographic Survey of the Admiralty suffices to delineate the configuration and the geology of England and the adjacent sea-beds with a completeness not surpassed in the case of any country. Statistics of every kind—of climate, agriculture, mining, manufactures, trade, population, births, marriages, deaths, disease, migration, education—are liberally furnished by Government agencies at the public expense; but the form in which they are compiled and published makes it impossible to utilize the data for the purpose of discussing general distributions in relation to the fixed geographical features. Hence this sketch is more imperfect than the space devoted to it necessitates. For a scheme for the complete geographical description of the British Islands and a specimen worked out in detail for a small area, see papers by H. R. Mill in *Geographical Journal*, vii., 1896, p. 345; xv., 1900, p. 205.

closely related, though the relationship is not so simple or so clearly marked as in Scotland. The land is highest in the west and north, where the rocks also are oldest, most disturbed, and hardest, and the land surface gradually sinks towards the east and south, where the rocks become successively less disturbed, more recent, and softer. The study of the scenery of England and Wales as a whole, or the study of orographical and geological maps of the country, allows a broad distinction to be drawn between the types of land-forms in the west and in the east. This distinction is essential, and applies to all the conditions of which geography takes account. The contrasted districts are separated by an intermediate area, which softens the transition between them, and may be described separately.

The Western Division is composed entirely of Archæan and Palæozoic rocks, embracing the whole range from pre-Cambrian up to Carboniferous. The outcrops of these rocks succeed each other in order of age in roughly concentric belts, with the Archæan mass of the island of Anglesea as a centre, but the arrangement in detail is much disturbed and often very irregular. Contemporary igneous outbursts are extremely common in some of the ancient formations, and add, by their resistance to atmospheric erosion, to the extreme ruggedness of the scenery. The hills and uplands of ancient rocks do not form regular ranges, but rise like islands in four distinct groups from a plain of New Red Sandstone (Permian and Triassic), which separates them from each other and from the newer rocks of the Eastern Division. Each of the uplands is a centre for the dispersal of streams; but with only one prominent exception (the Humber), these reach the sea without crossing into the Eastern Division of the country.

The Eastern Divison, lying to the east of the zone of New Red Sandstone, may be defined on the west by a slightly curved line drawn from the estuary of the Tees through Leicester and Stratford-on-Avon to the estuary of the Severn, and thence through Glastonbury to Sidmouth. It is built up of nearly uniform sheets of Mesozoic rock, the various beds of the Jurassic lying above the New Red Sandstone (Triassic), and dipping south-eastward under the successive beds of the Cretaceous system. In exactly the same way the whole of the south-east of the island appears to have been covered uniformly with gently dipping beds of Tertiary sands and clays, beneath which the Cretaceous strata dipped. At some period subsequent to this deposition there was a movement of elevation, which appears to have thrown the whole mass of rocks into a fold along an anticlinal axis running west and east, which was flanked to north and south by synclinal hollows. In these hollows the Tertiary rocks were protected from erosion, and remain to form the London and the Hampshire Basins respectively, while on the anticlinal axis the whole of the Tertiary and the upper Cretaceous strata have been dissected away, and a complex and beautiful configuration has been impressed on the district of the Weald. The general character of the landscape in the Eastern Division is a succession of steep escarpments formed by the edges of the outcropping beds of harder rock, and long gentle slopes or plains on the dip-slopes, or on the softer layers; clay and hard rock alternating throughout the series.

The contrast between the lower grounds of the Western and the Eastern Divisions is masked in many places by the general covering of the surface with glacial drift, a stiff clay composed on the whole of the detritus of the rocks upon which it rests, but usually containing fragments of rocks which have been transported from a considerable distance. This boulder clay covers almost all the low ground north of the Thames Basin, its southern margin fading away into washed sands and gravels.

The history of the origin of the land-forms of England, as far as they have been deduced from geological studies, is exceedingly complicated, and cannot be touched on here. The fact that every known geological formation (except the Miocene) is represented, proves of itself how long the history has been, and how multifarious the changes. It must suffice to say that the separation of Ireland from England was a comparatively recent episode, while the severance of the land-connection between England and the Continent by the formation of the Strait of Dover is so recent as probably to have come within the human period.

Climate.

Temperature.—The mean annual temperature of the whole of England and Wales (reduced to sea-level) is about 50° F., varying from something over 52° in the Scilly Isles to something under 48° at the mouth of the Tweed. The mean annual temperature diminishes very regularly from south-west to north-east, the west coast being warmer than the east, so that the mean temperature at the mouth of the Mersey is as high as that at the mouth of the Thames. During the coldest month of the year (January) the mean temperature of all England is about 40°. The influence of the western ocean is very strongly marked, the temperature falling steadily from west to east. Thus while the temperature in the west of Cornwall is 44°, the temperature on the east coast from north of the Humber to the Thames is under 38°, the coldest winters being experienced in the Fenland. In the hottest month (July) the mean temperature of England and Wales is about 61°·5, and the westerly wind then exercises a cooling effect, the greatest heat being found in the Thames basin immediately around London, where the mean temperature of the month exceeds 64°. The average temperature along the south coast is 62°, and that at the mouth of the Tweed a little under 59°. In the centre of the country along a line drawn from London to Carlisle the temperature is found to diminish gradually at an average rate of 1° per 60 miles. The coasts are cooler than the centre of the country, but the west coast is much cooler than the east, modified continental conditions prevailing over the North Sea. The natural effect of the heating of the air in summer and the cooling of the air in winter by contact with the land is largely masked in England on account of the strength of the prevailing south-westerly wind carrying oceanic influence into the heart of the country. This effect is well seen in the way in which the wind blowing directly up the Severn estuary is directed along the edges of the Oolitic escarpment north-eastward, thus displacing the centre of cold in winter to the east coast, and the centre of heat in summer to the lower Thames, from the normal position of both centres in a narrow strip running from Birmingham to Buckingham. As to how far the narrow portion of the North Sea modifies the influence of the European continent, there seems reason to believe that the prevailing winds blowing up the English Channel carry oceanic conditions some distance inland, along those parts of the Continent nearest to England. The Mersey estuary, being partly sheltered by Ireland and North Wales, does not serve as an inlet for modifying influences to the same extent as the Bristol Channel; and as the wind entering by it blows squarely against the slope of the Pennine Chain, it does not much affect the climate of the central plain.

Winds.—The average barometric pressure over England is about 29·940 inches, and normally diminishes from south-west to north-east at all seasons, the mean pressure on the south coast being 29·970, and that on the northern border 29·880. The pressure at any given latitude is normally highest in the centre of the country and on the east coast, and lowest on the west coast. The direction of the mean annual isobars shows that the normal wind in all parts of England and Wales must be from the south-west on the west coast, curving gradually until in the centre of the country, and on the east coast it is westerly, without a southerly component. The normal seasonal march of pressure-change produces a maximum gradient in December and January, and a minimum gradient in April; but for every month in the year the gradient is for winds from southerly and westerly quarters. In April the gradient is so slight that any temporary fall of pressure to the south of England, or any temporary rise of pressure to the north, which would suffice in other months merely to reduce the velocity of the south-westerly wind, is sufficient in that month to reverse the gradient and produce an east wind over the whole country. The liability to east wind in spring is one of the most marked features of the English climate, the effect being naturally most felt on the east coast. The southerly component in the wind is as a rule most marked in the winter months, the westerly component predominating in summer. The west end of a town receives the wind as it blows in fresh from the country at all seasons, and consequently the west end of an English town is with few exceptions the residential quarter, while smoke-producing industries are usually relegated to the east end.

Storms.—On account of the great frequency of cyclones passing in from the Atlantic, the average conditions of wind over the British Islands give no idea of the frequency of change in the direction and force of the wind. The chief cyclone paths are from south-west to north-east across England; one track runs across the south-east and eastern counties, and is that followed by a large proportion of the summer and autumn storms, thereby perhaps helping to explain the peculiar liability of the east of England to damage from hail accompanying thunderstorms. A second track crosses central England, entering by the Severn estuary and leaving by the Humber or the Wash; while a third crosses the north of England from the neighbourhood of Morecambe Bay to the Tyne. While these are tracks frequently followed by the centres of barometric depressions, individual cyclones may and do cross the country in all directions, though it is very rarely indeed that they move from east to west or from north to south.

Rainfall.—The rainfall of England, being largely due to passing cyclones, cannot be expected to show a very close relation to the physical features of the country, but looked at in a general way the relation between prevailing winds and orographic structure is not obscure. The western or mountainous division is the wettest at all seasons, each orographic group forming a centre of heavy precipitation. There are few places in the Western Division where the rainfall is less than 35 inches, while in Wales, the Cornwall-Devon peninsula, the Lake District, and the southern part of the Pennine Chain the precipitation exceeds 40 inches, and in Wales and the Lake District considerable areas have a rainfall of over 60 inches. In the Eastern Division, on the other hand, an annual rainfall exceeding 30 inches is rare, and in the low ground about the mouth of the Thames estuary and around the Wash the mean annual rainfall is less than 25 inches. In the Western Division and along the south coast the driest month is usually April or May, while in the Eastern Division it is February or March. The wettest month for most parts of England is October, the most noticeable exception being in East Anglia, where July is the month in which most rain falls, although October is not far behind. In the Western Division there is a tendency for the annual maximum of rainfall to occur later than October. It may be stated generally that the Western Division is mild and wet in winter, and cool and less wet in summer; while the Eastern Division is cold and dry in winter and spring, and hot and less dry in summer and autumn. The south coast occupies an intermediate position between the two as regards climate. Attention has been called to the fact that the bare rocks and steep gradients which are common in the Western Division allow of the heavy rainfall running off the surface rapidly, while the flat and often clayey lands of the Eastern Division retain the scantier rainfall in the soil for a longer time, so that for agricultural purposes the effect of the rainfall is not very dissimilar throughout the country.

Sunshine.—The distribution of sunshine is not yet fully investigated, but it appears that the sunniest part is the extreme south coast, where alone the total number of hours of bright sunshine reaches an average of 1600 per annum. The north-east, including the Pennine Chain and the whole of Yorkshire, has less than 1300 hours of sunshine, and a portion of North Wales is equally cloudy. Although little more than a guess, 1375 hours may be put down as approximately the average duration of bright sunshine for England as a whole, which may be compared with 2600 hours for Italy, and probably about 1200 hours for Norway.

For the purpose of forecasting the weather, the Meteorological Office divides England into six districts, which are known as England N.E., Midland Counties, England East, London and Channel, England N.W. and North Wales, and England S.W. and South Wales.

The western division.

Natural Divisions.—The four prominent groups of high land rising from the plain of the Red Rocks are: (1) the *Lake District*, bounded by the Solway Firth, Morecambe Bay, and the valleys of the Eden and the Lune; (2) the *Pennine Chain*, which stretches from the Scottish border to the centre of England, running due south; (3) *Wales*, occupying the peninsula between the Mersey and the Bristol Channel, and extending beyond the political boundaries of the principality to include Shropshire and Hereford; and (4) the peninsula of *Cornwall and Devon*. They are all similar in the great features of their land-forms, which have been impressed upon them by the prolonged action of atmospheric denudation rather than by the original order and arrangement of the rocks; but each group has its own geological character, which has imparted something of a distinctive individuality to the scenery. Taken as a whole, the Western Division depends for its prosperity on mineral products and manufactures rather than on farming; and the staple of the farmers is live-stock rather than agriculture. The people of the more rugged and remoter groups of this Division are by race survivors of the early Celtic stock, which, being driven by successive invaders from the open and fertile country of the Eastern Division, found refuges in the less inviting but more easily defended lands of the west. Even where, as in the Pennine region and the Lake District, the people have been completely assimilated with the Teutonic stock, they retain a typical character, marked by independence of opinion approaching stubbornness, and by great determination and enterprise.

Lake District.—The Lake District occupies the counties of Cumberland, Westmorland, and North Lancashire. It forms a roughly circular highland area, the drainage lines of which radiate outward from the centre in a series of narrow valleys, the upper parts of which cut deeply into the mountains, and the lower widen into the surrounding plain. Sheets of standing water are still numerous, and formerly almost every valley contained a single long narrow lake-basin; but some of these have been subdivided, drained, or filled up by natural processes. The existing lakes include Windermere and Coniston, draining south; Wastwater, draining south-west, Ennerdale water, Buttermere, and Crummock water (originally one lake, now divided by a delta), draining north-west; Derwent water and Bassenthwaite water (which were probably originally one lake), and Thirlmere, draining north; Ullswater and Haweswater, draining north-east. There are, besides, numerous mountain tarns of small size, most of them in hollows barred by the glacial drift which covers a great part of the district. The central and most picturesque part of the district is formed of great masses of volcanic ashes and tuffs, with intrusions of basalts and granite, all of Ordovician (Lower Silurian) age. Scafell and Scafell Pike (3210 feet and 3162 feet), at the head of Wastwater, and Helvellyn (3118), at the head of Ullswater, are the loftiest amongst many summits the grandeur of whose outlines is not to be estimated by their height. Sedimentary rocks of the same age form a belt to the north, and include Skiddaw (3054 feet); while to the south a belt of Silurian rocks, thickly covered with boulder clay, forms the finely wooded valleys of Coniston and Windermere. Round these central masses of early Palæozoic rocks there is a broken ring of Carboniferous Limestone, and several patches of Coal Measures, while the New Red Sandstone appears as a boundary belt outside the greater part of the district. Where the Coal Measures reach the sea at Whitehaven, there are coal-mines, and the hematite of the Carboniferous Limestones has given rise to the active ironworks of Barrow-in-Furness, now the largest town in the district. Except in the towns of the outer border, the Lake District is very thinly peopled; and from the economic point of view, the remarkable beauty of its scenery, attracting numerous residents and tourists, is the most valuable of its resources. The very heavy rainfall of the district, which is the wettest in England, has led to the utilization of Thirlmere as a reservoir for the water supply of Manchester, over 80 miles distant.

Pennine District.—The Pennine District, the centre of which forms the so-called Pennine Chain, occupies the country from the Eden valley to the North Sea in the north, and from the lower Tees, Yorkshire Ouse, and Trent, nearly to the Irish Sea, in the south. It includes the whole of Northumberland and Durham, the West Riding of Yorkshire, most of Lancashire and Derbyshire the north of Staffordshire, and the west of Nottinghamshire. The Pennine Chain forms a north and south watershed which determines the course of the rivers of the whole of the north. It is entirely composed of Carboniferous rocks, the system which transcends all others in the value of its economic minerals. The coal and iron have made parts of the region the busiest manufacturing districts, and the centres of densest population, in the country, or even in the world. The whole region may be looked upon as formed by an arch or anticline of Carboniferous strata, the axis of which runs north and south; the centre has been worn away by erosion, so that the Coal Measures have been removed, and the underlying Millstone Grit and Carboniferous Limestone exposed to the influences which form scenery. On both sides of the arch, east and west, the Coal Measures remain intact, forming outcrops which disappear towards the sea under the more recent strata of Permian or Triassic age. The northern part of the western side of the anticline is broken off by a great fault in the valley of the Eden, and the scarp thus formed is rendered more abrupt by the presence of a sheet of intrusive basalt. Seen from the valley, this straight line of lofty heights, culminating in Crossfell (2900 feet), presents the nearest approach in England to the appearance of a mountain range. In the north the Pennine region is joined to the Southern Uplands of Scotland by the Cheviot Hills, a mass of granite and Old Red Sandstone; and the northern part is largely traversed by dykes of contemporary volcanic or intrusive rock. The most striking of these dykes is the Great Whin Sill, which crosses the country from a short distance south of Durham almost to the source of the Tees, near Crossfell. The elevated land is divided into three masses by depressions, which furnish ready means of communication between east and west. The South Tyne and Irthing valleys cut off the Cheviots on the north from the Crossfell section, which is also marked off on the south by the valleys of the Aire and Ribble from the Kinderscout or Peak section. The numerous streams of the region carry off the rainfall down long valleys or dales to the east and the south, and by shorter and steeper valleys to the west. The dales are separated from each other by high uplands, which for the most part are heathery moorland or, at best, hill pastures. The agriculture of the region is confined to the bottoms of the dales, and is of small importance. Crossfell and the neighbouring hills are formed from masses of Carboniferous Limestone, which received its popular name of Mountain Limestone from this fact. Farther south, such summits as High Seat, Whernside, Bow Fell, Penyghent, and many others, all over 2000 feet in height, are capped by portions of the Grits and Sandstones, which rest upon the Limestone. The belt of Millstone Grit south of the Aire, lying between the great coal-fields of the North Riding and Lancashire, has a lower elevation, and forms grassy uplands and dales; but farther south, the finest scenery of the whole region occurs in the limestones of Derbyshire, in which the range terminates. The rugged beauty of the south-running valleys, and especially of Dovedale, is enchanced by the rich woods which still clothe the slopes. There are remarkable features underground as well as on the surface, the caverns and subterranean streams of Yorkshire and Derbyshire being amongst the deepest that have yet been explored. Compared with the rugged and picturesque scenery of the Lower Carboniferous rocks, that of the Coal Measures is, as a rule, featureless and monotonous. The coal-fields on the eastern side, from the Tyne nearly to the Trent, are sharply marked off on the east by the outcrop of Permian dolomite or Magnesian limestone, which forms a low terrace dipping towards the east under more recent rocks, and in many places giving rise to an escarpment facing westward towards the gentle slope of the Pennine dales. To the west and south the Coal Measures dip gently under the New Red Sandstone, to reappear at several points through the Triassic plain. The clear water of the upland becks and the plentiful supply of water-power led to the founding of small paper-mills in remote valleys before the days of steam, and many of these primitive establishments still exist. The prosperity and great population of the Pennine region dates from the discovery that pit-coal could smelt iron as well as charcoal; and this source of power once discovered, the people bred in the dales developed a remarkable genius for mechanical invention and commercial enterprise, which revolutionized the economic life of the world and changed England from an agricultural to an industrial country. The staple industry of the district in ancient times was sheep-rearing, and the villages in nearly all the dales carried on a small manufacture of woollen cloth. The introduction of cotton caused the woollen manufactures on the western side to be superseded by the working up of the imported raw material; but woollen manufactures, themselves carried on now almost entirely with imported raw material, have continued to employ the energies of the inhabitants of the east. Some quiet market-towns, such as Skipton and Keighley, remain, but most of them have developed by manufactures into great centres of population, lying, as a rule, at the junction of thickly peopled valleys, and separated from one another by the empty uplands. Such are Leeds, Bradford, Sheffield, Huddersfield, and Halifax on the great and densely peopled West Riding coal-field, which lies on the eastern slope of the Pennines. The iron ores of the Coal Measures have given rise to great manufactures of steel, from cutlery to machinery and armour-plates. High on the barren crest of the Pennines, where the rocks yield no mineral wealth, Harrogate, Buxton, and Matlock are types of health resorts, prosperous from their pure air and fine scenery. Across the moors, on the western side of the anticline, the vast and dense population of the *Lancashire coal-field* is crowded in the manufacturing towns which surround the great commercial centre, Manchester, which itself stands on the edge of the Triassic plain. Ashton, Oldham, Rochdale, Bury, Bolton, and Wigan form a nearly confluent semicircle of great towns, their prosperity founded on the underlying coal and iron, maintained by imported cotton. The Lancashire coal-field, and the portion of the bounding plain between it and the seaport of Liverpool, contains a population greater than that borne by any equal area in the country, the county of London and its surroundings not excepted. In the south-west of the Pennine region the coal-field of North Staffordshire supports the group of small but active towns known collectively from the staple of their trade as "The Potteries." On the north-east the great coal-field of Northumberland and Durham, traversed midway by the Tyne, supports the manufactures of Newcastle and its satellite towns, and leaves a great surplus for export from the Tyne ports.

Wales.—The low island of Anglesea, which is built up of the fundamental Archæan rocks, is important as a link in the main line of communication with Ireland, because it is separated from the mainland by a channel narrow enough to be bridged, and lies not far out of the straight line joining London and Dublin. The mainland of Wales rises into three main highlands, the mountain groups of North, Mid, and South Wales, connected together by land over 1000 feet in elevation in most places; but separated by valleys forming easy highways. The streams of the southern and western slopes are short and many, flowing directly to the Bristol Channel and the Irish Sea; but the no less numerous streams of the eastern slopes gather themselves into three river systems, and reach the sea as the Dee, the Severn, and the Wye. The mountain group of *North Wales* is the largest and loftiest; its scenery resembles that of the Scottish Highlands because of the juxtaposition of ancient Palæozoic rocks—Cambrian and Ordovician, often altered into slate—and contemporaneous volcanic outbursts and igneous intrusions. Here rises the peak of Snowdon (3560 feet), the culminating point of South Britain, and near it half a dozen summits exceed 3000 feet, while Cader Idris, farther south, though slightly lower, presents a singularly imposing outline. The mild winter climate has fringed the coast with seaside resorts; the rugged heights attract tourists in summer, and the vast masses of slate have given rise to the largest slate quarries in the world. The heavy rainfall of the upper valleys unfits them for agriculture, and the farms are poor. There are several lakes: that of Bala being the largest, except the old lake of Vyrnwy, reconstituted artificially to store the rainfall for the water supply of Liverpool, 68 miles distant. The Vyrnwy is tributary to the Severn; but north of it the streams gather into the Dee, and flow eventually northward. *Mid Wales* is built up, for the most part, of Silurian or Ordovician rocks, practically free from igneous intrusions except in the south-west. There the resistance of a series of igneous dykes gives prominence to the Pembroke peninsula, in which the fine fjord-like harbour of Milford Haven lies far out towards the Atlantic. The coast north of Pembroke and Merioneth has been worked into the grand sweep of Cardigan Bay, its surface carved into gently rounded hills, green with rich grass, which sweep downward into wide rounded valleys. Plynlymmon (2468 feet) is the highest of the hills, and forms a sort of hydrographic centre for the group, as from its eastern base the Severn and the Wye take their rise—the former describing a wide curve to east and south, the latter forming a chord to the arc in its southward course. Mid Wales is mainly a pastoral country, and very thinly peopled. The group of heights of *South Wales*, running on the whole from west to east, marks the outcrops of the Old Red Sandstone and Carboniferous strata which lie within a vast syncline of the Silurian rocks. The Brecon Beacons of Old Red Sandstone are the highest (2907 feet), but the Black Mountain bears a number of picturesque peaks carved out of Millstone Grit and Carboniferous Limestone, which rise frequently to over 2000 feet. Throughout Hereford, and in part of Monmouthshire, the Old Red Sandstone sinks to a great undulating plain, traversed by the exquisite windings of the Wye, and forming some of the richest pasture and fruit lands of England. This plain formed an easy passage from south to north, and since the time of the Romans was a strategical line of the greatest importance, a fact which has left its traces on the present distribution of towns. Around the western and northern edge of the Old Red Sandstone plain the underlying Silurian rocks (and even the Cambrian and Archæan in places) have been bent up so that their edges form hills of singular abruptness and beauty. Of these are the Malvern Hills, east of Hereford, and in particular the hills of Shropshire. Wenlock Edge, running from south-west to north-east, is an escarpment of Silurian limestone, while the broad upland of Long Mynd, nearly parallel to it on the north, is a mass of Archæan rock. The Wrekin, the Caradoc and Cardington Hills, are isolated outbursts of pre-Cambrian volcanic rocks. The outer rim of the Welsh area contains a broken series of coal-fields, where patches of Carboniferous strata come to the surface on the edge of the New Red Sandstone plain. Such are the coal-fields of Flint in the north, the Forest of Wyre and the Forest of Dean, close to the Severn, on the east. The great coal-field on the south is a perfect example of a synclinal basin, the Millstone Grit and Carboniferous Limestone which underlie the Coal Measures appearing all round the margin. This coal-field occupies practically the whole of Glamorgan and part of Monmouth, and its surface slopes from the Black Mountain and Brecon Beacons to the sea as a gently inclined plateau, scored by deep valleys draining south. Each chief valley has a railway connecting a string of mining villages, and converging seaward to the busy ports of Newport, Cardiff, and Barry Dock (a town created on a sandy island to form an outlet for the mines). In the north of the field, where the limestone crops out and supplies the necessary flux, Merthyr Tydfil has become great through iron-smelting; and in the west Swansea is the chief centre in the world for copper and tin smelting. The unity and ruggedness of the highlands of Wales have proved sufficient to isolate the people from those of the rest of South Britain, and to preserve a purely Celtic race, still very largely of Celtic speech.

Cornwall and Devon.—The peninsula of Cornwall and Devon may be looked upon as formed from a synclinal trough of Devonian rocks, which appear as plateaux on the north and south, while the centre is occupied by Lower Carboniferous strata at a lower level. The northern coast, bordering the Bristol Channel, is steep, with picturesque cliffs and deep bays or short valleys running into the high land, each occupied by a little seaside town or village. The plateau culminates in the barren heathy upland of Exmoor, which slopes gently southward from an elevation of

1600 feet, and is almost without inhabitants. The Carboniferous rocks of the centre form a soil which produces rich pasture under the heavy rainfall and remarkably mild and equable temperature, forming a great cattle-raising district. The Devonian strata on the south do not form such lofty elevations as those on the north, and are in consequence, like the plain of Hereford, very fertile and peculiarly adapted for fruit-growing and cider-making. The remarkable features of the scenery of South Devon and Cornwall are due to a narrow band of Archæan rock which appears in the south of the peninsulas terminating in Lizard Head and Start Point, and to huge masses of granite and other eruptive rocks which form a series of great bosses and dykes. The largest granite boss forms the wild upland of Dartmoor, culminating in Yes Tor at 2000 feet. The clay resulting from the weathering of the granite has formed marshes and peat bogs, and the desolation of the district has been emphasized by the establishment in its midst of a great convict prison. The Tamar flows from north to south on the Devonian plain, which lies between Dartmoor on the east and the similar granitic boss of Bodmin Moor (where Brown Willy rises to 1345 feet) on the west. There are several smaller granite bosses, of which the mass of Land's End is the most important. Most of the Lizard peninsula, the only part of England stretching south of 50° N., is a mass of serpentine. The great variety of the rocks which meet the sea along the south of Cornwall and Devon has led to the formation of a singularly picturesque coast—the headlands being carved from the hardest igneous rocks, the bays cut back in the softer Devonian strata. The fjord-like inlets of Falmouth, Plymouth, and Dartmouth are splendid natural harbours, which would have developed great commercial towns but for their remoteness from the centres of commerce and manufactures. China clay from the decomposing granites; tin and copper ore, once abounding at the contacts between the granite and the rocks it pierced, were the former staples of wealth, and the mining largely accounts for the exceptional density of population in Cornwall. Fishing has always been important, the numerous good harbours giving security to fishing-boats; and the fact that this coast is the mildest and almost the sunniest, though by no means the driest, part of Great Britain has led to the establishment of many health resorts, of which Torquay is the chief. The old Cornish language of the Celtic stock became extinct only in the 18th century, and the Cornish character remains as a heritage of the time when the land had leisure to mould the life and the habits of the man. Projecting farthest of all England into the Atlantic, it is not surprising that the West country has supplied a large proportion of the great naval commanders in British history, and of the crews of the navy.

The central plain.

Between the separate uplands there extends a plain of Permian and Triassic rocks, which may conveniently be considered as an intermediate zone between the two main divisions. To the eye it forms an almost continuous plain with the belt of Lias clays, which is the outer border of the Eastern Division; for although a low escarpment marks the line of junction, and seems to influence the direction of the main rivers, there is only one plain so far as regards free movement over its surface, and the construction of canals, roads, and railways. The plain usually forms a distinct border along the landward margins of the uplands of more ancient rock, though to the east of the Cornwall-Devon peninsula it is not very clear, and its continuity in other places is broken by inliers of the more ancient rocks, which everywhere underlie it. One such outcrop of Carboniferous Limestone in the south forms the Mendip Hills; another of the Coal Measures increases the importance of Bristol, where it stands at the head of navigation on the southern Avon. In the north-west a tongue of the Red rocks forms the Eden valley, separating the Lake District from the Pennine Chain, with Carlisle as its central town. Farther south, these rocks form the low coastal belt of Lancashire, edged with the longest stretches of blown sand in England, and dotted here and there by pleasure towns, like Blackpool and Southport. The plain sweeps round south of the Lancashire coal-field, forms the valley of the Mersey from Stockton to the sea, and farther south in Cheshire the salt-bearing beds of the Keuper marls give rise to a characteristic industry. The plain extends through Staffordshire and Worcester, forming the lower valley of the Severn. The greater part of Manchester, all Liverpool and Birkenhead, and innumerable busy towns of medium size, which in other parts of England would rank as great centres of population, stand on this soil. Its flat surface and low level facilitate the construction of railways and canals, which form a closer network over it than in other parts of the country. The great junction of Crewe, where railways from south-east, south-west, east, west, and north converge, is thus explained. South of the Pennines, the Red rocks extend eastward in a great sweep through the south of Derbyshire, Warwick, the west of Leicestershire, and the east of Nottingham, their margin being approximately marked by the Avon, flowing south-west, and the Soar and Trent, flowing north-east. South and east of these streams the very similar country is on the Lias clay. Several small coal-fields rise through the Red rocks—the largest, between Stafford and Birmingham, forms the famous "Black Country," with Wolverhampton and Dudley as centres, where the manufacture of iron has preserved a historic continuity, for the great Forest of Arden supplied charcoal until the new fuel from the pits took its place. This coal-field, ministering to the multifarious metal manufactures of Birmingham, constitutes the centre of the Midlands. Smaller patches of the Coal Measures appear near Tamworth and Burton, while deep shafts have been sunk in many places through the overlying Triassic strata to the coal below, thus extending the mining and manufacturing area beyond the actual outcrop of the Coal Measures. A few small outcrops occur where still more ancient strata have been raised to the surface, as, for instance, in Charnwood Forest, where the Archæan rocks, with intrusions of granite, create a patch of highland scenery in the very heart of the English plain; and in the Lickey Hills, near Birmingham, where the prominent features are due to volcanic rocks of very ancient date. The "Waterstones," or Lower Keuper Sandstones,—forming gentle elevations above the softer marls, and usually charged with an abundant supply of water, which can be reached by wells,—form the site of many towns, such as Birmingham, Warwick, and Lichfield, and of very numerous villages. The plain as a whole is fertile and undulated, rich in woods and richer in pasture: the very heart of rural England. Cattle-grazing is the chief farm industry in the west, sheep and horse-rearing in the east; the prevalence of the prefix "Market" in the names of the rural towns is noticeable in this respect. The manufacture of woollen and leather goods is a natural result of the raising of live stock; Leicester, Coventry, and Nottingham are manufacturing towns of the region. The historic castles, the sites of ancient battles, and the innumerable mansions of the wealthy, combine to give to Central England a certain æsthetic interest which the more purely manufacturing districts of the west and north fail to inspire. The central plain curves northward between the outcrop of the Dolomite on the west and the Oolitic heights on the east. It sinks lowest where the estuary of the Humber gathers in its main tributaries, and the greater part of the surface is covered with recent alluvial deposits. The Trent runs north in the southern half of this plain, the Ouse runs south through the northern half, which is known as the Vale of York, lying low between the Pennine heights on the west and the Yorkshire moors on the east. Where the plain reaches the sea, the soft rocks are cut back into the estuary of the Tees, and there Middlesbrough stands at the base of the Moors. The quiet beauty of the rural country in the south, where the barren Bunter pebble-beds have never invited agriculture, and where considerable vestiges of the old woodland still remain in and near Sherwood Forest, has attracted so many seats of the landed aristocracy as to earn for that part the familiar name of "the Dukeries." The central position of York in the north made it the capital of Roman Britain in ancient times, and an important railway junction in our own.

The eastern division.

Five natural regions may be distinguished in the Eastern Division of England, by no means so sharply marked off as those of the west, but nevertheless quite clearly characterized. The first is the Jurassic Belt, sweeping along the border of the Triassic plain from the south coast at the mouth of the Exe to the east coast at the mouth of the Tees. This is closely followed on the south-east by the Chalk country, occupying the whole of the rest of England except where the Tertiary Basins of London and Hampshire cover it, where the depression of the Fenland carries it out of sight, and where the lower rocks of the Weald break through it. Thus the Chalk appears to run in four diverging fingers from the centre or palm on Salisbury Plain, other formations lying wedge-like between them. Various lines of reasoning unite in proving that the Mesozoic rocks of the south rest upon a mass of Palæozoic rocks, which lies at no very great depth beneath the surface of the anticlinal axis that runs from the Bristol Channel to the Strait of Dover. The theoretical conclusion has been confirmed by the discovery of Coal Measures, with workable coal seams, at Dover at a depth of 2000 feet below the surface.

The Eastern Division is built up of parallel strata, the edges of the harder rocks forming escarpments, the sheets of clay forming plains; and on this account similar features are repeated in each of the successive geological formations. The rivers exhibit a remarkably close relation to the geological structure, and thus contrast with the rivers of the Western Division. There are two main classes of rivercourse—those flowing down the dip-slopes at right angles to the strike, and cutting through opposed escarpments by deep valleys, and those following the line of strike along a bed of easily eroded rock. A third class of streams, tributary to the second, flows down the steep face of the escarpments. By the study of the adjustment of these rivers to their valleys, and of the relation of the valleys to the general structure, Professor W. M. Davis has elaborated a theory of river classification, and a scheme of the origin of surface-features which is attractive in its simplicity. The Thames is the one great river of the division, rising on the Jurassic Belt, crossing the Chalk country, and finishing its course in the Tertiary London Basin, towards which, in its prevailing west-to-east direction, it draws its tributaries from north and south. The other rivers are shorter, and flow either to the North Sea on the east, or to the English Channel on the south. With the exception of the Humber, they all rise and pursue their whole course within the limits of the Eastern Division itself.

The Eastern Division is the richest part of England agriculturally, it is the part most accessible to trade with the Continent, and that least adapted for providing refuges for small bodies of men in conflict with powerful invaders. Hence the latest of the conquerors, the Saxon and other Germanic tribes, obtained an easy mastery, and spread over the whole country, holding their own against marauding Northmen, except on the northern part of the east coast; and even after the political conquest by the Normans, continuing to form the great mass of the population, though influenced not a little by the fresh blood and new ideas they had assimilated. The present population is so distributed as to show remarkable dependence on the physical features. The chalk and limestone plateaux are usually almost without inhabitants, and the villages of these districts occur grouped together in long strings, either in drift-floored valleys in the calcareous plateaux, or along the exposure of some favoured stratum at their base. In almost every case the plain along the foot of an escarpment bears a line of villages and small towns, and on a good map of density of population the lines of the geological map may be readily discerned.[1]

The Jurassic Belt.—The Jurassic belt is occupied by the counties of Gloucester, Oxford, Buckingham, Bedford, Northampton, Huntingdon, Rutland, Lincoln, and the North Riding of Yorkshire. The rocks of the belt may be divided into two main groups: the Lias beds, which come next to the Triassic plain, and the Oolitic beds. Each group is made up of an alternation of soft marls or clays and hard limestones or sandstones. The low escarpments of the harder beds of the Lias are the real, though often scarcely perceptible, boundary between the Triassic plain and the Jurassic belt. They run along the right bank of the Trent in its northward course to the Humber, and similarly direct the course of the Avon southward to the Severn. The great feature of the region is the long line of the Oolitic escarpment, formed in different places by the edges of different beds of rock. The escarpment runs north from Portland Island on the English Channel, curves north-eastward as the Cotswold Hills, rising abruptly from the Severn plain to heights of over 1000 feet; it sinks to insignificance in the Midland counties, is again clearly marked in Lincolnshire, and rises in the North Yorkshire moors to its maximum height of over 1500 feet. Steep towards the west, where it overlooks the low Lias plain as the Oolitic escarpment, the land falls very gently in slopes of Oxford Clay towards the Cretaceous escarpments on the south and east. Throughout its whole extent it yields valuable building stone, and in the Yorkshire moors the great abundance of iron ore has created the prosperity of Middlesbrough, on the plain below. The Lias plain is rich grazing country, the Oxford Clay forms valuable agricultural land, yielding heavy crops of wheat. The towns of the belt are comparatively small, not one attains a population of 75,000, and the favourite site is on the Lias plain below the great escarpment. They are for the most part typical rural market-towns, the manufactures, where such exist, being usually of agricultural machinery, or woollen and leather goods. Bath, Gloucester, Oxford, Northampton, Bedford, Rugby, Lincoln, and Scarborough are amongst the chief. North of the gap in the low escarpment in which the town of Lincoln stands, a close fringe of villages borders the escarpment on the west; and throughout the belt the alternations of clay and hard rock are reflected in the grouping of population.

The Chalk Country.—The dominating surface-feature formed by the Cretaceous rocks is the Chalk escarpment, the northern edge of the great sheet of chalk that once spread continuously over the whole south-east. It appears as a series of rounded hills of no great elevation running in a curve from the mouth of the Axe to Flamborough Head, roughly parallel with the Oolitic escarpment. Successive portions of this line of heights are known as the Dorset Downs, the Marlborough Downs, the Chiltern Hills, the East Anglian Heights, the Lincolnshire Wolds, and the Yorkshire Wolds. The rivers from the gentle southern slopes of the Oolitic heights pass by deep valleys through the Chalk escarpments, and flow on to the Tertiary plains within. The typical scenery of the Chalk country everywhere is unrelieved by small streams of running water; the hills rise into rounded downs, often capped with fine clumps of beech, and usually covered with thin turf, affording pasture for sheep. The chalk, when exposed on the surface, is an excellent foundation for roads, and the lines of many of the Roman roads were probably determined by this fact. The Chalk country extends over part of Dorset, most of Wiltshire, a considerable portion of Hampshire and Oxfordshire, most of Hertfordshire and Cambridgeshire, the west of Norfolk and Suffolk, the east of Lincoln, and the East Riding of Yorkshire. From the upland of Salisbury Plain, which corresponds to the axis of the anticline marking the centre of the double fold into which the strata of the south of England have been thrown, the great Chalk escarpment runs north-eastward; fingers of Chalk run eastward on each side of the Weald, forming the North and South Downs, while the southern edge of the Chalk sheet appears from beneath the Tertiary strata at several places on the south coast, and especially in the Isle of Wight. Flamborough Head, the South Foreland, Beachy Head, and the Needles are examples of the fine scenery into which chalk weathers where it fronts the sea, and these white cliffs gave to the island its early name of Albion. The Chalk is everywhere very thinly peopled, except where it is thickly covered with boulder clay, and so becomes fertile, or where it is scored by drift-filled valleys, in which the small towns and villages are dotted along the high roads. The thickest covering of drift is found in the Holderness district of Yorkshire, where, from the chalk cliffs of Flamborough Head to the sandspit of Spurn Point, the whole coast is formed of boulder-clay resting on chalk. Of the few towns in the Chalk country, the interest of which is largely historical or scholastic, Salisbury, Winchester, Marlborough, and Cambridge are the most distinguished. Reading flourishes from its position on the edge of the London Tertiary Basin, Croydon is a suburb of London, and Hull, though on the Chalk, derives its importance from the Humber estuary, which cuts through the Chalk and the Jurassic belts, to drain the Triassic plain and the Pennine region. The narrow strip of Greensands appearing from beneath the Chalk escarpment on its northern side is crowded with small towns and villages on account of the plentiful water supply.

The Weald.—The dissection of the great east and west anticline in the south-east of England has resulted in a remarkable piece of country, occupying the east of Hampshire and practically the whole of Sussex, Surrey, and Kent, in which each geological stratum produces its own type of scenery, and exercises its own specific influence on every natural distribution. The sheet of Chalk shows its cut edges in the escarpments facing the centre of the Weald, and surrounding it in an oval ring, the eastern end of which is broken by the Strait of Dover, so that its completion must be sought in France. From the crest of the escarpment, all round on south, west, and north, the dip-slope of the Chalk forms a gentle descent outwards, the escarpment a very steep slope inwards. The cut edges of the escarpment forming the Hog's Back and North Downs on the north, and the South Downs on the south, meet the sea in the fine promontories of the South Foreland and Beachy Head. The Downs are almost without population, waterless and grass-covered, with patches of beech wood. Their only important towns are on the coast, *e.g.*, Brighton, Eastbourne, Dover, Chatham, or in the gaps where rivers from the centre pierce the Chalk ring, as at Guildford, Rochester, Canterbury, Lewes, and Arundel. Within the Chalk ring, and at the base of the steep escarpment, there is a low terrace of the Upper Greensand, seldom so much as a mile in width, but in most places crowded with villages scarcely more than a mile apart, and ranged like beads on a necklace. Within the Upper Greensand an equally narrow ring of Gault is exposed, its stiff clay forming level plains of grazing pasture, without villages, and with few farmhouses even; and from beneath it the successive beds of the Lower Greensand rise towards the centre, forming a wider belt, and reaching a considerable height before breaking off in a fine escarpment, the crest of which is in several points higher than the outer ring of Chalk. Leith Hill and Hindhead are parts of this edge in the west, where the exposure is widest. Several towns have originated in the gaps of the Lower Greensand escarpment which are continuous with those through the Chalk: such are Dorking, Reigate, Maidstone, and Ashford. Folkestone and Pevensey stand where the two ends of the broken ring meet the sea. It is largely a region of oak and pine trees, in contrast to the beech of the Chalk Downs. The Lower Greensand escarpment looks inwards in its turn over the wide plain of Weald Clay, along which the Medway flows in the north, and which forms a fertile soil, well cultivated, and particularly rich in hops and wheat. The primitive forests have been largely cleared, the primitive marshes have all been drained, and now the Weald Clay district is fairly well peopled and sprinkled with villages. From the middle of this plain the core of Lower Cretaceous sandstones, known as the Hastings Beds, emerges steeply, and reaches in the centre an elevation of 796 feet at Crowborough Beacon. It is on the whole a region with few streams, and a considerable portion of the ancient woodland still remains in Ashdown Forest. The greater part of the area is almost without inhabitants. Towns are found only round the edge bordering the Weald Clay, such as Tonbridge, Tunbridge Wells, and Horsham; and along the line where it is cut off by the sea, *e.g.*, Hastings and St Leonards. The broad low tongue of Romney Marsh running

[1] See F. Bosse's Map of Density of Population in Bartholomew's "Handy Royal Atlas of England." London (Newnes), 1899.

out to Dungeness is a product of shore building by the Channel tides, attached to the Wealden area, but not essentially part of it.

The London Basin.—The London Basin occupies a triangular depression in the Chalk which is filled up with clays and gravels of Tertiary and later age. It extends from the eastern extremity of Wiltshire in a widening triangle to the sea, which it meets along an irregular line from Deal to Cromer. It thus occupies parts of Wiltshire, Hampshire, Surrey, Kent, Berkshire, Hertfordshire, the whole of Middlesex, the county of London and Essex, and the eastern edge of Suffolk and Norfolk. The scenery is quiet in its character, but the gravel hills are often prominent features, as at Harrow and in the northern suburbs of London; the country is well cultivated, and many parts, of which Epping Forest is a fine example, are still densely wooded, the oak being the prevailing tree. The coast is everywhere low and deeply indented by ragged and shallow estuaries, that of the Thames being the largest. Shallow lagoons formed along the lower courses of the rivers of Norfolk have given to that part of the country the name of the Broads, a district of low and nearly level land. Apart from the huge area of urban and suburban London, the London Basin has few large towns. Norwich and Ipswich, Yarmouth, Harwich, and Colchester may be mentioned in the north-eastern part, all depending for their prosperity on agriculture or on the sea; and a fringe of summer resorts on the low coast has arisen on account of the bracing climate. Reading and Windsor lie in the western portion, beyond the suburban sphere of London. The Bagshot Beds in the west form infertile tracts of sandy soil, covered with heath and pine, where space is available for the great camps and military training grounds round Aldershot, and for the extensive cemeteries at Woking. The London Clay in the east is more fertile and crowded with villages, while the East Anglian portion of the basin consists of the more recent Pliocene sands and gravels, which mix with the boulder clay to form the best wheat-growing soil in the country.

The Hampshire Basin.—The Hampshire Basin forms a triangle with Dorchester, Salisbury, and Worthing near the angles, and the rim of Chalk to the south appears in broken fragments in the Isle of Purbeck, the Isle of Wight, and to the east of Bognor. On the infertile Bagshot Beds the large area of the New Forest remains untilled under its ancient oaks. The London Clay of the east is more fertile, but the greatness of this district lies in its coast-line, which is deeply indented, like that of the London Basin. Southampton and Portsmouth have gained importance through their fine natural harbours, improved by engineering works and fortifications; Bournemouth and Bognor, from their favourable position in the sunniest belt of the country, as health resorts.

The Fenland.—The continuity of the belts of Chalk and of the Middle and Upper Oolites is broken by the shallow depression of the Wash and the Fenland. The Fenland comprises a strip of Norfolk, a considerable part of Cambridgeshire, and the Holland district of Lincoln. Formerly a great inlet with vague borders of lagoons and marshes, the Fenland has been reclaimed partly by natural processes, partly by engineering works patiently continued for centuries. The whole district is flat and low, for the most part within 15 feet of sea-level; the seaward edge in many places is below the level of high tide, and is protected by dykes as in Holland, while straight canals and ditches carry the sluggish drainage from the land. The soil is composed for the most part of silt and peat. A few small elevations of gravel, or of underlying formations, rise above the level of 25 feet; these were in former times islands, and now they form the sites of the infrequent villages. Boston and King's Lynn are memorials of the maritime importance of the Wash in the days of small ships. The numerous ancient churches and the cathedrals of Ely and Peterborough bear evidence to the share taken by religious communities in the reclamation and cultivation of the land.

Communications.—The configuration of England, while sufficiently pronounced to allow of the division of the country into natural regions, is not strongly enough marked to exercise any very great influence upon lines of communication. The navigable rivers are all connected by barge-canals, even across the Pennine Chain. Although the waterways are much neglected, compared with those of France or of Germany, they could easily be made very useful if they were developed by free competition with railways. The main roads developed as arteries of intercommunication by the Romans, suffered to fall into neglect, and revived in the coaching days of the beginning of the 19th century, fell into a second period of comparative neglect when the railway system was completed; but they are now recovering a considerable share of their old importance in consequence of the development of cycling and the use of motor-cars. Following the Roman roads, the high roads of the Eastern Division very frequently run along the crests of ridges or escarpments; but in the Western Division they are, as a rule, forced by the more commanding relief of the country to keep to the river valleys and cross the rougher districts through the dales and passes.

General.

The railways themselves, radiating from the great centres of population, and especially from London, are only in a few instances much affected by configuration. The Pennine Chain has always separated the traffic from south to north into an east coast route through the Vale of York, and a west coast route by the Lancashire plain. The Midland Railway, running through the high and rugged country between the two, was the last to be constructed. The most notable bridges over navigable water affording continuous routes are those across Menai Strait, the Tyne at Newcastle, the Severn at Severn Bridge, and the Manchester Ship Canal. It is more usual to tunnel under such channels, and the numerous Thames tunnels, the Mersey tunnel between Liverpool and Birkenhead, and the Severn tunnel, the longest in the British Islands (4½ miles), on the routes from London to South Wales, and from Bristol to the north of England, are all important. The Humber estuary is neither bridged nor tunnelled below Goole.

Density of Population.—The present distribution of population over England and Wales shows a dense concentration at all large seaports, in the neighbourhood of London, and on the coal-fields where manufactures are carried on. Agricultural areas are very thinly peopled; purely pastoral districts can hardly be said to have any settled population at all. There are very few dwellings situated at a higher level than 1000 feet, and on the lower ground the Chalk and the Oolitic limestones, where they crop out on the surface, are very thinly peopled, and so as a rule are areas of alluvial deposits and the Tertiary sands. But, on the other hand, the broad clay plains of all formations, and the Triassic plain, are peopled more densely than any other districts without mineral wealth or sea trade.

Political Divisions.—In the partition of England and Wales into counties, physical features play but a small part. The forty ancient counties, remnants of various historical groupings and partings, are occasionally bounded by rivers. Thus the Thames divides counties along nearly its whole length, forming the southern boundary of four and the northern boundary of three. Essex and Suffolk, Suffolk and Norfolk, Cornwall and Devon, Durham and Yorkshire, Lancashire and Cheshire, are all separated by rivers, while rivers form some part of the boundaries of almost every county. Still, it is noteworthy that the Severn and Trent nowhere form continuous county boundaries. Watersheds are rarely used as boundaries for any distance; but, although slightly overlapping the watershed on all sides, Yorkshire is very nearly coincident with the basin of the Ouse. The boundaries of the parishes, the fundamental units of English political geography, are very often either rivers or watersheds, and they frequently show a close relation to the strike of the geological strata. The hundreds, or groups of parishes, necessarily share their boundaries, and groups of hundreds are often aggregated to form larger subdivisions of counties. A wide grouping according to natural characteristics may be recognized still only in the cases of Wales, East Anglia, Wessex, and such less definite groups as the Home Counties around London, or the Midlands around Birmingham. Configuration is only one out of many conditions modifying distributions, and its effects on England as a whole appear to be suggestive rather than determinative.

For detailed descriptions of parts of England and Wales, see the articles on individual counties, towns, rivers, etc. For more general references, see EUROPE, GEOLOGY, METEOROLOGY.

(H. R. M.)

II. STATISTICS.

Area and Population.

The area of England and Wales, exclusive of 840,448 acres of tidal water and foreshore, consists of 37,317,885 acres or 58,309 square miles, 37,106,272 acres or 57,979 square miles being land, and 216,613 acres or 330 square miles being water. The population at the date of the census of March 31, 1901, was returned (preliminary report) at 32,526,075. The increase since 1871, and the decennial rate of increase, are shown in the following table :—

Date of Enumeration.	Population.	Decennial Increase.	Decennial Increase per cent.
1871, April 3	22,712,266	2,646,042	13·20
1881, April 4	25,974,439	3,262,173	14·36
1891, April 6	29,002,525	3,028,086	11·65
1901, March 31	32,526,075	3,523,550	12·17

The increase of population took place chiefly in the commercial centres and in the industrial and mining districts, there having been little or no increase, or even in some places in the west of England and in North Wales a considerable decrease, of the agricultural population. The following table shows the population of each of the eleven registration divisions of England and Wales in 1891 and 1901, and the increase per cent. in the intercensal period :—

Registration Divisions.	Population.		Increase per cent.
	1891.	1901.	1891–1901.
I. London	4,228,317	4,536,063	7·2
II. S.E. counties (Surrey, Kent, Sussex, Hampshire, Berkshire)	2,867,078	3,312,163	15·5
III. S. Midland (Middlesex, Hertfordshire, Buckinghamshire, Oxfordshire, Northamptonshire, Huntingdonshire, Bedfordshire, Cambridgeshire)	1,847,309	2,181,105	18·1
IV. Eastern (Essex, Suffolk, Norfolk)	1,575,311	1,891,922	20·1
V. S.W. (Wiltshire, Dorsetshire, Devonshire, Cornwall, Somersetshire)	1,855,262	1,913,082	3·1
VI. W. Midland (Gloucestershire, Herefordshire, Shropshire, Staffordshire, Worcestershire, Warwickshire)	3,305,841	3,679,264	11·3
VII. N. Midland (Leicestershire, Rutlandshire, Lincolnshire, Nottinghamshire, Derbyshire)	1,808,494	2,042,151	12·9
VIII. N.W. (Cheshire, Lancashire)	4,664,749	5,230,261	12·1
IX. Yorkshire	3,212,188	3,596,395	11·9
X. Northern (Durham, Northumberland, Cumberland, Westmorland)	1,863,166	2,128,633	14·2
XI. Monmouthshire and Wales	1,774,810	2,015,036	13·5
England and Wales	29,002,525	32,526,075	12·1

The total number of males and of females, and the number of females to 1000 males, at the last four enumerations were as follows :—

Year.	Population.	Males.	Females.	Females to 1000 Males.
1871	22,712,266	11,058,934	11,653,332	1054
1881	25,974,439	12,639,902	13,334,537	1055
1891	29,002,525	14,052,901	14,949,624	1064
1901	32,526,075	15,721,728	16,804,347	1069

The areas and population of the ancient counties of England and Wales in 1891 and 1901 (preliminary report), with the number of inhabited houses in 1901, were as follows :—

Counties.	Area. Statute Acres.	Inhabited Houses, 1901.	Population.	
			1891.	1901.
Bedford	298,494	38,356	160,704	171,249
Berks	462,224	53,889	238,709	254,931
Buckingham	475,694	43,476	185,284	195,534
Cambridge	549,749	44,430	188,961	190,687
Chester	657,068	169,191	730,058	814,555
Cornwall	868,208	72,601	322,571	322,957
Cumberland	970,161	54,823	266,549	266,921
Derby	658,876	128,039	528,033	620,196
Devon	1,667,097	123,598	631,808	660,444
Dorset	632,272	43,474	194,517	202,962
Durham	647,281	201,099	1,016,559	1,187,324
Essex	987,028	201,059	785,445	1,085,576
Gloucester	795,734	128,514	599,947	634,666

Total England	32,538,560	5,916,840	27,483,490	30,805,466
Total England and Wales	37,317,885	6,266,496	29,002,525	32,526,075

At the census of 1891 the number of inhabited houses was 5,451,497, so that there was an increase of 814,999 in the ten years. The average number of occupants to a house was 5·32 in 1891, as against 5·38 in 1881, and 5·33 in 1871. The proportion was highest in the larger towns: in London it was 7·72 per inhabited house; in Newcastle-on-Tyne, 7·73; in Sunderland, 7·00. The number of tenements (*i.e.*, houses or parts of houses separately occupied) was 6,131,001 in 1891. This gives an average of 4·7 persons to each tenement, and 1·12 tenements to each house. The density of population in England and Wales, and the average number of persons to an inhabited house, at the last four census enumerations, were as follows:—

Census Years.	Persons per Square Mile.	Acres per Person.	Persons to a House.
1871 . . .	390	1·64	5·33
1881 . . .	445	1·44	5·38
1891 . . .	497	1·29	5·32
1901 . . .	558	1·14	5·19

The density of population, and the average number of persons to a house in England and in Wales, as compared with Scotland and Ireland, in 1891 and 1901 were:—

	Persons per Square Mile.		Acres to a Person.		Persons to an Inhabited House.	
	1891.	1901.	1891.	1901.	1891.	1901.
England . .	540	606	1·18	1·05	5·33	5·21
Wales . . .	203	230	3·14	2·78	5·01	4·94
Scotland . .	135	150	4·73	4·26	4·92	4·83
Ireland . . .	148	140	4·32	4·56	5·40	5·19

The following table gives the Registrar-General's estimate of the population of England and Wales in the middle of every fifth year from 1871 to 1911, the estimates from 1901 to 1911 being provisional and based on the assumption that the rate of increase from 1891 to 1901 will be continued to 1911:—

Years.	Population.	Years.	Population.
1871 . .	22,788,594	1896 . .	30,799,461
1876 . .	24,370,267	1901 . .	32,619,410
1881 . .	26,046,142	1906 . .	34,546,904
1886 . .	27,522,532	1911 . .	36,588,288
1891 . .	29,081,053		

The population of the administrative county of London (comprising the 29 metropolitan boroughs), that of the 1121 urban districts (of which 67 are county boroughs, 248 municipal, but not county boroughs, and 806 non-municipal districts), and that of the 666 rural districts of England and Wales in 1901, with the population on the same groups of areas in 1891, are given as follows:—

Groups of Areas.	Population.		Increase 1891-1901.
	1891.	1901.	
Administrative county of London . .	4,228,317	4,536,063	307,746
Urban districts . .	17,515,660	20,518,205	3,002,545
Rural districts . .	7,258,145	7,471,242	213,097
Areas neither in urban nor in rural districts	403	565	162
England and Wales .	29,002,525	32,526,075	3,523,550

In 1901 there were 75 large towns (including London) each of which had over 50,000 inhabitants, their total population being 14,506,273; on the same areas in 1891 the total population amounted to 12,729,545, the increase in the ten years having been 13·96 per cent. The following is a list of 40 of the largest county boroughs with the population of each in 1901 and the population on the same areas in 1891:—

County Boroughs.	Enumerated Population.		County Boroughs.	Enumerated Population.	
	1891.	1901.		1891.	1901.
Liverpool . .	629,548	684,947	Brighton . .	115,873	123,478

Blackburn . .	120,064	127,527	Stockport . .	70,263	78,871

Movement of Population.—The number of marriages, births, and deaths in England and Wales in 1871, in every succeeding fifth year, and in 1898 and 1899, was as follows:—

Years.	Marriages.	Births.	Deaths.
1871 . . .	190,112	797,428	514,879
1876 . . .	201,874	887,968	510,315
1881 . . .	197,290	883,642	491,935
1886 . . .	196,071	903,760	537,276
1891 . . .	226,526	914,157	587,925
1896 . . .	242,764	915,331	526,727
1898 . . .	255,379	923,165	552,141
1899 . . .	262,334	928,646	581,799

In the same years the number of persons married, of births, and of deaths per 1000 persons living was:—

Years.	Persons Married in 1000 Living.	Births to 1000 Living.	Deaths to 1000 Living.
1871 . . .	16·7	35·0	22·6
1876 . . .	16·5	36·3	20·9
1881 . . .	15·1	33·9	18·9
1886 . . .	14·2	32·8	19·5
1891 . . .	15·6	31·4	20·2
1896 . . .	15·8	29·7	17·1
1898 . . .	16·3	29·4	17·6
1899 . . .	16·5	29·3	18·3

The marriage-rate is evidently closely associated with the general prosperity of the country. In the period embraced by the table given above, it was highest in 1873, when it was 17·6 per 1000 living, and lowest in 1886, when it fell to 14·2. In the former year the value of the total imports and exports per head of population of the United Kingdom was also at its highest, and in the latter year, at its lowest. The following figures for recent years illustrate this connexion:—

Years.	Marriage-Rate.	Value per Head of Population of United Kingdom.		
		Exports of British Produce.	Imports.	Total Exports and Imports.
		£ s. d.	£ s. d.	£ s. d.
1895 . . .	15·0	5 15 8	10 13 1	17 19 3
1896 . . .	15·8	6 1 8	11 3 11	18 14 1
1897 . . .	16·0	5 17 7	11 6 6	18 14 3
1898 . . .	16·3	5 16 2	11 14 1	19 0 5
1899 . . .	16·5	6 10 5	11 19 2	20 1 8

Since 1871 there has been a steady decline in the number of marriages of minors. Among the persons who married in the five years 1871–75, 81·6 per 1000 of the husbands and 223·2 per 1000 of the wives were under 21 years of age; in the five years 1891–95 the proportions were, 56·2 per 1000 of husbands, and 182·6 of wives; in the year 1899, 50 per 1000 of husbands, and 165 per 1000 of wives.

For the 29 years 1871–99 the average birth-rate of England and Wales was 31·1 to 1000 persons living. The rate was highest in 1876, when it rose to 36·3, and lowest in 1899, when it fell to 29·3, the lowest rate on record. In 1899 the birth-rate was highest in Durham (35·3), Staffordshire (35·1), and Northumberland (33·4); it was lowest in Westmorland (22·7) and Rutland (22·9). Within the period 1871–98 the proportion of illegitimate births has steadily decreased. In 1871 it was 56 to 1000 births; in 1881, 49; in 1891, 42. This proportion continued down to 1898, except that in 1894 the number rose temporarily to 43; in 1899 it fell to 40. The proportion varies widely in different parts of the country. In 1899 the lowest proportions were 28 per 1000 births in Essex, where the average of the preceding 10 years was 29, 29 in Monmouthshire, 30 in Warwickshire, 31 in Middlesex (average of 10 years, 31), 31 in South Wales (average 35). The highest proportions in 1899 were 60 per 1000 births in North Wales, where the average of the preceding 10 years was 66, 61 in Norfolk and in Huntingdon, 62 in Westmorland (average 63), 64 in Cumberland (average 71), 65 in Shropshire (average 73), and 66 in Herefordshire (average 71). Though, as already shown, the female population is considerably in excess of the male, yet the number of male births exceeds that of the female. During the 29 years 1871–99 the average number of male to 1000 female births was 1038; the highest was 1043 in 1875, and the lowest was 1032 in 1898; in 1899 the number was 1039. The variations in the proportion over the whole country range within comparatively narrow limits, but in particular localities they are considerable. In 1899 the lowest proportions of male to female births were 929 in Huntingdonshire, where the average of the preceding ten years was 1042, 933 in Rutland (average 1059), and 991 in Monmouthshire (average 1041). The highest were 1063 male to 1000 female births in South Wales (average of ten years, 1038), 1064 in Oxford (average 1037), 1064 in Buckinghamshire (average 1031), 1065 in Essex (average 1029), and 1094 in Dorsetshire (average 1051).

The average annual death-rate of England and Wales for the 29 years 1871–99 was 19·0 per 1000 persons living; the highest was 22·7 in 1875; the lowest was 16·6 in 1894. For the 5 years 1871–75 the average was 22·0; for 1891–95, 18·7. In the 5 years 1871–75 the average death-rate of males was 23·3 per 1000 living; of females, 20·7; in 1891–95, of males 19·8, and of females 17·7 per 1000 living. In 1899, 19·5 males died per 1000 living, and 17·3 females per 1000. In 1899 the lowest death-rates were 12·9 in Westmorland, where the average of the preceding 10 years was 14·9 per 1000 living, 14·7 in Middlesex (average 14·7), 4·9 in Cambridgeshire (average 16·4); the highest were 19·6 in Staffordshire (average 19·8), 20·1 in Northumberland (average 19·3), and 21·1 in Lancashire (average 21·4).

For the purpose of comparison the following table is given, showing for the United Kingdom and its several parts, and for various continental countries, the average number of births and of deaths per 1000 living in the 25 years 1874–98:—

Countries.	Births.	Deaths.	Countries.	Births.	Deaths.
United Kingdom	31·4	19·3	Austria	38·1	29·0
England and Wales	32·6	19·4	Hungary	43·0	33·2
Scotland	32·6	19·7	Switzerland	28·9	20·9
Ireland	24·0	18·1	Prussia	37·8	24·1
Denmark	31·4	18·6	Netherlands	34·4	20·9
Norway	30·7	16·7	Belgium	30·3	20·3
Sweden	28·9	17·2	France	23·8	22·0
			Italy	36·8	27·1

The increase of population is retarded and obscured by the large outflow and inflow of passengers to and from the United States and the British Colonies. In the 25 years 1876–1900 the gross number of emigrants, British and foreign, to countries out of Europe amounted to 7,172,800, of whom 5,010,707 were of British or Irish origin. On the other hand, the immigrants, British and foreign, from non-European countries numbered 3,123,025, of whom 2,122,150 were of British or Irish origin The net number of emigrants was thus 4,049,775, of whom 2,888,557 were of British or Irish origin. The following table shows the gross numbers and the percentages of emigrants, English, Scots, and Irish, who left the United Kingdom for non-European countries in quinquennial periods 1876–1900:—

Periods.	English. Number.	Per c.	Scots. Number.	Per c.	Irish. Number.	Per c.	Total. Number.
1876–80	425,550	60	70,596	10	213,236	30	709,382
1881–85	760,124	59	133,527	10	398,658	31	1,292,309
1886–90	788,841	62	141,568	11	335,817	27	1,266,226
1891–95	617,869	63	100,878	10	259,827	27	978,574
1896–00	478,022	63	85,104	11	201,090	26	764,216
1876–00	3,070,406	61	531,673	10	1,408,628	28	5,010,707

The following summary shows the movement of emigration and immigration between the United Kingdom and the United States, British North America, and Australasia in 25 years, 1876–1900:—

1876–1900.	To and from United States.	To and from British N. America.	To and from Australasia.	Total (including others).
Total Emigration	4,973,292	810,872	684,450	7,172,800
Total Immigration	2,230,206	226,810	214,312	3,123,025
Net Emigration	2,743,086	584,062	470,138	4,049,775
British and Irish Emigration	3,272,962	555,459	664,381	5,010,707
British and Irish Immigration	1,351,171	211,469	197,820	2,122,150
Net British and Irish Emigration	1,921,791	343,990	466,561	2,888,557

The total number of emigrants to Cape Colony and Natal, 1876–1900, was 339,334; the immigrants therefrom, 1882–1900, numbered 183,335. The number of British and Irish emigrants to these colonies, 1877–1900, was 268,729; of British and Irish immigrants therefrom, 1882–1900, 155,015. The net emigration of persons of British and Irish origin in quinquennial periods 1876–95 and in the 5 years 1896–1900 was as follows:—

Periods.	Emigrants.	Immigrants.	Balance of Emigrants.
1876–80	709,382	275,181	434,201
1881–85	1,292,309	358,046	934,263
1886–90	1,266,226	472,166	794,060
1891–95	978,574	530,663	447,911
1896	161,925	101,742	60,183
1897	146,460	95,221	51,239
1898	140,644	91,248	49,396
1899	146,362	100,246	46,116
1900	168,825	97,637	71,188
1876–1900	5,010,707	2,122,150	2,888,557

In the 25 years 1876–1900 the rate of British and Irish emigration fluctuated between wide limits. The smallest net emigration was in 1877, when the number was 31,305, or 0·09 per cent. of the population of the United Kingdom; the largest was in 1883, when the net number of emigrants was 246,314, or 0·69 per cent. of the whole population. The following table shows the rate of the net British and Irish emigration in recent years:—

Years.	Per cent. of Population.	Years.	Per cent. of Population.	Years.	Per cent. of Population.
1886	0·42	1891	0·31	1896	0·15
1887	0·54	1892	0·29	1897	0·13
1888	0·50	1893	0·28	1898	0·12
1889	0·41	1894	0·10	1899	0·11
1890	0·29	1895	0·19	1900	0·17

Aliens.—Regarding the increase of the foreign element in the population of the United Kingdom there is no precise information, but a rough estimate is formed on the basis of the figures showing the passenger movement between the United Kingdom and the Continent of Europe. The excess of the inward over the outward passengers is assumed to represent foreigners not returning to the Continent; from this excess the number of foreigners known to have emigrated within the year to places out of Europe, and the number of foreign sailors, coming as passengers but departing as crews of vessels, are deducted, and the remainder is taken to represent approximately the increase to the foreign population of the United Kingdom within the year. For 1898, 1899, and 1900 the figures are given as follows:—

	1898.	1899.	1900.
Inwards from Europe	620,123	666,230	748,725
Outwards to Europe	590,226	609,570	669,292
Excess inwards	29,897	56,660	79,433
Net foreign emigrants	14,801	31,231	50,685
Foreign sailors	12,299	13,362	14,950
Total to be deducted	27,100	44,593	65,635
Net foreign increase	2,797	12,067	13,798

The increase consists largely of Russian, Polish, and Rumanian Jews, who, arriving in a state of destitution, are assisted by Jewish Boards of Guardians and Relief Committees in London and other large towns.

Local Government.

Political divisions.

For most practical purposes the ancient counties of England and Wales have been superseded by the administrative counties created by the Local Government Act of 1888. The ancient division, however, forms the basis on which the system of distribution of parliamentary representation now in force was constructed. After the Representation of the People Act, 1884, had extended to householders and lodgers in counties the franchise which in 1867 had been conferred on householders and lodgers in boroughs, the Redistribution of Seats Act, 1885, made a new division of the country into county and borough constituencies. All the English counties, with the exception of Rutland, are now divided into two or more constituencies, each returning one member, the number of English county parliamentary areas being 234. In Wales the eight smaller or less populous counties form each one parliamentary constituency, while the four larger are divided, the number of Welsh county parliamentary areas being 19. The number of county areas for parliamentary purposes in England and Wales is thus 253, and the total number of their representatives is the same. Outside the county constituencies are the parliamentary boroughs. Of these there are 135 in England, one of them, Monmouth district, being made up of three contributory boroughs, while many are divided into several constituencies, the number of borough parliamentary areas in England being 205, of which 61 are in the metropolis. Of the 205 borough constituencies, 184 return each one member, and 21 return each two members, so that the total number of English borough members is 226. Besides the county and borough members there are in England five university members, namely, two for Oxford, two for Cambridge, and one for London. In Wales there are 10 borough parliamentary areas, all of which, except Merthyr Tydfil and Swansea town division, consist of groups of several contributory boroughs. Each Welsh borough constituency returns one member, except Merthyr Tydfil, which returns two, so that there are eleven Welsh borough members.

The following summary shows the population (1891), the registered electors (1901), the numbers, and representation of the various classes of constituencies in England and Wales:—

Description of Constituencies.	Population, 1891.	Electors, 1901.	Constituencies Number.	Representatives in Parliament.
England—				
County	13,848,294	2,835,019	234	234
Borough	13,636,100	2,232,278	205	226
University	...	17,702	3	5
Total England	27,484,394	5,084,999	442	465
Wales—				
County	999,957	211,881	19	19
Borough	518,174	92,985	10	11
Total Wales	1,158,131	304,866	29	30
England and Wales	29,002,525	5,389,865	471	495

At the general parliamentary election of 1895 the total number of votes recorded was 3,190,826. If the university constituencies are left out of account, the average representation, according to the census returns of 1901, is one member of parliament for every 66,380 inhabitants of England and Wales. The distribution, however, is still very unequal, ranging from one representative for 14,935 inhabitants in Durham, to one for 167,679 in the Cardiff district of boroughs. This inequality is shown by the following statement from the preliminary report on the census of 1901:—

Population to one Representative.	Number of Constituencies. 1891.	1901.
100,000 and upwards	7	41
90,000 and under 100,000	19	34
80,000 ,, ,, 90,000	26	47
70,000 ,, ,, 80,000	66	69
60,000 ,, ,, 70,000	108	82
50,000 ,, ,, 60,000	128	102
40,000 ,, ,, 50,000	79	56
30,000 ,, ,, 40,000	23	28
20,000 ,, ,, 30,000	19	19
10,000 ,, ,, 20,000	15	12
	490	490

Administrative divisions.

Under the Local Government (England and Wales) Act, 1888, which established a new system of county administration, 62 administrative counties have been created, each having a county council. Of the new counties, 14 coincide in area with ancient counties, and 7 others, together with county boroughs situated within their boundaries but now under separate administration, have areas coinciding with ancient counties of the same name. Generally, however, the areas of the new counties are different from those of the ancient. (1) In some cases portions of ancient counties are now administrative counties. Thus, the Isle of Ely in Cambridgeshire; the Parts of Holland, the Parts of Kesteven, the Parts of Lindsey, in Lincolnshire; the Soke of Peterborough in Northamptonshire; the Isle of Wight in Hampshire; the East Riding, the West Riding, and the North Riding of Yorkshire; the eastern portion and the western portion of Suffolk; and the eastern portion and the western portion of Sussex, have been formed each into a separate administrative county. The Scilly Islands, which form part of the ancient county of Cornwall, without being ranked as an administrative county, are provided with a county council and have separate administration. (2) The administrative county of London has an area taken entirely from the counties of Middlesex, Kent, and Surrey.

(3) All boroughs which on June 1, 1888, had a population of not less than 50,000, boroughs which were already counties having a population of not less than 20,000, and a few others, were formed into separate administrative areas, with the name of county boroughs. Of these there were originally 61, but their number has been increased to 67. (4) Provision was made for including entirely within one administrative county each of such urban districts (then called urban sanitary districts) as were situated in more than one ancient county.

The councils of the administrative counties consist of councillors chosen for three years by duly qualified electors in electoral divisions, aldermen chosen for six years by the councillors, either from among themselves or from outside, and a chairman chosen by the council, either from its own members or from outside. Municipal boroughs of sufficient importance to have separate representation on the councils form one or more electoral divisions, according to population. The county council of each administrative county is a body corporate, having perpetual succession and a common seal, and has power to acquire and hold land for the purposes of its constitution. The administrative business of the county councils is generally that formerly managed by the Quarter Sessions, with the exception of judicial business. Their powers relate principally to the levying of rates, the borrowing of money, the management of county buildings and property, the licensing of places for music and dancing and of racecourses, the maintenance of asylums for pauper lunatics, reformatories, and industrial schools, the management of bridges and roads, the regulation of fees of county officials and of salary and fees of coroners, the appointment of polling districts for parliamentary elections, and arrangement for the registration of electors and revision of electoral lists. County coroners, formerly chosen by popular election, are now elected by the county council. The county police is under the control of a standing committee of magistrates and members of the council in equal numbers, except in the county of London, where the police is under the Home Secretary. In the county boroughs the town councils have powers similar to those of the county councils.

Municipal boroughs.

The number of municipal boroughs in England and Wales has largely increased since the passing of the Municipal Reform Act of 1835. That Act applied to 178 boroughs, while 68 places (including London) with municipal powers of various origin were left outside its scope. These were mostly unimportant, and have either been reincorporated under the Municipal Corporations Act, 1883, or have ceased to exist as boroughs. The municipal boroughs in 1881 numbered 243; in 1891, 295; in 1901, 315 (exclusive of metropolitan boroughs). In 1900, under the London Government Act, 1899, the administrative county of London, exclusive of the City, was divided into 28 boroughs, the councils of which, with some additions and some limitations, took over the property, powers, and duties of the vestries.

The governing bodies in boroughs are the councils, consisting of the mayor, aldermen, and councillors. Their constitution and powers were amended by the Municipal Corporations Act, 1882, and to a large extent formed the models on which those of the county and district councils were framed in 1888 and 1894. The councillors are elected by the burgesses (in cities, citizens) for three years; the mayor and aldermen are elected by the council, either from within or from those outside who are qualified to be elected councillors, the mayor for one year and the aldermen for six years. The basis of the municipal franchise is ratepaying residence, and women may be enrolled and vote. The powers of the town councils comprise the levying of rates, the borrowing of money, management of borough property, police, markets, lighting, cleansing, water-supply, paving, bridges, and powers under various Acts relating to artizans' dwellings, cemeteries, free libraries, and matters affecting public health. As the urban district council the town council holds separate sittings.

Urban and rural district councils.

The areas into which England and Wales were divided under the Public Health Act of 1875 were called Urban and Rural Sanitary Districts. By the Local Government Act of 1894 this division was retained, but its purpose was greatly extended. In the designation the word "sanitary" was dropped, and, in urban and rural districts, district councils were established. In the boroughs this involved no change, but in Improvement Act districts, and in Local Government districts, the Improvement Commissioners and the Local Boards, respectively, were superseded by the new councils. In the rural districts the Boards of Guardians were formerly the sanitary authorities, but while such boards, under new regulations, continue to exist in urban districts, they are entirely abolished in rural districts, and their place is filled by rural district councils.

These councils, urban and rural, consist of councillors chosen for three years by the electors in wards or parishes, and a chairman chosen by the council for one year, either from within or outside this body, provided he have the qualification necessary for election as councillor. No disqualification for elector or councillor arises from sex. To the councils have been transferred powers formerly exercised by sanitary and highway authorities, and others exercised by justices out of session, and by Quarter Sessions, and they have duties relating to right of way, the Adoptive Acts, the compulsory purchase of land, and various other matters. Under the same Act every parish with a population of more than 300 has a *parish council*; parishes with smaller population may either be grouped together, or each have a council. Among other business, these councils appoint overseers and, except with respect to church affairs and ecclesiastical charities, exercise the powers formerly possessed by the vestries. In every rural parish there is a parish meeting held at least once a year, with powers relating to election of parish councillors, parish finance, and other matters.

Among the county, district, and parish councils there is much interdependence, and all of them are under the administrative and financial control of the central authority, the Local Government Board.

Poor Law.

Parishes, for local government purposes, are *poor-law parishes*, areas for each of which a separate poor-rate is or can be levied. In 1891 there were in England and Wales 14,684 such parishes, but under various Acts their boundaries and their number are subject to alteration. *Poor-law unions*, formed under an Act of 1834, are groups of parishes for the local administration of the Poor Laws. In 1898 the number of unions and of separate parishes was 649. *Registration districts* are generally, but not invariably, coextensive with unions of the same name. These districts are divided into sub-districts, within which the births and deaths are registered by registrars appointed for that purpose. *Registration counties* are groups of registration districts, and their boundaries differ more or less from those both of the ancient and the administrative counties. In England and Wales there are eleven registration divisions, consisting of groups of registration counties. Within the unions the local poor-law authorities are the *Boards of Guardians*. In rural districts the functions of these boards are, under the Local Government Act of 1894, performed by the district councils, and in other places their constitution is now similar to that of the urban and district councils. The guardians, elected for three years by the parochial electors, may choose two additional guardians, and the chairman, appointed annually, may be chosen either from within or from outside. There are now no *ex officio* or nominated guardians, and no disqualification for the office of guardian arises from sex or marriage. The principal duties of the guardians are the preparation or revision of the valuation lists on which the poor-rate is assessed, though the rates are levied not in union but in parish areas, and the administration of relief to the poor, involving the appointment of officers and the supervision of their work. The action of the guardians, however, in many cases requires the confirmation of the Local Government Board.

Pauperism.—The total number of paupers in England and Wales relieved, either within the union workhouses or outside, on January 1st of each fifth year from 1881 to 1896, and of each of the last three years, is given below. The few who received both indoor and outdoor relief are in the total counted only once:—

January 1.	Indoor Paupers.	Outdoor Paupers.	Total.
1881	195,286	614,232	809,341
1886	199,641	613,532	813,014
1891	198,218	582,413	780,457
1896	229,721	610,904	840,456
1899	230,915	590,323	821,096
1900	226,871	580,724	807,471
1901	227,148	574,312	801,460

The following table shows for entire parochial years, ending March 25th, the mean number per 1000 of estimated population of England and Wales:—(1) of indoor and outdoor paupers, (2) of in- and outdoor paupers, exclusive of vagrants and insane, (3) of adult able-bodied paupers only:—

Year ending March 25.	Paupers per 1000 of Estimated Population.		
	Total In- and Outdoor.	Exclusive of Vagrants and Insane.	Adults, able-bodied only.
1882 . .	30·3	27·0	3·9
1887 . .	28·9	26·2	3·7
1892 . .	25·6	22·8	3·2
1897 . .	26·5	23·3	3·3
1899 . .	26·5	23·2	3·4
1900 . .	25·0	21·7	3·0

The paupers relieved on January 1, 1901, exclusive of vagrants, were as follows:—

Description.	Male.	Female.	Children (under 16).	Total.
Indoor—				
Able-bodied . .	19,470	18,100	13,267	50,837
Not able-bodied . .	65,587	44,110	37,561	147,258
Insane . . .	7,486	8,959	1,083	17,528
Total indoor .	92,543	71,169	51,911	215,623
Outdoor—				
Able-bodied . .	10,632	48,456	130,696	189,748
Not able-bodied . .	77,109	201,120	27,417	305,646
Insane . . .	34,857	43,249	643	78,749
Total outdoor .	122,598	292,825	158,756	574,179
Total . .	215,141	363,994	210,667	789,802

The total number of vagrants relieved was 11,658 (11,525 indoor and 133 outdoor), and, including these, the total number of paupers relieved was 801,460, of whom 113 received both indoor and outdoor relief. Of the 10,632 "able-bodied" outdoor male paupers, the great majority were relieved on account of sickness or accident; of the 48,456 "able-bodied" female outdoor paupers, 34,082 were widows, 7588 were wives of "able-bodied" men relieved, 4183 were wives of non-resident males, 2374 were single women without children, and 229 were mothers of illegitimate children. The great majority of the children relieved out-of-doors were children of widows relieved.

The cost of poor-relief steadily increases. The gross expenditure, with the amount per head of population, and the relief expenditure from rates, with the average rate per £ of rateable value, in the parochial years 1891 and 1899 (ending March 25), were as follows:—

Years.	Gross Expenditure.	Per Head of Population.	Expenditure from Rates	Per £ of Rateable Value.
	£	s. d.	£	s. d.
1891 .	8,643,318	6 0	5,857,436	0 9¼
1899 .	11,286,973	7 2¼	8,161,532	1 0·2

In these years the sums expended on in-maintenance, out-relief, and on lunatics in asylums, etc., were:—

Years.	In-maintenance.	Out-relief.	Lunatics in Asylums, &c.
	£	£	£
1891 .	1,951,486	2,400,089	1,284,656
1899 .	2,462,008	2,764,854	1,748,558
Increase	510,522	364,765	463,902

Other expenditure in 1899 consisted of £919,313 for interest and repayment of workhouse loans, £1,971,614 for salaries, &c., and £1,420,626 for other purposes, bringing the total expenditure up to £11,286,973.

The number of paupers and the cost of poor-relief are very unequally distributed over England and Wales. The following table shows, for January 1, 1901, the number of in- and outdoor paupers per 1000 of estimated population, and for 1899 the gross expenditure on poor-relief per head of estimated population, in each of the eleven registration divisions:—

Divisions.	Per 1000 of Population.			Expenditure per Head of Population
	Indoor Paupers.	Outdoor Paupers.	Total, including Asylums, &c.	s. d.
London	14·9	8·7	26·9	15 3½
South-Eastern . .	7·3	15·0	24·7	6 10¾
South Midland . .	5·2	17·8	25·4	6 2¾
Eastern . . .	6·0	23·0	31·2	6 10¾
South-Western . .	5·5	27·2	35·5	6 11½
West Midland . .	6·8	17·6	26·8	6 0½
North Midland . .	4·7	20·2	26·9	6 2½
North-Western . .	6·9	10·1	19·0	4 10½
Yorkshire . .	4·4	13·4	19·6	4 11
Northern . . .	4·5	13·8	20·0	4 4¼
Welsh	3·9	23·8	29·8	6 6½
Total . .	7·1	15·6	25·0	7 2¼

Justice.

The highest court of appeal is the House of Lords, where the Lord Chancellor presides, the other judges being ex-Lords of Appeal in Ordinary (appointed under the Appellate Jurisdiction Act, 1887) and such other peers of Parliament as hold or have held high judicial office. The Judicial Committee of the Privy Council is concerned chiefly with appeals from Colonial and Indian Courts, but it has also ecclesiastical and other jurisdiction, and it decides concerning petitions for extension of letters patent. Its judgments are given in the form of reports to the King. Members of this court are the Lord Chancellor and the four Lords of Appeal, but the Lord Chief Justice, the Lords Justices, and others who hold or have held high judicial office, and are members of the Privy Council, are qualified to sit. One member of the court is a specially appointed expert in Indian law; and in 1897, under an Act of 1895, three colonial judges, the Chief Justices of Cape Colony, Canada, and South Australia, were added.

In the Supreme Court of Judicature there is a Court of Appeal, where the Master of the Rolls and five Lords Justices usually sit, the Lord Chancellor, the Lord Chief Justice, and the President of the Probate, Divorce, and Admiralty Division being also judges in this court.

In the Chancery Division of the High Court of Justice there are six judges, besides the Lord Chancellor; in the King's Bench Division are the Lord Chief Justice and fourteen other judges; in Probate, Divorce, and Admiralty Division are two judges; and in the Bankruptcy Division, one. The Court of Arches for ecclesiastical cases has one judge.

Assize courts, in which the the judges of the High Court try civil and criminal cases, are held in eight circuits, which at present are constituted as follows:— The South-Eastern, in two divisions—the Home Division (Sussex, Kent, Essex, Hertford) and the Norfolk Division (Norfolk, Suffolk, Huntingdon, Cambridge); the Midland (Buckingham, Bedford, Northampton, Leicester, Rutland, Lincoln, Derby, Nottingham, Warwick); the Northern (Westmorland, Cumberland, Lancashire); the North-

Eastern (Northumberland, Durham, York); the Oxford (Berkshire, Worcester, Gloucestershire, Monmouth, Hereford, Stafford, Shropshire, Oxford); the Western (Hampshire, Wiltshire, Somerset, Dorsetshire, Devonshire, Cornwall); the North Wales (Chester and the six northern Welsh counties); South Wales (the six southern Welsh counties).

Courts with jurisdiction in special matters are the Lunacy Commission, the Railway and Canal Commission, the Lancaster and Durham Chancery Courts. For the determination of civil cases in which the value in dispute is of small amount, there are County Courts, England and Wales being divided into sixty County Court circuits. Other civil courts which may be mentioned are the Lord Mayor's Court, London, Bankruptcy Courts, and Borough Courts of Record. The number of civil cases in which proceedings were commenced in courts of first instance in England and Wales in 1899 was 1,272,143. Of these 78,326 were in the High Court, and 1,159,062 in County Courts, the remainder being mostly in the Lord Mayor's Court, London, in Borough Courts of Record, and in Bankruptcy Courts. In the same year there were 446 appeals in the High Court from inferior courts; 826 in the Court of Appeal; 76 in the Judicial Committee of the Privy Council; and 75 in the House of Lords.

Crime.—The Queen's Bench Division of the High Court has power to try criminal cases, but this power is seldom used (in two cases in 1898), and, practically, the principal criminal courts are the Assize courts, and the Central Criminal Court, which, in law, is included in the assizes. Assize courts are usually held three times (in some cases four times) a year, by judges on circuit, or by commissioners appointed for the purpose. The Central Criminal Court holds twelve sessions a year. Courts with less extensive jurisdiction are Quarter Sessions, held by two or more justices of the peace in counties, and by the recorder in boroughs which have a separate court. These courts, sitting four times (in London thirty-six times) a year, dispose of the less serious cases, while more serious charges, *e.g.*, treason, murder, perjury, are tried at assizes. Neither from Assize courts nor from Quarter Sessions is there any appeal, but the judges or magistrates may reserve doubtful points of law for decision by the Court for Crown Cases Reserved, consisting of five or more judges of the High Court. At Assizes and Quarter Sessions all trials are by jury.

Courts of summary jurisdiction consist of at least two justices of a petty sessional division of a county or of a borough sitting in petty sessions, but in large towns the stipendiary magistrate may sit alone. In these courts there is no jury; the decisions are in most cases subject to appeal, but appeals are rare. The magistrates conduct the preliminary investigation of cases afterwards tried at Quarter Sessions or Assizes, and they have also certain civil jurisdiction.

The number of persons committed for trial at the Assizes and at Quarter Sessions, the number convicted, and the number acquitted (including those not proceeded against), in 1881, in each fifth year to 1896, and in 1898 and 1899, were as follows:—

Years.	Committed for Trial.	Convicted.	Acquitted.
1881 . .	14,786	11,353	3401
1886 . .	13,974	10,686	3245
1891 . .	11,695	9,055	2585
1896 . .	11,214	8,856	2317
1898 . .	11,594	9,273	2267
1899 . .	11,044	8,749	2240

The decrease in the number of persons annually convicted of serious crime since 1880 is evident, and is the more remarkable when it is considered that this absolute decrease has been concurrent with a large increase in the population.

The different classes of offences for which prisoners were committed, and of which they were convicted or acquitted, at Assizes and Quarter Sessions in the years 1897–1899, were as follows:—

Classes of Offences.	Years.	Persons Committed.	Persons Convicted.	Persons Acquitted, &c.
I. Against the person .	1897	2,606	1750	856
	1898	2,629	1800	829
	1899	2,649	1785	864
II. Against property, with violence .	1897	1,997	1762	235
	1898	2,136	1888	248
	1899	1,908	1702	206
III. Against property, without violence .	1897	5,524	4527	997
	1898	5,657	4625	1032
	1899	5,334	4340	994
IV. Malicious offences against property .	1897	277	209	68
	1898	251	189	62
	1899	259	180	79
V. Forgery and offences against the currency . . .	1897	304	275	29
	1898	351	317	34
	1899	311	275	36
VI. Other offences .	1897	507	344	163
	1898	430	314	116
	1899	441	326	115
Total . .	1897	11,215	8867	2348
	1898	11,454	9133	2321
	1899	10,902	8608	2294

In 1899, 39,592 persons were tried summarily for indictable offences, and 31,879 were convicted, the total number of convictions for indictable offences within the year having thus been 40,487.

The criminal statistics since 1895 show a slight increase in the number of cases, but this is due to increase not of the number of criminals, but of offences. Sentences of imprisonment are now for shorter terms than formerly; old offenders are more frequently at large, are oftener brought to justice, and thus swell the numbers in the statistical returns. This view is borne out by the following figures, showing for the years 1893–1898 the number of receptions of convicted prisoners into the prisons of England and Wales, and also the number and percentage that had been previously convicted:—

Years.	Number of Convicted Prisoners.	Number having Previous Convictions.	Percentage of the whole.
1893 . .	151,462	75,867	58·1
1894 . .	155,132	84,603	54·9
1895 . .	143,441	79,711	55·6
1896 . .	149,000	85,405	57·3
1897 . .	148,962	85,890	57·7
1898 . .	158,323	94,972	60·0
1899 . .	154,754	93,250	60·0

The total number of receptions into the various prisons, and the number of criminal and non-criminal prisoners, in 1899, were as follows:—

Prisoners.	Male.	Female.	Total.
Convicted on indictment .	6,718	787	7,505
Convicted summarily . .	102,657	44,592	147,249
Total convicted criminals	109,375	45,379	154,754
Convicted by court-martial	1,626	—	1,626
Remanded and discharged .	12,629	3,165	15,794
Total criminal prisoners .	123,630	48,544	172,174
Surety prisoners . .	1,248	648	1,896
Debtors	10,247	462	12,706
Others	56	8	64
Total . . .	137,178	49,662	186,840

In 1899 sentence of death was passed in 29 cases, and carried out in 15. Of the prisoners received into prisons, 735 were under sentence of penal servitude.

Of the 154,754 convicted prisoners received in 1899, 93,250 were old offenders. These, classed according to the number of their previous convictions, were:—

Previously Convicted.	Males.	Females.	Total.
Once	19,422	6,023	25,445
Twice	8,755	3,436	12,191
Three times . . .	5,557	2,606	8,163
Four times . . .	3,952	1,925	5,877
Five times	2,953	1,636	4,589
Six to ten times. . .	8,834	5,468	14,302
Above ten times . .	10,468	12,215	22,683
Total . .	59,941	33,309	93,250

The condition of the convicted criminals received into prisons in 1899 with respect to education, is shown in the subjoined statement:—

Prisoners.	Male.	Female.	Total.
Not able to read or write .	17,703	11,483	29,186
Per cent. of whole .	16·18	25·30	18·86
Able to read and write imperfectly . . .	84,854	33,114	117,968
Per cent. of whole	77·58	72·98	76·23
Able to read and write well	5,658	740	6,398
Per cent. of whole .	5·17	1·63	4·14
Superior instruction . .	84	6	90
Per cent. of whole .	0·08	0·01	0·05
Instruction not described .	1,075	37	1,112
Per cent. of whole .	0·99	0·08	0·72
Total . . .	109,374	45,380	154,754

With respect to age, the prisoners received in 1899 were as follows:—

Ages.	Male.	Female.	Total.
Under 16	1,286	72	1,358
16 and under 21 . .	12,826	2,386	15,212
21 ,, ,, 30 . .	29,777	12,006	41,783
30 ,, ,, 60 . .	57,352	28,856	86,208
60 and upwards . .	8,056	2,042	10,098
Age not ascertained . .	77	18	95
Total . . .	109,374	45,380	154,754

In 1899, 1134 offenders under 16 years of age were committed to reformatory schools, 44 being from Assize and Quarter Sessions, and 1090 from courts of summary jurisdiction. In the great majority of the cases the offence was larceny or other form of dishonesty. In 131 cases a preliminary term of imprisonment was imposed. In the same year 7245 offenders under 16 years of age were sent to industrial schools, many of them for such offences as begging and absenting themselves from school. The following are the figures showing receptions into reformatory and industrial schools in 1899:—

	Boys.	Girls.	Total.
Reformatory schools . . .	987	147	1134
Industrial schools . . .	2422	617	3039
Truant industrial schools .	2323	—	2323
Truant indus rial day schools .	1405	478	1883
Total, industrial schools .	6150	1095	7245

Police.—The average number of men employed daily in police duties in England and Wales in 1900, and the net cost of the police force in the same year, were as follows:—

	Average Number.	Net Cost.
		£
Counties	13,080	1,127,350
Cities and boroughs . .	13,296	1,225,595
Metropolitan police . .	13,588	1,291,070
City of London police . .	1,001	99,007
Total	40,965	3,743,022

Education.

The Board of Education, which was formed April 1, 1900, under an Act of 1899, is charged with the superintendence of all matters relating to education in England and Wales. It consists of a president, the Lord President of the Council (unless he is appointed president), the principal Secretaries of State, the First Lord of the Treasury, and the Chancellor of the Exchequer. This board has taken the place of the Education Department and the Department of Science and Art, and, under the Act by which it was created, Orders in Council have been made whereby it will exercise, concurrently with the Charity Commissioners, certain powers relating to educational endowments in England and Wales, and there have been transferred to it from those Commissioners powers relating to educational endowments in Wales and Monmouth, regulated by schemes under the Endowed Schools Acts. A consultative committee has been appointed to frame regulations for a register of teachers, and to advise the board on any matter on which the board may request advice. The Education Office has been organized in two branches, one concerned chiefly with elementary, and the other with secondary education, the administration of science and art instruction being intrusted to the latter. Arrangements are in progress to enable the board, with the Charity Commissioners, to undertake the complete inspection, administrative and educational, of schools which desire it.

The Elementary Education Act of 1870 has been amended, and its purpose extended, by several important Acts. By an Act of 1876 it was made a punishable offence for a parent to neglect the education of his child; and the employment of children at work under the age of ten, and of children over ten unless they should have reached a certain standard of proficiency, was made illegal. The age of exemption from attendance at school on account of proficiency was in 1893 raised to eleven, and in 1899 to twelve. The Act of 1876 further required that attendance at school should be enforced by school boards or, where there are no school boards, by school attendance committees appointed annually for the purpose; and it empowered the authorities to send neglected children to industrial schools. An Act of 1891 provided for the payment of a fee grant of ten shillings *per annum* for each child (over three and under fifteen years of age) of average attendance at day schools, the grant being made conditional on the abolition or reduction of school fees. The Voluntary Schools Act, 1897, provided that an aid grant, not exceeding in the aggregate five shillings per scholar, should be paid to public elementary schools not provided by school boards, and it also exempted such schools from the payment of rates. This Act contemplated the formation of associations of voluntary schools, and a school may be required to belong to an association to receive the grant. A separate Act of the same year provided for an increase in the grants to school boards, thus reducing the school board rates. Among other educational Acts passed in recent years are those of 1893 and 1899, providing for the instruction of blind and deaf, and of epileptic children.

The progress of elementary education in the country is roughly shown by the following table, which gives the annual average proportion of persons signing the marriage register with marks :—

Years.	Proportion signed by Mark in 1000 Marriages.		
	Husbands.	Wives.	Both.
1881–85 . .	123·4	154·8	54·4
1886–90 . .	84·0	98·2	30·2
1891–95 . .	51·2	59·6	16·6
1896 . .	37	43	11
1897 . .	33	40	10
1898 . .	31	36	10
1899 . .	29	34	9

The average proportion of persons who signed the marriage register by mark in 1889–98, and the proportion in 1899, in the registration counties, are given as follows :—

Registration County.	In 1000 Marriages signed by Mark.			
	1889–98.		1899.	
	Men.	Women.	Men.	Women.
London . . .	32	43	25	33

Monmouthshire . .	93	102	56	65
South Wales. . .	72	102	41	57
North Wales . .	87	94	50	53

According to this test, the illiteracy of both men and women is greater in the northern than in the southern counties; in the southern, except London, there are more illiterate men than women married, while in the northern and London, the women are the more illiterate.

Elementary Schools.—The number of elementary schools (both voluntary and board schools) inspected, the number of children for whom accommodation was provided in these schools, and the average attendance in years ending August 31, 1881, 1891, and in 1897–1900 were :—

Years.	Schools Inspected.	Accommodation.	Average Attendance.
1881 . .	18,062	4,389,633	2,863,535
1891 . .	19,508	5,628,201	3,749,956
1897 . .	19,958	6,215,199	4,488,543
1898 . .	19,937	6,316,866	4,554,165
1899 . .	20,064	6,417,514	4,636,938
1900 . .	20,100	6,509,611	4,666,130

Voluntary schools are Church of England (National), Roman Catholic, British, Wesleyan, and Jewish. The number of voluntary schools of various denominations, and of board schools inspected, and the average attendance at the schools in 1881, 1891, and 1900 were :—

Denomination and Year (ending August 31).		Schools Inspected.	Average Attendance.
Church of England .	1881	11,589	1,490,429
	1891	11,908	1,675,634
	1900	11,804	1,882,854
British, Wesleyan, &c.	1881	1,992	544,113
	1891	1,893	384,597
	1900	1,553	350,899
Roman Catholic . .	1881	789	152,641
	1891	955	195,663
	1900	1,052	255,124
Board schools . .	1881	3,692	856,351
	1891	4,779	1,498,599
	1900	5,691	2,177,253

In 1901 there were in England and Wales 2545 school boards and 788 school attendance committees. The voluntary school associations formed up to March 31, 1901, numbered 75, of which 46 were Church of England, 17 British and Wesleyan, 11 Roman Catholic, and 1 Jewish. There were 181 unassociated voluntary schools.

The increase in the number of teachers in elementary schools is shown thus :—

Years.	Certificated Teachers.	Assistant and Additional.	Pupil Teachers.
1881 . .	33,562	11,018	33,639
1891 . .	47,823	29,189	28,131
1900 . .	64,038	49,948	29,393

Of the certificated teachers in 1900, 24,557 were men, and 39,481 women. Of the assistant and additional teachers, 5121 were men. There are 44 residential training colleges, of which 30 belong to the Church of England, 11 are British, Wesleyan, &c., and 3 are Roman Catholic. They contained in 1899, 3866 students. There were also 1334 students in 16 day training colleges. In addition to the day schools there were, in 1900, 5263 evening continuation schools, with an average attendance of 206,335.

For the building of schools and for permanent structural improvements, loans are advanced to school boards by the Public Works Loan Commissioners, and are obtained otherwise on the security of the rates. Up to April 1, 1900, the loans amounted to £39,428,860; the outstanding balance on September 29, 1899, amounted to £29,352,590.

The income of public elementary schools is derived partly from Government grants and partly from local sources. The local income is mainly from endowment, voluntary contributions, school pence, rates, and county council grants. The local income, the total income, and the total expenditure of elementary schools in 1881, 1891, and 1900 were as follows :—

Years.	Revenue.		Expenditure.
	Local.	Total.	
	£	£	£
1881 . .	3,194,175	5,349,840	5,336,979
1891 . .	4,480,162	7,813,706	7,829,655
1900 . .	4,334,005	12,336,986	12 453,006

In the school year ending August 31, 1900, the income and expenditure of voluntary and board schools were :—

Schools.	Revenue.		Expenditure.
	Local.	Total.	
	£	£	£
Church of England .	937,609	4,345,148	4,418,988
British, Wesleyan, &c. .	223,607	881,758	909,248
Roman Catholic . .	93,835	556,327	572,555
Board	3,078,954	6,553,753	6,552,215
Total . .	4,334,005	12,336,986	12,453,006

Of the amount expended in 1900, £407,960 was devoted to evening continuation schools. In 1899 the average rate per £ on the rateable value for school purposes was in England 10·9d. In London it was 12·9d.; in boroughs, 10·1d.; and in rural parishes, 9·7d. In Wales the average rate was 11·1d.; in boroughs, 10·3d. ; in parishes, 11·5d.

Secondary Schools.—Many school boards maintain higher grade schools, with an upper portion arranged as an organized science school. Of these schools there were 54 in 1897. In 38 towns there were 43, with an average attendance of 681 pupils each. In 1901 an Act was passed obviating the effect of the legal decision in what was known as the Cockerton Case, and enabling school boards (with the sanction of county councils or other local authorities) to support from the rates higher or technical instruction in their schools. With respect to secondary schools in England, there are no comprehensive official statistics, but in 1897 the Committee of Council on Education instituted an inquiry into their number, and the numbers of their teaching staff and pupils. The great majority of the schools owe their existence to private enterprise, their administration and the instruction given in them being in the hands of the owners. Others are supported by subscriptions, and are controlled by committees of subscribers. A considerable number belong to companies, formed under articles of association with limited liability. The endowed schools are variously regulated—some under the Charitable Trusts Acts, others under the Endowed Schools Acts, while a few are regulated by their charters, special Acts of Parliament, and in other ways. A small number of secondary schools is under local public authority. The number of secondary schools in England, exclusive of Monmouthshire, and the number of their pupils on June 1, 1897, according to the results of the inquiry, are set forth as follows :—

Form of Control.	For Boys.		For Girls.		Mixed.	
	Schools.	Pupils.	Schools.	Pupils.	Schools.	Pupils.
Private enterprise	1311	46,617	2886	80,286	970	26,027
Subscribers .	70	8,719	99	6,321	28	3,626
Companies .	48	5,188	99	13,238	3	308
Endowed, &c. .	502	59,517	86	14,119	31	3,035
Local authority .	27	2,272	3	3,275	46	6,996

Of the 6209 schools to which the return relates, 1958 were for boys, 3173 were for girls, and 1078 were mixed. The total number of boys at the schools was 158,502, and of girls 133,042, or, respectively, 5·4 and 4·5 per 1000 of the total population of England (exclusive of Monmouthshire) in 1897. Of the pupils, 68,785, or 24·8 per cent. of the whole, were boarders. The teaching staff of the schools consisted of 8362 attached male teachers, and 14,980 female, with 6874 visiting male teachers, and 5204 female. Of the male teachers (attached and visiting), 5821 were university graduates ; of the female, 2323.

By the Board of Education Act, 1899, provision was made for the inspection of secondary schools desiring to be inspected, except those under the Welsh Intermediate Education Board. This board, constituted under the Welsh Intermediate Education Act, 1889, consists of 80 members appointed by councils of counties and county boroughs, school-governing bodies and other bodies interested, and it provides for the inspection and examination of secondary schools in Wales and Monmouthshire. In 1899, 93 schools were examined, of which 22 were for boys, 21 for girls, 43 dual, and 7 mixed. The teaching staff consisted of 241 male and 204 female attached teachers, besides 204 visiting teachers. Of 7390 pupils examined, 3877 were boys, and 3513 were girls.

In England and Wales technical instruction has made great progress, and technical schools have been multiplied. In London the City and Guilds Technical Institute has a central college, an intermediate college, and 2 schools, employing in all about 76 professors and teachers, and giving instruction to over 1600 students. The metropolis contains many other institutions of a similar nature, among them being the Northampton Institute, the Regent Street Polytechnic, the Bolt Court Technical School, the Camberwell School of Arts and Crafts, the Central School of Arts and Crafts, the Hackney Technical Institute, the Crafts School, Mile End, Herold's Institute, the Shoreditch Municipal Technical School, and the National Training School of Cookery. But in addition to such institutions primarily intended for technical instruction, over 100 schools and colleges and institutes in London have been turned to account for the same purpose. Throughout the counties and boroughs of England and Wales similar development has taken place. Municipal and other technical institutes have been founded in great numbers, while already-existing colleges, grammar schools, and board schools are encouraged and assisted in the work of technical instruction. The amount expended by local authorities on technical instruction in the year 1897–98 in England and Wales was : from grant under Local Taxation (Customs and Excise) Act, £756,717 ; from rates, £97,739 ; total, £854,456. The estimated total for the year 1898–99 was £870,087.

In 1899 the Board of Education had 2056 science schools in England and Wales and Ireland, the number of science pupils being 174,670, while the number of its art schools and classes was 1745, with 130,126 pupils. For the year 1901–02 the parliamentary vote for art and science schools amounted to £321,295.

Colleges.—In England, in 1900, there were 11 university colleges, receiving annual parliamentary grants amounting in the aggregate to £24,000 ; in Wales there were 3, each receiving annually a grant of £4000. Among the subsidized English colleges is Bedford College, London, for ladies ; similar institutions not receiving grants are Newnham College and Girton College, Cambridge ; Lady Margaret Hall and Somerville Hall, Oxford ; and the Royal Holloway College, Egham.

New Universities.—In 1878 the University of London received a supplemental charter whereby women are admitted equally with men to its degrees and honours, and in 1900 it was reconstituted so as to have teaching as well as examining functions. The first schools of the university are University College and King's College, London, 6 theological colleges, 2 colleges for ladies, 10 medical schools, and 4 other schools and colleges. Provision is also made for the admission from time to time of other institutions as schools of the university. Victoria University was created by charter in 1880, with power to grant degrees to men and women who have studied in its colleges ; in 1883 it was empowered to confer medical degrees. Its colleges are Owen's College, Manchester ; University College, Liverpool ; and the Yorkshire College, Leeds. The University of Wales was created in 1895, with power to grant degrees (but not medical degrees) to men and women. Its constituent colleges are those of Aberystwith, Bangor, and Cardiff. The University of Birmingham, created by charter of May, 1900, is a teaching and examining university, and confers degrees on persons of either sex.

University and College Attendances.—The University of Oxford in 1899 had 3446 undergraduates, 814 students having matriculated during the year. The University of Cambridge in 1900 had 2985 undergraduates ; in 1899–1900 there were 932 matriculations. The University of Durham had in 1899, 170 students. In 1900 the 2 Colleges for ladies at Oxford contained 141 students, and the 2 at Cambridge, 286 ; that in London had 183, and that at Egham, 120. At other university colleges (except those at Aberystwith, Bangor, and Lampeter, and the Medical College at Newcastle), the attendance of students is largely in the evening, and in the following figures, referring to the winter session of 1900, both day and evening students are included. University College and King's College, London, had together 2565 students. The 3 colleges associated together in the Victoria University had 2400 ; the 3 within the University of Wales had 2730 ; the 2 at Newcastle (1 of medicine and the other of science), connected with Durham University, had 1700 students ; Mason College, Birmingham, had 935 ; and the 4 colleges at Nottingham, Sheffield, Bristol, and Lampeter had altogether 3600 students.

Charities.

The information concerning the endowed charities of England and Wales contained in the Reports of the Commission of 1818 to 1837 has been and is being supplemented by digests compiled by the Charity Commissioners, and, since 1892, by the results of local inquiries, towards the cost of which the County Councils are authorized to contribute. As yet, however, there is no complete account of the income of these charities. According to a return laid before Parliament in 1898, the amount applicable for alms-people and pensioners, and the amount applicable to gifts of money and in kind, were at that date, as far as had been ascertained, as follows:—

	For Alms-people and Pensioners.	For Distribution.
	£	£
I. Results of Local Inquiry—		
West Riding of Yorkshire . .	37,918	13,330
Part of Wales	3,156	3,739
II. According to Digests, 1868–76, and Supplementary Digests, 1890–97	301,887	218,790
III. According to Digests, 1868–76 .	268,504	91,796
Total	611,465	327,655
	£939,120	

In the 48th Report of the Commissioners it is stated that the number of returns of accounts of charities made to their office in 1900 was 36,754; in 1899, 38,516; in 1898, 29,478; but according to the 46th Report the number of charities from which accounts were annually due in 1898 was 70,547. The stock and investments which had been transferred to the official trustees of charitable funds (exclusive of retransferments) from 1854 to December 31, 1900, amounted to £20,829,650.

The number and value of endowed charities is rapidly increasing. In the 20 years 1875–94 charities of £1000 and upwards subject to the Charitable Trusts Acts were founded, amounting to over £8,000,000, and in the 5 years 1895–99 the new charities in the aggregate amounted to over 2½ millions sterling. On the average, about 500 new charities are created annually, and the average amount annually so given is estimated at a capital value of about £1,000,000, of which about half is permanent, or subject to a perpetual trust for investment, and the remainder is not so subject.

Of the large amount annually raised by voluntary contribution for charitable purposes in England and Wales, no trustworthy estimate can be formed. In the metropolis the income of charitable institutions (exclusive of the amount devoted to religious purposes) is probably not much less than £4,000,000, of which about £950,000 goes to the hospitals, general and special. The number of hospitals in London and its suburbs is about 126; 23 are general and 76 are for special diseases, and there are about 27 suburban and cottage hospitals. Of the general hospitals, 13 are provided with medical schools. St Bartholomew's Hospital in 1899 had an income, from all sources, amounting to £72,454; treated 6343 in-patients and 14,017 out-patients, besides 125,233 cases of accident, &c. The income of St Thomas's Hospital was £72,841, of which £46,792 was from estates; the in-patients during 1899 numbered 5831; the out-patients, 18,417; and the cases of accident, &c., 44,920. In the same year the London Hospital had a total income of £93,679, of which £61,521 was ordinary income; the in-patients numbered 13,234, and the out-patients, 189,638. Guy's Hospital had an ordinary income of £41,541, and to meet current expenditure £38,479 was transferred from permanent funds; it had 7548 in-patients and 85,198 out-patients during the year. St George's Hospital had a total income of £29,692; St Mary's Hospital, £32,513; and the Royal Free Hospital, £11,930. The Bethlehem Hospital for lunatics had in 1899 a revenue of £39,000; the patients cared for during the year were 179 men and 259 women, besides 47 men and 63 women at the Witley convalescent estate. Owing to the decrease in the value of land and from other causes, the permanent income of several of the hospitals has decreased in recent years, and consequently many of the beds have been unoccupied. The amount raised by the Hospital Sunday Fund in 1901 was £51,000; in 1900, £49,500; in 1899, £53,504. The Hospital Saturday Fund in each of those years raised about £20,000. The Prince of Wales's Hospital Fund for London amounted, at the beginning of 1900, to £315,364, of which £176,015 remained in hand.

Religion.

There are no comprehensive statistics showing the population of England and Wales according to religious denominations. In the Registrar-General's Report for 1899 the number of churches and chapels of the Established Church in which marriages could be solemnized was stated to be 15,309, and the number of buildings on the register for marriages by rites other than those of the Church of England was 12,578. The latter number comprised 2551 Congregationalist buildings, 2195 Baptist, 2695 Wesleyan, 1124 Primitive Methodist, 533 United Methodist Free Church, 203 Methodist New Connexion, 96 other Wesleyan Methodist, 665 Calvinistic Methodist, 397 Presbyterian, 177 Unitarian, 149 Bible Christian, and 678 belonging to other bodies. Of 1000 marriages solemnized in each of the years 1881, 1891, 1898, and 1899, the proportion solemnized according to the rites of the Church of England, and of those solemnized otherwise was as follows:—

	1881.	1891.	1898.	1899.
Established Church .	715	699	685	678
Roman Catholic . .	45	42	40	41
Various other Christian .	111	118	121	124
Friends	0·3	0·3	0·4	0·3
Jews	2·5	4·6	5·7	6·4
In Registrar's office .	126	136	148	150

Judged by this test, the Church of England predominates over the length and breadth of England and Wales, except in the northern counties of Wales.

Established Church.—In 1900 the Established Church was governed by 2 archbishops, 33 bishops, 17 suffragan and 5 assistant bishops in England and Wales. Since the year 1880 five bishoprics have been founded or reconstituted, one of them, that of Bristol, being in the province of Canterbury, and the others in the province of York. These new dioceses, with the year of their foundation and the amount of annual income, are as follows:—Liverpool, 1880, income, £4000; Newcastle, 1882, income, £3500; Southwell, 1884, income, £3500; Wakefield, 1888, income, £3000; Bristol, 1897, income, £3000. The see of Bristol was originally founded in 1542, but in 1836 it was united with that of Gloucester. In 1897, however, it was, by Order in Council, reconstituted as a separate diocese. Steps were being taken in 1901 towards the foundation of a bishopric of Southwark, with an endowment of £4000 a year. Under the bishops are 31 deans, 91 archdeacons, and 810 rural deans. The total number of bishops and clergymen at work in 1899 was approximately 22,800, of whom 13,873 were beneficed, the remainder being curates and unbeneficed clergymen. Church extension is steadily progressing, churches and chapels being built, new districts and parishes formed, and the incomes of the poorer clergy increased. This work is being advanced with the assistance of diocesan funds, and by the labours of 31 diocesan Church extension societies. The number of new districts, parishes, &c., formed in the year 1898–99, under the Church Building and New Parishes Acts, was 26, and in the years 1818 to 1899, 3725. The voluntary contributions alone which were applied to this purpose in the 16 years 1884–99 amounted to £21,858,548, of which £17,531,626 was applied to church building and restoration, £2,348,611 to endowments, £1,567,739 to parsonages, and £410,572 to burial-grounds. Through the instrumentality of the Ecclesiastical Commissioners, assisted by private liberality, the incomes of the underpaid clergy have been largely increased, 5800 benefices having been augmented during the years 1840 to 1898, the total annual income being increased by £1,032,300. Within the Church there are many clerical and lay agencies for school work, for home and foreign mission work, and for many other purposes, for which voluntary contributions of large amount are received. The gross annual income of the Church of England, according to a return of the Ecclesiastical Commissioners in 1891, was as follows, from ancient endowments and from benefactions since 1703:—

	Ancient Endowments.	Private Benefactions since 1703.
	£	£
Archiepiscopal and Episcopal sees .	87,827	11,081
Cathedral and Collegiate churches	192,460	—
Ecclesiastical benefices . . .	3,941,057	272,605
Ecclesiastical Commissioners .	1,247,827	—
Queen Anne's bounty . . .	—	700
Total	£5,469,171	£284,386

The income from voluntary contributions for church purposes, raised by offertories in church and by parochial organization, in 1897–98 was £5,919,706, in 1898–99, £5,954,738, and in 1899–1900, £5,504,395. If to these sums be added the money contributed for general purposes, the total for 1898–99 rises to £7,464,430, and for 1899–1900, £7,770,993; but this is exclusive of many contributions devoted to church or parish purposes through other channels. The Church House at Westminster is regarded as a centre for the many societies within the Church of England. It contains a large hall, library, and offices, and though not yet complete, it began to be used by Convocation in 1896. It is intended that the building shall contain a hall for the use of the House of Laymen.

Roman Catholics.—The number of Roman Catholics in England and Wales in 1891 was estimated at about 1,500,000, but there are no trustworthy statistics on the subject. The Roman Catholic hierarchy in England in 1900 consisted of 1 archbishop and 14 bishops, besides 2 auxiliary bishops and a coadjutor bishop. In Wales there was a bishop, vicar-apostolic. At the same date the number of officiating Roman Catholic clergy in England and Wales was 2837, and of their chapels and stations, 1536.

Protestant Dissenting Bodies.—The Protestant Dissenting bodies are numerous and active, possessing organizations for charitable work and for home and foreign mission work, their efforts for the last-named purpoes being made largely through the London Missionary Society, while they raise large amounts annually for congregational purposes. The following list, which shows the number of members (communicants), of ministers, of local preachers, and of sittings in the churches and chapels of the several bodies, refers in general to the year 1900:—

	Members.	Ministers.	Local Preachers.	Sittings.
Congregational . .	398,741	2509	5,050	1,643,400
Baptist . . .	346,083	1855	5,074	1,273,325
Presbyterian . .	74,541	336	—	164,491
Wesleyan . . .	552,933	1858	17,834	2,224,057
Primitive Methodist .	185,075	1060	15,730	962,720
Calvinistic Methodist	156,058	626	409	451,200
United Methodist Free Church . . .	78,692	355	3,028	426,500
Meth. New Connexion	35,962	193	1,029	137,478
Bible Christian . .	29,150	169	1,473	153,600
Friends . . .	16,611	—	400	—
Churches of Christ .	11,939	—	397	20,000
Independent Methodist	8,599	—	495	33,000
Wesleyan Reform Union . . .	7,192	18	—	43,834
Moravians . . .	3,371	51	—	—
Lady Huntingdon Connexion . . .	2,355	29	—	13,347
Free Church of England . . .	1,500	27	—	6,500
Reformed Episcopal .	1,500	28	—	7,200

The Unitarians have about 345 chapels. Smaller bodies are the Catholic Apostolic Church, with about 80 churches, and the New Jerusalem Church, with about 75 societies. The Salvation Army, a religious body with a quasi-military organization, has carried on since 1865 active work, both of a spiritual and social nature, and has extended its labours to the colonies and to many foreign countries. In the United Kingdom alone it has 1610 corps and societies, with 4854 officers and others wholly engaged in its work, and it maintains 142 institutions for assisting the destitute, or for rescuing those who have lapsed into crime or immorality. At these institutions, in 1899, work was obtained for 12,460 applicants; over 2½ million cheap meals and nearly 1¾ million cheap lodgings were provided, for which (combined) the recipients paid £33,610. There were received into homes in the same year 2129 women and girls, of whom 1820 were sent to situations or restored to their friends.

The number of Jews in England and Wales in 1899 was estimated at 97,350, the great majority of them being in London. They have about 80 synagogues, and about 100 ministers.

Agriculture.

The land area of England and Wales extends over 37,120,000 acres, of which, on the average of the three years 1897–99, 27,591,000 acres are under crops and grass, 3,427,000 acres consist of mountain and heath land used for grazing, and 1,848,000 acres (according to an estimate of 1895) are under woods and plantations; the area which is not arable, nor pastoral, nor woodland, thus extends to 4,254,000 acres. The following statement shows the distribution of these areas in England and in Wales, and the proportion which each bears to the total land area:—

Description of Land.	England.		Wales.	
	Area.	Per cent.	Area.	Per cent.
	Acres.		Acres.	
Under crops and grass (1897–99) . .	24,763,000	76·6	2,828,000	59·6
Mountain and heath land used for grazing (1897–99) . .	2,243,000	6·9	1,184,000	24·9
Woods and plantations (1895) . . .	1,666,000	5·1	182,000	3·9
Other land areas .	3,703,000	11·4	551,000	11·6
Total land area .	32,375,000	100·0	4,745,000	100·0

The area under crops and grass in England and Wales in 1881, 1891, 1896, and 1900 was as follows:—

	1881.	1891.	1896.	1900.
	Acres.	Acres.	Acres.	Acres.
Corn crops—				
Wheat . .	2,731,071	2,253,983	1,656,228	1,796,210

Permanent pasture—				
For hay	13,471,238	4,349,685	4,467,991	4,241,343
Not for hay		10,747,864	10,862,960	11,079,579
Total . .	13,471,238	15,097,549	15,330,951	15,320,922
Total—Crops and grass	27,448,900	28,001,134	27,665,625	27,538,130

The horses (used for agriculture), cattle, sheep, and pigs in the same years were in number as follows :—

	1881.	1891.	1896.	1900.
	Number.	Number.	Number.	Number.
Horses . .	1,231,870	1,293,236	1,346,003	1,305,605
Cattle . .	4,815,430	5,629,524	5,286,582	5,607,084
Sheep . .	17,849,801	21,108,658	19,238,820	19,277,229
Pigs . .	1,925,072	2,731,267	2,734,186	2,249,519

In 1900 the agricultural animals were thus distributed between England and Wales :—

	Horses.	Cattle.	Sheep.	Pigs.
England . .	1,152,321	4,848,698	15,844,713	2,021,422
Wales . .	153,284	758,386	3,432,516	228,097

The figures given above show that between 1881 and 1900 the arable area of England and Wales decreased nearly 13 per cent., while the permanent pasture increased nearly 14 per cent. The acreage under wheat contracted 34 per cent., while that under oats extended 11 per cent. Flax cultivation, never extensive, shrank almost out of existence, while the cultivation of small fruit increased. It should be mentioned, also, that the orchard area of England and Wales, yielding grass or other produce, besides fruit, expanded from 183,033 acres in 1881 to 208,069 in 1891, 219,319 in 1896, and 226,378 in 1899.

The area of England (apart from Wales) is divided into two sections, "arable" and "grass," corresponding with the old division into "corn counties" and "grazing counties," except that the county of Leicester is included not in the "grass" but in the "arable" section." Most of the eastern part of England is "arable," while the western and northern part is "grass," the boundary between the sections being the western limit of the counties of Hants, Berks, Oxford, Warwick, Leicester, Nottingham, and of the East Riding of Yorkshire. The difference between the agricultural conditions of the sections is shown by the following table, giving the acreage under crops and grass, and the number of agricultural animals, with the proportion per cent. in each section in 1899 :—

	Acreage.		Percentage.	
	Arable Section.	Grass Section.	Arable Section.	Grass Section.
	Acres.	Acres.		
Arable land—				
Corn crops . .	3,692,240	2,063,236	64·2	35·8

The number of agricultural holdings in England and Wales arranged in 4 classes according to their size, and the acreage comprised in each class, in 1885 and in 1895, are given in the subjoined table. The first class includes holdings of 1 acre and not over 5 acres ; the second, those over 5 and not over 50 ; the third, those over 50 and not over 300 ; while the fourth class comprehends all over 300 acres :—

Holdings.		England.		Wales.	
Acres.		Number.	Acreage.	Number.	Acreage.
1–5	1885	103,229	286,526	11,044	34,352
	1895	101,428	279,641	11,763	36,633
5–50	1885	170,431	3,262,033	29,715	620,651
	1895	170,591	3,288,669	30.969	635,024
50–300	1885	104,073	13,571,338	17,888	1,969,045
	1895	106,955	13,837,899	18,113	1,988,034
Over 300	1885	16,148	7,761,654	460	193,789
	1895	15,578	7,452,852	443	179,668
Total	1885	393,881	24,881,551	59,107	2,817,837
	1895	394,552	24,859,061	61,288	2,839,359

In 1895 the number of allotments under 1 acre in size in England was 522,163; in Wales, 12,179. It would appear that between 1885 and 1895 the small holdings of 1 to 5 acres decreased in number and in acreage in England, but increased in Wales, and that the tendency was towards increase in the number and area of holdings from 5 up to 300 acres, but towards decrease in the case of those over 300 acres.

Most of the agricultural holdings in England and Wales are rented, but the acreage of those farmed by the owners is considerable. In the following table the holdings are grouped in 8 classes according to size, the first class consisting of those over 1 acre and not over 5 acres. The figures show for 1895 the aggregate area of the cultivated land, and the percentage of owner-farmed land in each class. For large farms this percentage is high ; it is at its lowest in the class embracing holdings of from 50 to 100 acres, and it slowly rises as the holdings decrease in size :—

Holdings of Acres.	England.		Wales.	
	Total Area.	Owner-Farmed. Per cent. of total.	Total Area.	Owner-Farmed. Per cent. of total.
	Acres.		Acres.	
1–5	265,268	17·5	35,633	11·8
5–20	1,210,716	15·3	211,267	12·6
20–50	2,077,953	13·0	423,757	11·0
50–100	3,403,761	11·5	749,465	10·8
100–300	10,434,138	11·6	1,238,569	11·0
300–500	4,188,651	15·8	142,925	12·8
500–1000	2,570,684	25·3	32,818	42·8
Over 1000	693,517	40·8	3,925	69·4
Over 1 .	24,844,688	14·9	2,838,359	11·6

Thus it appears that in England and Wales, in 1895, of the total acreage under crops and grass, 14·5 per cent. belonged to owner-farmed holdings.

In 1881, according to the census returns, there were in England and Wales 1,278,624 persons (including 64,171 females) engaged in agriculture, those who worked "in fields and pastures" being to the number of 1,196,836 (including 61,073 females). In 1891 there were 1,311,720 persons (including 51,696 females) engaged in agriculture, but the number of those who worked "in fields and pastures" had fallen to 1,096,362 (including 45,999 females).

Communications.

Roads.—In England and Wales the high-roads, or roads on which wheeled vehicles can travel, are of two classes: (1) the main roads, or the great arteries along which the main traffic of the country passes; and (2) ordinary highways, which are by-roads serving only local areas. The length of the former in 1882 was stated to be 12,199 miles; in 1899, 22,025 miles. The mileage of the ordinary highways in 1882 was stated to be 102,615; in 1899, 96,573. By the Local Government Act of 1888 the duty of maintaining main roads was imposed on county councils, but these bodies were enabled to make arrangements with the respective highway authorities for their repair. Under the Local Government Act of 1894 the duties of all the highway authorities were transferred to the rural district councils on or before March 31, 1899.

For the year 1898–99 the total receipts of all the highway authorities (exclusive of £29,721 from loans) amounted to £2,217,703, of which £1,410,931 was from rates, the remainder being chiefly from Local Taxation Account and County Council contributions. The expenditure (exclusive of £23,587 from loans) amounted to £2,188,422, of which £350,228 was spent on repairs of main roads, and £1,632,070 on repairs of ordinary highways. In England and Wales the assessable value for the purposes of highway authorities was £40,508,545, and on this value the rates levied for highway purposes were equivalent to 8·4d. on the £. The last turnpike trust ceased to exist on November 5, 1895, and the final accounts in connexion with its debt were closed in the year 1898–99.

Railways.—In the period from 1880 to 1899 the mileage of the railways of the United Kingdom increased by 21 per cent., while their paid-up capital was augmented to the extent of 58 per cent. In 1880 their total length was 17,933 miles; in 1890, 20,073 miles; in 1900, 21,855 miles. Their authorized capital in 1880 amounted to £802,014,004; in 1890, to £1,004,529,164; in 1900, to £1,302,674,079. The paid-up capital rose from £728,316,848 in 1880 to £897,472,026 in 1890, and £1,176,001,890 in 1900. The growth of the railway systems of England and Wales alone during the same period is shown by the following figures, giving the length of line, double (or more) and single, the authorized capital and the paid-up capital on December 31 of the years named :—

Years.	Length of Line.			Capital.	
	Double or More.	Single.	Total.	Authorised.	Paid-up.
	Miles.	Miles.	Miles.	£	£
1880	8,105	4551	12,656	663,067,719	602,242,578
1890	9,094	5025	14,119	833,049,003	740,033,907
1895	9,481	5170	14,651	924,256,307	825,195,880
1899	9,933	5111	15,044	1,071,417,937	950,179,607
1900	10,101	5086	15,187	1,095,042,057	970,147,581

The English and Welsh railways for their whole length, except 124 miles, have a gauge of 4 ft. 8½ in.

The number of passengers carried in the course of a year on the railways of the United Kingdom increased between 1880 and 1900 by 88 per cent., and the weight of goods carried, by 81 per cent., while the receipts from passenger traffic had an increase of 67 per cent., and those from goods traffic an increase of 49 per cent. The number of passengers conveyed (exclusive of season ticket-holders) in 1880 was 603,885,025; in 1890, 817,744,046; in 1900, 1,142,276,686. The total weight of goods carried in 1880 was 235,305,629 tons; in 1890, 303,119,427 tons; in 1900, 424,929,513 tons. The receipts from passenger traffic in 1880 amounted to £27,200,464; in 1890, to £34,327,965; in 1900, to £45,383,988. The receipts from goods traffic in 1880 reached £35,761,303; in 1890, £42,220,382; in 1900, £53,470,564. The number of season ticket-holders in 1880 was 502,174; in 1900, 1,749,804. In 1880 the goods traffic comprised 165,670,304 tons of minerals; in 1900, 306,389,083 tons, the receipts for the carriage of which amounted to £22,870,694. The expansion of the passenger and goods traffic and of the receipts therefrom in England and Wales alone are shown in the following statement:—

Years.	Passengers Conveyed.	Goods Carried.	Receipts for Carriage of	
			Passengers.	Goods.
	Number.	Tons.	£	£
1880 .	540,669,175	200,393,357	23,141,055	30,457,932
1890 .	721,114,781	259,150,132	29,207,694	35,976,180
1895 .	816,921,056	280,324,042	31,687,774	37,014,948
1899 .	959,601,776	350,070,663	37,225,740	44,186,881
1900 .	992,425,769	359,524,742	38,633,679	45,339,962

The number of season ticket-holders (not included in the number of passengers in the table) was, in 1880, 449,823; in 1900, 1,610,754. The weight of minerals carried on the English and Welsh railways in 1880 was 140,965,835 tons; in 1900, 256,895,900 tons, the receipts for the carriage of minerals in the latter year having amounted to £19,528,603. Of the railway passengers in the United Kingdom in 1900, 34,318,809 travelled in first-class carriages; 69,804,629 in second-class; and 1,038,873,248 in third-class. Of the passengers on the English and Welsh railways alone, 27,446,980 travelled in first-class, 65,157,076 in second-class, and 899,821,713 in third-class carriages. The total receipts of the railways of the United Kingdom for the year 1880 amounted to £65,491,625; the working expenses to £33,601,124; and the net receipts to £31,890,501, or 4·38 per cent. of the paid-up capital. For 1900 the total receipts reached the sum of £104,801,858; the working expenses, £64,743,520; and the net receipts, £40,058,338, or 3·41 per cent. of the paid-up capital. Of the railways in England and Wales alone, the total receipts, the working expenses, and the net receipts, with their proportion per cent. of paid-up capital, were as follows in various years. The receipts include not only those from traffic, but also those from rents, tolls, &c. :—

Years.	Receipts.	Working Expenses.	Net Receipts.	
			Amount.	Per cent. of Paid-up Capital.
	£	£	£	
1880 .	55,795,186	28,577,111	27,218,075	4·52
1890 .	68,272,908	36,964,577	31,308,331	4·23
1895 .	72,791,758	41,126,298	31,665,460	3·83
1899 .	86,708,006	51,922,103	34,785,903	3·65
1900 .	89,392,501	55,882,810	33,509,691	2·89

In 1880 the railways of the United Kingdom had 13,384 locomotive engines; in 1900, 21,195. In 1880 they had 29,565 carriages for passengers; in 1900, 47,433. In 1880 the waggons, &c., numbered 402,901; in 1900, 727,784. The increase in the rolling stock of the English and Welsh railways is shown as follows:—

Years.	Locomotives.	Passenger Carriages.	Waggons, &c.
1880	11,172	24,658	301,921
1890	13,731	31,374	426,791
1895	15,901	35,773	486,394
1899	17,411	38,805	537,786
1900	18,040	40,115	559,917

In England and Wales there are about 190 railway companies, but most of them are small, and of 81 companies the lines have been leased to, or are worked by, the great companies named in the subjoined table. The mileage and traffic include those of the absorbed companies' lines. The figures relate to the year 1900:—

Companies.	Miles Open.	Goods Carried.	Passengers Carried.
		Tons.	Number.
Great Western	2627	37,500,510	80,944,483
London and N.-Western	1937	44,465,277	82,069,743
North-Eastern	1654	53,126,913	57,573,747
Midland	1437	40,937,111	51,932,911
Great Eastern	1110	11,642,386	116,103,401
London and S.-Western	898	6,411,400	63,710,860
Great Northern	825	17,548,466	37,671,162
S.-E. and Chatham	609	6,655,824	73,834,089
Lancashire and Yorks	556	21,795,887	64,665,969
Great Central	494	20,779,795	18,443,272
London, Brighton, and S. Coast	448	4,262,974	55,770,005

On the Metropolitan Railway of 73 miles there were 77,126,753 passengers; on the Metropolitan District, 19 miles, 40,444,073 passengers; and on the North London, 12 miles, 38,382,728 passengers in 1900, the numbers being in each case exclusive of season ticket-holders.

Light Railways.—The railway statistics given above do not include those relating to light railways, for the construction of which in Great Britain encouragement was offered by the Light Railways Act, 1896, with a view to benefiting agricultural, fishing, and other interests. A Commission which is continued under the Expiring Laws Continuance Act (1901), examines schemes and submits its Orders to authorize light railways for confirmation by the Board of Trade. Local authorities, as well as companies or individuals, may apply for Orders, and may make advances for light railways, as the Treasury also, under certain conditions, is empowered to do. Up to December 31, 1900, out of 309 applications, 167 had been approved by the Commission, the aggregate length of the approved lines amounting to 1360 miles, and their estimated construction cost to £8,824,275. Those actually submitted to the Board of Trade numbered 133, and they related to 1063 miles of line, and a construction cost of £6,517,311. Of these Orders the Board of Trade had confirmed 71, of which 12 were for Scotland. Of the projected lines, about three-fourths in length resemble ordinary railways, the remainder being road or street railways.

Tramways.—On June 30, 1900, there were in the United Kingdom 177 tramway undertakings, with altogether 1177 miles of tramway line. Of these undertakings, 70 with 585 miles of line belonged to local authorities, while 107 with 592 miles of line belonged to others than local authorities. The capital expenditure on the former amounted to £10,203,604, on the latter to £11,532,384. The development of tramway enterprise in England and Wales, as shown by the mileage open, the paid-up capital, gross receipts, working expenses, and number of passengers carried, has been as follows:—

Years ending June 30.	Miles Open.	Paid-up Capital.	Gross Receipts.	Working Expenses.	Passengers carried during year.
		£	£	£	Number.
1880	269	4,206,637	972,513	812,876	118,218,415
1890	753	10,994,341	2,573,535	1,932,444	418,399,936
1895	774	11,312,338	3,038,804	2,344,302	525,838,417
1899	881	13,964,628	3,860,701	2,962,039	700,436,783
1900	933	15,901,923	4,347,142	3,316,590	816,768,639

For the whole of the United Kingdom in 1899–1900 the paid-up capital amounted to £20,582,692; the gross receipts, to £5,445,620; the working expenses to £4,075,352; and the number of passengers carried was 1,065,374,347. In the same year, in England and Wales the tramway cars numbered 5051, and they were drawn by 29,827 horses and 526 locomotive engines. In the United Kingdom there were 6410 cars, drawn by 37,481 horses and 558 locomotive engines.

Canals.—Of the canals and navigations in the United Kingdom in 1898, the total length reached 3907 miles, of which 2768 miles did not, and 1139 miles did, belong to railway companies. The total length in 1888 was given as 3813 miles, of which 2608 miles did not, and 1204 miles did, belong to railway companies. The canal returns for 1898 are more complete than those for 1888, but the figures as they stand indicate an increase of 160 miles in the length of the canals not belonging to railway companies, and a decrease of 66 miles in that of the railway canals, the net increase thus reaching 94 miles. In 1898 the total paid-up capital (from all sources) of the canals not belonging to railway companies amounted to £37,929,280; in 1888 it amounted to £24,285,175. Of the total paid-up capital in 1898, the sum of £35,091,404 stood against the names of canal companies in England and Wales. The development in canal enterprise in England and Wales between 1888 and 1898, according to Board of Trade Returns, is shown by the following figures, giving the mileage, the traffic conveyed, the gross revenue, and the expenditure in the respective years of A, canals and navigations not belonging to railway companies, and B, of those belonging to railway companies:—

A. *Non-Railway Canals and Navigations.*

Years.	Length.	Traffic.	Revenue.	Expenditure.
	Miles.	Tons Conveyed.	£	£
1888	2026	27,715,875	1,439,343	861,068
1898	2208	32,513,800	1,895,506	1,322,201
		B. *Railway Canals and Navigations.*		
1888	1024	6,609,304	437,080	335,503
1898	959	4,913,085	331,305	309,025

The increase in the length of the English canals is due mainly to the construction of the Manchester Ship Canal, which was opened in 1894. From its commencement at Eastham, where it joins the Mersey, to its termination in the city of Manchester, it has a length of 35½ miles, while, including the Bridgewater canals and the Mersey and Irwell navigations, the whole system has a length of about 110 miles. From Eastham to Manchester the canal may be used by vessels 550 feet in length and 60 feet wide, with 25 feet of draught and 70 feet of headway. The bottom width at the full depth is in general 120 feet, but at several places it exceeds this; while between Latchford Locks and Partington Canal Basin it does not exceed 90 feet. At Eastham there are three locks, and the Latchford, Irlam, Barton, and Modewheel locks are in pairs. A junction with the Shropshire Union Canal is made at Ellesmere Port; with the Weaver Navigation, at Weston Point; with the Bridgewater canals, at Runcorn; and with the Runcorn and Latchford Canal, at Stockton Heath Bridge. The paid-up capital (from all sources) of the canal up to December 31, 1898, amounted to £15,459,369. The traffic (not sea-borne) using the company's canals, &c., in the year 1898 reached 3,548,894 tons, while the sea-borne traffic to and from Manchester amounted to 2,540,961 tons. The receipts during the same year reached the sum of £551,039, and the working expenses amounted to £447,356. Many of the old canals are of importance for the development of the industries of the country. The Birmingham Canal Navigations consist of the Birmingham and Wolverhampton Canal, with many branches, the total length extending to 159 miles. In 1898 the traffic conveyed on this system amounted to 8,627,074 tons, of which 4,543,008 tons represented coal; the total revenue reached £208,036, and the expenditure, £88,843. The Leeds and Liverpool Canal, with its connected system, has a length of 141 miles; in 1898 the traffic conveyed on it reached 2,324,968 tons. The Grand Junction Canal, extending, with many branches, from Brentford to Aylesbury, Northampton, Leicester, and Market Harborough, besides joining other canal systems, has a length of 188 miles, and in 1898 served for the conveyance of 1,620,552 tons of goods.

See also the article United Kingdom, and the separate articles on Banking, Armies, Post Office, Local Government.

Books of Reference.—The following official publications are issued in London:—*Report on the Census of England and Wales,* 1891, 4 vols., 1893; *Preliminary Report on the Census of 1901*; *Annual*

Report and *Quarterly Returns of the Registrar-General; Annual Statistical Tables relating to Emigration and Immigration; Annual Report of Local Government Board; Judicial Statistics of England and Wales* (Annual); *Reports of Inspectors of Constabulary in England and Wales; Annual Report of the Board of Education; Return on Technical Education* (*Local Authorities*), 1900; *Reports from University Colleges. Agricultural Returns: Reports of Royal Commission on Agriculture, and Reports of Assistant Commissioners*, 24 vols., 1896; *Report of Royal Commission on Land in Wales and Monmouth*, 6 vols., 1896; *Returns as to Number and Size of Agricultural Holdings in Great Britain in 1895, 1896; Canals and Navigations, Returns made for 1898; Railway Returns* (Annual).

Other works relating to England and Wales are:—BOOTH. *Life and Labour of the People of London.* 9 vols. London, 1889–97. *The Aged Poor in England and Wales.* London, 1894.—LOCH. *The Annual Charities Register and Digest.* London.—MALTBIE. *English Local Government of To-day.* New York, 1897.—ODGERS. *Local Government in England and Wales.* London, 1899.—RHYS and JONES. *The Welsh People.* London, 1900.—PENDLETON. *Our Railways.* London, 1896.—STEPHEN. *History of the Criminal Law of England.* 3 vols. WALFORD. *Greater London.* 2 vols. (I. P. A. R.)

Englewood, a city of Bergen county, New Jersey, U.S.A., near the Palisades of the Hudson river, and on a branch of the Erie Railway. It was organized in 1871, its area being taken from the town of Hackensack. Population (1880), 4076; (1890), 4785; (1900), 6253.

English Bazar or **Angrazabad,** a town of British India, headquarters of Malda district in Bengal, situated on the right bank of the river Mahananda. The population is about 13,500. Silk-weaving, as a centre for which it was originally chosen, is now a decaying industry. There are a high school, with 171 pupils in 1896–97; three printing-presses, one of which issues a fortnightly newspaper in the vernacular; a public library, and a Mahommedan Association.

English Bible.—In accordance with the report presented by the Joint Committee of the two Houses of the Convocation of Canterbury in May 1870, two companies were formed for the revision of the Authorized Version of the Old and New Testaments. These companies consisted of the following. 1. For the Old Testament:—(*a*) *Appointed by Convocation.*—The Bishops of St Davids, Llandaff, Ely, Lincoln, and Bath and Wells, Archdeacon Rose, Canon Selwyn, Dr Jebb, and Dr Kay. (*β*) *Invited.*—Alexander, Dr W. L.; Chenery, Professor; Cook, Canon; Davidson, Professor A. B.; Davies, Dr B.; Fairbairn, Professor; Field, Rev. F.; Ginsburg, Dr; Gotch, Dr; Harrison, Archdeacon; Leathes, Professor; M'Gill, Professor; Payne Smith, Canon; Perowne, Professor J. H.; Plumptre, Professor; Pusey, Canon; Wright, Dr (British Museum); Wright, W. A. (Cambridge). Of these, Canons Cook and Pusey declined to serve, and ten members died during the progress of the work. The secretary of the company was Mr W. Aldis Wright, Fellow of Trinity, Cambridge. 2. For the New Testament:—(*a*) *Appointed by Convocation.*—Bishops of Winchester, Gloucester and Bristol, and Salisbury, The Prolocutor (Dr Bickersteth), The Deans of Canterbury and Westminster, Canon Blakesley. (*β*) *Invited.*—Angus, Dr; Brown, Dr David; Dublin, Archbishop of; Eadie, Dr; Hort, Rev. F. J. A.; Humphrey, Rev. W. G.; Kennedy, Canon; Lee, Archdeacon; Lightfoot, Dr; Milligan, Professor; Moulton, Professor; Newman, Dr J. H.; Newth, Professor; Roberts, Dr A.; Smith, Rev. G. Vance; Scott, Dr; Scrivener, Rev. F. H. A.; St Andrews, Bishop of; Thompson, Dr; Tregelles, Dr; Vaughan, Dr; Westcott, Canon. Of these, Dr Thompson and Dr Newman declined to serve. Dean Alford, Dr Tregelles, Bishop Wilberforce, and Dr Eadie were removed by death. Only the first vacancy was filled up. Dean Merivale was co-opted, and on his resignation Professor, afterwards Archdeacon, Palmer. The Rev. J. Troutbeck, Minor Canon of Westminster, acted as Secretary. Negotiations were opened with the leading scholars of the Protestant denominations in America, with the result that similar companies were formed in the United States. The work of the English Revisers was regularly submitted to their consideration; their comments were carefully considered and largely adopted, and their divergences from the version ultimately agreed upon were printed in an Appendix to the published work. Thus the Revised Version was the achievement of English-speaking Christendom as a whole; only the Roman Catholic Church, of the great English-speaking denominations, refused to take part in the undertaking. The Church of England, which had put forth the version of 1611, fitly initiated the work, but for its performance most wisely invited the help of the sister Churches. The delegates of the Clarendon Press in Oxford, and the syndics of the Pitt Press in Cambridge, entered into a liberal arrangement with the Revisers, by which the necessary funds were provided for all their expenses. On the completion of its work the New Testament Company divided itself into three Committees, working at London, Westminster, and Cambridge, for the purpose of revising the Apocrypha.

The work of the Old Testament Company was different in some important respects from that which engaged the attention of the New Testament Company. The Received Hebrew text has undergone but little emendation, and the revisers had before them substantially the same Massoretic text which was in the hands of the translators of 1611. It was felt that there was no sufficient justification to make any attempt at an entire reconstruction of the text on the authority of the versions. The Old Testament revisers were therefore spared much of the labour of deciding between different readings, which formed one of the most important duties of the New Testament Company. But the advance in the study of Hebrew since the early part of the 17th century enabled them to give a more faithful translation of the received text. The value of their work is evident, especially in Job, Ecclesiastes, and the prophetical books.

It is the work of the New Testament Committee which has attracted most attention, whether for blame or praise. The critical resources at the disposal of scholars in 1611 were very meagre, and the few early manuscripts with which they were acquainted failed to receive the attention they deserved. The translators appear to have mainly relied on the later editions of Stephanus and Beza, and also to a certain extent the Complutensian Polyglott. All these were founded, for the most part, on a few manuscripts of late date. It is evident, therefore, that the Greek text of 1611 is largely Erasmian, and has no claim to any great critical value. The ancient versions were not examined, with the exception of the Vulgate, which the translators possessed in late and corrupt texts. The testimony of the fathers received no attention. Nearly all the more ancient documentary authorities have become known since 1611, and some of the most important of them have only been studied in quite recent times. Not one of the four most ancient and most important manuscripts was known to be in existence. Codex D, though it was known, was scarcely considered. Even Beza was unaware of the true value of the manuscript which bears his name, and scarcely any weight was assigned to it.

It was not until the middle of the 17th century that the preparation for an effective critical study of the New Testament began. The subject from the first excited the interest of English scholars, and received a considerable impulse in Great Britain by the gift of the Alexandrian manuscript (A) to Charles I. by Cyril Lucar, the Patriarch of Constantinople. At the beginning of the 18th century Mill collated a mass of documentary evidence; and though he failed to arrange the information which he had gained, he laid the foundation of work that has helped all subsequent textual critics. It became clear that the value of documents depended on antiquity rather than on their numerical superiority. It was Griesbach who first carried out this principle of textual criticism, and became the pioneer of that work of tracing the genealogical relations of the whole extant documentary evidence of the New Testament which has been developed with so much learning and skill by Lachmann, Tischendorf, and Tregelles. The results of these critical methods could not fail to make the incompleteness of the "Received Text," and of the "Authorized Version," which was based on it, obvious. It had long been the opinion of all competent scholars that a thorough revision was necessary. A proposal in favour of this course was made in Convocation in 1856, but it was not until fourteen years later that the Committee was appointed to undertake the work. The Revisers' first task was to reconstruct the Greek text, as the necessary foundation of their work. In this difficult duty they were no doubt influenced by Westcott and Hort's edition of the New Testament. These two scholars were members of the Committee which prepared the Revised Version, and on the question of various readings they appear to have exercised a predominating influence. The Revisers were privately supplied with instalments of Westcott and Hort's text as their work required them. But it is scarcely necessary to say that the Revised Version is not the work of one or two scholars. Different schools of criticism were represented on the Committee, and the most careful discussion took place before any decision was formed. Every precaution was taken to ensure that the version should represent the result of the best scholarship of the time, applied to the work before it with constant devotion and with the highest sense of responsibility. The changes in the Greek text of the Authorized Version when compared with the *textus receptus* are numerous, but the contrast between the English Versions of 1611 and 1881 are all the more striking because of the difference in the method of translation which was adopted. The Revisers aimed at the most scrupulous faithfulness. They adopted the plan—deliberately rejected by the translators of 1611—of always using the same English word for the same Greek word. "They endeavoured to enable the English reader to follow the correspondences of the original with the closest exactness, to catch the solemn repetition of words and phrases, to mark the subtleties of expression, to feel even the strangeness of unusual forms of speech."

The revision of the New Testament was completed in 407 meetings, distributed over more than ten years. It was formally presented to Convocation on May 17, 1881. The revision of the Old Testament occupied 792 days, and was finished on June 20, 1884. The revised Apocrypha did not make its appearance until 1895.

The text of the Revised Version is printed in paragraphs, the old division of books into chapters and verses being retained for convenience of reference. By this arrangement the capricious divisions of some books is avoided. Various editions of the New Version have been published, the most complete being the edition of the whole Bible with marginal references. These references had their origin in the work of two small sub-committees of the Revisers, but they received their present form at the hands of a specially appointed committee. The marginal references given in the original edition of the Authorized Version of 1611 have been retained as far as possible.

The work of the Revisers was received without enthusiasm. It was too thorough for the majority of religious people. Partisans found that havock had been played with their proof texts. Ecclesiastical conservatives were scandalized by the freedom with which the traditional text was treated. The advocates of change were discontented with the hesitating acceptance which their principles had obtained. The most vulnerable side of the Revision was that on which the mass of English readers thought itself capable of forming a judgment. The general effect of so many small alterations was to spoil the familiar sonorous style of the Authorized Version. The changes were freely denounced as equally petty and vexatious; they were, moreover, too often inconsistent with the avowed principles of the Revisers. The method of determining readings and renderings by vote was not favourable to the consistency and literary character of the Version. A whole literature of criticism and apology made its appearance, and the achievement of so many years of patient labour seemed destined to perish in a storm of resentments. On the whole, the Revised Version weathered the storm more successfully than might have been expected. Its considerable excellences were better realized by students than stated by apologists. The hue and cry of the critics largely died away, and was replaced by a calmer and juster appreciation.

Quite recently the work of the Revisers has been sharply criticized from the standpoint of specialists in New Testament Greek. Dr Rutherford has stated the case briefly and pointedly in the Preface to his translation of the Epistle to the Romans (London, 1900). He maintains that "the Greek of the New Testament may never be understood as classical Greek is understood," and accuses the Revisers of distorting the meaning "by translating in accordance with Attic idiom phrases that convey in later Greek a wholly different sense, the sense which the earlier translators in happy ignorance had recognized that the context demanded."

The use of the new Version has become general. Familiarity has mitigated the harshness of the Revisers' renderings; scholarship, on the whole, has confirmed their readings. The Version has been publicly read in parish churches both in London and in the country. In Canterbury Cathedral and Westminster Abbey it has definitely displaced the older Version. Bishops have acquiesced and congregations approved. It is no longer possible to maintain the plausible and damaging contention that the Revised Bible is ill-suited for public use. The Upper House of the Convocation of Canterbury, in May 1898, appointed a Committee to consider the expediency of "permitting or encouraging" the use of the Revised Version in the public services of the Church.

The Revisers have fully explained their principles and methods in the Preface to their Version. The American Committee of Revision issued an historical account of their work (New York, 1885). The case against the Revisers is ably stated in *The Revision Revised*, by Dean Burgon (London, 1883). The literary defects of the Version are elaborately exhibited by G. Washington Moon in two works: *The Revisers' English* (London, 1882); and *Ecclesiastical English* (London, 1886). The Version is successfully defended by J. B. Lightfoot, *On a Fresh Revision of the English New Testament* (London, 1871; 3rd edition, 1891); Westcott, *Some Lessons of the Revised Version* (London, 1897); Kennedy, *Ely Lectures on the Revised Version* (London, 1882). Reference may also be made to *Some Thoughts on the Textual Criticism of the New Testament*, by G. Salmon, D.D. (London, 1897); Bishop Ellicott's *Charge* (1901). The Greek Text of the New Testament adopted by the Revisers was edited for the Clarendon Press by Archdeacon Palmer (Oxford, 1881). Parallel editions of the Bible, showing both the Authorized and Revised Versions, a large type edition for public use, a reference edition, and finally (1900) a "Two Version" edition, have been issued by one or both the University Presses.

(H. H. H*.)

ENGLISH HISTORY, 1837-1901.

THE death of William IV., on the 20th June 1837, placed on the throne of England a young princess, who was destined to reign for a longer period than any of her predecessors. The new Queen, the only daughter of the duke of Kent, the fourth son of George III., had just attained her majority. Educated in comparative seclusion, her character and her person were unfamiliar to her future subjects, who were a little weary of the extravagances and eccentricities of her immediate predecessors. Her accession gave them a new interest in the House of Hanover. And their loyalty, which would in any case have been excited by the accession of a young and inexperienced girl to the throne of the greatest empire in the world, was stimulated by her conduct and appearance. She displayed from the first a dignity and good sense which won the affection of the multitude who merely saw her in public, and the confidence of the advisers who were admitted into her presence.

Queen Victoria's accession.

The ministry experienced immediate benefit from the change. The Whigs, who had governed England since 1830, under Lord Grey and Lord Melbourne, were suffering from the reaction which is the inevitable consequence of revolution. The country which, in half a dozen years, had seen a radical reform of Parliament, a no less radical reform of municipal corporations, the abolition of slavery, and the reconstruction of the poor laws, was longing for a period of political repose. The alliance, or understanding, between the Whigs and the Irish was increasing the distrust of the English people in the ministry, and Lord Melbourne's Government, in the first half of 1837, seemed doomed to perish. The accession of the Queen gave it a new lease of power. The election, indeed, which followed her accession did not materially alter the composition of the House of Commons. But the popularity of the Queen was extended to her Government. Taper's suggestion in *Coningsby* that the Conservatives should go to the country with the cry, "Our young Queen and our old institutions," expressed, in an epigram, a prevalent idea. But the institution which derived most immediate benefit from the new Sovereign was the old Whig ministry.

The difficulties of the ministry, nevertheless, were great. In the preceding years they had carried most of the reforms which were demanded in Great Britain; but they had failed to obtain the assent of the House of Lords to their Irish measures. They had desired (1) to follow up the reform of English corporations by a corresponding reform of Irish municipalities; (2) to convert the tithes, payable to the Irish church, into a rent charge, and to appropriate its surplus revenues to other purposes; (3) to deal with the chronic distress of the Irish people by extending to Ireland the principles of the English poor law. In the year which succeeded the accession of the Queen they accomplished two of these objects. They passed an Irish poor law and a measure commuting tithes in Ireland into a rent charge. The first of these measures was carried in opposition to the views of the Irish, who thought that it imposed an intolerable burden on Irish property. The second was only carried on the Government consenting to drop the appropriation clause, on which Lord Melbourne's Administration had virtually been founded.

Lord Melbourne's difficulties.

It was not, however, in domestic politics alone that the ministry was hampered. In the months which immediately followed the Queen's accession news reached England of disturbances or even insurrection in Canada. The rising was easily put down; but the condition of the colony was so grave that the ministry decided to suspend the constitution of Lower Canada for three years, and to send out Lord Durham with almost dictatorial powers. Lord Durham's conduct was, unfortunately, marked by indiscretions which led to his resignation; but before leaving the colony he drew up a report on its condition and on its future, which practically became a text-book for his successors, and has influenced the government of British colonies ever since. Nor was Canada the only great colony which was seething with discontent. In Jamaica the planters, who had sullenly accepted the abolition of slavery, were irritated by the passage of an Act of Parliament intended to remedy some grave abuses in the management of the prisons of the island. The colonial House of Assembly denounced this Act as a violation of its rights, and determined to desist from its legislative functions. The governor dissolved the assembly, but the new house, elected in its place, reaffirmed the decision of its predecessor; and the British ministry, in face of the crisis, asked Parliament in 1839 for authority to suspend the constitution of the island for five years. The Bill introduced for this purpose placed the Whig ministry in a position of some embarrassment. The advocates of popular government, they were inviting Parliament, for a second time, to suspend representative institutions in an important colony. Supported by only small and dwindling majorities, they saw that it was hopeless to carry the measure, and they decided on placing their resignations in the Queen's hands. The Queen naturally sent for Sir Robert Peel, who undertook to form a government. In the course of the negotiations, however, he stated that it would be necessary to make certain changes in the household, which contained some great ladies closely connected with the leaders of the Whig party. The Queen shrank from separating herself from ladies who had surrounded her since she came to the throne, and Sir Robert thereupon declined the task of forming a ministry. Technically he was justified in adopting this course, but people generally felt that there was some hardship in compelling a young Queen to separate herself from her companions and friends, and they consequently approved the decision of Lord Melbourne to support the Queen in her refusal, and to resume office. The Whigs returned to place, but they could not be said to return to power. They did not even venture to renew the original Jamaica Bill. They substituted for it a modified proposal which they were unable to carry. They were obviously indebted for office to the favour of the Queen, and not to the support of Parliament.

The bedchamber question.

Yet the session of 1839 was not without important results. After a long struggle, in which ministers narrowly escaped defeat in the Commons, and in the course of which they suffered severe rebuffs in the Lords, they succeeded in laying the foundation of the English system of national education. In the same session they were forced against their will to adopt a reform, which had been recommended by Mr Rowland Hill, and to confer on the nation the benefit of a uniform penny postage. No member of the Cabinet foresaw the consequences of this reform. The postmaster-general, in opposing it, declared that, if the revenue of his office was to be maintained, the correspondence of the country, on which postage was paid, must be increased from 42,000,000 to 480,000,000 letters a year, and he contended that there were neither people to write, nor machinery to deal with,

Penny postage.

so prodigious a mass of letters. He would have been astonished to hear that, before the end of the century, his office had to deal with more than 3,000,000,000 postal packets a year, and that the net profit which it paid into the exchequer was to be more than double what it received in 1839.

In 1840 the ministry was not much more successful than it had proved in 1839. After years of conflict it succeeded indeed in placing on the statute book a measure dealing with Irish municipalities. But its success was purchased by concessions to the Lords, which deprived the measure of much of its original merit. The closing years of the Whig Administration were largely occupied with the financial difficulties of the country. The first three years of the Queen's reign were memorable for a constantly deficient revenue. The deficit amounted to £1,400,000 in 1837; to £400,000 in 1838, and to £1,457,000 in 1839. Mr Baring, the chancellor of the exchequer, endeavoured to terminate this deficiency by a general increase of taxation, but this device proved a disastrous failure. The deficit rose to £1,842,000 in 1840. It was obvious that the old expedient of increasing taxation had failed, and that some new method had to be substituted for it. This new method Mr Baring endeavoured to discover in altering the differential duties on timber and sugar, and substituting a fixed duty of 8s. per qr. for the sliding duties hitherto payable on wheat. By these alterations he expected to secure a large increase of revenue, and at the same time to maintain a sufficient degree of protection for colonial produce. The Conservatives, who believed in protection, at once attacked the proposed alteration of the sugar duties. They were reinforced by many Liberals, who cared very little for protection, but a great deal about the abolition of slavery, and consequently objected to reducing the duties on foreign or slave-grown sugar. This combination of interests proved too strong for Mr Baring and his proposal was rejected. As ministers, however, did not resign on their defeat, Sir Robert Peel followed up his victory by moving a vote of want of confidence, and this motion was carried in an exceptionally full house by 312 votes to 311.

Fiscal policy.

Before abandoning the struggle, the Whigs decided on appealing from the House of Commons to the country. The general election which ensued largely increased the strength of the Conservative party. On the meeting of the new Parliament in August 1841, votes of want of confidence in the Government were proposed and carried in both houses; the Whigs were compelled to resign office, and the Queen again charged Sir Robert Peel with the task of forming a government. If the Queen had remained unmarried, it is possible that the friction which had arisen in 1839 might have recurred in 1841. In February 1840, however, Her Majesty had married her cousin, Prince Albert of Saxe-Coburg. She was, therefore, no longer dependent on the Whig ladies, to whose presence in her court she had attached so much importance in 1839. By the management of the Prince—who later in the reign was known as the Prince Consort—the great ladies of the household voluntarily tendered their resignations; and every obstacle to the formation of the new government was in this way removed.

Sir R. Peel forms a ministry.

Thus the Whigs retired from the offices which, except for a brief interval in 1834-35, they had held for eleven years. During the earlier years of their administration they had succeeded in carrying many memorable reforms: during the later years their weakness in the House of Commons had prevented their passing any considerable measures. But, if they had failed in this respect, Lord Melbourne had rendered conspicuous service to the Queen. Enjoying her full confidence, consulted by her on every occasion, he had always used his influence for the public good; and perhaps those who look back now with so much satisfaction at the Queen's conduct during a reign of unexampled length, imperfectly appreciate the debt which in this respect is owed to her first prime minister. The closing years of the Whig Government were marked by external complications. A controversy on the boundary of Canada and the United States was provoking increasing bitterness on both sides of the Atlantic. The intervention of Lord Palmerston in Syria, which resulted in a great military success at Acre, was embittering the relations between France and England, while the unfortunate expedition to Afghanistan, which the Whigs had approved, was already producing embarrassment, and was about to result in disaster. Serious, however, as were the complications which surrounded British policy in Europe, in the East, and in America, the country, in August 1841, paid more attention to what a great writer called the "condition of England" question. There had never been a period in British history when distress and crime had been so general. There had hardly ever been a period when food had been so dear, when wages had been so low, when poverty had been so widespread, and the condition of the lower orders so depraved and so hopeless, as in the early years of the Queen's reign. The condition of the people had prompted the formation of two great associations. The Chartists derived their name from the charter which set out their demands. The rejection of a monster petition which they presented to Parliament in 1839 led to a formidable riot in Birmingham, and to a projected march from South Wales on London, in which twenty persons were shot dead at Newport. Another organization, in one sense even more formidable than the Chartist, was agitating at the same time for the repeal of the corn laws, and was known as the Anti-Corn Law League. It had already secured the services of two men, Mr Cobden and Mr Bright, who, one by clear reasoning, the other by fervid eloquence, were destined to make a profound impression on all classes of the people.

The new Government had, therefore, to deal with a position of almost unexampled difficulty. The people were apparently sinking into deeper poverty and misery year after year. As an outward and visible sign of the inward distress, the state was no longer able to pay its way. It was estimated that the deficit, which had amounted to £1,842,000 in 1840, would reach £2,334,000 in 1841. It is the signal merit of Sir Robert Peel that he terminated this era of private distress and public deficits. He accomplished this task partly by economical administration—for no minister ever valued economy more—and partly by a reform of the financial system, effected in three great budgets. In the budget of 1842 Sir Robert Peel terminated the deficit by reviving the income tax. The proceeds of the tax, which was fixed at 7d. in the £, and was granted in the first instance for three years, were more than sufficient to secure this object. Sir Robert used the surplus to reform the whole customs tariff. The duties on raw materials, he proposed, should never exceed 5 per cent., the duties on partly manufactured articles 12 per cent., and the duties on manufactured articles 20 per cent. of their value. At the same time he reduced the duties on stage coaches, on foreign and colonial coffee, on foreign and colonial timber, and repealed the export duties on British manufactures. The success of this budget in stimulating consumption and in promoting trade induced Sir Robert Peel to follow it up in 1845 with an even more remarkable proposal. Instead of allowing the income tax to expire, he induced Parliament to continue it for a further period, and with the resources which were thus placed at

Budget reforms.

his disposal he purged the tariff of various small duties which produced little revenue, and had been imposed for purposes of protection. He swept away all the duties on British exports; he repealed the duties on glass, on cotton wool, and still further reduced the duties on foreign and colonial sugar. This budget was a much greater step towards free trade than the budget of 1842. The chief object in his third budget in 1846—the reduction of the duty on corn to 1s. a quarter—was necessitated by causes which will be immediately referred to. But it will be convenient at once to refer to its other features. Sir Robert Peel told the house that, in his previous budgets, he had given the manufacturers of the country free access to the raw materials which they used. He was entitled in return to call upon them to relinquish the protection which they enjoyed. He decided therefore to reduce the protective duties on cotton, woollen, silk, metal and other goods, as well as on raw materials still liable to heavy taxation, such as timber and tallow. As the policy of 1842 and 1845 had proved unquestionably successful in stimulating trade, he proposed to extend it to agriculture. He reduced the duties on the raw materials which the farmers used, such as seed and maize, and in return he called on them to give up the duties on cattle and meat, largely to reduce the duties on butter, cheese, and hops, and to diminish the duty on corn by gradual stages to 1s. a quarter. In making these changes Sir Robert Peel avowed that it was his object to make the country a cheap one to live in. There is no doubt that they were followed by a remarkable development of British trade. In the twenty-seven years from 1815 to 1842 the export trade of Great Britain diminished from £49,600,000 to £47,280,000; while in the twenty-seven years which succeeded 1842 it increased from £47,280,000 to nearly £190,000,000. These figures are a simple and enduring monument to the minister's memory. It is fair to add that the whole increase was not due to free trade. It was partly attributable to the remarkable development of communications which marked this period.

Two other financial measures of great importance were accomplished in Sir Robert Peel's ministry. In 1844 some £250,000,000 of the national debt still bore an interest of 3½ per cent. The improvement in the credit of the country enabled the Government to reduce the interest on the stock to 3¼ per cent. for the succeeding ten years, and to 3 per cent. afterwards. This conversion, which effected an immediate saving of £625,000, and an ultimate saving of £1,250,000 a year, was by far the most important measure which had hitherto been applied to the debt; and no operation on the same scale was attempted for more than forty years. In the same year the necessity of renewing the charter of the Bank of England afforded Sir Robert Peel an opportunity of reforming the currency. He separated the issue department from the banking department of the Bank, and decided that in future it should only be at liberty to issue notes against (1) the debt of £14,000,000 due to it from the Government, and (2) any bullion actually in its coffers. Few measures of the past century have been the subject of more controversy than this famous Act, and at one time its repeated suspension in periods of financial crises seemed to suggest the necessity of its amendment. But opinion on the whole has vindicated its wisdom, and it has survived all the attacks which have been made upon it.

The administration of Sir Robert Peel is also remarkable for its Irish policy. The Irish, under O'Connell, had constantly supported the Whig ministry of Lord Melbourne. But their alliance, or understanding, with the Whigs had not procured them all the results which they had expected from it. The two great Whig measures, dealing with the church and the municipalities, had only been passed after years of controversy, and in a shape which deprived them of many expected advantages. Hence arose a notion in Ireland that nothing was to be expected from a British Parliament, and hence began a movement for the repeal of the Union which had been accomplished in 1801. This agitation, which smouldered during the reign of the Whig ministry, was rapidly revived when Sir Robert Peel entered upon office. The Irish contributed large sums, which were known as repeal rent, to the cause, and they held monster meetings in various parts of Ireland to stimulate the demand for repeal. The ministry met this campaign by coercive legislation regulating the use of arms, by quartering large bodies of troops in Ireland, and by prohibiting a great meeting at Clontarf, the scene of Brian Boru's victory, in the immediate neighbourhood of Dublin. They further decided in 1843 to place O'Connell and some of the leading agitators on their trial for conspiracy and sedition. O'Connell was tried before a jury chosen from a defective panel, was convicted on an indictment which contained many counts, and the court passed sentence without distinguishing between these counts. These irregularities induced the House of Lords to reverse the judgment, and its reversal did much to prevent mischief. O'Connell's illness, which resulted in his death in 1847, tended also to establish peace. Sir Robert Peel wisely endeavoured to stifle agitation by making considerable concessions to Irish sentiment. He increased the grant which was made to the Roman Catholic College at Maynooth; he established three colleges in the north, south, and west of Ireland for the undenominational education of the middle classes; he appointed a commission —the Devon Commission, as it was called, from the name of the nobleman who presided over it—to investigate the conditions on which Irish land was held; and, after the report of the commission, he introduced, though he failed to carry, a measure for remedying some of the grievances of the Irish tenants. These wise concessions might possibly have had some effect in pacifying Ireland, if in the autumn of 1845 they had not been forgotten in the presence of a disaster which suddenly fell on that unhappy country. The potato, which was the sole food of at least half the people of an overcrowded island, failed, and a famine of unprecedented proportions was obviously imminent. Sir Robert Peel, whose original views on protection had been rapidly yielding to the arguments afforded by the success of his own budgets, concluded that it was impossible to provide for the necessities of Ireland without suspending the corn laws; and that, if they were once suspended, it would be equally impossible to restore them. He failed, however, to convince two prominent members of his cabinet—Lord Stanley and the duke of Buccleuch—that Protection must be finally abandoned, and considering it hopeless to persevere with a disunited cabinet he resigned office. On Sir Robert's resignation the Queen sent for Lord John Russell, who had led the Liberal party in the House of Commons with conspicuous ability for more than ten years, and charged him with the task of forming a new ministry. Differences, which it proved impossible to remove, between two prominent Whigs—Lord Palmerston and Lord Grey—made the task impracticable, and after an interval Sir Robert Peel consented to resume power. Sir Robert Peel was probably aware that his fall had been only postponed. In the four years and a half during which his ministry had lasted he had done much to estrange his party. They said, with some truth, that, whether his measures were right or wrong, they were opposed to the principles which he had been placed in power to support. The general election of 1841 had been mainly fought on the rival policies of Protection and Free Trade.

Ireland.

Free trade.

The country had decided for Protection, and Sir R. Peel had done more than all his predecessors to give it Free Trade. The Conservative party, moreover, was closely allied with the church, and Sir Robert had offended the church by giving an increased endowment to Maynooth, and by establishing undenominational colleges—"Godless colleges" as they were called—in Ireland. The Conservatives were, therefore, sullenly discontented with the conduct of their leader. They were lashed into positive fury by the proposal which he was now making to abolish the corn laws. Lord George Bentinck, who, in his youth, had been private secretary to Mr Canning, but who in his maturer years had devoted more time to the turf than to politics, placed himself at their head. He was assisted by a remarkable man—Mr Disraeli—who joined great abilities to great ambition, and who, embittered by Sir Robert Peel's neglect to appoint him to office, had already displayed his animosity to the minister. The policy on which Sir Robert Peel resolved facilitated attack. For the minister thought it necessary, while providing for famine by repealing the corn laws, to ensure the preservation of order by a new Coercion Bill. The Financial Bill and the Coercion Bill were both pressed forward, and each gave opportunities for discussion and, what was then new in Parliament, for obstruction. At last, on the very night on which the fiscal proposals of the ministers were accepted by the Lords, the Coercion Bill was defeated in the Commons by a combination of Whigs, Radicals, and Protectionists; and Sir R. Peel, worn out with a protracted struggle, placed his resignation in the Queen's hands.

Thus fell the great minister, who perhaps had conferred more benefits on his country than any of his predecessors. The external policy of his ministry had been almost as remarkable as its domestic programme. When he accepted office the country was on the eve of a great disaster in India; it was engaged in a serious dispute with the United States; and its relations with France were so strained that the two great countries of Western Europe seemed unlikely to be able to settle their differences without war. In the earlier years of his administration the disaster in Afghanistan was repaired in a successful campaign; and Lord Ellenborough, who was sent over to replace Lord Auckland as governor-general, increased the dominion and responsibilities of the East India Company by the unscrupulous but brilliant policy which led to the conquest of Scinde. The disputes with the United States were satisfactorily composed; and not only were the differences with France terminated, but a perfect understanding was formed between the two countries, under which M. Guizot, the prime minister of France, and Lord Aberdeen, the foreign minister of England, agreed to compromise all minor questions for the sake of securing the paramount object of peace. The good understanding was so complete that a disagreeable incident in the Sandwich Islands, in which the injudicious conduct of a French agent very nearly precipitated hostilities, was amicably settled; and the ministry had the satisfaction of knowing that, if their policy had produced prosperity at home, it had also maintained peace abroad.

Peel's Foreign policy.

On Sir R. Peel's resignation the Queen again sent for Lord John Russell. The difficulties which had prevented his forming a ministry in the previous year were satisfactorily arranged, and Lord Palmerston accepted the seals of the Foreign Office, while Lord Grey was sent to the Colonial Office. The history of the succeeding years was destined, however, to prove that Lord Grey had had solid reasons for objecting to Lord Palmerston's return to his old post; for, whatever judgment may ultimately be formed on Lord Palmerston's foreign policy, there can be little doubt that it did not tend to the maintenance of peace. The first occasion on which danger was threatened arose immediately after the installation of the new ministry on the question of the Spanish marriages. The queen of Spain, Isabella, was a little girl still in her teens; the heir to the throne was her younger sister, the infanta Fernanda. Diplomacy had long been occupied with the marriages of these children; and Lord Aberdeen had virtually accepted the principle, which the French Government had laid down, that a husband for the queen should be found among the descendants of Philip V., and that her sister's marriage to the duc de Montpensier—a son of Louis Philippe—should not be celebrated till the queen was married and had issue. While agreeing to this compromise, Lord Aberdeen declared that he regarded the Spanish marriages as a Spanish and not as a European question, and that, if it proved impossible to find a suitable consort for the queen among the descendants of Philip V., Spain must be free to choose a prince for her throne elsewhere. The available descendants of Philip V. were the two sons of Don Francis, the younger brother of Don Carlos, and of these the French Government was in favour of the elder, while the British Government preferred the younger, brother. Lord Palmerston strongly objected to the prince whom the French Government supported; and, almost immediately after acceding to office, he wrote a despatch in which he enumerated the various candidates for the queen of Spain's hand, including Prince Leopold of Saxe-Coburg, a near relation of the Prince Consort, among the number. Louis Philippe regarded this despatch as a departure from the principle on which he had agreed with Lord Aberdeen, and at once hurried on the simultaneous marriages of the queen with the French candidate, and of her sister with the duc de Montpensier. His action broke up the *entente cordiale* which had been established between M. Guizot and Lord Aberdeen.

The Spanish marriages.

The second occasion on which Lord Palmerston's vigorous diplomacy excited alarm arose out of the revolution which broke out almost universally in Europe in 1848. A rising in Hungary was suppressed by Austria with Russian assistance, and, after its suppression many leading Hungarians took refuge in Turkish territory. Austria and Russia addressed demands to the Porte for their surrender. Lord Palmerston determined to support the Porte in its refusal to give up these exiles, and actually sent the British fleet to the Dardanelles with this object. His success raised the credit of Great Britain and his own reputation. The presence of the British fleet, however, at the Dardanelles suggested to him the possibility of settling another long-standing controversy. For years British subjects settled in Greece had raised complaints against the Greek Government. In particular, Don Pacifico, a Jew, but a native of Gibraltar, complained that, at a riot, in which his house had been attacked, he had lost jewels, furniture, and papers which he alleged to be worth more than £30,000. As Lord Palmerston was unable by correspondence to induce the Greek Government to settle claims of this character, he determined to enforce them; and by his orders a large number of Greek vessels were seized and detained by the British fleet. The French Government tendered its good offices to compose the dispute, and an arrangement was actually arrived at between Lord Palmerston and the French minister in London. Unfortunately, before its terms reached Greece, the British minister at Athens had ordered the resumption of hostilities, and had compelled the Greek Government to submit to more humiliating conditions. News of this settlement excited the strongest feelings both in Paris and London. In Paris, Prince Louis Napoleon, who had acceded to the presidency of the French republic, decided on recalling his representative from the British

Don Pacifico.

court. In London the Lords passed a vote of censure on Lord Palmerston's proceedings; and the Commons only sustained the minister by adopting a resolution approving in general terms the principles on which the foreign policy of the country had been conducted.

In pursuing the vigorous policy which characterized his tenure of the Foreign Office, Lord Palmerston frequently omitted to consult his colleagues in the Cabinet, the prime minister, or the Queen. In the course of 1849 Her Majesty formally complained to Lord John Russell that important despatches were sent off without her knowledge; and an arrangement was made under which Lord Palmerston undertook to submit every despatch to the Queen through the prime minister. In 1850, after the Don Pacifico debate, the Queen repeated these commands in a much stronger memorandum. But Lord Palmerston, though all confidence between himself and the court was destroyed, continued in office. In the autumn of 1851 the Queen was much annoyed at hearing that he had received a deputation at the Foreign Office, which had waited on him to express sympathy with the Hungarian refugees, and to denounce the conduct of "the despots and tyrants" of Russia and Austria, and that he had, in his reply, expressed his gratification at the demonstration. If the Queen had had her way, Lord Palmerston would have been removed from the Foreign Office after this incident. A few days later the *coup d'état* in Paris led to another dispute. The Cabinet decided to do nothing that could wear the appearance of interference in the internal affairs of France; but Lord Palmerston, in conversation with the French minister in London, took upon himself to approve the bold and decisive step taken by the president. The ministry naturally refused to tolerate this conduct, and Lord Palmerston was summarily removed from his office.

Palmerston dismissed.

The removal of Lord Palmerston led almost directly to the fall of the Whig Government. Before relating, however, the exact occurrences which produced its defeat, it is necessary to retrace our steps and describe the policy which it had pursued in internal matters during the six years in which it had been in power. Throughout that period the Irish famine had been its chief anxiety and difficulty. Sir Robert Peel had attempted to deal with it (1) by purchasing large quantities of Indian corn, which he had retailed at low prices in Ireland, and (2) by enabling the grand juries to employ the people on public works, which were to be paid out of monies advanced by the state, one-half being ultimately repayable by the locality. These measures were not entirely successful. It was found, in practice, that the sale of Indian corn at low prices by the Government checked the efforts of private individuals to supply food; and that the offer of comparatively easy work to the poor at the cost of the public prevented their seeking harder private work either in Ireland or in Great Britain. The new Government, with this experience before it, decided on trusting to private enterprise to supply the necessary food, and on throwing the whole cost of the works, which the locality might undertake, on local funds. If the famine had been less severe, this policy might possibly have succeeded. Universal want, however, paralysed every one. The people, destitute of other means of livelihood, crowded to the relief works. In the beginning of 1847 nearly 750,000 persons—or nearly one person out of every ten in Ireland—were so employed. With such vast multitudes to relieve, it proved impracticable to exact the labour which was required as a test of destitution. The roads, which it was decided to make, were blocked by the labourers employed upon them, and by the stones, which the labourers were supposed to crush for their repair. In the presence of this difficulty the Government decided, early in 1847, gradually to discontinue the relief works, and to substitute for them relief committees charged with the task of feeding the people. At one time no less than 3,000,000 persons—more than one-third of the entire population of Ireland—were supported by these committees. At the same time it decided on adopting two measures of a more permanent character. The poor law of 1838 had made no provision for the relief of the poor outside the workhouse, and outdoor relief was sanctioned by an act of 1847. Irish landlords complained that their properties, ruined by the famine, and encumbered by the extravagances of their predecessors, could not bear the cost of this new poor law; and the ministry introduced and carried a measure enabling the embarrassed owners of life estates to sell their property and discharge their liabilities. It is the constant misfortune of Ireland that the measures intended for her relief aggravate her distress. The Encumbered Estates Act, though it substituted a solvent for an insolvent proprietary, placed the Irish tenants at the mercy of landlords of whom they had no previous knowledge, who were frequently absentees, who bought the land as a matter of business, and who dealt with it on business principles by raising the rent. The new poor law, by throwing the maintenance of the poor on the soil, encouraged landlords to extricate themselves from their responsibilities by evicting their tenants. Evictions were made on a scale which elicited from Sir Robert Peel an expression of the deepest abhorrence. The unfortunate persons driven from their holdings and forced to seek a refuge in the towns, in England, or—when they could afford it—in the United States, carried with them everywhere the seeds of disease, the constant handmaid of famine.

Irish famine.

Famine, mortality, and emigration left their mark on Ireland. In four years, from 1845 to 1849, its population decreased from 8,295,000 to 7,256,000, or by more than a million persons; and the decline which took place at that time went on to the end of the century. The population of Ireland in 1901 had decreased to 4,457,000 souls. This fact is the more remarkable, because Ireland is almost the only portion of the British Empire, or indeed of the civilized world, where such a circumstance has occurred. We must go to countries like the Asiatic provinces of Turkey, devastated by Ottoman rule, to find such a diminution in the numbers of the people as was seen in Ireland during the last half of the 19th century. It was probably inevitable that the distress of Ireland should have been followed by a renewal of Irish outrages. A terrible series of agrarian crimes was committed in the autumn of 1847; and the ministry felt compelled, in consequence, to strengthen its hands by a new measure of coercion, and by suspending the Habeas Corpus Act in Ireland. The latter measure at once brought to a crisis the so-called Rebellion of 1848, for his share in which Mr Smith O'Brien, an Irish member of Parliament, was convicted of high treason. The Government, however, did not venture to carry out the grim sentence which the law still applied to traitors, and introduced an Act enabling it to commute the death penalty to transportation. The "insurrection" had from the first proved abortive. With Mr Smith O'Brien's transportation it practically terminated.

Rebellion of 1848.

In the meanwhile the difficulties which the Government was experiencing from the Irish famine had been aggravated by a grave commercial crisis in England. In the autumn of 1847 a series of failures in the great commercial centres created a panic in the City of London, which forced consols down to 78, and induced the Government to take upon itself the responsibility of suspending the Bank Charter Act. That step, enabling the directors of the Bank of

England to issue notes unsecured by bullion, had the effect of gradually restoring confidence. But a grave commercial crisis of this character is often attended with other than financial consequences. The stringency of the money market increases the distress of the industrial classes by diminishing the demand for work; and, when labour suffers, political agitation flourishes. Early in 1848, moreover, revolutions on the Continent produced a natural craving for changes at home. Louis Philippe was driven out of Paris, the emperor of Austria was driven out of Vienna, the Austrian soldiery had to withdraw from Milan, and even in Berlin the crown had to make terms with the people. While thrones were falling or tottering in every country in Europe, it was inevitable that excitement and agitation should prevail in Great Britain. The Chartists, reviving the machinery which they had endeavoured to employ in 1839, decided on preparing a monster petition to Parliament, which was to be escorted to Westminster by a monster procession. Their preparations excited general alarm, and on the invitation of the Government no less than 170,000 special constables were sworn in to protect life and property against a rabble. By the judicious arrangements, however, which were made by the duke of Wellington, the peace of the metropolis was secured. The Chartists were induced to abandon the procession which had caused so much alarm, and the monster petition was carried in a cab to the House of Commons. There it was mercilessly picked to pieces by a select committee. It was found that, instead of containing nearly 6,000,000 signatures, as its originators had boasted, less than 2,000,000 names were attached to it. Some of the names, moreover, were obviously fictitious or even absurd. The exposure of these facts turned the whole thing into ridicule, and gave Parliament an excuse for postponing measures of organic reform which might otherwise have been brought forward.

Chartism

If the ministry thus abstained from pressing forward a large scheme of political reform, it succeeded in carrying two measures of the highest commercial and social importance. In 1849 it supplemented the free trade policy, which Sir Robert Peel had developed, by the repeal of the Navigation Acts. Briefly stated, these Acts, which had been originated during the Protectorate of Cromwell, and continued after the Restoration, reserved the whole coasting trade of the country for British vessels and British seamen, and much of the foreign trade for British vessels, commanded and chiefly manned by British subjects. The Acts, therefore, were in the strictest sense protective, but they were also designed to increase the strength of Great Britain at sea, by maintaining large numbers of British seamen. They had been defended by Adam Smith on the ground that defence was "of much more importance than opulence," and by the same reasoning they had been described by Mr John Stuart Mill as "though economically disadvantageous, politically expedient." The Acts, however, threw a grave burden on British trade and British shipowners. Their provisions by restricting competition naturally tended to raise freights; and by restricting employment made it difficult for shipowners to man their vessels. Accordingly the Government wisely determined on their repeal; and one of the last and greatest battles between Free Trade and Protection was fought over the question. The second reading of the Government Bill was carried in the House of Lords by a majority of only ten: it would not have been carried at all if the Government had not secured a much larger number of proxies than their opponents could obtain.

Navigation Acts.

If the repeal of the Navigation Acts constituted a measure of the highest commercial importance, the passage of the Ten Hours Bill in 1847 marked the first great advance in factory legislation. Something, indeed, had already been done to remedy the evils arising from the employment of women and very young children in factories and mines. In 1833 Lord Ashley, better known as Lord Shaftesbury, had carried the first important Factory Act. In 1842 he had succeeded, with the help of the striking report of a Royal Commission, in inducing Parliament to prohibit the employment of women and of boys under ten years of age in mines. And in 1843 Sir James Graham, who was Home Secretary in Sir Robert Peel's Administration, had been compelled by the pressure of public opinion to introduce a measure providing for the education of children employed in factories, and for limiting the hours of work of children and young persons. The educational clauses of this Bill were obviously framed in the interests of the Church of England, and raised a heated controversy which led to the abandonment of the measure; and in the following year Sir James Graham introduced a new Bill dealing with the labour question alone. Briefly stated, his proposal was that no child under nine years of age should be employed in a factory, and that no young person under eighteen should be employed for more than twelve hours a day. This measure gave rise to the famous controversy on the ten hours clause, which commenced in 1844 and was protracted till 1847. Lord Ashley and the factory reformers contended, on the one hand, that ten hours were long enough for any person to work; their opponents maintained, on the contrary, that the adoption of the clause would injure the working-classes by lowering the rate of wages, and ruin the manufacturers by exposing them to foreign competition. In 1847 the reform was at last adopted. It is a remarkable fact that it was carried against the views of the leading statesmen on both sides of the House. It was the triumph of common-sense over official arguments.

Ten Hours Bill.

During the first four years of Lord John Russell's Government, his administration had never enjoyed any very large measure of popular support, but it had been partly sustained by the advocacy of Sir Robert Peel. The differences which estranged Sir Robert from his old supporters were far greater than those which separated him from the Whigs, and the latter were therefore constantly able to rely on his assistance. In the summer of 1850, however, a lamentable accident—a fall from his horse—deprived the country of the services of its great statesman. His death naturally affected the position of parties. The small remnant of able men, indeed, who had been associated with him in his famous administration, still maintained an attitude of neutrality. But the bulk of the Conservative party rallied under the lead of Lord Stanley (afterwards Derby) in the House of Lords, and gradually submitted to, rather than accepted, the lead of Mr Disraeli in the House of Commons.

Death of Peel.

In the autumn which succeeded Sir Robert Peel's death, an event which had not been foreseen agitated the country and produced a crisis. During the years which had succeeded the Reform Bill a great religious movement had influenced politics both in England and Scotland. In England, a body of eminent men at Oxford—of whom Mr, afterwards Cardinal, Newman was the chief, but who numbered among their leaders Mr Hurrell Froude, the brother of the historian, and Mr Keble, the author of the *Christian Year*—endeavoured to prove that the doctrines of the Church of England were identical with those of the primitive Catholic Church, and that every Catholic doctrine might be held by those who were within its pale. This view was explained in

Oxford Movement.

a remarkable series of tracts, which gave their authors the name of Tractarians. The most famous of these, and the last of the series, Tract XC., was published three years after the Queen's accession to the throne. In Scotland, the Presbyterian Church — mainly under the guidance of Dr Chalmers, one of the most eloquent preachers of the century—was simultaneously engaged in a contest with the state on the subject of ecclesiastical patronage. Both movements had this in common, that they indicated a revival of religious energy, and aimed at vindicating the authority of the church and resisting the interference of the state in church matters. The Scottish movement led to the disruption of the Church of Scotland and the formation of the Free Church in 1843. The Tractarian movement was ultimately terminated by the secession of Newman and many of his associates from the Church of England, and their admission to the Church of Rome. These secessions raised a feeling of alarm throughout England. The people, thoroughly Protestant, were excited by the proofs—which they thought were afforded—that the real object of the Tractarians was to reconcile England with Rome; and practices which are now regarded as venial or even praiseworthy — such as the wearing of the surplice in the pulpit, and the institution of the weekly offertory—were denounced because they were instituted by the Tractarians, and were regarded as insidious devices to lead the country Romewards. The sympathies of the Whigs, and especially of the Whig prime minister, Lord John Russell, were with the people; and Lord John displayed his dislike to the Romanizing tendencies of the Tractarians by appointing Mr Hampden—whose views had been formally condemned by the Hebdomadal Board at Oxford—to the bishopric of Hereford. The High Church party endeavoured to oppose the appointment at every stage; but their attempts exposed them to a serious defeat. The courts held that, though the appointment of a bishop by the crown required confirmation in the archbishop's court, the confirmation was a purely ministerial act which could not be refused. The effort which the High Church party had made to resist Dr Hampden's appointment had thus resulted in showing conclusively that authority resided in the crown and not in the archbishop. It so happened that about the same time this view was confirmed by another judicial decision. The lord chancellor presented Mr Gorham to a living in Devonshire; and Dr Phillpotts, the bishop of Exeter, declined to institute him, on the ground that he held heretical views on the subject of baptism. The Court of Arches upheld the bishop's decision. The finding of the court, however, was reversed by the Privy Council, and its judgment dealt a new blow at the Tractarian party. For it again showed that authority—even in doctrine—resided in the crown and not in the church. Within a few months of this famous decision the Pope—perhaps encouraged by the activity and despondency of the High Church party—issued a brief "for re-establishing and extending the Catholic faith in England," and proceeded to divide England and Wales into twelve sees. One of them—Westminster—was made an archbishopric, and the new dignity was conferred on Mr Wiseman, who was almost immediately afterwards created cardinal. The publication of this brief caused much excitement throughout the country, which was fanned by a letter from the prime minister to the bishop of Durham, condemning the brief as "insolent and insidious" and "inconsistent with the Queen's supremacy, with the rights of our bishops and clergy, and with the spiritual independence of the nation." Somewhat unnecessarily the prime minister went on to condemn the clergymen of the Church of England who had subscribed the Thirty-nine Articles, "who have been the most forward in leading their own flocks, step by step, to the very edge of the precipice."

In accordance with the promise of Lord John Russell's letter, the ministry, at the opening of the session of 1851, introduced a measure forbidding the assumption of territorial titles by the priests and bishops of the Roman Catholic Church, declaring all gifts made to them and all acts done by them under these titles null and void, and forfeiting to the crown all property bequeathed to them. The Bill naturally encountered opposition from many Liberals, while it failed to excite any enthusiasm among Conservatives, who thought its remedies inadequate. In the middle of the debates upon it the Government was defeated on another question—a proposal to reduce the county franchise—and, feeling that it could no longer rely on the support of the House of Commons, tendered its resignation. But Lord Stanley, whom the Queen entrusted with the duty of forming a new administration, was compelled to decline the task, and Lord John resumed office. Mild as the original Ecclesiastical Titles Bill had been thought, the new edition of it, which was introduced after the restoration of the Whigs to power, was still milder. Though, after protracted debates, it was at last placed on the Statute Book, it satisfied nobody. Its provisions, as was soon found, could be easily evaded, and the Bill, which had caused so much excitement, and had nearly precipitated the fall of a ministry, remained a dead letter. The Government, in fact, was experiencing the truth that, if a defeated ministry may be occasionally restored to place, it cannot be restored to power. The dismissal of Lord Palmerston from the Foreign Office in 1851 further increased the embarrassments of the Government. In February 1852 it was defeated on a proposal to revive the militia, and resigned.

Ecclesiastical Titles Bill.

The circumstances which directly led to the defeat of the Whigs were, in one sense, a consequence of the revolutionary wave which had swept over Europe in 1848. The fall of Louis Philippe in that year created a panic in Great Britain. Men thought that the unsettled state of France made war probable, and they were alarmed at the defenceless condition of England. Lord Palmerston, speaking in 1845, had declared that "steam had bridged the Channel"; and the duke of Wellington had addressed a letter to Sir John Burgoyne, in which he had demonstrated that the country was not in a position to resist an invading force. The panic was so great that the ministry felt it necessary to make exceptional provisions for allaying it. Lord John Russell decided on asking Parliament to sanction increased armaments, and to raise the income tax to 1s. in the pound in order to pay for them. The occasion deserves to be recollected as the last on which a prime minister, who was not also chancellor of the exchequer, has himself proposed the budget of the year. But it was still more memorable because the remedy which Lord John proposed at once destroyed the panic which had suggested it. A certain increase of the income tax to a shilling seemed a much more serious calamity than the uncertain prospect of a possible invasion. The estimates were recast, the budget was withdrawn, and the nation was content to dispense with any addition to its military and naval strength. Events in France, in the meanwhile, moved with railway speed. Louis Napoleon became president of the French Republic: in 1851 he became emperor of the French. The new emperor, indeed, took pains to reassure a troubled Continent that "the empire was peace." The people insisted on believing—and, as the event proved, rightly—that the empire was war. Notwithstanding the success of the Great Exhibition of 1851, which was supposed to inaugurate a new reign of peace,

French scare.

the panic, which had been temporarily allayed in 1848, revived at the close of 1851, and the Government endeavoured to allay it by reconstituting the militia. There were two possible expedients. An Act of 1757 had placed a militia, composed of men selected in each parish by ballot, under the direct authority of the crown, liable to be called out for active service, and to be placed under military law. But the Act had been supplemented by a series of statutes passed between 1808 and 1812, which had provided a local militia, raised, like the regular militia, by ballot, but, unlike the latter, only liable for service for the suppression of riots, or in the event of imminent invasion. Lord John Russell's Government, forced to do something by the state of public opinion, but anxious—from the experience of 1848—to make that something moderate, decided on reviving the local militia. Lord Palmerston at once suggested that the regular and not the local militia should be revived; and, in a small house of only 265 members, he succeeded in carrying a resolution to that effect. He had, in this way, what he called his "tit for tat" with Lord John; and the Queen, accepting her minister's resignation, sent for Lord Derby—for Lord Stanley had now succeeded to the title—and charged him with the task of forming a ministry.

Lord Derby.

The Government which Lord Derby succeeded in forming was composed almost exclusively of the men who had rebelled against Sir Robert Peel in 1845. It was led in the House of Commons by the brilliant but somewhat unscrupulous statesman who had headed the revolt. With the exception of Lord Derby and one other man, its members had no experience of high office; and it had no chance of commanding a majority of the House of Commons in the existing Parliament. It owed its position to the divisions of its opponents. Profiting by their experience, it succeeded in framing and passing a measure reconstituting the regular militia, which obtained general approval. It is perhaps worth observing that it maintained the machinery of a ballot, but reserved it only in case experience should prove that it was necessary. Voluntary enlistment under the new Militia Bill was to be the rule: compulsory service was only to be resorted to if voluntary enlistment should fail. This success, to a certain extent, strengthened the position of the new ministry. It was obvious, however, that its stability would ultimately be determined by its financial policy. Composed of the men who had resisted the free trade measures of the previous decade, its fate depended on its attitude towards free trade. In forming his administration Lord Derby had found it necessary to declare that, though he was still in favour of a tax on corn, he should take no steps in this direction till the country had received an opportunity of expressing its opinion. His leader in the House of Commons went much farther, and declared that the time had gone by for recurring to protection. The view which Mr Disraeli thus propounded in defiance of his previous opinions was confirmed by the electors on the dissolution of Parliament. Though the new Government obtained some increased strength from the result of the polls, the country, it was evident, had no intention of abandoning the policy of free trade, which by this time, it was clear, had conferred substantial benefits on all classes. When the new Parliament met in the autumn of 1852 it was at once plain that the issue would be determined on the rival merits of the old and the new financial systems. Mr Disraeli courted the decision by at once bringing forward the budget, which custom, and perhaps convenience, would have justified him in postponing till the following spring. His proposal—in which he avowedly threw over his friends on the ground that "he had greater subjects to consider than the triumph of obsolete opinions"—was, in effect, an attempt to conciliate his old supporters by a policy of doles, and to find the means for doing so by the increased taxation of the middle classes. He offered to relieve the shipping interest by transferring some of the cost of lighting the coasts to the Consolidated Fund; the West India interest by sanctioning the refining of sugar in bond; and the landed classes by reducing the malt tax by one-half, and by repealing the old war duty on hops. He suggested that the cost of these measures should be defrayed by extending the income tax to Ireland, to industrial incomes of £100 and to permanent incomes of £50 a year, as well as by doubling the house tax, and extending it to all £10 householders. The weight, therefore, of these measures was either purposely or unintentionally thrown mainly on persons living in houses worth from £10 to £20 a year, or on persons in receipt of incomes from £50 to £150 a year. This defect in the budget was exposed in a great speech by Mr Gladstone, which did much to ensure the defeat of the scheme and the fall of the ministry.

Coalition, 1853.

On the resignation of Lord Derby, the Queen, anxious to terminate a period of weak governments, decided on endeavouring to combine in one cabinet the chiefs of the Whig party and the followers of Sir Robert Peel. With this view she sent both for Lord Aberdeen, who had held the Foreign Office under Sir Robert, and for Lord Lansdowne, who was the Nestor of the Whigs; and with Lord Lansdowne's concurrence charged Lord Aberdeen with the task of forming a government. In the new ministry Lord Aberdeen became first lord of the treasury, Mr Gladstone chancellor of the exchequer, Lord John Russell foreign minister—though he was almost immediately replaced in the Foreign Office by Lord Clarendon, and assumed himself the presidency of the Council. Lord Palmerston went to the Home Office. One other appointment must also be mentioned. The secretary of state for the colonies was also at that time secretary of state for war. No one in 1852, however, regarded that office as of material importance, and it was entrusted by Lord Aberdeen to an amiable and conscientious nobleman, the duke of Newcastle.

Budget of 1853.

The first session of the Aberdeen Administration will be chiefly recollected for the remarkable budget which Mr Gladstone brought forward. It constituted a worthy supplement to the measures of 1842, 1845, and 1846. Mr Gladstone swept away the duty on one great necessary of life—soap; he repealed the duties on 123 other articles; he reduced the duties on 133 others, among them on tea; and he found means for paying for these reforms and for the gradual reduction and ultimate abolition of the income tax, which had become very unpopular, by (1) extending the tax to incomes of £100 a year; (2) an increase of the spirit duties; and (3) applying the death duties to real property, and to property passing by settlement. There can be little doubt that this great proposal was one of the most striking which had ever been brought forward in the House of Commons; there can also, unhappily, be no doubt that its promises and intentions were frustrated by events which proved too strong for its author. For Mr Gladstone, in framing his budget, had contemplated a continuance of peace, and the country was, unhappily, already drifting into war.

The holy places.

For some years an obscure quarrel had been conducted at Constantinople about the custody of the holy places at Jerusalem. France, relying on a treaty concluded in the first half of the 18th century, claimed the guardianship of these places for the Latin Church. But the rights which the Latin Church had thus obtained had practically fallen into disuse, while the Greek branch of the Christian Church had occupied and repaired the shrines which the Latins had neglected. In the years which preceded 1853, however, France had shown more activity in asserting her claims; and the new emperor of the French, anxious to conciliate the church which had supported his elevation to the throne, had a keen interest in upholding them. If, for reasons of policy, the emperor had grounds for his action, he had personal motives for thwarting the Tsar of Russia; for the latter potentate had been foolish enough, in recognizing the second empire, to address its sovereign as "Mon Cher Ami," instead of, in the customary language of sovereigns, as "Monsieur Mon Frère." Thus at the close of 1852, and in the beginning of 1853, Russia and France were both addressing opposite and irreconcilable demands to the Porte, and France was already talking of sending her fleet to the Dardanelles, while Russia was placing a corps d'armée on active service and despatching Prince Mentschikoff on a special mission to Constantinople. So far the quarrel which had occurred at the Porte was obviously one in which Great Britain had no concern. The Aberdeen ministry, however, thought it desirable that it should be represented in the crisis by a strong man at Constantinople; and it selected Lord Stratford de Redcliffe for the post, which he had filled in former years with marked ability. Whatever merits Lord Stratford possessed—and he stands out in modern diplomacy as the one strong man whom England has produced —there was no doubt that he had this disqualification: the Emperor Nicholas had refused some years before to receive him as ambassador at St Petersburg, and Lord Stratford had resented, and never forgiven, the discourtesy of this refusal. Lord Stratford soon discovered that Prince Mentschikoff was the bearer of larger demands, and that he was requiring the Porte to agree to a treaty acknowledging the right of Russia to protect the Greek Church throughout the Turkish dominions. By Lord Stratford's advice the Porte—while making the requisite concession respecting the holy places—refused to grant the new demand; and Prince Mentschikoff thereupon withdrew from Constantinople.

The rejection of Prince Mentschikoff's ultimatum was followed by momentous consequences. Russia—or rather her Tsar—resolved on the occupation of the principalities; the British ministry—though the quarrel did not directly concern Great Britain—sent a fleet to the Dardanelles and placed it under Lord Stratford's orders. Diplomacy, however, made a fresh attempt to terminate the dispute, and in July 1853 a note was agreed upon by the four neutral Powers, France, Great Britain, Austria, and Prussia, which it was decided to present to Constantinople and St Petersburg. This note, the adoption of which would have insured peace, was accepted at St Petersburg; at Constantinople it was, unfortunately, rejected, mainly on Lord Stratford's advice, and in opposition to his instructions from home. Instead, however, of insisting on the adoption of the note to which it had agreed, Lord Aberdeen's ministry recommended the Tsar to accept some amendments to it suggested by Lord Stratford, which it was disposed to regard as unimportant. It then discovered, however, that the Tsar attached a different meaning to the original note than it had itself applied to it, and in conjunction with France it thereupon ceased to recommend the Vienna Note—as it was called—for acceptance. This decision separated the two western Powers from Austria and Prussia, who were disposed to think that Russia had done all that could have been required of her in accepting the note which the four Powers had agreed upon.

It was obvious that the control of the situation was passing from the hands of the Cabinet at home into those of Lord Stratford at Constantinople. The ambassador, in fact, had the great advantage that he knew his own mind; the Cabinet laboured under the fatal disadvantage that it had, collectively, no mind. Its chief, Lord Aberdeen, was dominated by a desire to preserve peace; but he had not the requisite force to control the stronger men who were nominally serving under him. Lord John Russell was a little sore at his own treatment by his party. He thought that he had a claim to the first place in the ministry, and he did not, in consequence, give the full support to Lord Aberdeen which the latter had a right to expect from him. Lord Palmerston, on the other hand, had no personal grudge to nurture, but he was convinced that the first duty of England was to support Turkey and to resist Russia. He represented in the Cabinet the views which Lord Stratford was enforcing at Constantinople, and step by step Lord Stratford, thus supported, drove the country nearer and nearer to war.

In October the Porte, encouraged by the presence of the British fleet in the Bosphorus, took the bold step of summoning the Russians to evacuate the principalities. Following up this demand the Turkish troops attacked the Russian army, and inflicted on it one or two sharp defeats. The Russians retaliated by loosing their squadron from Sebastopol, and on the 30th of November it attacked and destroyed the Turkish fleet at Sinope. The massacre of Sinope—as it was rather inaccurately called in Great Britain, for it is difficult to deny that it was a legitimate act of a belligerent Power — created an almost irresistible demand for war among the British people. Yielding to popular opinion, the British ministry assented to a suggestion of the French emperor that the fleets of the Allied Powers should enter the Black Sea and "invite" every Russian vessel to return to Sebastopol. The decision was taken at an unfortunate hour. Diplomatists, pursuing their labours at Vienna, had succeeded in drawing up a fresh note which they thought might prove acceptable both at St Petersburg and at Constantinople. Presented almost at the moment at which the Tsar learned that the French and British fleets had entered the Black Sea, the Russian Government, instead of considering it, withdrew its ministers from London and Paris; the French and British ambassadors were thereupon withdrawn from St Petersburg. An ultimatum was soon afterwards addressed to Russia requiring her to evacuate the principalities, and war began. In deciding on war the British Government relied on the capacity of its fleet, which was entrusted to the command of Sir Charles Napier, to strike a great blow in the Baltic. The fleet was despatched with extraordinary rejoicings, and amidst loud and confident expressions of its certain triumph. As a matter of fact it did very little. In the south of Europe, however, the Turkish armies on the Danube, strengthened by the advice of British officers, were more successful. The Russians were forced to retire, and the principalities were evacuated. A prudent Administration might possibly have succeeded in stopping the war at this point. But the temper of the country was by this time excited, and it was loudly demanding something more than a preliminary success. It was resolved to invade the Crimea and attack the great arsenal, Sebastopol, whence the Russian fleet had sailed to Sinope, and in September 1854 the Allied armies landed in the Crimea. On the 20th the Russian army, strongly posted on the banks of the Alma, was completely defeated, and it is almost certain that, if the victory had been at once followed up, Sebastopol would have fallen. The commanders of the Allied armies, however, hesitated to throw themselves

Crimean war.

against the forts erected to the north of the town, and decided on the hazardous task of marching round Sebastopol and attacking it from the south. The movement was successfully carried out, but the Allies again hesitated to attempt an immediate assault. The Russians, who were advised by Colonel Todleben, the only military man who attained a great reputation in the war, thus gained time to strengthen their position by earthworks; and the Allies found themselves forced, with scanty preparations, to undertake a regular siege against an enemy whose force was numerically superior to their own. In the early days of the siege, indeed, the Allied armies were twice in great peril. A formidable attack on the 20th October on the British position at Balaclava led to a series of encounters which displayed the bravery of British troops but did not enhance the reputation of British commanders. A still more formidable sortie on the 5th of November was with difficulty repulsed at Inkerman. And the Russians soon afterwards found, in the climate of the country, a powerful ally. The Allied armies, imperfectly organized, and badly equipped for such a campaign, suffered severely from the hardships of a Crimean winter. The whole expedition seemed likely to melt away from want and disease.

The terrible condition of the army, vividly described in the letters which the war correspondents of the newspapers sent home, aroused strong feelings of indignation in Great Britain. When Parliament met Mr Roebuck gave notice that he would move for a committee of inquiry. Lord John Russell—who had already vainly urged in the Cabinet that the duke of Newcastle should be superseded, and the conduct of the war entrusted to a stronger minister—resigned office. His resignation was followed by the defeat of the Government, and Lord Aberdeen, thus driven from power, was succeeded by Lord Palmerston. In selecting him for the post, the Queen undoubtedly placed her seal on the wish of the country to carry out the war to the bitter end. But it so happened that the formation of a new ministry was accompanied by a fresh effort to make terms of peace. Before the change of administration a conference had been decided on, and Lord Palmerston entrusted its management to Lord John Russell. While the latter was on his way to Vienna an event occurred which seemed at first to facilitate his task. The Tsar, worn out with disappointment, suddenly died, and was succeeded by his son Alexander. Unfortunately the conference failed, and the war went on for another year. In September 1855 the Allied troops succeeded in obtaining possession of the southern side of Sebastopol, and the emperor of the French, satisfied with this partial success, or alarmed at the expense of the war, decided on withdrawing from the struggle. The attitude of Napoleon made the conclusion of peace only a question of time. In the beginning of 1856 a congress to discuss the terms was assembled at Paris; in February hostilities were suspended; and in April a treaty was concluded. The peace set back the boundaries of Russia from the Danube to the Pruth; it secured the free navigation of the first of these rivers; it opened the Black Sea to the commercial navies of the world, closing it to vessels of war and forbidding the establishment of arsenals upon its shores. The last condition, to which Great Britain attached most importance, endured for about fourteen years. Peace without this provision could undoubtedly have been secured at Vienna, and the prolongation of the war from 1855 to 1856 only resulted in securing this arrangement for a little more than one decade.

Palmerston's Ministry.

The Crimean war left other legacies behind it. The British Government had for some time regarded with anxiety the gradual encroachments of Russia in Central Asia. Russian diplomacy was exerting an increasing influence in Persia, and the latter had always coveted the city of Herat, which was popularly regarded as the gate of India. In 1856 the Persian Government, believing that England had her hands fully occupied in the Crimea, seized Herat, and, in consequence, a fresh war—in which a British army under Sir James Outram rapidly secured a victory—broke out. The campaign, entered upon when Parliament was not in session, was unpopular in the country. A grave constitutional question, which was ultimately settled by legislation, was raised as to the right of the Government to undertake military operations beyond the boundaries of India without the consent of Parliament. But the incidents of the Persian war were soon forgotten in the presence of a still graver crisis; for in the following year, 1857, the country suddenly found itself involved in war with China, and face to face with one of the greatest dangers which it has ever encountered—the mutiny of the Sepoy army in India. The Chinese war arose from the seizure by the Chinese authorities of a small vessel, the *Arrow*, commanded by a British subject, and at one time holding a license (which, however, had expired at the time of the seizure) from the British superintendent at Hongkong, and the detention of her crew on the charge of piracy. Sir John Bowring, who represented Great Britain in China, failing to secure the reparation and apology which he demanded, directed the British admiral to bombard Canton. Lord Palmerston's Cabinet decided to approve and support Sir John Bowring's vigorous action. Mr Cobden, however, brought forward a motion in the House of Commons condemning these high-handed proceedings. He succeeded in securing the co-operation of his own friends, of Lord John Russell, and of other independent Liberals, as well as of the Conservative party, and in inflicting a signal defeat on the Government. Lord Palmerston at once appealed from the House to the country. The constituencies, imperfectly acquainted with the technical issues involved in the dispute, rallied to the minister, who was upholding British interests. Lord Palmerston obtained a decisive victory, and returned to power apparently in irresistible strength. Lord Elgin had already been sent to China with a considerable force to support the demand for redress. On his way thither he learned that the British in India were reduced to the last extremities by the mutiny of the native army in Bengal, and, on the application of Lord Canning, the governor-general, he decided on diverting the troops, intended to bring the Chinese to reason, to the more pressing duty of saving India for the British crown.

Wars with Persia and China.

During the years which had followed the accession of the Queen, the territories and responsibilities of the East India Company had been considerably enlarged by the annexation of Scinde by Lord Ellenborough, the conquest of the Punjab after two desperate military campaigns under Lord Dalhousie, the conquest of Pegu, and the annexation of Oudh. These great additions to the empire had naturally imposed an increased strain on the Indian troops, while the British garrison, instead of being augmented, had been depleted to meet the necessities of the Russian war. Several circumstances, moreover, tended to propagate disaffection in the Indian army. Indian troops operating outside the Company's dominions were granted increased allowances, but these were automatically reduced when conquest brought the provinces in which they were serving within the British pale. The Sepoys again had an ineradicable dislike to serve beyond the sea, and the invasion of Pegu necessitated their transport by water to the seat of war. Finally, the invention of a new rifle led to the introduction of a cartridge which, though it was

Indian Mutiny.

officially denied at the moment, was in fact lubricated with a mixture of cow's fat and lard. The Sepoys thought that their caste would be destroyed if they touched the fat of the sacred cow or unclean pig; they were even persuaded that the British Government wished to destroy their caste in order to facilitate their conversion to Christianity. Isolated mutinies in Bengal were succeeded by much more serious events at Cawnpore in Oudh, and at Meerut in the North-West Provinces. From Meerut the mutineers, after some acts of outrage and murder, moved on Delhi, the capital of the old Mogul empire, which became the headquarters of the mutiny. In Oudh the native regiments placed themselves under a Mahratta chief, Nana Sahib, by whose orders the British in Cawnpore, including the women and children, were foully murdered. In the summer of 1857 these events seemed to imperil British rule in India. In the autumn the courage of the troops and the arrival of reinforcements gradually restored the British cause. Delhi, after a memorable siege, was at last taken by a brilliant assault. Lucknow, where a small British garrison was besieged in the Residency, was twice relieved, once temporarily by Sir James Outram and General Havelock, and afterwards permanently by Sir Colin Campbell, who had been sent out from England to take the chief command. Subsequent military operations broke up the remnants of the revolt, and in the beginning of 1858 the authority of the Queen was restored throughout India. The mutiny, however, had impressed its lesson on the British people, and, as the first consequence, it was decided to transfer the government from the old East India Company to the crown. Lord Palmerston's administration was defeated on another issue before it succeeded in carrying the measure which it introduced for the purpose, though Lord Derby's second ministry, which succeeded it, was compelled to frame its proposals on somewhat similar lines. The home government of India was entrusted to a secretary of state, with a council to assist him; and though the numbers of the council have been reduced, the form of government which was then established has endured.

Orsini.

The cause which led to the second fall of Lord Palmerston was in one sense unexpected. Some Italian refugees living in London, of whom Orsini was the chief, formed a design to assassinate the emperor of the French. On the evening of 14th January 1858, while the emperor, accompanied by the empress, was driving to the opera, these men threw some bombs under his carriage. The brutal attempt happily failed. Neither the emperor nor the empress was injured by the explosion, but the carriage in which they were driving was wrecked, and a large number of persons who happened to be in the street at the time were either killed or wounded. This horrible outrage naturally created indignation in France, and it unfortunately became plain that the conspiracy had been hatched in England and that the bombs had been manufactured in Birmingham. On these facts becoming known, Count Walewski, the chief of the French Foreign Office, who was united by ties of blood to the emperor, called on the British Government to provide against the danger to which France was exposed. "Ought the right of asylum to protect such a state of things?" he asked. "Is hospitality due to assassins? Ought the British Legislature to continue to favour their designs and their plans? And can it continue to shelter persons who by these flagrant acts place themselves beyond the pale of common rights?" Lord Clarendon, the head of the British Foreign Office, told the French ambassador, who read him this despatch, that "no consideration on earth would induce the British Parliament to pass a measure for the extradition of political refugees," but he added that it was a question whether the law was as complete and as stringent as it should be, and he stated that the Government had already referred the whole subject to the law officers of the crown for their consideration. Having made these remarks, however, he judged it wise to refrain from giving any formal reply to Count Walewski's despatch, and contented himself with privately communicating to the British ambassador in Paris the difficulties of the British Government. After receiving the opinion of the law officers the Cabinet decided to introduce a Bill into Parliament increasing in England the punishment for a conspiracy to commit a felony either within or without the United Kingdom. The first reading of this Bill was passed by a considerable majority. But, before the Bill came on for a second reading, the language which was being used in France created strong resentment in England. The regiments of the French army sent addresses to the emperor congratulating him on his escape and violently denouncing the British people. Some of these addresses, which were published in the *Moniteur*, spoke of London as "an assassins' den," and invited the emperor to give his troops the order to destroy it. Such language did not make it easier to alter the law in the manner desired by the Government. The House of Commons, reflecting the spirit of the country, blamed Lord Clarendon for neglecting to answer Count Walewski's despatch, and blamed Lord Palmerston for introducing a Bill at French dictation. The feeling was so strong that, when the Conspiracy Bill came on for a second reading, an amendment hostile to the Government was carried, and Lord Palmerston at once resigned.

Lord Derby's second ministry.

For a second time Lord Derby undertook the difficult task of carrying on the work of government without the support of a majority of the House of Commons. If the Liberal party had been united his attempt would have failed immediately. In 1858, however, the Liberal party had no cohesion. The wave of popularity which had carried Lord Palmerston to victory in 1857 had lost its strength. The Radicals, who were slowly recovering the influence they had lost during the Crimean war, regarded even a Conservative government as preferable to his return to power, while many Liberals desired to entrust the fortunes of their party to the guidance of their former chief, Lord John Russell. It was obvious to most men that the dissensions thus visible in the Liberal ranks could be more easily healed in the cold shade of the Opposition benches than in the warmer sunlight of office. And therefore, though no one had much confidence in Lord Derby, or in the stability of his second Administration, every one was disposed to acquiesce in its temporary occupation of office.

Jews in Parliament.

Ministries which exist by sufferance are necessarily compelled to adapt their measures to the wishes of those who permit them to continue in power. The second ministry of Lord Derby experienced the truth of this rule. For some years a controversy had been conducted in the Legislature in reference to the admission of the Jews to Parliament. This dispute had been raised in 1847 into a question of practical moment by the election of Baron Rothschild as representative of the City of London, and its importance had been emphasized in 1851 by the return of another Jew, Alderman Salomons, for another constituency. The Liberal party generally in the House of Commons was in favour of such a modification of the oaths as would enable the Jews so elected to take their seats. The bulk of the Conservative party, on the contrary, and the House of Lords, were strenuously opposed to the change. Early in 1858 the House of Commons, by an increased majority, passed a Bill amending the oaths imposed by law on members of both Houses, and directing the omission of the words "on the true faith of a Christian" from the oath of abjuration when it was taken by a Jew. If the Conservatives had remained in Opposition there can be little doubt that this Bill would have shared the fate of its predecessors and have been rejected by the Lords. The lord chancellor, indeed, in speaking upon the clause relieving the Jews, expressed a hope that the peers would not hesitate to pronounce that our "Lord is king, be the people never so impatient." But some Conservative peers realized the inconvenience of maintaining a conflict between the two Houses when the Conservatives were in power; and Lord Lucan, who had commanded the cavalry in the Crimea, suggested as a compromise that either House should be authorized by resolution to determine the form of oath to be administered to its members. This solution was reluctantly accepted by Lord Derby, and Baron Rothschild was thus enabled to take the seat from which he had been so long excluded. Eight years afterwards Parliament was induced to take a fresh step in advance. It imposed a new oath from which the words which disqualified the Jews were omitted. The door of the House of Lords was thus thrown open, and Baron Rothschild, raised to the peerage, was enabled to take his seat in the upper chamber.

This question was not the only one on which a Conservative Government, without a majority at its back, was compelled to make concessions. For some years past a growing disposition had been displayed among the more earnest Liberals to extend the provisions of the Reform Act of 1832. Lord John Russell's ministry had been defeated in 1851 on a proposal of Mr Locke King to place £10 householders in counties on the same footing as regards the franchise as £10 householders in towns, and Lord John himself in 1854 had actually introduced a new Reform Bill. After the general election of 1857 the demand for reform increased, and, in accepting office in 1858, Lord Derby thought it necessary to declare that, though he had maintained in Opposition that the settlement of 1832, with all its anomalies, afforded adequate representation to all classes, the promises of previous governments and the expectations of the people imposed on him the duty of bringing forward legislation on the subject. The scheme which Lord Derby's Government adopted was peculiar. Its chief proposal was the extension of the county franchise to £10 householders. But it also proposed that persons possessing a 40s. freehold in a borough should in future have a vote in the borough in which their property was situated, and not in the county. The Bill also conferred the franchise on holders of a certain amount of stock, on depositors in savings banks, on graduates of universities, and on other persons qualified by position or education. The defect of the Bill was that it did nothing to meet the only real need of reform—the enfranchisement of a certain proportion of the working classes. On the contrary, in this respect it perpetuated the settlement of 1832. The £10 householder was still to furnish the bulk of the electorate, and the ordinary working man could not afford to pay £10 a year for his house. While the larger proposals of the Bill were thus open to grave objection, its subsidiary features provoked ridicule. The suggestions that votes should be conferred on graduates and stockholders were laughed at as "Fancy Franchises." The Bill, moreover, was not brought forward with the authority of a united Cabinet. Two members of the Government—Mr Spencer Walpole and Mr Henley—declined to be responsible for its provisions, and placed their resignations in Lord Derby's hands. In Mr Walpole's judgment the Bill was objectionable because it afforded no reasonable basis for a stable settlement. There was nothing in a £10 franchise which was capable of permanent defence, and if it was at once applied to counties as well as boroughs it would sooner or later be certain to be extended. He himself advocated with some force that it would be wiser and more popular to fix the county franchise at £20 and the borough franchise at £6 rateable value; and he contended that such a settlement could be defended on the old principle that taxation and representation should go together, for £20 was the minimum rent at which the house tax commenced, and a rateable value of £6 was the point at which the householder could not compound to pay his rates through his landlord. Weakened by the defection of two of its more important members, the Government had little chance of obtaining the acceptance of its scheme. An amendment of Lord John Russell, condemning its main provisions, was adopted in an unusually full house by a substantial majority, and the Cabinet had no alternative but to resign or dissolve. It chose the latter course. The general election, which almost immediately took place, increased to some extent the strength of the Conservative party. For the first time since their secession from Sir Robert Peel the Conservatives commanded more than three hundred votes in the House of Commons, but this increased strength was not sufficient to ensure them a majority. When the new Parliament assembled, Lord Hartington, the eldest son of the duke of Devonshire, was put forward to propose a direct vote of want of confidence in the Administration. It was carried by 323 votes to 310, and the second Derby Administration came to an end.

Reform Bill, 1859.

It was plain that the House of Commons had withdrawn its support from Lord Derby, but it was not clear that any other leading politician would be able to form a government. The jealousies between Lord John Russell and Lord Palmerston still existed; the more extreme men, who were identified with the policy of Mr Cobden and Mr Bright, had little confidence in either of these statesmen; and it was still uncertain whether the able group who had been the friends of Sir Robert Peel would finally gravitate to the Conservative or to the Liberal camp. The Queen, on the advice of Lord Derby, endeavoured to solve the first of these difficulties by sending for Lord Granville, who led the Liberal party in the Lords, and authorizing him to form a government which should combine, as far as possible, all the more prominent Liberals. The attempt, however, failed, and the Queen thereupon fell back upon Lord Palmerston. Lord John Russell agreed to accept office as foreign minister; Mr Gladstone consented to take the chancellorship of the exchequer. Mr Cobden was offered, but declined, the presidency of the Board of Trade; and the post which he refused was conferred on a prominent free trader, who had associated himself with Mr Cobden's fortunes, Mr Milner Gibson. Thus Lord Palmerston had succeeded in combining in one ministry the various representatives of political progress. He had secured the support of the Peelites, who had left him after the fall of Lord Aberdeen in 1855, and of the free traders, who had done so much to defeat him in 1857 and 1858. His new Administration was accordingly based on a broader bottom, and contained greater elements of strength than his former Cabinet. And the country was requiring more stable government. The three first ministries of the Queen had endured from the spring of 1835 to the spring of 1852, or for very nearly seventeen years; but the next seven years had seen the formation and dissolution of no less than four Cabinets. It was felt that these frequent changes were unfortunate for the country, and every one was glad to welcome the advent of a Government which seemed to promise greater permanence. That promise was fulfilled. The Administration which Lord Palmerston succeeded in forming in 1859 endured till his death in 1865, and with slight modifications, under its second chief Lord John (afterwards Earl) Russell, till the summer of 1866. It had thus a longer life than any Cabinet which had governed

Palmerston's second ministry.

England since the first Reform Act. But it owed its lasting character to the benevolence of its opponents rather than to the enthusiasm of its supporters. The Conservatives learned to regard the veteran statesman, who had combined all sections of Liberals under his banner, as the most powerful champion of Conservative principles; a virtual truce of parties was established during his continuance in office; and, for the most part of his ministry, a tacit understanding existed that the minister, on his side, should pursue a Conservative policy, and that the Conservatives, on theirs, should abstain from any real attempt to oust him from power. Lord John Russell, indeed, was too earnest in his desire for reform to abstain from one serious effort to accomplish it. Early in 1860 he proposed, with the sanction of the Cabinet, a measure providing for the extension of the county franchise to £10 householders, of the borough franchise to £6 householders, and for a moderate redistribution of seats. But the country, being in enjoyment of considerable prosperity, paid only a languid attention to the scheme; its indifference was reflected in the House; the Conservatives were encouraged in their opposition by the lack of interest which the new Bill excited, and the almost unconcealed dislike of the prime minister to its provisions. The Bill, thus steadily opposed and half-heartedly supported, made only slow progress; and at last it was withdrawn by its author. He did not again attempt during Lord Palmerston's life to reintroduce the subject. Absorbed in the work of the Foreign Office, which at this time was abnormally active, he refrained from pressing home the arguments for internal reform.

Mr Gladstone's budgets.

In one important department, however, the ministry departed from the Conservative policy it pursued in other matters. Mr Gladstone signalized his return to the exchequer by introducing a series of budgets which excited keen opposition at the time, but in the result largely added to the prosperity of the country. The first of these great budgets, in 1860, was partly inspired by the necessity of adapting the fiscal system to meet the requirements of a commercial treaty which, mainly through Mr Cobden's exertions, had been concluded with the emperor of the French. The treaty bound France to reduce her duties on English coal and iron, and on many manufactured articles; while, in return, Great Britain undertook to sweep away the duties on all manufactured goods, and largely to reduce those on French wines. But Mr Gladstone was not content with these great alterations, which involved a loss of nearly £1,200,000 a year to the exchequer; he voluntarily undertook to sacrifice another million on what he called a supplemental measure of customs reform. He proposed to repeal the duties on paper, by which means he hoped to increase the opportunities of providing cheap literature for the people. The budget of 1860 produced a protracted controversy. The French treaty excited more criticism than enthusiasm on both sides of the Channel. In France the manufacturers complained that they would be unable to stand against the competition of English goods. In England many people thought that Great Britain was wasting her resources and risking her supremacy by giving the French increased facilities for taking her iron, coal, and machinery, and that no adequate advantage could result from the greater consumption of cheap claret. But the criticism which the French treaty aroused was drowned in the clamour which was created by the proposed repeal of the paper duties. The manufacture of paper was declared to be a struggling industry, which would be destroyed by the withdrawal of protection. The dissemination of cheap literature, and the multiplication of cheap newspapers, could not compensate the nation for the ruin of an important trade. If money could be spared, moreover, for the remission of taxation, the paper duties were much less oppressive than those on some other articles. The tax on tea, for example, which had been raised during the late war to no less than 1s. 5d. a ℔, was much more injurious; and it would be far wiser—so it was contended—to reduce the duty on tea than to abandon the duties on paper. Notwithstanding the opposition which the Paper Duties Bill undoubtedly excited, the proposal was carried in the Commons; it was, however, thrown out in the Lords, and its rejection led to a crisis which seemed at one time to threaten the good relations between the two houses of Parliament. It was argued that if the Lords had the right to reject a measure remitting existing duties, they had in effect the right of imposing taxation, since there was no material difference between the adoption of a new tax and the continuance of an old one which the Commons had determined to repeal. Lord Palmerston, however, with some tact postponed the controversy for the time by obtaining the appointment of a committee to search for precedents; and, after the report of the committee, he moved a series of resolutions affirming the right of the Commons to grant aids and supplies as their exclusive privilege, stating that the occasional rejection of financial measures by the Lords had always been regarded with peculiar jealousy, but declaring that the Commons had the remedy in their own hands by so framing Bills of Supply as to secure their acceptance. In accordance with this suggestion the Commons in the following year again resolved to repeal the paper duties; but, instead of embodying their decision in a separate Bill, they included it in the same measure which dealt with all the financial arrangements of the year, and thus threw on the Lords the responsibility of either accepting the proposal, or of paralysing the whole machinery of administration by depriving the crown of the supplies which were required for the public services. The Lords were not prepared to risk this result, and they accordingly accepted a reform which they could no longer resist, and the Bill became law. In order to enable him to accomplish these great changes, Mr Gladstone temporarily raised the income tax, which he found at 9d. in the pound, to 10d. But the result of his reforms was so marked that he was speedily able to reduce it. The revenue increased by leaps and bounds, and the income tax was gradually reduced till it stood at 4d. in the closing years of the Administration. During the same period the duty on tea was reduced from 1s. 5d. to 6d. in the ℔; and the national debt was diminished from rather more than £800,000,000 to rather less than £780,000,000, the charge for the debt declining, mainly through the falling in of the Long Annuities, by some £2,600,000 a year. With the possible exception of Sir Robert Peel's term of office, no previous period of British history had been memorable for a series of more remarkable financial reforms. Their success redeemed the character of the Administration. The Liberals, who complained that their leaders were pursuing a Conservative policy, could at least console themselves by the reflection that the chancellor of the exchequer was introducing satisfactory Budgets. The language, moreover, which Mr Gladstone was holding on other subjects encouraged the more advanced Liberals to expect that he would ultimately place himself at the head of the party of progress. This expectation was the more remarkable because Mr Gladstone was the representative in the Cabinet of the old Conservative party which Sir Robert Peel had led to victory. As lately as 1858 he had reluctantly refused to serve under Lord Derby; he was still a member of the Carlton Club; he sat for the university of Oxford; and on many questions he displayed a constant sympathy with Conservative traditions. Yet, on all the chief domestic questions which came before Parliament in Lord Palmerston's second Administration, Mr

Paper duties repealed.

Gladstone almost invariably took a more Liberal view than his chief. It was understood, indeed, that the relations between the two men were not always harmonious; that Lord Palmerston disapproved the resolute conduct of Mr Gladstone, and that Mr Gladstone deplored the Conservative tendencies of Lord Palmerston. It was believed that Mr Gladstone on more than one occasion desired to escape from a position which he disliked by resigning office, and that the resignation was only averted through a consciousness that the ministry could not afford to lose its most eloquent member.

While on domestic matters other than those affecting finance the Liberal ministry was pursuing a Conservative policy, its members were actively engaged on, and the attention of the public was keenly directed to, affairs abroad. For the period was one of foreign unrest, and the wars which were then waged have left an enduring mark on the map of the world, and have affected the position of the Anglo-Saxon race for all time. In the far East, the operations which it had been decided to undertake in China were necessarily postponed on account of the diversion of the forces, intended to exact redress at Peking, to the suppression of mutiny in India. It was only late in 1858 that Lord Elgin and Baron Gros, the French plenipotentiary (for France joined England in securing simultaneous redress for grievances of her own), were enabled to obtain suitable reparation. It was arranged that the treaty, which was then provisionally concluded at Tientsin, should be ratified at Peking in the following year; and in June 1859 Mr Bruce, Lord Elgin's brother, who had been appointed plenipotentiary, attempted to proceed up the Peiho with the object of securing its ratification. The Allied squadron, however, was stopped by the forts at the mouth of the Peiho, which fired on the vessels; a landing party, which was disembarked to storm the forts, met with a disastrous check, and the squadron had to retire with an acknowledged loss of three gunboats and 400 men. This reverse necessitated fresh operations, and in 1860 Lord Elgin and Baron Gros were directed to return to China, and, at the head of an adequate force, were instructed to exact an apology for the attack on the Allied fleets, the ratification and execution of the treaty of Tientsin, and the payment of an indemnity for the expenses of the war. The weakness of the Chinese empire was not appreciated at that time; the unfortunate incident on the Peiho in the previous summer had created an exaggerated impression of the strength of the Chinese arms, and some natural anxiety was felt for the success of the expedition. But the Allied armies met with no serious resistance. The Chinese, indeed, endeavoured to delay their progress by negotiation rather than by force; and they succeeded in treacherously arresting some distinguished persons who had been sent into the Chinese lines to negotiate. But by the middle of October the Chinese army was decisively defeated; Peking was occupied; those British and French prisoners who had not succumbed to the hardships of their confinement were liberated; Lord Elgin determined on teaching the rulers of China a lesson by the destruction of the Summer Palace; and the Chinese Government was compelled to submit to the terms of the Allies, and to ratify the treaty of Tientsin. There is no doubt that these operations helped to open the Chinese markets to British trade; but incidentally, by regulating the emigration of Chinese coolies, they had the unforeseen effect of exposing the industrial markets of the world to the serious competition of cheap "yellow" labour. A distinguished foreign statesman observed that Lord Palmerston had made a mistake. He thought that he had opened China to Europe; instead, he had let out the Chinese. It was perhaps a happier result of the war that it tended to the continuance of the Anglo-French alliance. French and British troops had again co-operated in a joint enterprise, and had shared the dangers and successes of a campaign.

China war, 1859-60.

War was not confined to China. In the beginning of 1859 diplomatists were alarmed at the language addressed by the emperor of the French to the Austrian ambassador at Paris, which seemed to breathe the menace of a rupture. Notwithstanding the exertions which Great Britain made to avert hostilities, the provocation of Count Cavour induced Austria to declare war against Piedmont, and Napoleon thereupon moved to the support of his ally, promising to free Italy from the Alps to the Adriatic. As a matter of fact, the attitude of northern Germany, which was massing troops on the Rhine, and the defenceless condition of France, which was drained of soldiers for the Italian campaign, induced the emperor to halt before he had carried out his purpose, and terms of peace were hastily concerted at Villafranca, and were afterwards confirmed at Zurich, by which Lombardy was given to Piedmont, while Austria was left in possession of Venice and the Quadrilateral, and Central Italy was restored to its former rulers. The refusal of the Italians to take back the Austrian grand dukes made the execution of these arrangements impracticable. Napoleon, indeed, used his influence to carry them into effect; but Lord John Russell, who was now in charge of the British Foreign Office, and who had Lord Palmerston and Mr Gladstone on his side in the Cabinet, gave a vigorous support to the claim of the Italians that their country should be allowed to regulate her own affairs. The French emperor had ultimately to yield to the determination of the inhabitants of Central Italy, when it was backed by the arguments of the British Foreign Office, and Tuscany, Modena, Parma, as well as a portion of the States of the Church, were united to Piedmont. There was no doubt that through the whole of the negotiations the Italians were largely indebted to the labours of Lord John Russell. They recognized that they owed more to the moral support of England than to the armed assistance of France. The French emperor, moreover, took a step which lost him the sympathy of many Italians. Before the war he had arranged with Count Cavour that France should receive, as the price of her aid, the duchy of Savoy and the county of Nice. After Villafranca, the emperor, frankly recognizing that he had only half kept his promise, consented to waive his claim to these provinces. But, when he found himself unable to resist the annexation of Central Italy to Piedmont, he reverted to the old arrangement. The formation of a strong Piedmontese kingdom, with the spoliation of the papal dominion, was unpopular in France; and he thought—perhaps naturally—that he must have something to show his people in return for sacrifices which had cost him the lives of 50,000 French soldiers, and concessions which the whole Catholic party in France resented. Count Cavour consented to pay the price which Napoleon thus exacted, and the frontier of France was accordingly extended to the Alps. But it is very doubtful whether Napoleon did not lose more than he gained by this addition to his territory. It certainly cost him the active friendship of Great Britain. The Anglo-French alliance had been already strained by the language of the French colonels in 1858 and the Franco-Austrian war of 1859; it never fully recovered from the shock which it received by the evidence, which the annexation of Savoy and Nice gave, of the ambition of the French emperor. The British people gave way to what Mr Cobden called the last of the three panics. Lord Palmerston proposed and carried the provision of a large sum of money for the fortification of the coasts; and the volunteer movement, which had its origin in 1859, received a remarkable stimulus in 1860. In this year the course of events in

Unification of Italy.

Italy emphasized the differences between the policy of Great Britain and that of France. Garibaldi, with a thousand followers, made his famous descent on the coast of Sicily. After making himself master of that island, he crossed over to the mainland, drove the king of Naples out of his capital, and forced him to take refuge in Gaeta. In France these events were regarded with dismay. The emperor wished to stop Garibaldi's passage across the Strait, and stationed his fleet at Gaeta to protect the king of Naples. Lord John Russell, on the contrary, welcomed Garibaldi's success with enthusiasm. He declined to intervene in the affairs of Italy by confining the great liberator to Sicily; he protested against the presence of the French fleet at Gaeta; and when other foreign nations denounced the conduct of Piedmont, he defended it by quoting Vattel and citing the example of William III. When, finally, Italian troops entered the dominions of the pope, France withdrew her ambassador from the court of Turin, and England under Lord John Russell's advice at once recognized the new kingdom of Italy.

In these great events—for the union of Italy was the greatest fact which had been accomplished in Europe since the fall of the first Napoleon—the British ministry had undoubtedly acquired credit. It was everywhere felt that the new kingdom owed much to the moral support which had been steadily and consistently given to it by Great Britain. Soon afterwards, however, in the autumn of 1863, the death of the king of Denmark led to a new revolution in the north of Europe, in which Lord Palmerston's Government displayed less resolution and lost much of the prestige which it had acquired by its Italian policy. The duchies of Schleswig and Holstein had been for centuries united to the kingdom of Denmark by the golden link of the crown; in other respects they had been organically kept distinct, while one of them—Holstein—was a member of the German confederation.

Schleswig-Holstein question.

The succession to the crown of Denmark, however, was different from that in the duchies. In Denmark the crown could descend, as it descends in Great Britain, through females. In the duchies the descent was confined to the male line; and, as Frederick VII., who ascended the Danish throne in 1848, had no direct issue, the next heir to the crown of Denmark under this rule was Prince Christian of Glucksburg, afterwards king; the next heir to the duchies being the duke of Augustenburg. In 1850 an arrangement had been made to prevent the separation of the duchies from the kingdom. As a result of a conference held in London, the duke of Augustenburg was induced to renounce his claim on the receipt of a large sum of money. Most of the Great Powers of Europe were parties to this plan. But the German confederation was not represented at the conference, and was not therefore committed to its conclusions. During the reign of Frederick VII. the Danish Government endeavoured to cement the alliance between the duchies and the kingdom, and specially to separate the interests of Schleswig, which was largely Danish in its sympathies, from those of Holstein, which was almost exclusively German. With this object, in the last year of his life, Frederick VII. granted Holstein autonomous institutions, and bound Schleswig more closely to the Danish monarchy. The new King Christian IX. confirmed this arrangement. The German Diet at Frankfort at once protested against it. Following up words with acts it decided on occupying Holstein, and it delegated the duty of carrying out its order to Hanover and Saxony. While federal execution was taking place, the duke of Augustenburg—regardless of the arrangements to which he had consented—delegated his rights in the duchies to his son, who formally claimed the succession. So far the situation, which was serious enough, had been largely dependent on the action of Germany. In the closing days of 1863 it passed mainly into the control of the two chief German Powers. In Prussia Bismarck had lately become prime minister, and was animated by ambitious projects for his country's aggrandizement. Austria, afraid of losing her influence in Germany, followed the lead of Prussia, and the two powers required Denmark to cancel the arrangements which Frederick VII. had made, and which Christian IX. had confirmed, threatening in case of refusal to follow up the occupation of Holstein by that of Schleswig. As the Danes gave only a provisional assent to the demand, Prussian and Austrian troops entered Schleswig. These events created much excitement in England. The great majority of the British people, who imperfectly understood the merits of the case, were unanimous in their desire to support Denmark by arms. Their wish had been accentuated by the circumstance that the marriage in the previous spring of the prince of Wales to the daughter of the new king of Denmark had given them an almost personal interest in the struggle. Lord Palmerston had publicly expressed the views of the people by declaring that, if Denmark were attacked, her assailants would not have to deal with Denmark alone. The language of the public press and of Englishmen visiting Denmark confirmed the impression which the words of the prime minister had produced; and there is unfortunately no doubt that Denmark was encouraged to resist her powerful opponents by the belief, which she was thus almost authorized in entertaining, that she could reckon in the hour of her danger on the active assistance of the United Kingdom. If Lord Palmerston had been supported by his Cabinet, or if he had been a younger man, he might possibly, in 1864, have made good the words which he had rashly uttered in 1863. But the Queen, who, it is fair to add, understood the movement which was tending to German unity much better than most of her advisers, was averse from war. A large section of the Cabinet shared the Queen's hesitation, and Lord Palmerston—with the weight of nearly eighty summers upon him—was not strong enough to enforce his will against both his sovereign and his colleagues. He made some attempt to ascertain whether the emperor of the French would support him if he went to war. But he found that the emperor had not much fancy for a struggle which would have restored Holstein to Denmark; and that, if he went to war at all, his chief object would be the liberation of Venice and the rectification of his own frontiers. Even Lord Palmerston shrank from entering on a campaign which would have involved all Europe in conflagration, and would have unsettled the boundaries of most Continental nations; and the British Government endeavoured thenceforward to stop hostilities by referring the question immediately in dispute to a conference in London. The labours of the conference proved abortive. Its members were unable to agree upon any methods of settlement, and the war went on. Denmark, naturally unable to grapple with her powerful antagonists, was forced to yield, and the two duchies, which were the subject of the dispute, were taken from her.

The full consequences of this struggle were not visible at the time. It was impossible to foresee that it was the first step which was to carry Prussia forward, under her ambitious minister, to a position of acknowledged supremacy on the Continent. But the results to Great Britain were plain enough. She had been mighty in words and weak in deeds. It was no doubt open to her to contend, as perhaps most wise people consider, that the cause of Denmark was not of sufficient importance to justify her in going to war. But it was not open to her to encourage a weak Power to resist, and then desert her in the hour of her necessity. Lord

Palmerston should not have used the language which he employed in 1863, if he had not decided that his brave words would be followed by brave action. His conduct lowered the prestige of Great Britain at least as much as his Italian policy had raised it. Continental statesmen thenceforward assumed that Great Britain, however much she might protest, would not resort to arms, and the influence of England suffered, as it was bound to suffer, in consequence.

Meanwhile, in this period of warfare, another struggle was being fought out on a still greater scale in North America. The election of Mr Abraham Lincoln to the presidency of the United States emphasized the fact that the majority of the inhabitants of the Northern States were opposed to the continuance of slavery; and, in the beginning of 1861, several of the Southern States formally seceded from the union. A steamer sent by the Federal Government with reinforcements to Fort Sumter was fired upon, and both parties made preparations for the civil war which was apparently inevitable. On the one side the Confederate States—as the seceding states were called—were animated by a resolution to protect their property. On the other side the "conscience" of the North was excited by a passionate desire to wipe out the blot of slavery. Thus both parties were affected by some of the most powerful considerations which can influence mankind, while the North were further actuated by the natural incentive to preserve the union, which was threatened with disruption. The progress of the great struggle was watched with painful attention in England. The most important manufacturing interest in England was paralysed by the loss of the raw cotton, which was obtained almost exclusively from the United States, and tens of thousands of workpeople were thrown out of employment. The distress which resulted naturally created a strong feeling in favour of intervention, which might terminate the war and open the Southern ports to British commerce; and the initial successes which the Confederates secured seemed to afford some justification for such a proceeding. In the course of 1862 indeed, when the Confederate armies had secured many victories, Mr Gladstone, speaking at Newcastle, used the famous expression that President Jefferson Davis had "made a nation"; and Lord Palmerston's language in the House of Commons—while opposing a motion for the recognition of the South—induced the impression that his thoughts were tending in the same direction as Mr Gladstone's. The Emperor Napoleon, in July of the same year, confidentially asked the British minister whether the moment had not come for recognizing the South; and in the following September Lord Palmerston was himself disposed in concert with France to offer to mediate on the basis of separation. Soon afterwards, however, the growing exhaustion of the South improved the prospects of the Northern States: an increasing number of persons in Great Britain objected to interfere in the interests of slavery; and the combatants were allowed to fight out their quarrel without the interference of Europe.

American Civil War.

At the beginning of the war, Lord John Russell (who was made a peer as Earl Russell in 1861) acknowledged the Southern States as belligerents. His decision caused some ill-feeling at Washington; but it was inevitable. For the North had proclaimed a blockade of the Southern ports; and it would have been both inconvenient and unfair if Lord Russell had decided to recognize the blockade and had refused to acknowledge the belligerent rights of the Southern States. Lord Russell's decision, however, seemed to indicate some latent sympathy for the Southern cause; and the irritation which was felt in the North was increased by the news that the Southern States were accrediting two gentlemen to represent them at Paris and at London. These emissaries, Messrs Mason and Slidell, succeeded in running the blockade and in reaching Cuba, where they embarked on the *Trent*, a British mail steamer sailing for England. On her passage home the *Trent* was stopped by the Federal steamer *San Jacinto;* she was boarded, and Messrs Mason and Slidell were arrested. There was no doubt that the captain of the *San Jacinto* had acted irregularly. While he had the right to stop the *Trent*, examine the mails, and, if he found despatches for the enemy among them, carry the vessel into an American port for adjudication, he had no authority to board the vessel and arrest two of her passengers. "The British Government," to use its own language, "could not allow such an affront to the national honour to pass without due reparation." They decided on sending what practically amounted to an ultimatum to the Federal Government, calling upon it to liberate the prisoners and to make a suitable apology. The presentation of this ultimatum, which was accompanied by the despatch of troops to Canada, was very nearly provoking war with the United States. If, indeed, the ultimatum had been presented in the form in which it was originally framed, war might have ensued. But at the Prince Consort's suggestion its language was considerably modified, and the responsibility for the outrage was thrown on the officer who committed it, and not on the Government of the Republic. It ought not to be forgotten that this important modification was the last service rendered to his adopted country by the Prince Consort before his fatal illness. He died before the answer to the despatch was received; and his death deprived the Queen of an adviser who had stood by her side since the earlier days of her reign, and who, by his prudence and conduct, had done much to raise the tone of the court and the influence of the Crown. Happily for the future of the world, the Government of the United States felt itself able to accept the despatch which had been thus addressed to it, and to give the reparation which was demanded; and the danger of war between the two great branches of the Anglo-Saxon race was averted. But, in the following summer, a new event excited fresh animosities, and aroused a controversy which endured for the best part of ten years.

The "Trent" incident.

The Confederates, naturally anxious to harass the commerce of their enemies, endeavoured from the commencement of hostilities to purchase armed cruisers from builders of neutral nations. In June 1862 the American minister in London drew Lord Russell's attention to the fact that a vessel, lately launched at Messrs Laird's yard at Birkenhead, was obviously intended to be employed as a Confederate cruiser. The solicitor to the Commissioners of Customs, however, considered that no facts had been revealed to authorize the detention of the vessel, and this opinion was reported in the beginning of July to the American minister, Mr Adams. He thereupon supplied the Government with additional facts, and at the same time furnished them with the opinion of an eminent English lawyer, Mr Collier (afterwards Lord Monkswell), to the effect that "it would be difficult to make out a stronger case of infringement of the Foreign Enlistment Act, which if not enforced on this occasion is little better than a dead letter." These facts and this opinion were at once sent to the Law Officers. They reached the Queen's advocate on Saturday, the 26th July; but, by an unfortunate mischance, the Queen's advocate had just been wholly incapacitated by a distressing illness; and the papers, in consequence, did not reach the Attorney- and Solicitor-

The "Alabama"

General till the evening of the following Monday, when they at once advised the Government to detain the vessel. Lord Russell thereupon sent orders to Liverpool for her detention. In the meanwhile the vessel—probably aware of the necessity for haste—had put to sea, and had commenced the career which made her famous as the *Alabama*. Ministers might even then have taken steps to stop the vessel by directing her detention in any British port to which she resorted for supplies. The Cabinet, however, shrank from this course. The *Alabama* was allowed to prey on Federal commerce, and undoubtedly inflicted a vast amount of injury on the trade of the United States. In the autumn of 1862 Mr Adams demanded redress for the injuries which had thus been sustained, and this demand was repeated for many years in stronger and stronger language. At last, in 1871, long after Lord Palmerston's death and Lord Russell's retirement, a joint commission was appointed to examine into the many cases of dispute which had arisen between the United States and Great Britain. The commissioners agreed upon three rules by which they thought neutrals should in future be bound, and recommended that they should be given a retrospective effect. They decided also that the claims which had arisen out of the depredations of the *Alabama* should be referred to arbitration. In the course of 1872 the arbitrators met at Geneva. Their finding was adverse to Great Britain, which was condemned to pay a large sum of money—more than £3,000,000—as compensation. A period of exceptional prosperity, which largely increased the revenue, enabled a chancellor of the exchequer to boast that the country had drunk itself out of the *Alabama* difficulty.

Lord Russell's second ministry.

In October 1865 Lord Palmerston's rule, which had been characterized by six years of political inaction at home and by constant disturbance abroad, was terminated by his death. The ministry, which had suffered many losses from death during its duration, was temporarily reconstructed under Lord Russell; and the new minister at once decided to put an end to the period of internal stagnation, which had lasted so long, by the introduction of a new Reform Bill. Accordingly, in March 1866 Mr Gladstone, who now led the House of Commons, introduced a measure which proposed to extend the county franchise to £14 and the borough franchise to £7 householders. The Bill did not create much enthusiasm among Liberals, and it was naturally opposed by the Conservatives, who were reinforced by a large section of moderate Liberals, nicknamed, in consequence of a phrase in one of Mr Bright's speeches, Adullamites. After many debates, in which the Commons showed little disposition to give the ministry any effective support, an amendment was carried by Lord Dunkellin, the eldest son of Lord Clanricarde, basing the borough franchise on rating instead of rental. The Cabinet, recognizing from the division that the control of the House had passed out of its hands, resigned office, and the Queen was compelled to entrust Lord Derby with the task of forming a new administration.

Lord Derby's third ministry.

For the third time in his career Lord Derby undertook the formidable task of conducting the government of the country with only a minority of the House of Commons to support him. The moment at which he made this third attempt was one of unusual anxiety. Abroad, the almost simultaneous outbreak of war between Prussia and Austria was destined to affect the whole aspect of Continental politics. At home, a terrible murrain had fallen on the cattle, inflicting ruin on the agricultural interest; a grave commercial crisis was creating alarm in the City of London, and, in its consequences, injuring the interests of labour; while the working classes, at last roused from their long indifference, and angry at the rejection of Lord Russell's Bill, were assembling in their tens of thousands to demand reform. The Cabinet determined to prohibit a meeting which the Reform League decided to hold in Hyde Park on the 23rd July, and closed the gates of the park on the people. But the mob, converging on the park in thousands, surged round the railings, which a little inquiry might have shown were too weak to resist any real pressure. Either accidentally or intentionally, the railings were overturned in one place, and the people, perceiving their opportunity, at once threw them down round the whole circuit of the park. Few acts in Queen Victoria's reign were attended with greater consequences. For the riot in Hyde Park led almost directly to a new Reform Act, and to the transfer of power from the middle classes to the masses of the people.

Reform, 1867.

Yet, though the new Government found it necessary to introduce a Reform Bill, a wide difference of opinion existed in the Cabinet as to the form which the measure should take. Several of its members were in favour of assimilating the borough franchise to that in force in municipal elections, and practically conferring a vote on every householder who had three years' residence in the constituency. General Peel, however—Sir Robert Peel's brother—who held the seals of the War Office, objected to this extension; and the Cabinet ultimately decided on evading the difficulty by bringing forward a series of resolutions on which a scheme of reform might ultimately be based. Their success in 1858, in dealing with the government of India in this way, commended the decision to the acceptance of the Cabinet. But it was soon apparent that the House of Commons required a definite scheme, and that it would not seriously consider a set of abstract resolutions which committed no one to any distinct plan. Hence on the 23rd February 1867 the Cabinet decided on withdrawing its resolutions and reverting to its original Bill. On the following day Lord Cranborne—better known afterwards as Lord Salisbury—discovered that the Bill had more democratic tendencies than he had originally supposed, and refused to be a party to it. On Monday, the 25th, the Cabinet again met to consider the new difficulty which had thus arisen; and it decided (as was said afterwards by Sir John Pakington) in ten minutes to substitute for the scheme a mild measure extending the borough franchise to houses rated at £6 a year, and conferring the county franchise on £20 householders. The Bill, it was soon obvious, would be acceptable to no one; and the Government again fell back on its original proposal. Three members of the Cabinet, however, Lord Cranborne, Lord Carnarvon, and General Peel, refused to be parties to the measure, and resigned office, the Government being necessarily weakened by these defections. In the large scheme which the Cabinet had now adopted, the borough franchise was conferred on all householders rated to the relief of the poor, who had for two years occupied the houses which gave them the qualification; the county franchise was given to the occupiers of all houses rated at £15 a year or upwards. But it was proposed that these extensions should be accompanied by an educational franchise, and a franchise conferred on persons who had paid twenty shillings in assessed taxes or income tax; the taxpayers who had gained a vote in this way being given a second vote in respect of the property which they occupied. In the course of the discussion on the Bill in the House of Commons, the securities on which its authors had relied to enable them to stem the tide of democracy were, chiefly through Mr Gladstone's exertions, swept away. The dual vote was abandoned, direct payment of rates was surrendered, the county franchise was extended to £12 householders, and the redistribution of seats was largely increased. The Bill, in the shape in which it had been introduced, had been surrounded with safeguards to property. With their loss it involved a great radical change, which placed the working classes of the country in the position of predominance which the middle classes had occupied since 1832.

The passage of the bill necessitated a dissolution of Parliament; but it had to be postponed to enable Parliament to supplement the English Reform Act of 1867 with measures applicable to Scotland and Ireland, and to give time for settling the boundaries of the new constituencies which had been created. This delay gave the Conservatives another year of office. But the first place in the Cabinet passed in 1868 from Lord Derby to his lieutenant, Mr Disraeli. The change added interest to political life. Thenceforward, for the next thirteen years, the chief places in the two great parties in the state were filled by the two men, Mr. Gladstone and Mr Disraeli, who were unquestionably the ablest representatives of their respective followers. But the situation was also remarkable because power thus definitely passed from men who, without exception, had been born in the 18th century, and had all held Cabinet offices before 1832, to men who had been born in the 19th century, and had only risen to Cabinet rank in the 'forties and the 'fifties. It was also interesting to reflect that Mr Gladstone had begun life as a Conservative, and had only gradually moved to the ranks of the Liberal party; while Mr. Disraeli had fought his first election under the auspices of Mr O'Connell and Mr Hume, had won his spurs by his attacks on Sir Robert Peel, and had been only reluctantly adopted by the Conservatives as their leader in the House of Commons.

Disraeli Prime Minister.

The struggle commenced in 1868 on an Irish question. During the previous years considerable attention had been paid to a secret conspiracy in Ireland and among the Irish in America. The Fenians, as they were called, actually attempted insurrection in Ireland, and an invasion of Canada from the United States. At the beginning of 1866 Lord Russell's Government thought itself compelled to suspend the Habeas Corpus Act in Ireland; and in 1867 Lord Derby's Government was confronted in the spring by a plot to seize Chester Castle, and in the autumn by an attack on a prison van at Manchester containing Fenian prisoners, and by an atrocious attempt to blow up Clerkenwell Prison. Conservative politicians deduced from these circumstances the necessity of applying firm government to Ireland. Liberal statesmen, on the contrary, desired to extirpate rebellion by remedying the grievances of which Ireland still complained. Chief among these was the fact that the Established Church in Ireland was the church of only a minority of the Irish people. In March 1868 Mr Maguire, an Irish Roman Catholic, asked the House of Commons to resolve itself into a committee to take into immediate consideration the affairs of Ireland. Mr Gladstone, in the course of the debate, declared that in his opinion the time had come when the Irish Church, as a political institution, should cease; and he followed up his declaration by a series of resolutions, which were accepted by considerable majorities, pledging the House to its disestablishment. Mr Disraeli, recognizing the full significance of this decision, announced that, as soon as the necessary preparations could be made, the Government would appeal from the House to the country. Parliament was dissolved at the end of July, but the general election did not take place till the end of the following November. The future of the Irish Church naturally formed one of the chief subjects which occupied the attention of the electors, but the issue was largely determined by wider considerations. The country, after the long political truce which had been maintained by Lord Palmerston, was again ranged in two hostile camps, animated by opposing views. It was virtually asked to decide in 1868 whether it would put its trust in Liberal or Conservative, in Mr Gladstone or Mr Disraeli. By an overwhelming majority it threw its lot in favour of Mr Gladstone; and Mr Disraeli, without even venturing to meet Parliament, took the unusual course of at once placing his resignation in the Queen's hands.

Irish Church.

The Conservative Government, which thus fell, will be chiefly recollected for its remarkable concession to democratic principles by the passage of the Reform Act of 1867; but it deserves perhaps a word of praise for its conduct of a distant and unusual war. The emperor of Abyssinia had, for some time, detained some Englishmen prisoners in his country; and the Government, unable to obtain redress in other ways, decided on sending an army to release them. The expedition, entrusted to Sir Robert Napier, afterwards Lord Napier of Magdala, was fitted out at great expense, and was rewarded with complete success. The prisoners were released, and the Abyssinian monarch committed suicide. Mr Disraeli—whose oriental imagination was excited by the triumph—incurred some ridicule by his bombastic declaration that "the standard of St George was hoisted upon the mountains of Rasselas." But the ministry could at least claim that the war had been waged to rescue Englishmen from captivity, that it had been conducted with skill, and that it had accomplished its results. The events of the Abyssinian war, however, were forgotten in the great political revolution which had swept the Conservatives from office and placed Mr Gladstone in power. His Government was destined to endure for more than five years. During that period it experienced the alternate prosperity and decline which nearly forty years before had been the lot of the Whigs after the passage of the first Reform Act. During its first two sessions it accomplished greater changes in legislation than had been attempted by any ministry since that of Lord Grey. In its three last sessions it was destined to sink into gradual disrepute; and it was ultimately swept away by a wave of popular reaction, as remarkable as that which had borne it into power.

Abyssinian war.

It was generally understood that Mr Gladstone intended to deal with three great Irish grievances—"the three branches of the upas tree"—the religious, agricultural, and educational grievances. The session of 1869 was devoted to the first of these subjects. Mr Gladstone introduced a Bill disconnecting the Irish Church from the state, establishing a synod for its government, and—after leaving it in possession of its churches and its parsonages, and making ample provision for the life-interests of its existing clergy—devoting the bulk of its property to the relief of distress in Ireland. The Bill was carried by large majorities through the House of Commons; and the feeling of the country was so strong that the Lords did not venture on its rejection. They satisfied themselves with engrafting on it a series of amendments which, on the whole, secured rather more liberal terms of compensation for existing interests. Some of these amendments were adopted by Mr. Gladstone; a compromise was effected in respect of the others; and the Bill, which had practically occupied the whole session, and had perhaps involved higher constructive skill than any measure passed in the previous half-century, became law. Having dealt with the Irish Church in 1869, Mr Gladstone turned to the more complicated question of Irish land. So far back as the 'forties Sir R. Peel had appointed a commission, known from its chairman as the Devon Commission, which had recommended that the Irish tenant,

Gladstone's first ministry.

Irish land.

in the event of disturbance, should receive some compensation for certain specified improvements which he had made in his holding. Parliament neglected to give effect to these recommendations; in a country where agriculture was the chief or almost only occupation, the tenant remained at his landlord's mercy. In 1870 Mr. Gladstone proposed to give the tenant a pecuniary interest in improvements, suitable to the holding, which he had made either before or after the passing of the Act. He proposed also that, in cases of eviction, the smaller tenantry should receive compensation for disturbance. The larger tenantry, who were supposed to be able to look after their own interests, were entirely debarred, and tenants enjoying leases were excluded from claiming compensation except for tillages, buildings, and reclamation of lands. A special court, it was further provided, should be instituted to carry out the provisions of the Bill. Large and radical as the measure was, reversing many of the accepted principles of legislation by giving the tenant a *quasi*-partnership with the landlord in his holding, no serious opposition was made to it in either House of Parliament. Its details, indeed, were abundantly criticized, but its principles were hardly disputed, and it became law without any substantial alteration of its original provisions. In two sessions two branches of the upas tree had been summarily cut off. But Parliament in 1870 was not solely occupied with the wrongs of Irish tenantry. In the same year Mr Forster, as vice-president of the Council, succeeded in carrying the great measure which for the first time made education compulsory. In devising his scheme, Mr Forster endeavoured to utilize, as far as possible, the educational machinery which had been voluntarily provided by various religious organizations. He gave the institutions which had been thus established the full benefit of the assistance which the Government was prepared to afford to board schools, on their adopting a conscience clause under which the religious susceptibilities of the parents of children were protected. This provision led to many debates, and produced the first symptoms of disruption in the Liberal party. The Nonconformists contended that no such aid should be given to any school which was not conducted on undenominational principles. Supported by the bulk of the Conservative party, Mr Forster was enabled to defeat the Dissenters. But the victory which he secured was, in one sense, dearly purchased. The first breach in the Liberal ranks had been made; and the Government, after 1870, never again commanded the same united support which had enabled it to pursue its victorious career in the first two sessions of its existence.

Elementary education.

Towards the close of the session of 1870 other events, for which the Government had no direct responsibility, introduced new difficulties. War unexpectedly broke out between France and Prussia. The French empire fell; the German armies marched on Paris; and the Russian Government, at Count Bismarck's instigation, took advantage of the collapse of France to repudiate the clause in the treaty of 1856 which neutralized the Black Sea. Lord Granville, who had succeeded Lord Clarendon at the Foreign Office, protested against this proceeding. But it was everywhere felt that his mere protest was not likely to affect the result; and the Government at last consented to accept a suggestion made by Count Bismarck, and to take part in a conference to discuss the Russian proposal. Though this device enabled them to say that they had not yielded to the Russian demand, it was obvious that they entered the conference with the foregone conclusion of conceding the Russian claim. The attitude which the Government thus chose to adopt was perhaps inevitable in the circumstances, but it confirmed the impression, which the abandonment of the cause of Denmark had produced in 1864, that Great Britain was not prepared to maintain its principles by going to war. The weakness of the British Foreign Office was emphasized by its consenting, almost at the same moment, to allow the claims of the United States, for the depredations of the *Alabama*, to be settled under a rule only agreed upon in 1871. Most Englishmen now appreciate the wisdom of a concession which has gained for them the friendship of the United States. But in 1871 the country resented the manner in which Lord Granville had acted. Whatever credit the Government might have derived from its domestic measures, it was discredited, or it was thought to be, by its foreign policy. In these circumstances legislation in 1871 was not marked with the success which had attended the Government in previous sessions. The Government succeeded in terminating a long controversy by abolishing ecclesiastical tests at universities. But the Lords ventured to reject a measure for the introduction of the ballot at elections, and refused to proceed with a Bill for the abolition of purchase in the Army. The result of these decisions was indeed remarkable. In the one case, the Lords in 1872 found it necessary to give way, and to pass the Ballot Bill, which they had rejected in 1871. In the other, Mr Gladstone decided on abolishing, by the direct authority of the Crown, the system which the Lords had refused to do away with by legislation. But his high-handed proceeding, though it forced the Lords to reconsider their decision, strained the allegiance of many of his supporters, and still further impaired the popularity of his Administration. Most men felt that it would have been permissible for him at the commencement of the session, to have used the Queen's authority to terminate the purchase system; but they considered that, as he had not taken this course, it was not open to him to reverse the decision of the Legislature by resorting to the prerogative. Two appointments, one to a judicial office, the other to an ecclesiastical preferment, in which Mr Gladstone, about the same time, showed more disposition to obey the letter than the spirit of the law, confirmed the impression which the abolition of purchase had made. Great reforming ministers would do well to recollect that the success of even liberal measures may be dearly purchased by the resort to what are regarded as unconstitutional expedients.

Black Sea neutrality.

Army purchase.

In the following years the embarrassments of the Government were further increased. In 1872 Mr Bruce, the home secretary, succeeded in passing a measure of licensing reform. But the abstainers condemned the Bill as inadequate; the publicans denounced it as oppressive; and the whole strength of the licensed victuallers was thenceforward arrayed against the ministry. In 1873 Mr Gladstone attempted to complete his great Irish measures by conferring on Ireland the advantage of a university which would be equally acceptable to Protestants and Roman Catholics. But his proposal again failed to satisfy those in whose interests it was proposed. The second reading of the Bill was rejected by a small majority, and Mr Gladstone resigned; but, as Mr Disraeli could not form a government, he resumed office. The power of the great minister was, however, spent; his ministry was hopelessly discredited. History, in fact, was repeating itself. The ministry was suffering, as Lord Grey's Government had suffered nearly forty years before, from the effect of its own successes. It had accomplished more than any of its supporters had expected, but in doing so it had harassed many interests and excited much opposition. Mr Gladstone endeavoured to meet the storm by a rearrangement of his crew. Mr Bruce, who had offended the licensed victuallers, was removed from the Home

1872-1874.

Office, and made a peer and president of the Council. Mr Lowe, who had incurred unpopularity by his fiscal measures, and especially by an abortive suggestion for the taxation of matches, was transferred from the Exchequer to the Home Office, and Mr Gladstone himself assumed the duties of chancellor of the exchequer. He thereby created a difficulty for himself which he had not foreseen: Up to 1867, a minister leaving one office and accepting another vacated his seat; after 1867 a transfer from one post to another did not necessitate a fresh election. But Mr Gladstone in 1873 had taken a course which had not been contemplated in 1867. He had not been transferred from one office to another. He had accepted a new in addition to his old office. It was, to say the least, uncertain whether his action in this respect had or had not vacated his seat. It would be unfair to suggest that the inconvenient difficulty with which he was thus confronted determined his policy, though he was probably insensibly influenced by it. However this may be, on the eve of the session of 1874 he suddenly decided to dissolve Parliament and to appeal to the country. He announced his decision in an address to his constituents, in which, among other financial reforms, he promised to repeal the income tax. The course which Mr Gladstone took, and the bait which he held out to the electors, were generally condemned. The country, wearied of the ministry and of its measures, almost everywhere supported the Conservative candidates. Mr Disraeli found himself restored to power at the head of an overwhelming majority, and the great minister who, five years before, had achieved so marked a triumph temporarily withdrew from the leadership of the party with whose aid he had accomplished such important results. His ministry had been essentially one of peace, yet its closing days were memorable for one little war in which a great soldier increased a reputation already high. Sir Garnet Wolseley triumphed over the difficulties which the climate of the west coast of Africa imposes on Europeans, and brought a troublesome contest with the Ashantees to a successful conclusion.

Disraeli's second ministry.

The history of Mr Disraeli's second Administration affords an exact reverse to that of Mr Gladstone's first Cabinet. In legislation the ministry attempted little and accomplished less. They did something to meet the wishes of the publicans, whose discontent had contributed largely to Mr Gladstone's defeat, by amending some of the provisions of Mr Bruce's licensing Bill; they supported and succeeded in passing a measure, brought in by the Primate, to restrain some of the irregularities which the Ritualists were introducing into public worship; and they were compelled by the violent insistence of Mr Plimsoll to pass an Act to protect the lives of merchant seamen. Mr Disraeli's Government, however, will be chiefly remembered for its foreign policy. Years before he had propounded in *Tancred* the theory that England should aim at eastern empire. Circumstances in his second term of office enabled him to translate his theory into practice. In 1875 the country was suddenly startled at hearing that it had acquired a new position and assumed new responsibilities in Egypt by the purchase of the shares which the Khedive of Egypt held in the Suez Canal. In the following spring a new surprise was afforded by the introduction of a measure authorizing the Queen to assume the title of Empress of India. But these significant actions were almost forgotten in the presence of a new crisis; for in 1876 misgovernment in Turkey had produced its natural results, and the European provinces of the Porte were in a state of armed insurrection. In the presence of a grave danger, Count Andrassy, the Austrian minister, drew up a note which was afterwards known by his name, declaring that the Porte had failed to carry into effect the promises of reform which she had made, and that some combined action on the part of Europe was necessary to compel her to do so. The note was accepted by the three Continental empires, but Great Britain refused in the first instance to assent to it, and only ultimately consented at the desire of the Porte, whose statesmen seem to have imagined that the nominal co-operation of England would have the effect of restraining the action of other Powers. Turkey accepted the note and renewed the promises of reform which she had so often made, and which meant so little. The three northern Powers thereupon agreed upon what was known as the Berlin Memorandum, in which they demanded an armistice, and proposed to watch over the completion of the reforms which the Porte had promised. The British Government refused to be a party to this memorandum, which in consequence became abortive. The insurrection increased in intensity. The Sultan Abdul Aziz, thought unequal to the crisis, was hastily deposed; he was either murdered or led to commit suicide; and insurrection in Bulgaria was stamped out by massacre. The story of the "Bulgarian atrocities" was published in Great Britain in the summer of 1876. Mr Disraeli characteristically dismissed it as "coffee-house babble," but official investigation proved the substantial accuracy of the reports which had reached England. The people regarded these events with horror. Mr Gladstone, emerging from his retirement, denounced the conduct of the Turks. In a phrase which became famous he declared that the only remedy for the European provinces of the Porte was to turn out the Ottoman Government "bag and baggage." All England was at once arrayed into two camps. One party was led by Mr Disraeli, who was supposed to represent the traditional policy of England of maintaining the rule of the Turk at all hazards; the other, inspired by the example of Mr Gladstone, was resolved at all costs to terminate oppression, but was at the same time distrusted as indirectly assisting the ambitious views by which the Eastern policy of Russia had always been animated. The crisis soon became intense. In June 1876 Servia and Montenegro declared war against Turkey. In a few months Servia was hopelessly beaten. Through the insistence of Russia an armistice was agreed upon; and Lord Beaconsfield—for Mr Disraeli had now been raised to the peerage—endeavoured to utilize the breathing space by organizing a conference of the Great Powers at Constantinople, which was attended on behalf of Great Britain by Lord Salisbury. The Constantinople Conference proved abortive, and in the beginning of 1877 Russia declared war. For some time, however, her success was hardly equal to her expectations. The Turks, entrenched at Plevna, delayed the Russian advance; and it was only towards the close of 1877 that Plevna at last fell and Turkish resistance collapsed. With its downfall the war party in England, which was led by the prime minister, increased in violence. From the refrain of a song, sung night after night at a London music hall, its members became known as Jingoes. The Government ordered the British fleet to pass the Dardanelles and go up to Constantinople; and though the order was subsequently withdrawn, it asked for and obtained a grant of £6,000,000 for naval and military purposes. When news came that the Russian armies had reached Adrianople, that they had concluded some arrangement with the Turks, and that they were pressing forward towards Constantinople, the fleet was again directed to pass the Dardanelles. Soon afterwards the Government decided to call out the reserves and to bring a contingent of Indian troops to the Mediterranean. Lord Derby, who was at the Foreign Office, thereupon retired from the ministry, and was succeeded by

Bulgarian "atrocities."

Lord Salisbury. Lord Derby's resignation was everywhere regarded as a proof that Great Britain was on the verge of war. Happily war did not occur. At Prince Bismarck's suggestion Russia consented to refer the treaty which she had concluded at San Stefano to a congress of the Great Powers; and the congress, at which Great Britain was represented by Lord Beaconsfield and Lord Salisbury, succeeded in substituting for the treaty of San Stefano the treaty of Berlin. The one great advantage derived from it was the tacit acknowledgment by Russia that Europe could alone alter arrangements which Europe had made. In every other sense it is doubtful whether the provisions of the treaty of Berlin were more favourable than those of the treaty of San Stefano. On Lord Beaconsfield's return, however, he claimed for Lord Salisbury and himself that they had brought back "peace with honour," and the country accepted with wild delight the phrase, without taking much trouble to analyse its justice.

Berlin treaty.

If Lord Beaconsfield had dissolved Parliament immediately after his return from Berlin, it is possible that the wave of popularity which had been raised by his success would have borne him forward to a fresh victory in the constituencies. His omission to do so gave the country time to meditate on the consequences of his policy. One result soon became perceptible. Differences with Russia produced their inevitable consequences in fresh complications on the Indian frontier. The Russian Government, confronted with a quarrel with Great Britain in eastern Europe, endeavoured to create difficulties in Afghanistan. A Russian envoy was sent to Kabul, where Shere Ali, who had been placed on the throne after the war of 1841, was still reigning; and the British Government, alarmed at this new embarrassment, decided on sending a mission to the Afghan capital. The mission was stopped on the frontier by an agent of Shere Ali, who declined to allow it to proceed. The British Government refused to put up with an affront of this kind, and their envoy, supported by an army, continued his advance. Afghanistan was again invaded. Kabul and Kandahar were occupied; and Shere Ali was forced to fly, and soon afterwards died. His successor, Yakoob Khan, came to the British camp and signed, in May 1879, the treaty of Gandamuk. Under the terms of this treaty the Indian Government undertook to pay the new Ameer a subsidy of £60,000 a year; and Yakoob Khan consented to receive a British mission at Kabul, and to cede some territory in the Himalayas which the military advisers of Lord Beaconsfield considered necessary to make the frontier more "scientific." This apparent success was soon followed by disastrous news. The deplorable events of 1841 were re-enacted in 1879. The new envoy reached Kabul, but was soon afterwards murdered. A British army was again sent into Afghanistan, and Kabul was again occupied. Yakoob Khan, who had been made Ameer in 1879, was deposed, and Abdurrahman Khan was selected as his successor. The British did not assert their superiority without much fighting and some serious reverses. Their victory was at last assured by the excellent strategy of Sir Donald Stewart and Sir Frederick (afterwards Lord) Roberts. But before the final victory was gained Lord Beaconsfield had fallen. His policy had brought Great Britain to the verge of disaster in Afghanistan: the credit of reasserting the superiority of British arms was deferred till his successors had taken office.

Afghan wars.

It was not only in Afghanistan that the new imperial policy which Lord Beaconsfield had done so much to encourage was straining the resources of the empire. In South Africa a still more serious difficulty was already commencing. At the time at which Lord Beaconsfield's administration began, British territory in South Africa was practically confined to Cape Colony and Natal. Years before, in 1852, the British Government, at that time a little weary of the responsibilities of colonial rule, had recognized the independence of the two Dutch republics, the Transvaal and the Orange Free State. Powerful native tribes occupied the territory to the north of Natal and the east of the Transvaal. War broke out between the Transvaal Republic and one of the most powerful of these native chieftains, Secoceni; and the Transvaal was worsted in the struggle. Alarmed at the possible consequences of this defeat, and conscious of their inability to carry on the struggle, a party in the Transvaal openly recommended the annexation of the country to British territory. Sir Theophilus Shepstone, who was sent to inquire into the proposal, mistook the opinion of a party for the verdict of the republic, and declared the Transvaal a part of the British empire. His policy entailed far more serious consequences than the mission to Afghanistan. The first was a war with the Zulus, the most powerful and warlike of the native African tribes, who under their ruler, Cetewayo, had organised a formidable army. A dispute had been going on for some time about the possession of a strip of territory which some British arbitrators had awarded to the Zulu king. Sir Bartle Frere, who had won distinction in India, and was sent out by Lord Beaconsfield's Government to the Cape, kept back the award; and, though he ultimately communicated it to Cetewayo, thought it desirable to demand the disbandment of the Zulu army. In the war which ensued, the British troops who invaded Zulu territory met with a severe reverse; and, though the disaster was ultimately retrieved by Lord Chelmsford and Sir Garnet Wolseley, the war involved heavy expenditure and brought little credit to the British army, while one unfortunate incident, the death of Prince Napoleon, who had obtained leave to serve with the British troops, and was surprised by the Zulus while reconnoitring, created a deep and unfortunate impression. Imperialism, which had been excited by Lord Beaconsfield's policy in 1878, and by the prospect of a war with a great European Power, fell into discredit when it degenerated into a fresh expedition into Afghanistan, and an inglorious war with a savage African tribe. A period of distress at home increased the discontent which Lord Beaconsfield's external policy was exciting; and, when Parliament was at last dissolved in 1880, it seemed no longer certain that the country would endorse the policy of the minister who only a short time before had acquired such popularity. Mr Gladstone, emerging from his retirement, practically placed himself again at the head of the Liberal party. In a series of speeches in Midlothian, where he offered himself for election, he denounced the whole policy which Lord Beaconsfield had pursued. His impassioned eloquence did much more than influence his own election. His speeches decided the contest throughout the kingdom. The Liberals secured an even more surprising success than that which had rewarded the Conservatives six years before. For the first time in the Queen's reign, a solid Liberal majority, independent of all extraneous Irish support, was returned, and Mr Gladstone resumed in triumph his old position as prime minister.

Zulu war.

The new minister had been swept into power on a wave of popular favour, but he inherited difficulties from his predecessors in almost every quarter of the world; and his own language had perhaps tended to increase them. He was committed to a reversal of Lord Beaconsfield's policy; and, in politics, it is never easy, and perhaps rarely wise, suddenly and violently to change a system. In one quarter of

Gladstone's second ministry.

the world the new minister achieved much success. The war in Afghanistan, which had begun with disaster, was creditably concluded. A better understanding was gradually established with Russia; and, before the ministry went out, steps had been taken which led to the delimitation of the Russian and Afghan frontier. In South Africa, however, a very different result ensued. Mr Gladstone, before he accepted office, had denounced the policy of annexing the Transvaal; his language was so strong that he was charged with encouraging the Boers to maintain their independence by force; his example had naturally been imitated by some of his followers at the general election; and, when he resumed power, he found himself in the difficult dilemma of either maintaining an arrangement which he had declared to be unwise, or of yielding to a demand which the Boers were already threatening to support in arms. The events of the first year of his administration added to his difficulty. Before its close the Boers seized Heidelberg and established a republic; they destroyed a detachment of British troops at Bronker's Spruit; they treacherously murdered a British officer; and they surrounded and attacked the British garrisons in the Transvaal. Troops were of course sent from England to maintain the British cause; and Sir George Colley, who enjoyed a high reputation and had experience in South African warfare, was made governor of Natal, and entrusted with the military command. The events which immediately followed will not be easily forgotten. Wholly miscalculating the strength of the Boers, Sir George Colley, at the end of January 1881, attacked them at Laing's Nek, in the north of Natal, and was repulsed with heavy loss. Some ten days afterwards he fought another action on the Ingogo, and was again forced to retire. On the 26th February, with some 600 men, he occupied a high hill, known as Majuba, which, he thought, dominated the Boer position. The following day the Boers attacked the hill, overwhelmed its defenders, and Sir George Colley was himself killed in the disastrous contest on the summit. News of these occurrences was received with dismay in England. It was, no doubt, possible to say a good deal for Mr Gladstone's indignant denunciation of his predecessor's policy in annexing the Transvaal; it would have been equally possible to advance many reasons for reversing the measures of Lord Beaconsfield's Cabinet, and for conceding independence to the Transvaal in 1880. But the great majority of persons considered that, whatever arguments might have been urged for concession in 1880, when British troops had suffered no reverses, nothing could be said for concession in 1881, when their arms had been tarnished by a humiliating disaster. Great countries can afford to be generous in the hour of victory; but they cannot yield, without loss of credit, in the hour of defeat. Unfortunately this reasoning was not suited to Mr Gladstone's temperament. The justice or injustice of the British cause seemed to him a much more important matter than the vindication of military honour; and he could not bring himself to acknowledge that Majuba had altered the situation, and that the terms which he had made up his mind to concede before the battle could not be safely granted till military reputation was restored. The independence of the Transvaal was accordingly recognized, though it was provided that the Republic should remain under the suzerainty of the Queen. Even this great concession did not satisfy the ambition of the Boers, who were naturally elated by their victories. Three years later some Transvaal deputies, with their president, Kruger, came to London and saw Lord Derby, the Secretary of State for the Colonies. Lord Derby consented to a new convention, from which any verbal reference to suzerainty was excluded; and the South African Republic was made independent, subject only to the condition that it should conclude no treaties with Foreign Powers without the approval of the Crown. (For the details and disputes concerning the terms of this Convention the reader is referred to the articles TRANSVAAL and SUZERAINTY.)

Boer war, 1881.

Mr Gladstone's Government declined in popularity from the date of the earliest of these concessions. Mr Gladstone, in fact, had succeeded in doing what Lord Beaconsfield had failed to accomplish. Annoyance at his foreign policy had rekindled the imperialism which the embarrassments created by Lord Beaconsfield had done so much to damp down. And, if things were going badly with the new Government abroad, matters were not progressing smoothly at home. At the general election of 1880, the borough of Northampton, which of late years has shown an unwavering preference for Liberals of an advanced type, returned as its members Mr Henry Labouchere and Mr Bradlaugh. Mr Bradlaugh, who had attained some notoriety for an aggressive atheism, claimed the right to make an affirmation of allegiance instead of taking the customary oath, which he declared was, in his eyes, a meaningless form. The Speaker, instead of deciding the question, submitted it to the judgment of the House, and it was ultimately referred to a select committee, which reported against Mr Bradlaugh's claim. Mr Bradlaugh, on hearing the decision of the committee, presented himself at the bar and offered to take the oath. It was objected that, as he had publicly declared that the words of the oath had no clear meaning for him, he could not be permitted to take it; and after some wrangling the matter was referred to a fresh committee, which supported the view that Mr Bradlaugh could not be allowed to be sworn, but recommended that he should be permitted to make the affirmation at his own risk. The House refused to accept the recommendation of this committee when a Bill was introduced to give effect to it. This decision naturally enlarged the question before it. For, while hitherto the debate had turned on the technical points whether an affirmation could be substituted for an oath, or whether a person who had declared that an oath had no meaning for him could properly be sworn, the end at which Mr Bradlaugh's opponents were thenceforward aiming was the imposition of a new religious test—the belief in a God—on members of the House of Commons. The controversy which thus began continued through the Parliament of 1880, and led to many violent scenes, which lowered the dignity of the House. It was quietly terminated, in the Parliament of 1886, by the firm action of a new Speaker. Mr Peel, who had been elected to the chair, decided that neither the Speaker nor any other member had the right to intervene to prevent a member from taking the oath if he was willing to take it. Parliament subsequently, by a new Act, permitted affirmations to be used, and thenceforward religion, or the absence of religion, was no disqualification for a seat in the House of Commons. The atheist, like the Roman Catholic and the Jew, could sit and vote.

Bradlaugh.

The Bradlaugh question was not the only difficulty with which the new Government was confronted. Ireland was again attracting the attention of politicians. The Fenian movement had practically expired; some annual motions for the introduction of Home Rule, made with all the decorum of parliamentary usage, had been regularly defeated. But the Irish were placing themselves under new leaders and adopting new methods. During the Conservative Government of 1874, the Irish members had endeavoured to arrest attention by organized obstruction. Their efforts had increased the difficulties of Government and taxed the endurance of Parliament. These tactics were destined to be raised to a fine art by Mr Parnell,

Parnell

who succeeded to the head of the Irish party about the time of the formation of Mr Gladstone's Government. It was Mr Parnell's determination to make legislation impracticable and Parliament unendurable till Irish grievances were redressed. It was his evident belief that by pursuing such tactics he could force the House of Commons to concede the legislation which he desired. The Irish members were not satisfied with the legislation which Parliament had passed in 1869-1870. The Land Act of 1870 had given the tenant no security in the case of eviction for non-payment of rent; and the tenant whose rent was too high or had been raised was at the mercy of his landlord. It so happened that some bad harvests had temporarily increased the difficulties of the tenantry, and there was no doubt that large numbers of evictions were taking place in Ireland. In these circumstances, the Irish contended that the relief which the Act of 1870 had afforded should be extended, and that, till such legislation could be devised, a temporary measure should be passed giving the tenant compensation for disturbance. Mr Gladstone admitted the force of this reasoning, and a Bill was introduced to give effect to it. Passed by the Commons, it was thrown out towards the end of the session by the Lords; and the Government acquiesced—perhaps could do nothing but acquiesce—in this decision. In Ireland, however, the rejection of the measure was attended with disastrous results. Outrages increased, obnoxious landlords and agents were "boycotted"—the name of the first gentleman exposed to this treatment adding a new word to the language; and Mr Forster, who had accepted the office of chief secretary, thought it necessary, in the presence of outrage and intimidation, to adopt stringent measures for enforcing order. A measure was passed on his initiation, in 1881, authorizing him to arrest and detain suspected persons; and many well-known Irishmen, including Mr Parnell himself and other members of Parliament, were thrown into prison. It was an odd commentary on Parliamentary government that a Liberal ministry should be in power, and that Irish members should be in prison; and early in 1882 Mr Gladstone determined to liberate the prisoners on terms. The new policy—represented by what was known as the Kilmainham Treaty—led to the resignation of the viceroy, Lord Cowper, and of Mr Forster, and the appointment of Lord Spencer and Lord Frederick Cavendish as their successors. On the 6th May 1882 Lord Spencer made his entry into Dublin, and on the evening of the same day Lord Frederick, unwisely allowed to walk home alone with Mr Burke, the under-secretary to the Irish Government, was murdered with his companion in Phoenix Park. This gross outrage led to fresh measures of coercion. The disclosure, soon afterwards, of a conspiracy to resort to dynamite still further alienated the sympathies of the Liberal party from the Irish nation. Mr Gladstone might fairly plead that he had done much, that he had risked much, for Ireland, and that Ireland was making him a poor return for his services.

Egypt.

In the meanwhile another difficulty was further embarrassing a harassed Government. The necessities of the Khedive of Egypt had been only temporarily relieved by the sale to Lord Beaconsfield's Government of the Suez Canal shares. Egyptian finance, in the interests of the bondholders, had been placed under the dual control of England and France. The new arrangement naturally produced some native resentment, and Arabi Pacha placed himself at the head of a movement which was intended to rid Egypt of foreign interference. His preparations eventually led to the bombardment of Alexandria by the British fleet, and still later to the invasion of Egypt by a British army under Sir Garnet, afterwards Lord Wolseley, and to the battle of Tel-el-Kebir, after which Arabi was defeated and taken prisoner. The bombardment of Alexandria led to the immediate resignation of Mr Bright, whose presence in the Cabinet had been of importance to the Government; the occupation of Egypt broke up the dual control, and made Great Britain responsible for Egyptian administration. The effects of British rule were, in one sense, remarkable. The introduction of good government increased the prosperity of the people, and restored confidence in Egyptian finance. At the same time it provoked the animosity of the French, who were naturally jealous of the increase of British influence on the Nile, and it also threw new responsibilities on the British nation. For, south of Egypt, lay the great territory of the Sudan, which to some extent commands the Nile, and which with Sir Samuel Baker's assistance had been conquered by the Khedive. In 1881 a fanatic sheikh —known as the Mahdi—had headed an insurrection against the Khedive's authority; and towards the close of 1883 an Egyptian army under an Englishman, Colonel Hicks, was almost annihilated by the insurgent soldiery. The insurrection increased the responsibilities which intervention had imposed on England, and an expedition was sent to Suakin to guard the littoral of the Red Sea; while, at the beginning of 1884, General Gordon—whose services in China had gained him a high reputation, and who had previous experience in the Sudan—was sent to Khartum to report on the condition of affairs. These decisions led to momentous results. The British expedition to Suakin was engaged in a series of battles with Osman Digna, the Mahdi's lieutenant; while General Gordon, after alternate reverses and successes, was isolated at Khartum. Anxious as Mr Gladstone's ministry was to restrict the sphere of its responsibilities, it was compelled to send an expedition to relieve General Gordon; and at the close of 1884 Lord Wolseley, who was appointed to the command, decided on moving up the Nile to his relief. The expedition proved much more difficult than Lord Wolseley had anticipated. And, before it reached its goal, Khartum was forced to surrender, and General Gordon and his few faithful followers were murdered. General Gordon's death inflicted a fatal blow on the Liberal Government. It was thought that the General, whose singular devotion to duty made him a popular hero, had been allowed to assume an impossible task; had been feebly supported; and that the measures for his relief had been unduly postponed and at last only reluctantly undertaken. The ministry ultimately experienced defeat on a side issue. The budget, which Mr Childers brought forward as chancellor of the exchequer, was attacked by the Conservative party; and an amendment proposed by Sir Michael Hicks-Beach, condemning an increase in the duties on spirits and beer, was adopted by a small majority. Mr Gladstone resigned office, and Lord Salisbury, who, after Lord Beaconsfield's death, had succeeded to the lead of the Conservative party, was instructed to form a new Administration.

Gordon.

Reform Act, 1884.

It was obvious that the new Government, as its first duty, would be compelled to dissolve the Parliament that had been elected when Mr Gladstone was enjoying the popularity which he had lost so rapidly in office. But it so happened that it was no longer possible to appeal to the old constituencies. For, in 1884, Mr Gladstone had introduced a new Reform Bill; and, though its passage had been arrested by the Lords, unofficial communications between the leaders of both parties had resulted in a compromise which had led to the adoption of a large and comprehensive Reform Act. By this measure, household franchise was extended to the counties. But counties and boroughs were broken up into a number of small constituencies, for the most part returning only one member each; while the necessity of increasing the relative weight of Great Britain, and the reluctance to inflict disfranchisement on Ireland, led to an increase in the numbers of the House of Commons from 658 to 670 members. This radical reconstruction of the electorate necessarily made the result of the elections doubtful. As a matter of fact, the new Parliament comprised 334 Liberals, 250 Conservatives, and 86 Irish Nationalists. It was plain beyond the possibility of doubt that the future depended on the course which the Irish Nationalists might adopt. If they threw in their lot with Mr Gladstone, Lord Salisbury's Government was evidently doomed. If, on the contrary, they joined the Conservatives, they could make a Liberal Administration impracticable.

Home Rule.

In the autumn of 1885 it was doubtful what course the Irish Nationalists would take. It was generally understood that Lord Carnarvon, who had been made Viceroy of Ireland, had been in communication with Mr Parnell; that Lord Salisbury was aware of the interviews which had taken place; and it was whispered that Lord Carnarvon was in favour of granting some sort of administrative autonomy to Ireland. Whatever opinion Lord Carnarvon may have formed—and his precise view is uncertain—a greater man than he had suddenly arrived at a similar conclusion. In his election speeches Mr Gladstone had insisted on the necessity of the country returning a Liberal majority which could act independently of the Irish vote; and the result of the general election had left the Irish the virtual arbiters of the political situation. In these circumstances Mr Gladstone arrived at a momentous decision. He recognized that the system under which Ireland had been governed in the past had failed to win the allegiance of her people; and he decided that it was wise and safe to entrust her with a large measure of self-government. It was perhaps characteristic of Mr Gladstone, though it was unquestionably unfortunate, that, in determining on this radical change of policy, he consulted few, if any, of his previous colleagues. On the meeting of the new Parliament Lord Salisbury's Government was defeated on an amendment to the address, demanding facilities for agricultural labourers to obtain small holdings for gardens and pasture—the policy, in short, which was described as "Three acres and a cow." Lord Salisbury resigned, and Mr Gladstone resumed power. The attitude, however, which Mr Gladstone was understood to be taking on the subject of Home Rule threw many difficulties in his way. Lord Hartington, and others of his former colleagues, declined to join his Administration; Mr Chamberlain, who, in the first instance, accepted office, retired almost immediately from the ministry; and Mr Bright, whose eloquence and services gave him a unique position in the House, threw in his lot in opposition to Home Rule. A split in the Liberal party thus began, which was destined to endure; and Mr Gladstone found his difficulties increased by the defection of the men on whom he had hitherto largely relied. He persevered, however, in the task which he had set himself, and introduced a measure endowing Ireland with a parliament, and excluding the Irish members from Westminster. He was defeated, and appealed from the House which had refused to support him to the country. For the first time in the Queen's reign, two general elections occurred within twelve months. The country showed no more disposition than the House of Commons to approve the course which the minister was taking. A large majority of the members of the new Parliament were pledged to resist Home Rule. Mr Gladstone, bowing at once to the verdict of the people, resigned office, and Lord Salisbury returned to power.

The new Cabinet, which was formed to resist Home Rule, did not succeed in combining all the opponents to this measure. The secessionists from the Liberal party—the Liberal Unionists, as they were called—held aloof from it; and Lord Salisbury was forced to form his Cabinet out of his immediate followers. The most picturesque appointment was that of Lord Randolph Churchill, who was made chancellor of the exchequer, and leader of the House of Commons. But before many months were over, Lord Randolph—unable to secure acceptance of a policy of financial retrenchment—resigned office, and Lord Salisbury was forced to reconstruct his ministry. Though he again failed to obtain the co-operation of the Liberal Unionists, one of the more prominent of them—Mr Goschen—accepted the seals of the Exchequer. Mr W. H. Smith moved from the War Office to the Treasury, and became leader of the House of Commons; while Lord Salisbury himself returned to the Foreign Office, which the dramatically sudden death of Lord Iddesleigh, better known as Sir Stafford Northcote, vacated. These arrangements lasted till 1891, when, on Mr Smith's death, the Treasury and the lead of the Commons were entrusted to Lord Salisbury's nephew, Mr Arthur Balfour, who had made a great reputation as chief secretary for Ireland (*q.v.*).

Unionism.

The ministry of 1886, which endured till 1892, gave to London a county council; introduced representative government into every English county; and made elementary education free throughout England. The alliance with the Liberal Unionists was, in fact, compelling the Conservative Government to promote measures which were not wholly consistent with the stricter Conservative traditions or wishes. In other respects, the legislative achievements of the Government were not great; and the time of Parliament was largely occupied in devising rules for the conduct of its business, which the obstructive attitude of the Irish members made necessary, and in discussing the charges brought against the Nationalist party by the *Times*, of complicity in the Phoenix Park murders. Under the new rules, the sittings of the House on ordinary days were made to commence at 3 P.M., and opposed business was automatically interrupted at midnight, while for the first time a power was given to the majority in a House of a certain size to conclude debate by what was known as the closure. Notwithstanding these new rules obstructive tactics continued to prevail; and, in the course of the Parliament, many members were suspended for disorderly conduct. The hostility of the Irish members was perhaps increased by some natural indignation at the charges brought against Mr Parnell. The *Times*, in April 1887, printed the facsimile of a letter purporting to be signed by Mr Parnell, in which he declared that he had no other course open to him but to denounce the Phoenix Park murders, but that, while he regretted "the accident" of Lord Frederick Cavendish's death, he could not "refuse to admit that Burke got no more than his deserts." The publication of this letter, and later of other similar documents, naturally created a great sensation; and the Government ultimately appointed a special commission of three judges to inquire into the charges and allegations that were made. In the course of the inquiry it was proved that the letters had emanated from a man named Pigott, who had at one time been associated with the Irish Nationalist movement, but who for some time past had earned a precarious living by writing begging and threatening letters. Pigott, subjected to severe cross-examination by Sir Charles Russell (afterwards Lord Russell of Killowen), broke down, fled from justice, and committed suicide. His flight practically settled the question; and an inquiry, which many people had thought at its inception would brand Mr Parnell as a criminal, raised him to an influence which he had never enjoyed before. But in the same year, which witnessed his triumph, his fall was doomed. He was made co-respondent in a divorce suit brought by Captain O'Shea—another Irishman—for the dissolution of his marriage; and the disclosures made at the trial induced Mr Gladstone, who was supported by the Nonconformists generally throughout the United Kingdom, to request Mr Parnell to withdraw from the leadership of the Irish party. Mr Parnell refused to comply with this request, and the Irish party was shattered into fragments by his decision. Mr Parnell himself did not long survive the disruption of the party which he had done so much to create. The exertions which he made to retrieve his waning influence proved too much for his strength, and in the autumn of 1891 he died suddenly at Brighton. Mr Parnell's death radically altered the political situation. At the general elections of 1885 and 1886 the existence of a strong, united Irish party had exercised a dominating influence. As the Parliament of 1886 was drawing to a close, the dissensions among the Irish members, and the loss of their great leader, were visibly sapping the strength of the Nationalists. At the general election of 1892, Home Rule was still the prominent subject before the electors. But the English Liberals were already a little weary of allies who were quarrelling among themselves, and whose disputes were introducing a new factor into politics. The political struggle virtually turned not on measures but on men. Mr Gladstone's great age, and the marvellous powers which he displayed at a time when most men seek the repose of retirement, were the chief causes which affected the results. His influence enabled him to secure a small Liberal majority. But it was noticed that the majority depended on Scottish, Irish, and Welsh votes, and that England—the "predominant partner," as it was subsequently called by Lord Rosebery—returned a majority of members pledged to resist any attempt to dissolve the union between the three kingdoms.

Nationalist split.

On the meeting of the new Parliament Lord Salisbury's Government was defeated on a vote of want of confidence, and for a fourth time Mr Gladstone became prime minister. In the session of 1893 he again introduced a Home Rule Bill. But the measure of 1893 differed in many respects from that of 1886. In particular, the Irish were no longer to be excluded from the Imperial Parliament at Westminster. The bill which was thus brought forward was actually passed by the Commons. It was, however, rejected by the Lords. The dissensions among the Irish themselves, the hostility which English constituencies were displaying to the proposal, emboldened the Peers to arrive at this decision. Some doubt was felt as to the course which Mr Gladstone would take in this crisis. Many persons thought that he should at once have appealed to the country, and have endeavoured to obtain a distinct mandate from the constituencies to introduce a new Home Rule Bill. Other persons imagined that he should have followed the precedent which had been set by Lord Grey in 1831, and, after a short prorogation, have re-introduced his measure in a new session. As a matter of fact, Mr Gladstone adopted neither of these courses. The Government decided not to take up the gauntlet thrown down by the Peers, but to proceed with the rest of their political programme. With this object an autumn and winter session was held, during which the Parish Councils Act, introduced by Mr Fowler, was passed, after several important amendments which had been introduced into it in the House of Lords had been reluctantly accepted by Mr Gladstone. On the other hand an Employers' Liability Bill, introduced by Mr Asquith, the Home Secretary, was ultimately dropped by Mr Gladstone after passing all stages in the House of Commons, rather than that an amendment of the Peers, allowing "contracting out," should be accepted.

Home Rule Bill, 1893.

Before, however, the session had quite run out (3rd March 1894), Mr Gladstone, who had now completed his eighty-fourth year, laid down a load which his increasing years made it impossible for him to sustain (see the article GLADSTONE). He was succeeded by Lord Rosebery, whose abilities and attainments had raised him to a high place in the Liberal counsels. Lord Rosebery did not succeed in popularizing the Home Rule proposal which Mr Gladstone had failed to carry. He declared, indeed, that success was not attainable till England was converted to its expediency. He hinted that success would not even then be assured until something was done to reform the constitution of the House of Lords. But if, on the one hand, he refused to introduce a new Home Rule Bill, he hesitated, on the other, to court defeat by any attempt to reform the Lords. His Government, in these circumstances, while it failed to conciliate its opponents, excited no enthusiasm among its supporters. It was generally understood, moreover, that a large section of the Liberal party resented Lord Rosebery's appointment to the first place in the ministry, and thought that the lead should have been conferred on Sir W. Harcourt. It was an open secret that these differences in the party were reflected in the Cabinet, and that the relations between Lord Rosebery and Sir W. Harcourt were too strained to ensure either the harmonious working or the stability of the Administration. In these circumstances the fall of the ministry was only a question of time. It occurred—as often happens in Parliament—on a minor issue which no one had foreseen. Attention was drawn in the House of Commons to the insufficient supply of cordite provided by the War Office, and the House—notwithstanding the assurance of the War minister (Sir Henry Campbell-Bannerman) that the supply was adequate — placed the Government in a minority. Lord Rosebery resigned office, and Lord Salisbury for the third time became prime minister, the duke of Devonshire, Mr Chamberlain, and other Liberal Unionists joining the Government. The Parliament of 1892 was dissolved, and a new Parliament, in which the Unionists obtained an overwhelming majority, was returned.

Lord Rosebery.

The Government of 1892, which was successively led by Mr Gladstone and Lord Rosebery, will, on the whole, be recollected for its failures. Yet it passed two measures which have exercised and are exercising a wide influence. The Parish Councils Act introduced electoral institutions into the government of every parish, and in 1894 Sir W. Harcourt, as Chancellor of the Exchequer, availed himself of the opportunity, which a large addition to the navy invited, to reconstruct the death duties. He swept away in doing so many of the advantages which the owner of real estate and the life tenant of settled property had previously enjoyed, and drove home a principle which Mr Goschen had tentatively introduced a few years before by increasing the rate of the duty with the amount of the estate. Rich men, out of their superfluities, were thenceforward to pay more than poor men out of their necessities.

It is difficult to recapitulate the history of the Unionist Government of 1895, which (with minor changes) was still in office in 1901. History may hereafter conclude that the most significant circumstance of the period is to be found in the demonstration of loyalty and affection to which the sixtieth anniversary of Queen Victoria's accession led in 1897. Ten years before, her jubilee had been the occasion of enthusiastic rejoicings, and the Queen's progress through London to a service of thanksgiving at Westminster had impressed the imagination of her subjects and proved the affection of her people. But the rejoicings of 1887 were forgotten amid the more striking demonstrations ten years later. It was seen then that the Queen, by her conduct and character, had gained a popularity which has had no parallel in history, and had won a place in the hearts of her subjects which perhaps no other monarch had ever previously enjoyed. There was no doubt that, if the opinion of the English-speaking races throughout the world could have been tested by a plebiscite, an overwhelming majority would have declared that the fittest person for the rule of the British empire was the gracious and kindly lady who for sixty years, in sorrow and in joy, had so worthily discharged the duties of her high position. This remarkable demonstration was not confined to the British empire alone. In every portion of the globe the sixtieth anniversary of the Queen's reign excited interest; in every country the Queen's name was mentioned with affection and respect; while the people of the United States vied with the subjects of the British empire in praise of the Queen's character and in expressions of regard for her person. Only a year or two before, an obscure dispute on the boundary of British Venezuela had brought the United States and Great Britain within sight of a quarrel. The jubilee showed conclusively that, whatever politicians might say, the ties of blood and kinship, which united the two peoples, were too close to be severed by either for some trifling cause; that the wisest heads in both nations were aware of the advantages which must arise from the closer union of the Anglo-Saxon races; and that the true interests of both countries lay in their mutual friendship. A war in which the United States was subsequently engaged with Spain cemented this feeling. The Government and the people of the United States recognized the advantage which they derived from the goodwill of Great Britain in the hour of their necessity, and the two nations drew together as no other two nations had perhaps ever been drawn together in the history of the world.

The two jubilees.

If the jubilee was a proof of the closer union of the many sections of the British empire, and of their warm attachment to their Sovereign, it also gave expression to the "Imperialism" which was becoming a dominant factor in British politics. Few people realized the mighty change which in this respect had been effected in thought and feeling. Forty years before, the most prominent English statesmen had regarded with anxiety the huge responsibilities of a world-wide empire. In 1897 the whole tendency of thought and opinion was to enlarge the burden of which the preceding generation had been weary. The extension of British influence, the protection of British interests, were almost universally advocated; and the few statesmen who repeated in the 'nineties the sentiments which would have been generally accepted in the 'sixties, were regarded as "Little Englanders." It is perhaps needless in this page to refer to the effect which these new ideas had on Oriental politics, whether in China or Turkey. But a few words must be added on the consequences which they produced in Africa. Both in the north and in the south of this great and imperfectly explored continent, memories still clung which were ungrateful to Imperialism. In the north, the murder of Gordon was still unavenged; and the vast territory known as the Sudan had escaped from the control of Egypt. In the south, war with the Transvaal had been concluded by a British defeat; and the Dutch were elated, the English irritated, at the recollection of Majuba. In 1898 Lord Salisbury's Government decided on extending the Anglo-Egyptian rule over the Sudan, and a great expedition was sent from Egypt under the command of Sir Herbert (afterwards Lord) Kitchener to Khartum. Few military expeditions have been more elaborately organized, or have achieved a more brilliant success. The Sudanese forces were decisively beaten, with great slaughter, in the immediate neighbourhood of Omdurman; and Khartum became thenceforward the capital of the new province, which was placed under Lord Kitchener's rule. Soon after this decisive success, a French exploring expedition under Major Marchand reached the Upper Nile and hoisted the French flag at Fashoda. It was obvious that the French could not be allowed to remain at a spot which the Khedive of Egypt claimed as Egyptian territory; and after some negotiation, and some irritation, the French were withdrawn. In South Africa still more important events were in the meanwhile progressing. Ever since the independence of the South African Republic had been virtually conceded by the Convention of 1884, unhappy differences had prevailed between the Dutch and British residents in the Transvaal. The discovery of gold at Johannesburg and elsewhere had led to a large immigration of British and other colonists. Johannesburg had grown into a great and prosperous city. The foreign population of the Transvaal, which was chiefly English, became actually more numerous than the Boers themselves, and they complained that they were deprived of all political rights, that they were subjected to unfair taxation, and that they were hampered in their industry and unjustly treated by the Dutch courts and Dutch officials. Failing to obtain redress, at the end of 1895 certain persons among them contemplated a revolution. Dr Jameson, who was administering the adjacent territory of Rhodesia, accompanied by some British officers, actually attempted an invasion of the Transvaal. His force, utterly inadequate for the purpose, was stopped by the Boers, and he and his fellow-officers were taken prisoners. There was no doubt that this raid on the territory of a friendly state was totally unjustifiable. Unfortunately, Dr Jameson's original plans had been framed with the knowledge of Mr Rhodes, the Prime Minister at the Cape, and many persons thought that they ought to have been suspected by the Colonial Office in London. England at any rate would have had no valid ground of complaint if the leaders of a buccaneering force had been summarily dealt with by the Transvaal authorities. The president of the republic, Mr Kruger, however, handed over his prisoners to the British authorities, and Parliament instituted an inquiry by a select committee into the circumstances of the raid. The inquiry was terminated somewhat abruptly. The committee acquitted the Colonial Office of any knowledge of the plot; but a good many suspicions remained unanswered. The chief actors in the raid were tried under the Foreign Enlistment Act, found guilty, and subsequently released after short terms of imprisonment. Mr Rhodes himself was not removed from the privy council, as his more extreme accusers demanded; but he had to abandon his career in Cape politics for a time, and confine his energies to the development of Rhodesia.

Omdurman, Fashoda.

Jameson Raid.
