PRINTED FOR WILLIAM BLACKWOOD;
AND JOHN WAUGH, EDINBURGH; JOHN MURRAY; BALDWIN & CRADOCK;
J. M. RICHARDSON, LONDON; AND THE OTHER PROPRIETORS.

M.DCCC.XXX.

THE

EDINBURGH ENCYCLOPÆDIA.

FUCI.

The Fuci constitute a tribe of plants commonly included, along with Ulvæ and Marine Confervæ, under the more general title of Submersed Algæ, or *Thalassiophyta*, (from θαλασσιος *marine*, and φυτον *a plant*), and well known in this country by the popular name of Sea Weeds, (a familiar appellation which we shall not scruple to employ). In Scotland, the name *wrack* (probably from the French *varec*) is often applied to those fuci which are cut on the shores for the manufacture of kelp. In the Sexual System, the fuci form part of the third order, Algæ, of the last class Cryptogamia; an order in which Linnæus included Jungermannia, and the other genera now denominated Hepaticæ. In the system of Tournefort, they form part of the second section, *Plantæ marinæ*, &c. of the 17th class, *Aspermæ vulgo habitæ*. The word *fucus*, (φυκος), which means a paint, may be supposed to allude to the quality possessed by some of the small reddish species, of affording a sort of rouge.

Alliances.

It is not easy to class the thalassiophytes with any of the families of land plants. In the most recent systematic works, they are placed after the Tremellæ, with which they are connected by the Ulvæ. To the Lichenes, which follow them, they are more closely allied: So great is the affinity of one little species, Fucus pygmæus,* that in the *Flora Danica* it is described by the name of Lichen confinis, and in the *Methodus Lichenum* of Dr Acharius, as a Stereocaulon. The general resemblance between the rein-deer lichen and two plants figured by Mr Turner, in his *History of Fuci*, F. viscidus, t. 119, and F. amphibius, t. 109, is striking; and the ramuli of F. Chemnitzia, (t. 200), greatly resemble the shields of Parmelia perforata elevated on peduncles. If more illustration be wanting, it may be noticed, that four different species of sea-weed have, at different times, on account of their similarity to lichens, received the trivial name of *lichenoides*.

In some of the fuci, other striking resemblances to certain land plants may be traced; but these are of no importance towards their classification. To creeping land plants, they are allied by a curious family, known by the title of Caulerpæ, to be afterwards described. In general appearance, some fuci resemble filices, and others musci: F. membranaceus, (*Turn.* t. 158), and F. Woodwardia, (*Ner. Brit.* p. 13, t. 6), are very like ferns of the genus Woodwardia; and the frond of F. scalpelliformis, (*Turn.* t. 174), has a great similarity to some mosses of the genus Fissidens.

With the animal kingdom, sea-weeds are connected by F. tomentosus, and F. bursa, (*Turn.* t. 135, 6,) both of which resemble sponges in imbibing water, and giving it out on being pressed; and also in emitting a peculiar disagreeable odour a few hours after being taken from the sea. F. bursa, indeed, is classed, both by Linnæus and Pallas, as a zoophyte. F. simpliciusculus of Turner, (t. 175), and F. lycopodium, (t. 199), approach very near to that class of beings; but, of all others, a small caulerpa, found by Mr Brown in King George's Sound, attached to mytili, and lately figured by Turner, under the title of F. peniculus, (t. 228), forms a link that most closely unites sea-weeds to the animal kingdom.

If it is a difficult task to distinguish and arrange the vegetable productions of the surface of the earth, which can be examined at all seasons, the difficulty is evidently greatly increased in regard to marine plants. In these last the organization is more simple, and consequently they exhibit fewer distinctive characters; and their place of growth almost precludes the possibility of watching their progress and reproduction. Those best able to delineate their characters are often situated at a distance, and must decribe from the examination of specimens not always judiciously selected by others; frequently from such as are torn from the rocks, and thrown ashore in storms, when the root or means of attachment is generally wanting.

History.

The older botanists, such as Clusius, the Bauhins, Barrelier, and Morison, contented themselves with giving very short descriptions, or a few figures of sea plants. About the year 1711, Reaumur first examined the parts of fructification in some fuci. He fell into a mistake similar to that which long prevailed concerning the seeds of ferns and mosses; in considering as seeds what are truly capsules, or tubercles, containing seeds. The opinions of Reaumur seem to have been

Reaumur.

* Excellently figured in Lightfoot's *Flora Scotica*, p. 964, t. 32. (The first time that any species of fucus is mentioned, a good figure of it is, in general, referred to.)

Fuci. History. Linnæus. almost implicitly adopted by botanists down to the close of the 18th century. The celebrated Linnæus had too much to do in reforming the arrangement of phænogamous plants, to pay very great attention to the cryptogamia. His situation at Upsala was certainly not favourable for the investigation of the submersed algæ, and his herbarium contained but comparatively a few species; yet he described near 60 species of fuci. In 1768, Gmelin published, in 4to, his *Historia generalis et specialis Fucorum*, a work in which he not only collected whatever was previously known, but added very considerably to the stock of knowledge. Indeed, considering it as the first general work on this branch of natural history, the author deserves great praise. He divided the plants of which he treated into nine orders: Vesiculosi, Globuliferi, Penicilliferi, Corallini, Membranacei, Radicati, Agara, Tremellæ, and Ulvæ. He described 101 species; of which number he considered 37 as new, for he gives no synonimes with them. Linnæus's name is given to 27 species only. His notions, in general, concerning the fructification of fuci, and particularly the supposition of *unisexual* and *asexual* plants, were rather crude, and have not been adopted.

Gmelin.

Ray. The numerous fuci which inhabit our own shores, have been gradually illustrated by a series of writers since the days of Ray, who enumerated a good many in his *Synopsis*. Those kinds of algæ which Dillenius considered as entitled to a place in his *Historia Muscorum*, which were chiefly Confervæ, he arranged according to general habit and structure. But in the minute kinds, the want of a microscope has often led him into error; for instance, to describe as jointless, plants in which the dissepiments are obvious under an ordinary lens. Withering, in his Arrangement of British Plants, gives descriptions of a number of species. He subdivides the genus into several sections: those with bladders; with pod-like leaves; necklace-like, or jointed; flat; cylindrical; and capillary: the flat he farther distinguishes as either mid-ribbed or ribless; and these he still further separates, as either opake or pellucid: both the cylindrical and capillary he likewise subdivides by the same character of opake and pellucid. Hudson, in his *Flora Anglica*, is remarkable for care and accuracy; in evidence of which it may be mentioned, that his nomenclature is seldom altered by that most scrupulously exact naturalist Mr Turner of Yarmouth, in his writings on this branch of natural history. The descriptions of Lightfoot, in his *Flora Scotica*, when made from specimens picked up by himself, and examined on the spot, are highly characteristic and luminous. The *Nereis Britannica* of Stackhouse, which appeared, in fasciculi, between 1795 and 1802, has very considerable merit. The author had good opportunities of examining the English sea-weeds, as he resided on the shores of Cornwall. He divided the genus Fucus into several genera, chiefly according to the fructification; and although he was but imperfectly acquainted with this, his arrangement deserves attention, and shall be afterwards detailed. Major Velley's figures, which are highly finished, and his dissertation on the propagation of fuci, do him great credit. In the third volume of the Transactions of the Linnean Society, the Bishop of Carlisle and Mr Woodward not only gave a most accurate summary of the state of knowledge with regard to British fuci; but added several new species, and amended the specific characters of others. In the course of editing the extensive periodical work *English Botany*, Sir James Edward Smith likewise added several new species to the list. In 1802, Mr Dawson Turner, of Yarmouth, produced his *Synopsis of British Fuci*, a valuable little work, which gave the most encouraging earnest of what might be expected from this writer, in his great work on fuci, then only projected, but the publication of which is now considerably advanced.

Dillenius. Withering. Hudson. Lightfoot. Stackhouse. Velley. Goodenough and Woodward. Sir J. E. Smith. Turner.

Corréa da Serra. In the Philosophical Transactions for 1796, M. Corréa da Serra, a Portuguese naturalist of merit, published his remarks on the fructification of those fuci which are furnished with distinct receptacles. In the following year, Dr Albert William Roth of Bremen published his *Bemerkungen über das Studium der cryptogamischen Wassergewächse*, in which he divided cryptogamic water plants into new genera, to be afterwards mentioned. In the *Catalecta Botanica* of the same writer, considerable additional light has been thrown on marine plants, particularly by the communications of Professor Mertens of Bremen, characterised by Mr Turner as one of the most able algologists of the present day. Professor Esper's *Icones Fucorum cum characteribus systematicis, &c.* in 4to. appeared in 1799. It is a useful work, though, as the author described and figured from dried specimens only, both his descriptions and representations are occasionally imperfect and unsatisfactory. Professor Weber and the late Dr Mohr, in their *Beiträge zur Naturkunde*, have endeavoured to subdivide the genus Fucus by the character and disposition of the seeds; and in the course of this attempt, have made many excellent observations on this tribe of plants. In 1803, Baron Xavier du Wulfen published a little work, entitled *Cryptogamia Aquatica*, containing some useful information concerning fuci. In the *Flora Danica*, published in folio, at the expence of the Danish government, (a lesson to governments that are more rich and powerful,) a number of fuci, from the shores of the Baltic, and likewise from the distant settlements of that industrious nation, have been figured and described by the successive editors, Oeder, Vahl, and Hornemann. Several other foreign writers have, at various times, contributed to a general knowledge of fuci; particularly the Count Ginanni Ravennate, Bishop Gunner in his *Flora Norvegica*, Rumphius in his *History of Amboyna*, Seba in his *Thesaurus*, and Forskael in the *Flora Ægyptiaco-Arabica*.

Roth. Esper. Weber and Mohr. Wulfen.

French writers. The French have of late distinguished themselves in this branch of natural history. The labours of Decandolle deserve much praise. There is a very good general account of fuci given by M. Poiret, in the botanical part of the *Encyclopedie Methodique*. The *Flora Atlantica* of Desfontaines is a work of great merit. But above all, M. Lamouroux of Agen, now Professor of Natural History at Caen, has studied the fuci with uncommon diligence and success. He published, in 1804, dissertations on several new or rare species; and in 1813 he gave a new arrangement of the family, in the twentieth volume of the *Annales du Museum d'Histoire Naturelle*. Of this arrangement we think it right to give a pretty full account, because at present it is the best. We must however confess, that in our opinion there has been some precipitancy in bringing it before the public. It would certainly have been far better, first to have published descriptions and figures of the many *species ineditæ* referred to by the author, and to have left the classification to the last. This is the plan wisely adopted by Mr Turner; and circumstances seem to intimate, that the French naturalist has not been entirely free of a wish to anticipate our countryman. But, in any case, it may be deemed fortunate for Mr Turner, that M. Lamouroux has actually given his views to the world; for while the can-

Lamouroux.

Fuci. History.

dour of the former will induce him to bestow all due honour on any rival arrangement, we confidently trust that he will not suffer his own sound judgment to be shackled, but will proceed, unembarrassed, on the foundation which he has so well laid, to rear a system worthy of his name; and we are therefore not displeased to find it announced as his opinion, that previously to any permanent classification being established, it will be proper to reduce the present genera, Fucus, Ulva, and Conferva, into one mass, and to proceed in arranging *de novo*.

Turner and Hooker.

The first fasciculus of the *Historia Fucorum*, or General History of Fuci, by Mr Turner, was published in 1807. Above forty fasciculi have now (1815) come out; in which about 240 species have been described and illustrated. We speak the opinion of very competent judges on the Continent when we say, that both the descriptions and the coloured engravings are admirable, and do honour to the country. The latter are chiefly from drawings from the masterly pencil of Mr William Jackson Hooker, well known for his Tour in Iceland, and his beautiful monograph of the Jungermanniæ. Never, as remarked by Sir James Edward Smith, was there a more perfect combination of the skill of the painter and the botanist than in this work. It is meant to include figures of all those plants which have, by Linnæus and subsequent botanists, been arranged under the genus Fucus. Many new species have already been added, communicated by distinguished botanists and travellers, particularly Mr Robert Brown, (the associate of the unfortunate Flinders), who remained for more than a year about Van Diemen's Land and Kent's Islands, and had thus a precious opportunity of collecting the marine plants of those distant countries, which he did not fail to improve. The fuci collected by Lord Valentia and Mr Salt, in the Red Sea, also enrich the work; and Professor Mertens has communicated the Asiatic fuci collected in the first Russian voyage round the world, in the ships Newa and Nadeshda. The distinguished Dr William Wright, of Edinburgh, freely communicated those he had gathered on the shores of Jamaica, during his residence in that island. The illustrious Presidents of the Royal and the Linnean Society (Sir Joseph Banks and Sir J. E. Smith) are likewise contributors. The descriptions by Mr Turner are ample and luminous, and are given both in Latin and English. Particular care is bestowed in illustrating the physiology and fructification, and on this account the work is doubly interesting. In no botanical production was there ever greater attention paid to minute accuracy; and some very general allegations of occasional incorrectness, thrown out by Lamouroux in the *Annales du Museum*, are perhaps sufficiently confuted by this fact—that not one instance of real error is specified by the critic. The names at present attached to the plants by Mr Turner, may, in some measure, be considered as temporary; at least new generic names must be adopted. It is probable, however, that, in the *arrangement* with which he is to conclude his work, few of the specific or trivial names will need to be changed. Every classification of fuci must, in the present state of our knowledge of them, be to a certain extent artificial; but from this author, as near an approach to a natural arrangement as possible, may confidently be expected.

Explanation of Terms.

Before going farther, it seems proper to explain, in a general way, a very few terms, chiefly connected with the fructification of the fuci, as these terms must frequently recur in the subsequent part of this article, and are scarcely to be found explained in elementary books, as applicable to this class of plants.

Receptacle. Plate CCLXI. Figs. 3, 4, 5.

By a *receptacle* is meant a process, often resembling a pod, and generally containing many tubercles, which again contain the seeds, as in Claudea elegans, (Plate CCLXI. Fig. 3.); F. vesiculosus, Fig. 4.; and F. nodosus, Fig. 5. at *a a a*.

Tubercle.

Tubercles are nearly solid, generally roundish, often composed of minute fibres, among which the seeds lie; they frequently resemble pimples or warts, and are often perforated, or marked with a pore; frequently clustered together; sometimes half immersed in the frond; sometimes on short peduncles. See Plate CCLXI. Figs. 3, 4, 5, above referred to; and also Fig. 7.

Fig. 7. Capsule. Figs. 10, 11.

Capsules are seed-vessels, often partly hollow; frequently placed singly; smooth on the surface; sometimes spherical, but often of a lanceolate shape, like minute siliquæ. See Plate CCLXI. Fig. 10. spherical capsules; Fig. 11. lanceolate capsules. In some cases, it may be observed, the terms *tubercle* and *capsule* become nearly synonymous: they seem to be used almost promiscuously by Mr Turner, in speaking of particular species, as F. bracteatus, gigartinus, and kaliformis, (*Turn.* t. 25, 28, 29.)

Vesicle.

Vesicles are the air-bladders, well known in F. vesiculosus, Plate CCLXI. Fig. 4. *b*; and nodosus, Fig. 5. *b*, and others; but these *vesiculæ* have no connection with the fructification.

Previous to the account of Lamouroux's system, it may be right to notice very shortly some of the methods suggested since the time of Linnæus and Gmelin, particularly those of Walker, Stackhouse, Roth, Decandolle, and Wahlenberg.

Dr Walker's Method.

Method of Dr Walker.

The method of Dr John Walker, late professor of natural history in the University of Edinburgh, was never published; but it has been kindly communicated by his friend Mr Charles Stewart (author of Elements of Natural History, in 2 vols. 8vo. 1801, and editor of the new edition of Dillenius's *Historia Muscorum*), as contained in vol. 6th of the Doctor's Adversaria, dated 1771. We trust that we do an acceptable service to botanists in here preserving it. Not that it is preferable to some later methods, but that it constitutes matter of some curiosity, and enables us to trace the progress of the science. It has besides been indirectly alluded to by Mr Turner, in his *Historia Fucorum*, vol. i. p. 96.

Dr Walker divides the submersed algæ into fourteen genera: Cervina, Flabellaria, Bombycina, Annularia, Nodularia, Catenaria, Fucus, Platyceros, Phasganon, Ulva, Chartacea, Plumarium, Neurophyllum, and Spongia. Of these we shall give a very brief account, stating only the essential character, and the description of the fructification; and we think that fairness requires that the characters and descriptions be given in his own words.

The 1st genus *Cervina* or Hornweed, has the following character: "Coriacea, dichotoma, inarticulata. *Fr.* Vesiculæ terminales vel superficiales, sessiles." It is divided into two sections; compressed, as Fucus nodosus, and round, as F. fastigiatus, Lin. (rotundus, *Turn.* t. 5.) By *vesiculæ*, it is scarcely necessary to remark, the author means receptacles: He uses *bullæ* to express air-vesicles.

2d genus, *Flabellaria* or Fanweed: "Coriacea, pen-

Method of Walker.

nata, inarticulata. *Fr.* Vesiculæ rotundatæ solidæ terminales." It is likewise divided into two sections; with air-bladders as F. siliquosus (*Turn.* t. 159); and without air-bladders, as F. pinnatifidus, (t. 20.)

3d, *Bombycina* or Silkweed: "Cartilaginea abulla, inarticulata, ramis filamentosis. *Fr.* Vesiculæ globosæ, solidæ, ramis solidis." This includes Conferva scoparia, C. tomentosa, and similar plants.

4th, *Annularia* or Ringweed: "Cartilaginea annulata, ramis filamentosis. *Fr.* Tuberculæ globosæ solidæ terminales." This is subdivided into several sections, and embraces a number of Confervæ, as C. fucoides and pennata of Hudson.

5th, *Nodularia* or Knob-weed: "Herbacea, viridia, ramis alternis, capillaceis, nodosis. *Fr.* Tubercula ramos per intervalla occupantia." This is divided into sections, with simple filiform fronds, as Conferva plicata of Hudson, and with filiform fronds much branched, as C. glomerata.

6th, *Catenaria* or Chain-weed: "Gelatinosa, ramosa, articulata; articulis tumidis." The fructification was unknown to the author. The genus was divided into several sections, with verticillate, opposite, dichotomous, and alternate branches, and included Ulva articulata of Hudson, Conferva corallinoides of Linnæus, and similar plants.

7th, *Fucus* or Wrack: "Coriaceus, dichotomus, costatus. *Fr.* Vesiculæ terminales, intus gelatinosæ, tuberculis seminalibus rotundis." This is divided into sections; with air-bladders, as F. vesiculosus; without air-bladders, as F. serratus, (*Turn.* t. 90.); and with inflated fronds, as F. inflatus of Linnæus, now ascertained to be a variety only of F. vesiculosus.

8th, *Platyceros*: "Palmatus, dichotomus, enervius. *Fr.* Vesiculæ superficiales, sessiles, sparsæ, subglobosæ." This is subdivided into leathery, membranaceous, and gelatinous, and, according to Dr Walker, embraces F. ceranoides and lacerus of Linnæus.

9th, *Phasganon* or Tangle: "Stipitatum, monophyllum, coriaceum. *Fr.* Vesiculæ superficiales globosæ, gelatinosæ, inter corticem et epidermidem folii tumidæ." This is subdivided into two sections; those which are nerveless or destitute of a midrib, and those which have a midrib. The former section includes Ph. balteiforme, or Sea-belt of Dr Walker, (F. saccharinus, Lin.); Ph. Mariæ or St Mary's thistle, Walk. (F. polyschides, Lightf.); and Ph. esculentum, or Common tang, Walk. (F. digitatus, Lin.) The latter section includes Ph. Scoticum, Walk. or F. esculentus, Lin.

10th, *Ulva*, or Laver: "Sessilis, monophylla, membranacea, enervia. *Fr.* Tubercula intra membranas, Lin." There are three sections, by means of which plants very widely different are brought together: (1.) Frondescent, including U. umbilicalis, or slake; (2.) completely tubular, such as the common U. compressa; and (3.) tubular, divided by septæ, embracing F. filum of Linnæus, afterwards described (*Turn.* t. 86).

11th, *Chartacea*, or Dilse: "Sessilis, monophylla, enervia, palmata, laciniata." The fructification was unknown to Dr Walker. There are two sections; membranaceous and gelatinous. The first includes the common dilse, F. palmatus (*Turn.* t. 115.), with F. prolifer, (*Lightf.* t. 30.) and others: the second, F. gelatinosus of Hudson, the Sea ragged staff of Pallas, 353. It may be observed, that Fucus Sarniensis of Roth, (*Turn.* t. 44.) was known to Dr Walker by the name of Chartacea dichotoma.

12th, *Plumarium*, or Feather-weed: "Stipitatum, cartilagineum, inarticulatum, ramosum, pennatum; fronde composita. *Fr.* Globuli laterales sessiles." This genus is divided into several sections, being cartilaginous or membranaceous, and possessing or wanting a midrib; and includes F. plumosus, (*Turn.* t. 60.) dentatus, (t. 13.) and others.

13th, *Neurophyllum*, or Nerve-weed: "Stipitatum, ramosum; foliis membranaceis distinctis. *Fr.* Tubercula globosa pedunculata, superficie foliorum." F. sanguineus is a good example of this genus, (*Turn.* t. 36.)

Spongia is the last genus of Dr Walker; and he divides sponges into sessile and branched; but it is now generally admitted that they belong to the animal, and not to the vegetable kingdom.

Mr Stackhouse's Method.

Method of Stackhouse.

Mr Stackhouse published his arrangement, in his *Nereis Britannica*, about the year 1797. He formed six genera: Fucus, Palmaria, Chondrus, Sphærococcus, Corda, and Codium; the characters of which are taken chiefly from the fructification, but partly from structure.

1. *Fucus* has this generic character: "Fructification a jelly-like mass, with imbedded seed-bearing granules, and external conical papillæ, terminating." This genus is divided into two sections; with the fruit exserted, as F. serratus and vesiculosus; or innate, as F. loreus, (*Turn.* t. 196.)

2. *Palmaria.* "Skin smooth, glossy, polished on each side, with a colourless mucus within; forming together a thick consistent substance, with the seeds very minute, naked, orbicular, of the colour of the skin of the plant, disposed in patches or in lines, just within the surface of the cuticle." This includes F. digitatus, (*Turn.* t. 162.) and edulis, (t. 114.)

3. *Chondrus.* "Fructification an ovate rigid imbedded pericarp, containing seeds in a clear mucus, and prominent on either surface." This embraces only one species, F. crispus, and its numerous varieties. (*Turn.* t. 216, 217.)

4. *Sphærococcus.* "Fructification, external globular pericarps, adnate or immersed; sessile or pedunculate; containing seeds as in the others." This genus is subdivided into several sections; with distinct leaves, as F. sanguineus; with a midrib, as F. alatus, (*Turn.* t. 160.); with a compressed frond, as F. coccineus; or a round frond, as F. rotundus.

5. *Chorda.* "Fructification a mucous fluid in the hollow part of a cylindrical frond, with naked seeds affixed inwardly." The principal example of this genus is F. filum.

6. *Codium.* "Fructification invisible to the naked eye; frond roundish; soft and spongy when wet; velvety when dry." This embraces only the sponge-like fuci, particularly F. tomentosus, a fine downy or spongy sea-weed found on the south-west shores of England, (*Turn.* t. 135.)

Mr Stackhouse expresses his conviction, that his genera Fucus and Sphærococcus will soon fall to be further divided into several new genera; and he mentions some species having anomalous fructification, particularly F. ligulatus, (*Fl. Scot.* t. 29.) and lycopodiodes, (*Turn.* t. 12.) to which he had not been able to give a place in his arrangement.

Dr Roth's Method.

Method of Roth.

Dr Roth, in his *Catalecta Botanica*, and in his *Re-*

Fuci. Method of Roth.

marks on the Study of Cryptogamic Water Plants, proposes the following genera: Fucus, Ceramium, Batrachospermum, Conferva, Mertensia, Hydrodictyon, Ulva, Rivularia, Linckia, and Tremella. The plants usually denominated sea-weeds, are contained in four of these genera, viz. Fucus, Ceramium, Conferva, and Ulva.

Fucus is characterised thus: "Vesicles (receptacles) aggregate, imbedded in the substance of the frond, and furnished with mucifluous pores."

Ceramium thus: "Plant filiform, substance membranaceo-cartilaginous, with adnate granuliferous capsules." Of this genus there are two divisions: 1st, With uniform capillary fronds, containing some of the more slender fuci, and of the unjointed capsuliferous confervæ; 2d, With the fronds irregularly jointed, comprehending the jointed fuci, and the remainder of the capsuliferous confervæ. It may here be noticed, that Mr Stackhouse at one time, while the French revolutionary wars prevented the naturalists of this country from knowing what was done by their brethren on the Continent, proposed to constitute a very different genus, embracing the broad smooth-fronded fuci, under the title of Ceramium; but that he afterwards dropt that name, and substituted the appropriate one of Palmaria.

The *Confervæ* of Roth, are defined as consisting of small tubes, or herbaceous filaments, with granules of fructification scattered on the inside coats of the tubes; and the *Ulvæ*, as presenting expanded diaphanous membranes, with granules of imbedded fructification principally towards the margins, which the Doctor considered as liable first to decay, and thus to liberate the seeds.

M. Decandolle's Method.

Method of Decandolle.

M. Decandolle, in the *Flora Gallica*, and *Flore Française* (1805), has given an arrangement of the submersed algæ, chiefly founded on the writings of Dr Roth, and M. Vaucher of Geneva. Eleven genera are enumerated: Nostoch, Rivularia, Ulva, Fucus, Ceramium, Diatoma, Chantransia, Conferva, Batrachospermum, Hydrodictyon, and Vaucheria. Of these, Ulva, Fucus, and Ceramium, comprize the sea-weeds.

Ulva includes all those with membranaceous fronds, in which the seeds or capsules are placed under the epidermis, without any means of being discharged but by the destruction of the frond itself. The genus seems rather heterogeneous, and is divided into no fewer than six sections: (1.) Those that are gelatinous within, as F. tomentosus; (2.) Those that are tubular, as the well-known Ulva compressa; (3.) Flat, without peduncle, and without mid-rib, as U. umbilicalis, or laver; (4.) Flat, with a longitudinal mid-rib, as F. membranaceus; (5.) Flat, with a peduncle, as the well-known tangle F. digitatus; (6.) Flat, marked with transverse zones, as U. pavonia.

Fucus is characterized as flat or filiform, with the seeds or capsules united in groups or tubercles, sometimes lateral, sometimes terminal; the seeds being discharged by a distinct external pore. This description takes in a part only of the plants usually considered as fuci, particularly F. vesiculosus, serratus, siliquosus; some having, as already noticed, passed to the genus Ulva, and others, as F. filum, going to the following genus.

Ceramium is distinguished by having filiform fronds, which are either simple or branched, and with or without articulations, bearing tubercles full of globules, which globules appear to be capsules. This includes the species of Dr Roth's second division of Ceramium, with articulations, those of the first being sent back to the genus Fucus: it likewise embraces the marine Confervæ. The genus Conferva of the Flore Française is confined to those fresh-water species which were huddled together by Linnæus, under the name of *Conferva bullata*.

Dr Wahlenberg's Method.

Method of Wahlenberg.

Dr Wahlenberg* proposes the division of the Linnean genus Fucus into three genera, or rather tribes: *Fucus*, properly so called; *Sphærococcon*; and *Palmaria*.

1. *Fucus*: "Semina in capsulis poro dehiscentibus, aggregatis, frondi immersis; simulque adsunt vesiculæ simplices seu articulatæ." This includes F. serratus, vesiculosus, siliquosus, nodosus, loreus.

2. *Sphærococcon*: "Semina in capsulis imperforatis, solitariis, superficialibus; simulque adsunt granula immersa in appendicibus foliorum, fere ut in confervis." This takes in F. sanguineus, alatus, plumosus.

3. *Palmaria*: "Semina solitaria nuda, in frondium superficie." This includes the large fuci, as F. digitatus, and saccharinus, (*Turn.* t. 163.)

He adopts the following subdivisions:

(1.) Frondescent, with a simple mid-rib or nerve in the centre of the frond; as F. serratus and vesiculosus.

(2.) Frondescent, with branched veins or nerves; as F. sanguineus, and sinuosus, (*Turn.* t. 35.)

(3.) Stipitate, with a simple stem, proceeding from a fingered root, and spreading out into a broad frond; as F. digitatus and saccharinus.

(4.) Foliaceous and stemless, membranaceous, without nerves or veins; as F. palmatus, and canaliculatus (*Turn.* t. 3.)

(5.) Caulescent, with distinct fruit-bearing processes, (i. e. receptacles), which are deciduous; as F. siliquosus and nodosus.

(6.) Caulescent, naked and compressed; as F. loreus and plumosus.

(7.) Filiform, with spherical fronds; as F. filum and lycopodiodes.

M. Lamouroux's Method.

Method of Lamouroux.

Lamouroux, far from confining himself to the fructification as the basis of his divisions, derives his characters from every part of the plant, or even from any remarkable accessary circumstance. He divides all the thalassiophytes, into six Orders, viz. Fucaceæ, Florideæ, Dictyoteæ, Ulvaceæ, Alcyonideæ, and Spongodeæ.

1. Fucaceæ.

The *first order*, Fucaceæ, is the most numerous. They are distinguished by their "woody structure, and their colour being somewhat olive, drying to blackish."

Most of the species of this family have distinct stems and leaves. In the stems of the larger kinds, particularly in F. digitatus, may be observed parts analogous to the epidermis, bark, wood and pith of land plants. The Fucaceæ are readily torn in a longitudinal direction, and a well characterized fibrous organization is then displayed. In general the fibres are divided by septa; the partitions being more distant and of a looser texture than in herbaceous plants. In most of the Fucaceæ the organs of fructification are complicated: According to Lamouroux, the *seeds* are inclosed in *capsules*; these

* Georgii Wahlenberg *Flora Lapponica*, Berlin, 1812, 8vo.

Fuci. Method of Lamouroux. FUCACEÆ.

capsules are themselves enveloped by a particular membrane, and form *tubercles*; and these tubercles are grouped into polymorphous *masses*. These masses are attached to the branches or to the extremities of fronds; they contain a mucilaginous matter, the quantity and viscidity of which increase as the seeds ripen; and when they are dispersed, it disappears with them. The fronds of the Fucaceæ vary in composition, situation, general or particular shape, with or without nerves; exhibiting a variety almost as great as the leaves of dicotyledonous plants.

Fucus.

The 1st genus is *Fucus*, which is thus defined: "Tubercles numerous, collected in cylindrical receptacles, which are flat or compressed, solitary or in pairs; the root an expanding callous disk." This character has no doubt the effect greatly to reduce the numbers of the old genus Fucus; but it is still very extensive, and the author has judged it necessary to divide it into no fewer than eleven sections. Plants which materially differ in general aspect and habit are still brought together: thus F. natans, siliquosus, vesiculosus, loreus, and canaliculatus, are arranged under this one genus; while we might expect them to form as many distinct genera. In specifying the different sections, some of the best known or most remarkable species shall be mentioned as examples.

Sect. (1.) With petiolated air-vesicles; leaves distinct, either sessile or petiolated. This includes F. natans and F. bacciferus of Turner, (t. 46, 47.) both of them found floating in the ocean, and forming much of the Mar do Sargasso of the Portuguese. But not one British species falls under this section, unless, perhaps, F. salicifolius of Poiret.

(2.) With petiolated air-vesicles, furnished with a terminal foliaceous membrane; as F. turbinatus, (*Turn.* t. 24.) found in the East and West Indies.

(3.) With oblong vesicles, winged with a triple membrane, producing a three-sided or angular appearance. A single species only belongs to this section, viz. F. triqueter, (*Turn.* t. 34.) from the sea near the Cape.

(4.) With petiolated vesicles lengthening in the form of a pod. Highly characteristic of this section, a well known British species occurs, F. siliquosus; but the *vesicles* or air-bladders may be readily overlooked by a careless observer, on account of their resemblance to the *receptacles* generally to be found on the same plant.

(5.) The vesicles forming a part of the branches; leaves distinct. For example, F. tamariscifolius of Hudson, (F. ericoides, *Turn.* t. 191.)

(6.) Fructification at the ends of the fronds, which are flat, branched, generally provided with a single nerve, and with vesicles. This includes the two very abundant and well known species, F. vesiculosus and serratus.

(7.) Vesicles innate in the branches; the fructification on peduncles. This likewise includes a very general species, F. nodosus.

(8.) Without leaves; vesicles like a string of beads, and covered with the fructification. This section is created solely for the very remarkable sea-weed named by Labillardiere F. moniliformis, and by Mr Turner F. Banksii, (*Hist. Fuc.* t. 1.) The former name is so expressive of the character of the plant, that any change is to be deprecated, particularly as the illustrious President of the Royal Society is already loaded with well merited botanical honours.

(9.) Without vesicles, and with a single round umbilicated frond at the base of the branches.—This section embraces only the remarkable species F. loreus, common on many of our shores, and which attracts attention chiefly on account of the round umbilicated frond above mentioned, which, in the early stage of growth, resembles a large peziza, and gives the rocks the appearance of being covered with a crop of mushrooms.

(10.) Without leaves and without vesicles; fructification at the ends of the branches, which are channelled. —This takes in F. canaliculatus (*Turn.* t. 3.), common on our shores; and F. Mackaii (t. 52.), a species found on the west coast of Scotland, and named in honour of the discoverer Mr James Townsend Mackay, of the College Botanic Garden, Dublin, an excellent and most deserving botanist.

(11.) Without leaves or vesicles; branches cylindrical, with the fructification at the tips; as F. tuberculatus, (*Turn.* t. 7.)

Laminaria.

2. *Laminaria*: "With the root fibrous and branched." This generic character is perhaps objectionable, on the ground that the root is frequently wanting in specimens of sea-weeds which are cast ashore; but, on the other hand, the fructification, from which generic characters are commonly taken, is also frequently wanting, and at any rate it is very little known. Most of the laminariæ are large plants, with broad fronds, inhabiting deep places of the shores, where they are much exposed to the action of waves, and requiring therefore the strong mode of attachment with which they are furnished, and from which the generic character is derived. Some have air-vesicles, as F. pyriferus (*Turn.* t. 110.), and F. buccinalis (t. 139.); and in others, vesicles seem entirely wanting. Not only the gigantic sea-weeds of the Southern Seas, some of them described as more than 1000 feet in length, belong to this genus; the largest of the British fuci also fall under it, the well known great *tangles*, F. polyschides or bulbosus, F. digitatus and saccharinus.

Osmundaria.

3. *Osmundaria*: "Fructifications minute, oblong, on footstalks, situated at the points of the leaves; the leaves entirely covered with small spiny mamillæ."—This genus, named from its resemblance to some ferns of the genus Osmunda, is formed for the sake of one species of trifling size, brought from the shores of New Holland. Till, however, it be examined by some botanist in a recent state, its characters cannot be accurately known.

Desmarestia.

4. *Desmarestia*: "Fructification unknown; branches and leaves broad, contracted at their origin, so as to appear supported on petioles; the edges garnished with small spines."—This includes F. aculeatus (*Turn.* t. 187.), which is very common on our shores, and F. ligulatus (t. 98.), which is rare. Lamouroux, as well as Stackhouse, is inclined to consider the marginal spinules as containing the seeds of the plants; but Mr Turner has doubts on the subject.

Furcellaria.

5. *Furcellaria*: "Fructification pod-shaped, subulated, simple or branched, smooth, stem and branches cylindrical, and without leaves."—This includes only F. lumbricalis (*Turn.* t. 6.) and its varieties.

Chorda.

6. *Chorda*: "Fructification unknown; stem simple, cylindrical, divided by internal dissepiments,"—the *genicula intergerina* of Roth. The name Chorda was first applied by Stackhouse to a small group of fuci, consisting chiefly of F. filum and F. thrix. The latter is now known to be nothing but the filum in a young state; so that at present F. filum is the only species of this genus.

2. FLORIDEÆ.

The *second order*, FLORIDEÆ, are distinguished by their "organization being coralloidal; their colour be-

Fuci. Method of Lamouroux. Floridеæ.

ing purple or reddish, and acquiring lustre on exposure to the air." While fresh and living, the Florideæ are of a purplish red colour, but have nothing of the lustre which they acquire when dead, and when they have been exposed for some time, in a moist state, to the action of light and air, so as that a degree of fermentation may be excited. It is in this order that the double mode of fructification (afterwards described) is chiefly to be observed. The leaves of the Florideæ are flat expansions, divided rather than branched, proceeding from a cylindrical stem, fixed by a disc more convex and less extensive than that of the Fucaceæ. The leaf is just an expansion or continuation of the stem, and it is sometimes difficult to assign the respective limits of these parts. All the flat portions are reckoned leaf, and all the round or compressed parts, branch or stem. Some of the leaves have nerves, of a deeper colour than the rest of the leaf: in these, the fructification is situated on the nerves, or at their extremities. In leaves destitute of nerves, the fructification is spread over the surface of the leaf. The size of the Florideæ is not considerable, none of them much exceeding two feet in length. Lamouroux considers them all as annual or biennial productions.

He makes two divisions: 1st, With flat leaves, Claudea, Delesseria, Chondrus: 2d, With cylindrical leaves, and wanting leaves, Gelidium, Laurencia, Hypnea, Acanthophora, Dumontia, Gigartina, Plocamium, and Champia.

Claudea. 1. *Claudea.* "Tubercles in a pod-shaped receptacle, which is attached to the nerve by its two extremities."—There is only one species, Claudea elegans, which, according to Lamouroux, is the most beautiful of all sea-weeds, for variety of colour, elegance of shape, and delicacy of organization. It is certainly the most curious of all the tribe. (See Plate CCLXI. Fig. 1, 2, 3.) It was found on the coast of New Holland by the unfortunate Peron. The frond consists of a very fine membrane, which when dried is almost invisible to the naked eye, crossed by nerves forming a net-work. The fructification, as stated in the generic character, consists of rows of siliques, suspended by the two extremities between parallel nerves. Dried specimens exhibit fine tints of red, green, yellow, and violet, passing into each other in the most pleasing manner. It is figured in *Annales du Muséum*, tom. 20. pl. 8. fig. 2. from whence our figure in Plate CCLXI. is copied. It is always desirable that a generic name should, if possible, suggest some idea of the kind of plant intended; but although this could easily have been accomplished in the present case, the unmeaning title of Claudea has been imposed;—borrowed, we are told, from the Christian name of Lamouroux's father, *Claude*, and a better proof, surely, of filial attachment than of judicious nomenclature.

Plate CCLXI. Figs. 1, 2, 3.

Delesseria. 2. *Delesseria.* "Tubercles spherical, generally compressed, somewhat like grape-stones (subgigartina), innate, sessile, or pedunculated, situated on the nerves, the branches, the margin of the leaves, or scattered on their surface."—The colours are varied and brilliant. From rose-colour, or even bright scarlet, they descend to dark brown, passing through yellow, green, violet, and purple. Many of them are parasitical on the larger sea-weeds. The genus is subdivided into three sections.

a. With a single longitudinal nerve, simple or branched.—This includes several beautiful species, common on all our shores, F. sanguineus, sinuosus, alatus, and dentatus; with F. ruscifolius, (*Turn.* t. 15.) found on the south coast of England. Speaking of the first of these, F. sanguineus, Mr Turner remarks, that "in the elegance of its appearance, and the exquisite colour of its most delicately veined leaves, this plant so much excels all its congeners, that it carries away the palm with no less justice from the vegetables of the ocean, than the rose, the flower of the poets, from its rivals in the garden."

b. With the longitudinal nerves buried in the substance of the leaves. This takes in F. rubens and laceratus, found on our shores. The former is admirably described and figured by Lightfoot, in the *Flora Scotica*, vol. ii. p. 919. t. 30. under the title of F. prolifer. The latter is one of the variable fuci, Mr Turner (*Hist. Fuc.* t. 68.) describing no fewer than eight varieties. It is F. endiviæfolius of the *Flora Scotica*, t. 32. and it is to be observed that the longitudinal veins not being readily perceived, have been overlooked by Lightfoot and others.

c. Without any nerve or midrib. This includes the well-known F. palmatus, or *dilse* of Scotland, with the remarkably variable F. ciliatus, (*Turn.* t. 70.) which is also eaten; as well as F. edulis, (t. 114.) which, as implied in the trivial name, is considered as fit for food. F. Brodiæi of Turner, t. 72. likewise falls under this section: this species was found on the shores of Nairnshire, by Mr Brodie of Brodie, who likewise detected its fructification, and ascertained the specific differences of the plant.

Chondrus. 3. *Chondrus.* "Tubercles hemispherical or oval, situated on the surface of the leaves, never on the edges nor the extremities; leaves flat, branched, sometimes mamillary."—The generic name, it will be observed, is adopted from Stackhouse; but the character is changed. The small black lichen-like fucus, F. pygmæus, which covers many of our sandstone and greenstone rocks at high-water mark, belongs to this genus.

Gelidium. 4. *Gelidium:* "Tubercles nearly opake, oblong, situated on the branches or at their extremities." The generic name is derived from the quality which the plants possess, of being almost entirely reduced to a gelatinous substance, by boiling or maceration. The foreign species of which the swallows in India construct the edible nests, Lamouroux considers as belonging to this genus. F. corneus (*Stackh.* p. 61. t. 12.) and F. coronopifolius (*Turn.* t. 122.) rarely found on the English coast, are likewise gelidia.

Laurencia. 5. *Laurencia:* "Tubercles globular, somewhat like grape-stones, situated at the extremities of the branches and their divisions." F. pinnatifidus, the pepper-dilse of Scotland, may be mentioned as an example.

Hypnea. 6. *Hypnea:* "Tubercles subulated, almost opake." This is named from its general resemblance to the branched mosses or hypnums; but the fructification is not readily seen without a lens. F. Wigghii, (*Turn.* t. 102.) belongs to this genus. All the species are annuals.

Acanthophora. 7. *Acanthophora:* "Tubercles roundish, and spiny." The species of this genus are equatorial plants, in general appearance resembling Hypneæ.

Dumontia. 8. *Dumontia:* "Capsules solitary, scattered, innate in the substance of the plant; stem and branches fistular." The species are all of very delicate structure, and annuals.

Gigartina. 9. *Gigartina:* "Tubercles spherical or hemispherical, sessile, like grape-stones, filled with a semitransparent mucilaginous substance; stem uniformly cylindrical."—This includes most of the genus Ceramium of Roth. It is divided into three sections.

a. With distinct leaves; as F. subfuscus (*Turn.* t. 10.) and tenuissimus, (t. 100.) not uncommon on our shores.

Fuci. Method of Lamouroux. Florideæ.

b. Without leaves; stem and branches without contractions; as F. confervoides, (*Turn.* t. 84.) purpurascens (t. 9.) and plicatus (t. 180.) of our shores.

c. With evident contractions, as F. kaliformis, (*Turn.* t. 29.), articulatus (t. 106.), and opuntia (t. 107.) of the British shores.

Plocamium. 10. *Plocamium:* "Tubercles somewhat like grapestones; stems and branches compressed, the extremities partitioned, or divided by septa."—The plants of this genus approach nearest to the truly articulated sea-weeds or marine confervæ. They are all annual; and many of them parasitical on the perennial species. The elegant F. plumosus of our shores belongs to this genus; and the dissepiments in the extreme branches, or pinnæ, are beautifully delineated by Mr Turner, (*Hist. Fuc.* t. 60.) It must, however, be remarked, that though this new genus is evidently named from F. plocamium of Gmelin (F. coccineus of Hudson and others); yet this species, instead of affording a characteristic example of the genus, exhibits no traces of dissepiments in its branchlets.

Champia. 11. *Champia:* "Capsules numerous, somewhat egg-shaped; situated in papillæ rising from the stem and branches."—This consists only of one species, a native of the shores of the Cape of Good Hope.

3. Dictyoteæ. The *third order*, Dictyoteæ, is distinguished by the "organization being reticulated and foliaceous; the colour greenish, and not liable to become black on exposure to the air." This family consists of four genera, Amansia, Dictyopteris, Dictyota, and Flabellaria, all of them well characterized by the reticulated organization, which is visible with a common lens, or even by the naked eye. The fructifications are numerous, covering the surface of the leaves, on which they occur in groups of various shapes. The root consists of a fibrous callosity, furnished with very fine long whitish hairs, which become yellowish or brown in drying. In some species these hairs extend up the stem, or are continued on one side of the frond. They increase in number with the age of the plant. They seem analogous to the tufts observable on F. serratus, vesiculosus, and natans, and are probably secreting and absorbing organs. The dictyoteæ, which have nerves or midribs, are perennial, and are found chiefly in equatorial latitudes: those destitute of nerves are annual, and found chiefly in the northern seas.

Amansia. 1. *Amansia:* "Reticulations hexagonal, regular and elongated, with the points acute."—The species are foreign.

Dictyopteris. 2. *Dictyopteris:* "Capsules forming masses slightly elevated; scattered over the leaves, which are divided by a single nerve."—All the species are natives of warm climates.

Dictyota. 3. *Dictyota:* "Capsules collected in masses, forming lines having various directions."—This is divided into two sections: a. *Padina*, with the fructification in transverse, incurvated, and concentric lines: b. *Dictyota* proper, with the fructification in longitudinal lines, rarely transverse and never concentric, often entirely or partially scattered. The padina are analogous to the *fuci corallini* of Gmelin, and include those species which the late M. Draparnaud proposed to associate as a genus, under the title of *Zonaria.*

Flabellaria. 4. *Flabellaria:* "Fructification unknown; reticulations very fine and intermixed, so as to produce an appearance of felt."—This includes only one species, found in the Mediterranean.

4. Ulvaceæ. The *fourth order*, Ulvaceæ, is distinguished by the "organization being herbaceous and uniform, the colour green, becoming yellowish or whitish in drying."—This order comprises four genera, Asperococcus, Ulva, Bryopsis, and Caulerpa. It includes most of the species of the genus Ulva of Linnæus and others. The organization resembles that of the seminal leaves of many land plants, a herbaceous tissue destitute of fibres and vessels. The plants of this order abound with a mucilaginous matter, in which the colouring principle resides. The nature of the fructification is not yet accurately known. It is apparently very simple, seeming to consist of naked seeds imbedded in the frond at its surface. The bodies which have been taken for seeds, however, may in reality prove to be capsules, containing granules or seeds.

Fuci. Method of Lamouroux. Ulvaceæ.

1. *Asperococcus:* "Seeds solitary, scattered, at first innate, but afterwards prominent; stems fistular."—Of this genus, Ulva rugosa, Lin. may be considered as an example. Asperococcus.

2. *Ulva:* "Seeds solitary, innate in the substance of the plant, scattered, never prominent."—This genus is divided into two sections: Ulva.

a. With flat leaves; as U. lactuca, latissima, umbilicalis, all very common on our shores.

b. With fistular leaves; as U. compressa, which covers with its fine green colour almost all rocks where brackish water occurs.

3. *Bryopsis:* "Seeds globular, green, contained in the stem, or the branches, which are always fistular."—All the species are foreign. Bryopsis.

4. *Caulerpa:* "Fructification unknown; stem cylindrical, horizontal, creeping, and branched."—This is a curious genus, first described and figured in the French *Annals of Botany* for 1811, by M. Lamouroux. It is not clearly ascertained whether some, or perhaps even all the species, should not rather be considered as belonging to the animal than to the vegetable kingdom. The organization certainly differs from that of marine plants in general, and is more analogous to that of some zoophytes. Weber and Mohr rightly remark, that the stiff straw-coloured stem of a caulerpa exhibits few traces of vegetable organization. Even with the aid of a microscope, neither fibres nor reticulations can be detected; an epidermis is observable, and a cellular tissue, the cells of which are so extremely minute, that it is impossible to determine their form. The caulerpæ are destitute of any gelatinous or viscid property. Their membranaceous substance, and their uniformly green colour, have induced Lamouroux to place them among the Ulvaceæ. Sometimes the leaves of a particular species, Caulerpa prolifera, are partly covered with small opake points; such leaves have not the brilliancy nor half the transparency of the others; they are of a dull earthy green colour. If these points prove to be seed-vessels, then is Caulerpa properly placed among the Ulvaceæ; but the fructification is at present completely unknown. The roots are entirely fibrous, like those of many of the flexible zoophytes. The Caulerpæ grow, not on rocks, but on sandy shores, generally near high water mark, creeping in the loose sand and soil; and no other sea-weeds possess a similar mode of attachment. Viewed as plants, they may be considered (as formerly stated) as connecting sea-weeds with the vegetables of the earth. All the species are foreign, most of them tropical. When fresh, they are of a fine grass-green colour, which is liable to pass to a transparent horny white. Several of them are figured by Turner, under the names of F. pinnatus, taxifolius, clavifer, (*Hist. Fuc.* t. 53, 54, 57); and he has added some, entirely unknown to Lamouroux. Among these may be mentioned. Caulerpa.

F. cactoides, (t. 171.) brought by Mr Brown from the south coast of New Holland; and F. hypnoides, (t. 173.) brought from Kent's Islands by the same naturalist. This last is not only singular for its beauty, but is very remarkable for the exterior of the stem being closely beset with small scales, like some of the fern tribe: to this there is nothing analogous among the rest of the fuci; the appearance of scales in F. squamulosus (*Turn.* t. 128.) being occasioned merely by the remains of old ramuli. The other new species of Caulerpa published by Turner, were brought from the Red Sea by Mr Salt, and are likewise very curious. The Caulerpæ appear to be perennials, or at least to endure for more than one year. We may remark, that the sea-weed of a fine green colour, described by Humboldt as found growing in the sea at the great depth of 192 feet, and by him named Fucus vitifolius, belongs to this genus.

5. ALCYONIDEÆ. The *fifth order*, ALCYONIDEÆ, is characterised by the "organization being gelatinous, or like that of a tremella, of a dirty olive red colour, becoming darker on exposure to the air." The Alcyonideæ evidently approach very near to the zoophytes of the genus Alcyonium; but neither polypi, nor the habitations of polypi, are to be observed in them. A transverse section of these plants, exhibits large hexagonal or irregular reticulations, which diminish in size towards the sides of the stem. In a longitudinal section, these reticulations appear lengthened, and form at the exterior a very fine epidermis. The fructification of this order is conspicuous enough. It consists of yellowish capsules, situated in the epidermis, and full of small black seeds. The Alcyonideæ have considerable affinity to the genus Dumontia of the Florideæ, above described. They decompose rapidly when left by the tide on the shore. Their texture is so loose, that when once dried and compressed, they never resume their original form.

Alcyonidium. The only genus is *Alcyonidium*: "Capsules containing seeds, innate in the fleshy or gelatinous substance of the plant." The principal species is the Ulva diaphana of former writers, (*Eng. Bot.* t. 263), and which is not uncommon on our shores. It is remarked by M. Lafoy, that, at certain times of the year, the Ulva diaphana is phosphorescent; but this fact has not been accurately ascertained, and it is possible that the phosphorescence alluded to, may depend merely on numbers of a minute shining nereis adhering to the plant, when newly cast ashore, or drawn from the sea. We have frequently observed a brilliant phosphorescent appearance produced by this cause, in specimens of Fucus dentatus, and in various species of Sertulariæ, recently taken from the sea, the phosphorescence being renewed upon moving the specimens, or disturbing the minute animals.

SPONGODEÆ. The *sixth order*, SPONGODEÆ, has this character: "Organization spongy, colour green, tarnishing on exposure to the air." This order, as published by Lamouroux, consists only of a single genus, which Olivi, a distinguished Italian naturalist, proposed in his *Zoology of the Adriatic Sea*, under the name of Lamarckia. This name, however, having been pre-occupied by a genus of phænogamous plants, Stackhouse suggested Codium. Lamouroux has preferred *Spongodium*, on account of the general resemblance of the plants which constitute the genus, to some kinds of sponges, and because, like them, they imbibe water. It has this character: "Seeds scattered through the substance of the plant, but most abundant at the extremities of the filaments which clothe its surface." One of the principal species is Spongodium dichotomum, the Fucus tomentosus of former authors, figured in *English Botany*, t. 712, and in the *History of the Fuci*, t. 135. The substance of the plant consists of a collection of interwoven fistular tubes, full of a transparent fluid. The surface, as noticed in the character, is covered with small capillary filaments, which seem to serve for the absorption of water, and among which vesicles and capsules are to be looked for. These filaments are best observed while the plant remains in the sea: when it has been withdrawn for some time from that element, they nearly disappear. The colour is a dark grass green, which becomes paler by drying. It may be proper to add, that the Fucus fungosus, found on the coast of Barbary by Desfontaines, and described in the *Flora Atlantica*, is to be considered as only a variety of F. tomentosus. Another species of Spongodium is Fucus bursa of our shores, (*Turn.* t. 136.) the Alcyonium bursa of Linnæus. It may here be mentioned, that since the publication of Lamouroux's system, Turner has described and figured (*Hist. Fuc.* t. 175) a new spongodium, by the title of *Fucus simpliciusculus*, a name which is to be understood as applicable only in a relative sense, being meant to distinguish it from either the dichotomous ramification of F. tomentosus, or the spherical shape of F. bursa. Instead of having a soft velvety exterior like these, it is papillose; but its internal structure is quite similar. Turner remarks, that F. simpliciusculus, in external appearance, closely resembles the caulerpæ, having the same colour, the same glossy surface, and the same kind of substance, intermediate between the submersed algæ and the zoophytes, or even approaching more to the nature of the latter than of the former. The spongodeæ appear to last more than one year. They inhabit places never completely uncovered by the tide. They are nearly allied to the Ulvaceæ, and might perhaps commodiously follow them.

In Lamouroux's arrangement of sea-plants which has now been detailed, no fewer than 273 ascertained species are referred to by the author. There are, besides, near 200 unpublished species alluded to by him: of 20 of these, figures are given in the *Annales*, but no descriptions; and when, or in what form, the remainder are to be brought before the public, does not appear. There are nearly 100 *varieties* of different species mentioned; but in no tribe of plants is there greater difficulty in determining the limits between species and varieties; it will be nowise surprizing, therefore, if several of these varieties be hereafter established as species; and, on the other hand, a few of the species degraded to the rank of varieties. Marine plants are not only liable to very considerable diversity of form, but, as already noticed, it is nearly impossible to cultivate them with a view to observe their germination, and extremely difficult even to watch their progress, on their native submarine rocks, from infancy to maturity. Of the ascertained species, 148 are found on the shores of France.

In the course of our ample account of Lamouroux's arrangement, a number of particulars connected with the general history and physiology of these plants have been incidentally stated. There remain, however, several points deserving of further and separate consideration, particularly their germination and growth, their general structure, and the nature of their fructification.

Notwithstanding the many observations of late inquirers, in no department of natural history does there

Fuci.

remain greater room for discovery, than in tracing the progress of living fuci. The *habitat* of the plants presents many difficulties. It is only in a few favourable situations, in calm weather, and at low ebb tides, that observations can be made either as to the earliest appearance of the plants when germinating, or as to the progress of the fructification, and shedding of the seeds in the mature plant. To afford any satisfactory information, individual plants must be watched, visited at every season of the year, and the observations must be continued for a series of years.

Germination and Fructification of Fuci.

Germination.

Mr Stackhouse, we believe, is the only person who has succeeded in vegetating the seeds of fuci, or in convincing himself that he has done so; for doubts have been started as to the accuracy of his experiments. So extremely minute are the real seeds, and so great is the liability to error from other seeds floating unperceived in the waters of the ocean, that to prosecute discovery in this way, would probably be a hopeless task. It may be right, however, to state his mode of proceeding. He selected three species for his experiments, Fucus serratus, canaliculatus, and bifurcatus, (by which last, F. tuberculatus is to be understood.) He detached some specimens of these very carefully from the rocks, preserving their bases or roots uninjured. He placed them in wide-mouthed jars, and changed the water every twelve hours, drawing it off by means of a syphon, to prevent agitation. In the course of a week he succeeded in procuring what he considered to be the seeds. These, when ripe, he says, burst asunder transversely in the middle, with a kind of explosion. They appear therefore to have been, in reality, capsules containing seeds. They were inclosed in a bright mucus, immiscible with sea water, and likewise specifically heavier than it; so that this mucus was calculated to serve the double purpose of carrying the seeds to the bottom, and fixing them to the rocks. He thus ascertained that some marine plants scatter their seeds when ripe, without awaiting the decay of the frond. The next point was to cause the seeds to germinate. He took some pebbles and small fragments of rock from the beach, the surfaces of which he considered as having been thoroughly purified by friction; and after having drained off the greater part of the water in the jars, he poured the remaining drops on the stones. He left them to dry for some time, that the seeds might fix themselves. He then placed the stones in wide-mouthed jars, and alternately sunk them for some hours in sea-water, and exposed them to the air and rain, in order to imitate their peculiar situation between high and low water mark. In less than a week, a thin membrane was discoverable on the stones, precisely on the spots where the drops of water containing the seeds had been poured, and where of course the seeds had lodged. This membrane gradually extended itself and became of a blackish olive colour. There at last appeared mucous papillæ or buds coming up from the membrane. These buds were somewhat hollow in the centre, from whence a shoot pushed forth: in some instances they seemed to rise on a short thick footstalk, and in this case resembled minute pezizæ, favouring the supposition that other fuci besides F. loreus present at their base the mushroom appearance, though on a very reduced scale.

Fructification.

Till within these few years, the fructification of the fuci was little known; and even yet it is not by any means well understood. To the minute and accurate investigations of Mr Turner, Mr Hooker, Sir J. E. Smith, the late Miss Hutchins, and Mr Sowerby, jun. we are much indebted. But the fructification of the largest species in the world, F. pyriferus and buccinalis, and even of some of the largest and most common British species, such as F. digitatus, filum, and aculeatus, still remains to be discovered. Of the nature of the fructification of the caulerpæ, no conjecture has hitherto been formed.

By attending to the characters in Lamouroux's arrangement, a general idea may be gathered of the families of fuci in which the different kinds of fructification occur, whether consisting of receptacles, tubercles, capsules, or patches. It seems unnecessary, therefore, to enlarge much on this subject. A few farther remarks on the *double mode of fructification*, may however be proper. This double mode, it will be remembered, occurs either on the same plant, or on separate individuals of the same species; and it is of various kinds, some of which may be mentioned.

Double mode of fructification.

a. On different individuals of the same species, globular capsules and lanceolate capsules are observed, as in F. subfuscus, alatus, pinastroides (*Turn*. t. 11.), and coccineus: (see Plate CCLXI. Fig. 10, 11.) and both these kinds of capsules sometimes occur on the same frond of the last named species. This fact did not escape Mr Stackhouse; for in his *Nereis Britannica*, he makes it part of the specific character of F. coccineus, that it bears polymorphous fructification; and Mr Turner, in his *Synopsis*, afterwards divided it into two varieties, one with spherical capsules, the other with lanceolate or elliptical capsules.

Plate CCLXI. Figs. 10, 11.

b. On the same individual, lineari-lanceolate capsules, and also pedunculate capsules of an urceolate form, as in F. dentatus. (Plate CCXLI. Fig. 8, 9.) Figs. 8, 9.

c. Lanceolate capsules and small patches of naked seeds are found on the same plant; as in F. hypoglossum, (*Turn*. t. 14.)

d. Ovate capsules and spherical immersed seeds, on the same individual; as in F. dasyphyllus, (*Turn*. t. 22.)

e. Ovate and oblong capsules, on the same plant; as in F. acanthophorus of Lamouroux, (*Turn*. t. 32.)

f. Cilia containing seeds, on the margins and midrib of the plant; and spherical tubercles immersed in obovate processes on different parts of the plant; as in F. sinuosus. (Plate CCLXI. Fig. 6, 7.) Figs. 6, 7.

g. Urceolate sessile capsules on one plant, and naked seeds immersed in the frond on another plant of the same species; as in F. articulatus. It is a remark of M. Lamouroux, that the double fructification is never found on the truly articulated sea-weeds, that is, the marine confervæ: but in this he seems mistaken, as the double mode occurs in the plant named Fucus fruticulosus, (*Turn*. t. 227), which, as Mr Turner properly remarks, belongs to the confervæ.

In a few capsuliferous species, as F. plumosus and flaccidus, (*Turn*. t. 61), the seeds, or what are reckoned the seeds, are not inclosed in proper capsules, but merely surrounded by setæ, producing the appearance of an involucrum. In the large species, F. saccharinus and bulbosus, the fructification is in irregular patches on the frond, and consists of a profusion of seeds imbedded among whitish fibres, but without any covering or epidermis. Mr Brodie of Brodie, in a communication to Mr Turner, (*Hist. Fuc*. vol. iii. p. 62.) very aptly compares a section of the last-named species when in fruit, and placed under the microscope, to a section of a syngenesious flower, with the seeds protruding from the receptacle among the bristly pappus.

It has already been stated, that in some species there are found both seeds in tubercles, and seeds scattered in the substance of the frond. Mr Turner was at one time of opinion, that the seeds in the tubercles might become subsequently disseminated through the frond; but more careful examination with the microscope, enabled him to satisfy himself that the capsular granules differ as to shape from those which lie naked in the frond.

He is inclined to believe, that those plants on which the two modes of fructification occur on different individuals, are truly diœcious, though a plant, possessing each mode of fructification, may frequently arise from the same basis, and thus occasion ambiguity. Dr Solander, it may be remarked, first suggested that these might be male and female. It would evidently be almost a hopeless attempt, to endeavour to observe the mode of impregnation in their native element; and it is not improbable that this may for ever remain among the arcana of nature.

A few species have a proliferous tendency, putting forth peltate leaves, ready to lengthen into branches, if the plant have sufficient vigour. Mr Turner seems to think it probable, that, like the bulbs of allia, these new productions may fall off when the frond decays, and shoot up into independent individuals. Some species, that have broad terminal receptacles, have been observed occasionally to become viviparous, particularly F. vesiculosus and serratus; the seeds vegetating while in the receptacles, and thus producing the viviparous character.

Seeds of Fuci.

We have already seen, that what Stackhouse considered as seeds, were probably capsules, as they burst asunder and discharged smaller bodies. Turner makes the remark, that the seeds of different species have been observed to discharge very minute granular globules; and with that candour and diffidence which distinguish the accurate observer, he confesses his doubts whether the small bodies, generally accounted seeds, may not themselves be seed-vessels. It may be remarked, indeed, that his representation of the bursting of a *capsule*, (*Hist. Fuc.* t. 181.), and his figure of a *seed* pouring out its contents, (t. 61.), bear the greatest resemblance to each other. The seeds of fuci, in general, must be very minute: they seem to abound imperceptibly in the sea, as the impalpable seeds of fungi, musci, and lichens, do in the air.

In most of the tuberculiferous fuci there are visible, besides the seeds, and intermixed with them, numerous elliptical *pellucid granules*, much more minute than the seeds; together also with many small *jointed fibres*, among which the seeds and pellucid granules lie imbedded.

Duration of Fuci, and their Rapidity of Growth.

Duration.

The fuci, like land plants, reach maturity in different spaces of time, and endure for different periods. Many of the smaller and more delicate are annual; others of the herbaceous kind seem to be biennial, or at least frequently perish at the end of the second season; and many continue for several seasons. Those with stems of woody texture endure for a considerable number of years, in situations where they are protected from the violence of the waves during storms. Old stems of Fucus digitatus are frequently to be observed, not only completely invested with parasitic fuci, confervæ, and flustræ, like old trees with lichens and mosses, but with the epidermis and bark become split and rough, and loosened from the woody part of the stem.

The well known Fucus saccharinus has been observed to renew its frond in a very curious way, the new growth proceeding from the base, and pushing before it the old frond after it has discharged its office, in the same way as the human nails are renewed. "The plant," observes Mr Turner, "thus acquires a perennial growth, and as Tibullus beautifully says of the serpent, *novus exuit annos.*" It is the opinion of Mr Turner, that Fucus agarum (t. 75.) renews its frond in the same way.

In judging whether a fucus belongs to the class of annuals or perennials, besides attending to the general structure and habit, Lamouroux has pointed out another mark: he has very commonly found, that those fuci, which bear their fructification on the branches, are perennial, while those which have it on the tips of the fronds are annual.

Rapidity of growth.

It is remarked by Mr Turner, that the smaller and more delicate sea-weeds produce their fruit in the beginning of autumn; while the larger and coarser species prefer for this purpose the "stormy months of winter." But the rapidity of growth of some of the large coriaceous kinds throughout the winter, is wonderful, and it is believed has only of late been fully ascertained. The facts shall therefore be stated with some minuteness of detail. They were observed in the course of the very arduous undertaking of erecting a stone-beacon on a low rock called the Carr, situated near the entrance of the Frith of Forth: and when we mention as the observer the distinguished civil engineer Mr Stevenson, a man accustomed to habits of accurate observation, it is perhaps superfluous to add, that particular attention was bestowed at the request of the writer of this article, and specimens of the fuci transmitted to him. The Carr Rock is about 20 feet broad, and 60 feet long: it is only uncovered at the lowest ebb of spring tides. It was completely clothed with the larger fuci, particularly Fucus esculentus and F. digitatus. In the course of autumn 1813, the workmen had succeeded in clearing out and levelling with the pick and axe a considerable part of the foundation of the intended beacon, when, in the beginning of November, the operations were necessarily abandoned for the winter. At this time the rock was reduced to a bare state. The coating of sea-weed had at first been cut away by the workmen; the roots or bases were afterwards trampled by their feet; and much of the surface of the rock had been chiselled. Upon returning to the Carr in May 1814, in order to recommence operations, it was matter of no slight surprise to find the surface again as completely invested with large sea-weeds as ever it was, although little more than six months had elapsed since the work had been left off, when, as already said, the rock was cleared of weed. In particular it was observed, that many newly produced specimens of Fucus esculentus measured six feet in length, and were already furnished with the small appendages near the base, or pinnæ, which at maturity contain the seeds of the plant. Lightfoot mentions four feet as the ordinary length of this fucus, but adds that it sometimes reaches nine feet. Those at the Carr Rock, therefore, were nearly full sized. The common tangle, F. digitatus, was generally only about two feet long; but this species when fully grown seldom exceeds three or four feet. It is to be observed, that the specimens here alluded to were taken from that part of the surface of the rock which had been dressed off with the pick and chisel the preceding autumn, they had therefore grown from the seed; and indeed it was remarked, in general, that the sea-weeds had grown more luxuriantly on the newly-dressed rock, which is sandstone, than from the old stools, which had been merely cut over, or trodden

Fuci.

down by the workmen's feet. It appears, therefore, that the seeds of these fuci, floating about abundantly in the waters of the Frith of Forth, must have attached themselves to the dressed surface of the sandstone after the middle of November, and must have vegetated and increased with great rapidity during a winter remarkable for severity: for this, it will be remembered, was the winter of the *great frost* as it was styled, which continued nearly the whole of the month of January 1814, and of which a very full account will be found in the *Scots Magazine* for February of that year. Other circumstances, it may be observed, were here favourable to their growth. During the winter and spring months, the Carr Rock must have been almost constantly under water. The incessant struggle of the tides at Fifeness is calculated to produce that degree of agitation which has long been considered favourable to the growth of the stronger sea-weeds; and this does not seem to have been interrupted by the rolling of heavy waves for many weeks during winter.

If, however, still further proof of the rapid growth were wanted, the experience of the following season afforded ample evidence. In autumn 1814, a course of large hewn freestone was completed, and the operations were again suspended till the following summer. It was as late as the beginning of July 1815 before the weather permitted boats to approach the rock at low water; when, on the new course of the beacon, a crop of Fucus esculentus was found, the fronds of which measured on an average six feet long, and were, as before, furnished with pinnæ. This must of necessity have been the growth of not more than eight months from the time of the very minute seeds having attached themselves to the hewn stone.

The opinion of Lamouroux, therefore, that during winter the vegetation of sea plants is suspended like that of land plants, is proved to be erroneous.

It may here be mentioned, that Dr Walker states, * on the authority of the kelp-makers, that "sea-weeds do not grow so much in seven years upon freestone as they do in two years on whinstone." The facts above detailed shew that this remark is not universally applicable, although it may be true of the loose masses of stone on the shores, which, if soft, must be liable to be worn by the striking of smaller boulder stones.

It is not improbable, that the growth of the large pelagic fuci may even be much more rapid than that now described. The Fucus giganteus of the Pacific Ocean attains several hundred feet in length: Forster mentions specimens even 800 feet long. In the bays of this country, F. filum frequently reaches 30 or 40 feet, and in some places, as Scalpa Flow in Orkney, this is considered as the growth of the summer and autumn months, from May to October.

General Structure, &c. of Fuci.

General structure.

From the characters of the orders in Lamouroux's arrangement, some notion of the general structure of the different tribes of marine plants must already have been acquired. In treating farther of the same subject, brevity shall therefore be studied.

In general it may be observed, that some species are coriaceous, often branched and shrub-like; some are membranaceous, and traversed by a longitudinal nerve or midrib; others are filiform, generally not jointed: they produce receptacles, tubercles, or capsules; and most of them are furnished with air-vesicles.

Decandolle considers marine plants as composed entirely of cellular tissue; attributing the difference of structure observable in the stems, the mid-ribs or nerves, and the fronds, to modifications in the form of this cellular tissue. Mirbel is of the same opinion. It is certain that all the parts of sea plants are much more nearly of uniform texture than in land plants in general; most of them seeming to be capable of changing into others; the peduncle becoming a branch, the air-vesicle a frond, and so on. Lamouroux, however, has remarked, that the stem of Fucus digitatus is formed of four distinct parts, analogous in situation, relative size, and even organization, to the epidermis, bark, wood and pith of dicotyledonous plants. It perhaps requires some aid from the imagination to enable the observer to see all this. But it is certain that a section of the stem of Fucus digitatus forms a curious microscopic object, and that it is distinctly perceived to be composed of longitudinal parallel jointed colourless fibres, disposed in concentric circles, and constituting altogether a pretty solid mass. Lamouroux has likewise discovered, or imagined he has discovered, in certain sea-weeds belonging to different tribes, most of the characters which distinguish the brilliant corollas of phænogamous plants, the stems and leaves of trees, and the herbaceous structure in general.

That marine algæ are not furnished with continuous vessels of the same nature as those of land plants, is obvious, from the well known remark, that if one portion of a sea plant be plunged in water, and the other left exposed to the air, only the immersed portion remains in vigour; no fluid seems to rise speedily enough through the frond to nourish or refresh the other part of the plant. The result of microscopic observation, and attempts at injection, support the same view. On the other hand, the fructification of some families, as the Fucaceæ and Florideæ of Lamouroux, is observed to be placed almost always on the stems or branches, near to the masses of fibres, or at their extremities. In the Dictyodeæ of the same writer, the more regular and visible the structure of the reticulations, or cellular tissue, appears, the situation of the fructification is found to be more uniform; and the less regular and distinct, the fructification is more scattered. The production of capsules regularly at the extremities of branches or fronds, which is observed in many species, proves the existence of some kind of vessels, and the elaboration of particular fluids. Upon the whole, therefore, as something analogous to circulation is indispensable, the masses of fibres, or cellular tissue with lengthened cells, may be considered as calculated to perform the functions of longitudinal vessels. Horizontal vessels are distinctly seen in some species, particularly F. vesiculosus and nodosus.

Some of the fuci are quite cartilaginous in texture; such as the stem and midrib of F. esculentus, and the whole plant of F. aculeatus. A few species dissolve into jelly on being placed in boiling hot water. Some are quite flexible when recent, and become stiff and apt to break when dry: others, on the contrary, as the genus Dictyopteris of Lamouroux, are stiff and frangible when living, and become flexible when dried.

Jointed structure.

The jointed structure of the frond was long considered as characteristic of *Confervæ;* but this, it is now admitted, does not effectually distinguish them from several fuci, such as F. fruticulosus and pinastroides, or even some lichens and fungi; and it has therefore been abandoned as a generic distinction. Lamouroux remarks, that it is easy to distinguish the truly ar-

* *Transactions of the Highland Society*, vol. i. p. 27.

Fuci. ticulated sea-weeds, or marine confervæ, from those fuci that are marked by contractions or partitions. If the stem of these last be cut longitudinally, the substance shews no mark of interruption, but appears quite homogeneous. In the former, the tissue appears at every joint to change its quality and form, and the colour varies. Some of the small cylindrical fuci seem to acquire the appearance of contractions or partitions just before the time of fructification; nature perhaps producing these partitions, to give firmness to the stems, or to delay the circulation of the juices, and make them undergo a more complete elaboration at this crisis. It was first observed by Mr Dillwyn, that the aculei of F. aculeatus are regularly jointed, and that the main filaments towards their extremities have a jointed internal tube: all of these jointed appearances vanish as the plant grows old. The tufted fibres of F. radiciformis (*Turn.* t. 189.) are also jointed; as are those likewise of F. pedunculatus (t. 188). F. dasyphyllus (t. 22), it may be noticed, is sometimes, but rarely jointed; generally it is without joints.

Vesicles. No part of the structure of fuci has more universally attracted notice than the inflated portions of the stem or frond resembling bladders, seen in many species, and particularly conspicuous in the well-known F. vesiculosus and nodosus. (See Plate CCLXI. Fig. 4, 5.) They are now generally denominated Air-vesicles, or simply Vesicles. Most of the sea-weeds having a texture approaching to ligneous, are provided with distinct air-vesicles; and those that are not so provided, have in their stems empty spaces, sometimes visible to the naked eye. These probably serve the purpose of air-vessels: they proceed from the root or base, rise with the stem, and disappear in the frond.

Plate CCLXI. Figs. 4, 5.

Formerly, the air-vesicles were generally supposed to be the male fructification. The generic character of Fucus, given by Linnæus, was the following: "*Male*, Vesicles smooth, hollow, with villose hairs within, interwoven. *Female*, Vesicles smooth, filled with jelly, sprinkled with immersed grains, prominent at the tip, seeds solitary." If the reader imagine to himself the application of this character to the common F. nodosus, he will perceive, that by *male vesicles* must be meant the air-bladders; and by *female vesicles*, the receptacles, the *immersed grains prominent at the tip*, being a sufficiently distinct description of the *tubercles*. They were afterwards for a long time considered as destined merely to give buoyancy to the plant. It is now, however, generally believed, that they serve some important purpose in the economy of sea-weeds. Lamouroux considers them as respiratory organs; and he observes, that where they are wanting, the organization is less complicated, and the vital functions are more simple. He affirms, that sea plants exert the same action on atmospheric air as land plants. The ligneous fucaceæ, he says, absorb oxygen during the night, and give it out during the day, though in very small quantity. Analogy would lead us to consider this statement as probably correct; but whether it is founded on direct experiment, is not explained by the author. The Florideæ, he adds, exhale less oxygen than the former. They retain it, in his opinion, in order to produce the brilliant tints which adorn them. The Ulvaceæ, like herbaceous land plants, give out by the action of light, a great quantity of oxygen gas, and a little carbonic acid. The decomposition of the atmospheric air must take place in the vesicles, or in the spaces or cells already alluded to; these perhaps at once serving as reservoirs, and as organs for decomposing the air. On some species, vesicles have never yet been found; but Turner is inclined to think, that none are entirely and at all times destitute of them; so that the division "absque vesiculis" might be given up.

Pencils of white hairs. Many fuci, such as the common F. vesiculosus and serratus, have small tufts of white filaments like hairs scattered over their surface. Reaumur conjectured, that these might be a sort of male flowers, and as such he described them. In this notion, he was followed by some distinguished botanists. But they are now known to be analogous merely to the hairs on land plants, and to be useful probably for the secretion or absorption of particular fluids. It has generally been said, that they occur on the plant in every stage of its growth, and at all seasons of the year. Lamouroux, however, asserts, that they are not permanent, but disappear at certain seasons, and at certain stages of the life of the plant. They are never seen on the stem or the nerve, but on the frond only.

Food of sea-weeds. It does not appear probable that the submersed algæ derive much of their nourishment from the processes by which they are attached to rocks or other substances, although these processes in many instances resemble roots, and usually receive that name. It appears likely, that the principal part of their food is imbibed by their general surface. They are attached to rocks of mica-slate, greenstone, basalt, sandstone, and limestone. Many of the smaller kinds grow on the stems of the larger plants. It is to be observed, however, that Mr Turner, in the introduction to his *Synopsis of British Fuci*, hints it as his opinion, that the root-like processes are not merely intended for fixing the plants, but are to a certain degree useful as organs of nutrition; and he mentions that some species seem peculiar to chalk, some to sandstone, and others to still harder rocks. On the other hand, at least one species, Fucus bacciferus of Turner, (t. 47), has never been found with a root or base: it evidently lives and increases while floating about. The extensive meadows of sea-weeds through which navigators to distant countries continue to sail for days in the unfathomable ocean, and which are found in a fresh and growing state, afford convincing evidence that certain kinds of fuci at least are not entirely, nor even chiefly, dependent on their roots for nourishment. M. Desvaux, editor of the *Journal de Botanique*, has lately made a direct experiment on this subject. Having detached some fuci above the roots, he fixed them to stones by means of cords or other artificial methods, and plunged them again in the sea. Having visited them some time after, he found that they had increased very sensibly.

Some authors have supposed that the fuci are nourished by their mucilage: but this is only removing the difficulty one step; and besides, particular species, as F. esculentus, possess little or no mucilage. It has been remarked, however, that the cups or discs of F. loreus become flaccid and destitute of juice, whenever the *thongs* of the plant have attained full size; and this has been ascribed to the exhaustion of the mucilage by their growth.

The Caulerpæ of Lamouroux creep in the sand, and seem to possess true roots; but these, though at present associated with the fuci, form not only a very distinct genus, but a separate family.

Colours of Fuci.

Colours of sea-weeds. The colours of sea-weeds have not yet been much attended to. A great proportion of the fuci are of an olive hue; olive brown, olive yellow, or olive green. A good many are red or brownish red. Some are verdigris green, particularly F. æruginosus, (*Turn.*

Fuci.

t. 147,) a species from the Red Sea, resembling Lichen prunastri, and F. Valentiæ, (t. 78), brought also from the Red Sea, by the nobleman whose name it bears; the latter rendered more remarkable by producing bright red spherical tubercles, which form a striking contrast with the glaucous frond.

Some phænomena not uninteresting to the physiological chemist are slightly mentioned by Professor Mertens in the *Allgemeine literatur Zeitung* for 1810, in his critique on Mr Turner's *History of Fuci.* He states that F. ligulatus and F. viridis (*Turn.* t. 97.) possess the property of suddenly altering the colour of other fuci along with which they happen to be steeped in a vessel full of fresh water; the red colour of Conferva rubra, or Fucus ovalis, being changed to purple, and these plants rendered at the same time much more prone to decomposition, while the ligulatus and viridis remain unhurt. F. viridis itself undergoes remarkable changes. While the plant is growing, it is of a deep rich orange; but, says Mr Turner, "no botanist can have gathered it without being struck by the circumstance, that before he had conveyed it home, it had changed its original golden hue to a bright verdigris green." At the same time, it undergoes a change in its substance; from being stiff and elastic, it becomes completely flaccid.

Humboldt and Bonpland describe,* under the name of *Fucus vitifolius,* (as already mentioned,) a species of a fine grass green colour, brought up, at l'Alegranza, from the great depth of 192 feet, at which depth it had vegetated. The light at that depth could only have been equal to half the light of an ordinary candle; yet, according to Humboldt's experiments, common garden-cresses, exposed during vegetation to the light of two Argand's lamps, acquire only a slight tint of green. That distinguished philosopher therefore concludes, that it is only under the influence of the solar rays, however weak, that the carburet of hydrogen is formed in the organs of plants, the presence of which makes the parenchyma appear of a lighter or darker green, according as the carbon preponderates in the mixture.

The colour of all the soft and annual fuci depends on a very fugacious extractive. Those that are horny in texture retain their colour with more force. Several of them become of a greenish hue when boiled; and every one who has seen dulse fried, must have remarked the change to green produced by the application of heat. The ultimate tendency to a green hue observable in several species, may probably be ascribed to the more complete developement of the alkali contained in the plant.

To the botanist it may be useful to know, that when there is reason to suspect that the appearance of the plant is changed by exposure to the air or rains, the original colour may often be detected by holding up the specimen against a strong light. For example, F. sinuosus, which is frequent on the stems of F. digitatus, and has fronds resembling in shape the leaves of Alnus incana, is, when fresh, of a rosy red colour; in decaying on the shore, this changes first to violet, and then to tile red: but on holding the specimen against the light, the original rosy hue may be detected. Wahlenberg notices concerning F. plumosus, that when repeatedly washed in fresh water, it becomes green; that, in dilute muriatic acid, it preserves its colour, and when removed from it becomes green, as if an alkali had been poured on it.

Another species, F. ericoides, (*Turn.* t. 191), possesses the more extraordinary property of reflecting bright glaucous tints when seen under water in a growing state. It is naturally of a yellowish green colour, but under water appears as if in a state of vivid phosphorescence. On withdrawing it from the sea, the brightness vanishes. The phenomenon has not been thoroughly examined. This fucus grows on the shores of Devonshire and Cornwall; but Mr Stackhouse, who spent his days in those districts, and had many opportunities of observing the appearance, only says that the colour resides in, or is occasioned by a slimy mucus which covers the frond. When dried, the plant becomes of a reddish brown colour.

Concerning F. ligulatus, a species which occurs, though not plentifully, on our shores, and is excellently figured by Lightfoot in his *Flora,* (t. 29,) Professor Mertens mentions a curious fact: in the sea it is of an olive green colour; but as soon as it is brought in contact with the air, it becomes of a deep orange, or rather the colour of decayed leaves. The only specimens we have seen, which were taken from the rubbish of a fishing-boat at Newhaven in the Frith of Forth, were of a pale dull green; but to this colour, Mertens observes, the orange tint soon declines.

It has been remarked of some of the smaller and more delicate fuci, that the same species seems to vary in appearance, size, and especially colour, according to the nature of the substance to which it happens to be attached, whether a stone or shell, or the stem of a larger sea-weed. But this observation is by no means of universal application. Variations are more generally occasioned by the climate in which the plant grows; the depth of water; the exposed or sheltered nature of the situation; or the proximity to the mouth of a river or body of fresh water.

General Distribution of Fuci.

General distribution over the globe.

A few remarks on the general distribution of the fuci may here be made. Some may be considered as properly pelagic, as F. pyriferus, (*Turn.* t. 110), the giganteus of Foster, or the *badreux* of the Falkland Islands. This sends out numerous fronds, and the upper and under fronds are frequently found soldered as it were together, at certain spots of the edges. This species occurs so abundantly in the South American seas as to resemble islands, and it is one of the chief of the gigantic fuci alluded to by circumnavigators. Linnæus merely says, that it is the longest and largest of the fuci. Solander measured some of the apices, and found them to be from ten to twelve feet; but he gives no guess as to the length of the entire plant, which is said to extend from 500 to 1000, or even 1500 feet. F. *potatorum* of Labillardiere, is another of the great pelagic fuci, of such ample dimensions, that particular parts of it furnish various household implements to the natives of New Holland.

Others, of a small size, which are never found but in the great ocean, may, it is thought, have originally been torn from the shores: this is the case with the numerous species which have long been confounded together under the convenient name of Fucus natans, and which constitute the well known fields of floating seaweeds met with in the great oceans.

New Holland.

The fuci of the northern seas are in general different in character and appearance from those of the tropics or of high southern latitudes. To take for example New Holland. It is well known that the land plants of this singular country have a peculiar character, arising chiefly from many of the trees and shrubs being aphyl-

* *Plantæ Æquinoctiales,* vol. ii. p 8. t. 69.

Fuci.

lous, and many others having leaves pointing upwards, or presenting both surfaces equally to the light. The shores afford a tribe of fuci equally different from those of other parts of the world. They belong to the *fuci proprii*, and are all composed of a stem repeatedly pinnated with different series of branches, the whole of which, as well as the stem itself, are flat, and formed, as it were, of a set of distinct joints, placed upon each other in a sort of zigzag direction; the branches almost always arising from the flat part of the stem, and not, as in Europe, from the angles. This tribe of fuci was brought to light by our justly celebrated countryman, Mr Brown, during his voyage with Captain Flinders and residence in Van Diemen's land already alluded to, M. Labillardiere having happened to observe only one species of the tribe: this one was the very remarkable F. Banksii, (*Turn.* t. 1.) which occupies on the Australasian shores the place of our vesiculosus. Instead of our serratus, these shores possess F. confluens, (*Turn.* t. 141.) a species which resembles it, but wants the midrib. The place of our large digitatus and bulbosus is there supplied by a distinct species considerably resembling them, described and figured by Mr Turner under the name of F. radiatus, t. 134.

The temperature of the ocean in different regions may be supposed to vary much less than that of the land: on account of the moveable nature of the element, the means of transportation of fuci must be more easy than in the case of land plants: and the waters of the sea appear almost every where to teem with the seeds of fuci. It is not surprising, therefore, that some tropical species should make their appearance in high latitudes, or that particular kinds should be found in places the most remote from each other, and climates the most opposite. Fucus agarum is found chiefly in the Indian Ocean; but it occurs also at Nova Scotia and in Hudson's Bay. F. cartilagineus of Linnæus, (*Turn.* t. 124.), which is abundant at the Cape of Good Hope, and often gathered there to form ornamental pictures, is found also on the shores of Finmark; and F. flagelliformis of Flora Danica, (t. 650.) is found both at the North Cape of Norway, and at the southern promontory of Africa. Some are most widely distributed over the globe, but are not abundant in any particular quarter. F. musciformis of Wulfen (*Jac. Coll.* iii. t. 14.) has been found on the coast of France in the Adriatic, off the coast of Egypt, at Ceylon, in the West Indies, at New Zealand, and in Nootka Sound. F. thyrsoides is marked by Mr Turner (vol. i. p. 38.) as found at New Zealand by Sir Joseph Banks, at Jamaica by Dr Wright, and in the Red Sea by Lord Valentia. F. turbinatus, Lin. (*Turn.* t. 24.) is a native equally of the seas of the East and West Indies. F. acanthophorus of Lamouroux, (*Turn.* t. 32.) is found on the coast of North America and in the Red Sea. F. Wrightii of Turner, (t. 148.) on the shores of Jamaica and the Red Sea. F. triangularis (*Turn.* t. 33.) has been picked up at Jamaica, New Holland, and New Zealand. Several species inhabit the shores on both sides of the Atlantic, as the common kelp weeds, F. vesiculosus and nodosus. F. dentatus, which is common in the Frith of Forth, grows also in the Chesapeak. Some other British species are very widely disseminated over the world. The elegant pinastroides of our shores was observed on the coast of New Zealand by Sir Joseph Banks, and has been found also at Ceylon. F. fibrosus (*Turn.* t. 209.) is common to England and the coast of Guiana; F. plicatus, to this country and New Holland. F. tomentosus, (*Turn.* t. 135.) which occurs on the southern shores of England and Ireland, has been found also in the Mediterranean, in Nootka Sound, and at the Cape of Good Hope. A very common British species, F. siliquosus, inhabits likewise the Mediterranean and Adriatic, and has been observed at Newfoundland, and in the Chinese seas.

A local disposition may be traced in some cases. In the East Indies, for example, the Straits of Sunda have afforded two curious species, with leaves resembling holly and dwarf-oak, F. aquifolius and ilicifolius of Turner (t. 50, 51.) The uncommon looking F. muricatus of the same author, (t. 112.) is a native of the same Straits. None of these have hitherto been found elsewhere. F. tenax, (*Turn.* t. 125.) one of the most useful of the tribe, is peculiar to the seas of China. The Caulerpæ may be considered as belonging to the Red Sea and New Holland. At the Cape of Good Hope, the place of our digitatus and bulbosus is occupied by F. buccinalis, (*Turn.* t. 139.) which is often observed floating about in great quantity, and, from its fistular and inflated stem, has received from navigators the name of *trumpet-weed*: by them its appearance is hailed as a sure prognostic of the vicinity of the Cape. F. flaccidus of Turner (t. 61.) is there parasitical on the larger fuci, like alatus and coccineus with us. Two Cape species are remarkable for being elegantly fringed along the margin, F. erinaceus (*Turn.* t. 26.) and F. vittatus, or ribbon-weed, (t. 64.) Some are peculiar to the north-west coasts of America. Among these may be mentioned F. Menziesii, (*Turn.* t. 27.) named in honour of Mr Menzies, who attended Captain Vancouver in his voyage of discovery, but whose valuable researches in the department of natural history are brought to light only in a tardy and almost accidental manner, he having received no encouragement from Government to publish his many botanical discoveries. To it may be added F. herbaceus, of Turner, (t. 99.) resembling a broad-fronded ligulatus; two others of Turner, F. osmundaceus (t. 105.), cordatus (t. 116.), and F. floccosus of Esper (*Icones*, t. 100.); with F. costatus of Turner, (t. 226.) curiously ribbed. Others of the north-west American species are found also in other countries: F. bracteatus (*Hist. Fuc.* t. 25.) occurs at the Cape, and F. ovalis (*Id.* t. 81.) is common to Nootka Sound and the shores of Britain. A few may be set down as peculiar to the Mediterranean, as F. nervosus of Decandolle (*Turn.* t. 43.), and linifolius of Turner, (t. 168.) F. purpurens, (*Hist. Fuc.* t. 224.) is very plentiful in the Mediterranean; but it is likewise found in the Red Sea. F. viridis, which is met with on the southern shores of England, but so sparingly as to be accounted a botanical discovery, occurs abundantly as a parasite on F. vesiculosus and serratus on the coast of France. These, as is well known, are two of our most common kelp fuci on the shores of Scotland; but in this country F. viridis never appears upon them. The very elegant small species F. asparagoides and Wigghii, (*Hist. Fuc.* t. 101, 102.) have not, it is believed, been found beyond the precincts of the British islands, and have more frequently occurred on the beach at Yarmouth than elsewhere. F. pusillus seems also to be local, and is described as creeping like a jungermannia, on the red sandstone rocks at Sidmouth in Devonshire. (*Ner. Brit.* t. 6.) A few may be ranked as arctic species; particularly F. distichus of Linnæus, (*Turn.* t. 4.) and ramentaceus, (t. 149.) F. lycopodioides grows plentifully on the most remote shores of Norway, and occurs sparingly on the coast of Scotland. F. soboliferus (*Flor. Dan.* t. 1066.) is common in Finmark, and has been detected on the shores of the Orkney Islands by Mr Fothergill. F. plumosus is one of the ornaments of the shores of the south of England; but it increases in

Fuci.

size and beauty as we proceed northwards, and is much finer in Orkney than in Cornwall: it has been observed even in Davis Straits.

Many species which grow most abundantly on all the shores of Europe which are exposed to the great ocean, are not to be found in the Baltic Sea, the waters of which are less salt, and are little affected by the influence of the tides. Hasselquist, in his Travels, expressess delight at meeting with our common F. saccharinus when he first cleared the Baltic. Some of those species, particularly F. vesiculosus, which grow very far up in the lochs or friths of the west of Scotland, do not appear in the Baltic. F. nodosus and serratus, it may be added, continue near to the heads of the Scottish arms of the sea; and F. canaliculatus is found in the most extreme corners to which the sea-beach can be said to extend; being exceeded only by F. amphibius, (*Turn.* t. 109,) which grows like a coralloidal lichen, parasitically on herbaceous plants, in salt marshes. On the banks of rivers too, where they enter the sea, F. caniculatus is found very high up, even among the brackish water.

Order in which fuci grow on the shore.

On our open sea-shores a certain order is observed in the habitat of the fuci, each species occupying pretty regularly its own zone or station. F. filum or sea-laces grows in water some fathoms deep. In places where the tide seldom entirely ebbs, but generally leaves from two to three feet of water, grow F. esculentus and bulbosus, and the larger specimens of digitatus and saccharinus, with some small kinds, as F. palmatus, siliquosus, and sanguineus. In places uncovered only at the lowest ebbs, smaller plants of digitatus and saccharinus abound, with F. loreus or sea-thongs. On the beaches uncovered by every tide, F. serratus occurs lowest down, along with crispus and mamillosus; next comes F. nodosus; and higher up, F. vesiculosus. Beyond this F. canaliculatus (already mentioned) still grows, thriving very well if only wet at flood tide, and though liable to become dry and shrivelled during a great part of the day. Lastly, F. pygmæus, figured by Lightfoot, (t. 32.) is satisfied if it be within reach of the spray.

Floating Sea-weeds.

Floating sea-weeds.

The great accumulations of sea-weed found floating in the Atlantic, Pacific, and Indian Oceans, on each side of the equator, nearly to the 40th degree of north and south latitude, have already been alluded to; but they are not undeserving of further attention.

Mar do Sargasso.

The *Mar do Sargasso* (or sea of sea-weeds) of the Portuguese, stretches between the 18th and 32d parallels of north latitude, and the 25th and 40th meridians of west longitude. It is often called the Grassy Sea, and is mentioned by many navigators. It is thus described by Barrow, in his *Voyage to Cochinchina:* "The surface of the sea for several days was literally covered with plants. Some of them were many feet in diameter; others only a few inches: all appeared in a growing state. The globose berries (by which Mr Barrow means the air-vesicles) were in some plants green; in others red. If taken out of the water, the plant became flaccid, and in the space of four and twenty hours turned brown or black. The naturalist in every plant may find a great variety of marine insects and worms, some naked and others with testaceous coverings." Those plants with green vesicles, it may be remarked, were probably specifically distinct from such as had red.

It is stated by Humboldt in his Personal Narrative, that in the great basin of the Atlantic Northern Ocean, there exist two banks of floating sea-weed. The most extensive is a little west of the meridian of Fayal, one of the Azores, between latitude 25° and 36°. Violent north winds sometimes prevail in this space, and drive the sea-weed to the low latitudes, as far as 24° or even 20°. Vessels returning to Europe either from Monte Video or the Cape of Good Hope, cross the bank nearly at an equal distance from the Antilles and Canaries. The other occupies a much smaller space between 22° and 26°, eighty leagues west of the meridian of the Bahama Islands. It is generally traversed by vessels on the passage from the Caiques to the Bermudas.

Columbus and Lerius encountered most extensive banks of floating fuci in their adventurous voyage: they compare them to extensive inundated meadows, and complain of their impeding the progress of the vessels. So novel a scene produced no little consternation and alarm in the crew of the Santa Maria.

Detached patches of floating sea-weeds of various extent, but not deserving the name of banks or meadows, are met with in different parts of the Atlantic. Bonpland observed such patches to the north of the Cape Verd Islands.

Linnæus, speaking of Fucus natans in the *Species Plantarum*, says, "Vegetabile, in fallor, inter omnia in orbe numerosissimum." But under this title he included a considerable number of species, indeed all that generally occur in the "sea of sea-weeds." Turner was the first who effectually distributed the Linnæan Fucus natans into various species. He remarks that they form a tribe by themselves, though very clearly allied to the *Fuci proprii* of Weber and Mohr. Their leaves never in any case lengthening into branches, and their vesicles being altogether empty, seem characteristic circumstances. It was formerly thought that these floating sea-weeds were natives of the Gulf of Mexico, and were carried across the Atlantic by the Great Stream: hence the common name of *Gulf-weed.* It is very evident, however, that the Gulf Stream would convey them rather to the Banks of Newfoundland than to the latitudes in which they usually occur; and it could not in any case accumulate them to the south of the Azores.

There is no doubt that it was the opinion of Linnæus that they vegetated in the ocean, and floated about without ever being attached. This notion is likewise now exploded. Several of the species and varieties have been found with roots or bases, and some have been gathered in their native place of growth, where they were fixed to the rocks. It appears likely that they grow on rocks, probably at very considerable depths, in the Atlantic, Pacific, and Indian Oceans, whence they are carried, among other rejectamenta of the seas, to the shores of almost every country, accumulating however on the surface of the ocean, in certain latitudes, owing to prevailing winds and currents. Some are inclined to think, that, being torn from their native rocks before they attain maturity, they perfect their seeds while in a floating state; and it seems not unlikely that this may sometimes be the case. M. Humboldt, however, is of a different opinion: he thinks that vegetation can scarcely continue for a longer time in a detached floating sea-weed, than it would do in the branch of a tree torn from its trunk; and he considers these floating fields as composed of plants which have passed maturity.

It is certainly very difficult to explain why great moving masses of marine plants should be found for ages nearly in the same local positions. When decaying, they may indeed be supposed to be carried away by the equinoctial currents; which may scatter them even towards the coasts of France and Norway. But how the fresh weed is supplied; by what causes it is detached from depths perhaps of forty or sixty fathoms, where it is generally thought the sea scarcely suffers agitation, are problems which remain to be solved. Lamouroux indeed states, that although fuci adhere firmly before the fructification appears, they separate very readily after this period; and Humboldt remarks, that fish and molluscous animals, by gnawing their stems, may also contribute to detach them.

The spherical vesicles, supported on flat stalks, and resembling juniper berries, interspersed on the stem and branches of the plants, were erroneously regarded by Linnæus as the fructification; but the true fructification, as ascertained by Turner, occurs in the form of cylindrical receptacles on the branches, inclosing globular tubercles, which again contain the seeds. It may be noticed, that Don Hippolyto Ruiz, in his *Flora of Peru*, and in his pamphlet, "*De vera Fuci natantis Fructificatione*," described the sexual organs of the floating sea-weeds in a manner that surprised botanists in general. Stamens and pistils were declared to be as obvious in this fucus as in most of the phænogamous vegetables! But the observations of M. Bonpland rectified the mistake of Ruiz. Certain appendages in the form of little cups and feathers, which he took for the parts of fructification, were found, on close examination, to be nothing else than parasitical zoophytes belonging to the family of ceratophyta. When dried, they effervesced with acids, as the calcareous substance of any common sertularia or flustra would do.

Very frequently the spherical vesicles, which have already been compared to juniper berries, are as large as small purple grapes, and have a striking resemblance to them. For this reason, the name of *Tropic Grape* is often applied to the floating sea-weed. As a proof that the vesicles are intended in the case of F. natans, chiefly to give buoyancy to the plant, Ruiz states that when the vesicles are all cut off, the plant sinks.

The great collections of floating sea-weed which have now been described, are not without their use in the economy of nature; for they afford both food and shelter to myriads of fishes and mollusca, and probably tend, by giving forth oxygen, to maintain the wholesome purity of the sea. To the mariner, the young or most succulent shoots of F. natans offer an acceptable salad, or they are prepared as a pickle like samphire.

Economical Uses of Sea-weeds.

Economical uses of sea-weeds in general.

It is observable on most coasts, that sea-weeds, or many species at least, very suddenly disappear from the rocks in the autumn. They do not decay, like land plants, on the spot where they grow; but, losing their hold, are washed away by the tides; and, in the narrow seas at least, generally wafted ashore to offer their services to man. Among the Romans, indeed, they were proverbially useless. When they wished to stigmatise any thing as utterly worthless, it was declared to be *algâ projectâ vilior;* and Horace, when he speaks of *alga* covering the shores as drift-ware, thrusts in the epithet *inutilis.* In modern times, the alga marina has become useful and valuable in various respects. To the agriculturist it furnishes a most important manure. To the glass-maker and soap-boiler it yields the fixed alkali; and the manufacture of kelp for this purpose, has become a valuable source of revenue to the proprietors of the rocky shores of Europe, particularly of Britain, and more especially to those of the Northern and Western Islands of Scotland. Of such importance has this manufacture appeared, that in some places attempts have even been made, and not without success, to *cultivate* the fuci. By merely covering sandy bays with large boulder stones, a crop of fuci has been procured in the course of two or three years, the sea appearing every where to abound with the necessary seeds. From the ashes of the fuci the chemist has of late years derived the very curious elementary substance named *iodine.* Several of them are so rich in saccharine matter, and vegetable mucilage, that on the shores of the northern countries of Europe, and in the Scottish islands, much of the winter provender of cattle is derived from them; and in the city of Edinburgh these plants are occasionally given as a useful stimulus to the stomach of milch-cows kept in confinement during the winter. A few of them even afford food to man. What might least of all be expected, two or three of them furnish fuel to the inhabitants of coasts where materials for firing are scarce. Some of the smaller sorts yield various condiments, or afford fresh salads; while others are employed as medicines. From a few of them, substances useful in the arts are procured; and with some of the more delicate and elegant species, ornamental pictures are constructed.

While considering the different purposes to which marine plants may thus be applied, it may be agreeable to the reader to see the descriptions of those chiefly employed, and more especially of such useful species as inhabit the British shores. The descriptions, however, must consist chiefly of the very accurate specific characters drawn up by Mr Turner, to which some explanations shall be added where they seem requisite.

As manure.

It is scarcely necessary to say, that every kind of seaweed may be employed as manure. In point of fact, what is used for this purpose is that which is cast ashore by storms in the winter months, consisting of all sorts, mixed with zoophytes, and all the other rejectamenta of the sea. In many places, the value of such manure is duly appreciated; while in others it is unaccountably neglected; not that it is any where entirely despised, but it frequently happens that on one day many tons of drift-ware are cast on a particular shore, and that on the next the whole is swept away. They who would avail themselves of this bounty of the deep, must snatch the moment of its being placed within their power, and muster all hands to drag it at least beyond the reach of the returning tide. It must not be left very long in the heap, nor suffered to run into the putrefactive fermentation; for in this case, sulphureted hydrogen, and other gases highly important in promoting vegetation, escape rapidly, and in great quantity; leaving a comparatively inert mass. But for details as to the mode of applying this manure to lands, so as best to secure its fertilizing effects, reference may be had to the article AGRICULTURE.

For making kelp.

The nature of kelp, and the mode of its manufacture, are now generally understood. It is a very impure carbonate of soda; containing sulphate and muriate of soda, and also sulphuret of soda, with a portion of charcoal. In Scotland the manufacture is carried on chiefly in the months of July and August. The kelp kiln is nothing but a round pit or basin dug in the sand or earth on the beach, and surrounded with a few loose stones. In the morning a fire is kindled in this pit, generally by means of peat or turf. This fire is gradually fed with sea-weed, in such a state of dryness that it will merely burn. In the course of eight or ten hours,

Fuci.

the furnace is found to be nearly full of melted matter. Iron rakes are then drawn rapidly backward and forward through the mass in the furnace, in order to *compact* it, or bring it into an equal state of fusion. It is then allowed to cool, when it is broken in pieces, and carried into a store-house, to remain till shipped.

The making of kelp from sea-weed was practised in France and England for more than half a century before the manufacture was introduced into Scotland. Mr James Fea of Whitehall in Stronsay was the first person in Orkney who (about 1722) exported a cargo of kelp; he sailed with it himself to Newcastle; and his success in the enterprize soon aroused the attention of the Orcadians. At present, in coasting these islands, as well as the Hebrides, in the summer months, great volumes of smoke are every where to be seen rolling from the kelp furnaces, and the peculiar odour, probably arising chiefly from muriatic acid gas, is felt to a considerable distance. From £40,000 to £50,000 sterling, are thus yearly brought into the country; but it must not be concealed, that in most of the islands agriculture has suffered, from the attention of the small tenants having been diverted from the land, and, by the influence of the landholders, turned almost exclusively to the manufacture of kelp.

The fuci which are chiefly cut on our shores for this manufacture, are Fucus vesiculosus, nodosus, and serratus. In some places, F. loreus and filum are employed, but not to a great extent. By means of a boat and long sharp hooks or bills, F. digitatus is cut in some places; and this species, together with F. saccharinus, bulbōsus, and esculentus, form much of the drift-ware employed in making of kelp. Some of these are no doubt richer in the alkaline salt than others; but of all of them it may be said, that when dry and fit for burning, they are capable of yielding about one-fifth of their weight in kelp.

Iodine.

Besides the alkali, kelp affords, as already hinted, a peculiar simple or hitherto undecomposed substance named *iodine*. It was discovered in the year 1812, by a manufacturer of saltpetre at Paris named Courtois, and has since been examined by the most eminent French and English chemists. It is readily procured by pouring concentrated sulphuric acid on the mother water of kelp from which soda has been extracted, or from spent soapers' leys. Heat is speedily produced, and the new substance appears as a violet-coloured gas, perfectly homogeneous and transparent. This, on being collected in the usual mode, soon condenses, and assumes the appearance of plumbago. It forms acids with hydrogen, chlorine and tin, called the hydrionic, chlorionic, and stannionic acids; and it combines readily with metals. The late Mr Tennant could detect no iodine in sea-water; so that it appears to be entirely a product of marine plants. French kelp, it is remarked by Sir Humphry Davy, yields more iodine than British; but for this, no reason is assigned. Iodine has a peculiar odour, and is decidedly poisonous. The name is derived from ιωδης, *violaceus*, in allusion to the very striking circumstance of the substance yielding a violet coloured gas on being exposed to an increase of temperature. The following is the mode of procuring iodine recommended by Dr Wollaston: "Dissolve the soluble part of kelp in water; concentrate the liquid by evaporation, and separate all the crystals that can be obtained; pour the remaining liquid into a clean vessel, and mix with it an excess of sulphuric acid; boil this liquid for some time; sulphur is precipitated, and muriatic acid driven off; decant off the clear liquid, and strain it through wool; put it into a small flask, and mix it with as much black oxide of manganese as you used before of sulphuric acid; apply to the top of the flask a glass tube shut at one end; then upon heating the mixture in the flask, the iodine will sublime into the glass tube." *

Kelp fuci.

The species reckoned kelp fuci shall now be more particularly described; and as most of them, besides yielding kelp, serve other useful purposes, these shall at the same time be noticed.

F. vesiculosus.

Fucus *vesiculosus*: "The frond is coriaceous, flat, mid-ribbed, linear, dichotomous, and quite entire; the vesicles are spherical, and innate in the membrane of the frond; the receptacles (containing tubercles and seeds) solitary, terminal, compressed, turgid, mostly elliptical."—In Scotland this is sometimes called *Black tang*; sometimes *Kelp ware*; and when the receptacles are large and swollen, *Strawberry-ware*. The Norwegians call it *Kue tang*, because their cows feed on it. It is the Quercus marina or *Sea oak* of the older writers. F. inflatus of Linnæus and Lightfoot, and F. spiralis of English Botany, are to be considered as varieties only of this species. The colour is a pale olive green, which becomes dull and almost black as the plant dries. It grows most plentifully on all our rocky shores, often not much below flood-mark. It is readily distinguished from F. nodosus by the air-vesicles very generally occurring in parallel pairs, while in F. nodosus they are single; and from F. serratus, by the edges of the frond being entire, or wanting the serratures which mark that species. It is generally from one to three feet long. It is the species most highly prized for the manufacture of kelp; being rich in alkaline salts. According to one account, 5 oz. of the ashes of the plant yielded about $2\frac{1}{2}$ oz. of alkali; and Dr Walker states that 1 lb. avoirdupois gave him 3 oz. of kelp. In the north and west of Scotland many hundred tons of this species are for this purpose yearly cut from the rocks, with old reaping hooks. To the Scottish islanders it is likewise valuable in another way; it constitutes a considerable part of the winter food of their horses, cattle and sheep, which seem instinctively to migrate from the hills to the sea-shore at the ebbing of the tide. Lightfoot mentions that during severe snow-storms, stags have been known to descend from the Scottish mountains to the shores, and to feed chiefly on this species. The same author states, that in some of the islands, the inhabitants cover their cheeses with its ashes, and thus supply the place of salt. Linnæus says, that the people in Gothland often boil the plant, and mixing it with some coarse flour, feed their pigs with it, and that it has hence received the name of *Swine-tang*. In the Channel islands it affords firing. In Jersey, in particular, it is collected and dried in July, and then housed for winter fuel. It is there also employed in smoke-drying pork, beef and fish. †

F. nodosus.

F. *nodosus*: "The frond is coriaceous, compressed, veinless, sub-dichotomous, branched in a pinnated manner; the receptacles are distichous, pedunculated, roundish, mostly solitary."—This is very common on the rocky shores of this country, growing about half way between flood-mark and the ebb; often on the intermediate space between F. vesiculosus and serratus, though it sometimes grows nearest to high-water mark. The fronds are from two to six feet in length, and at short distances swell into large oblong vesicles or air-bladders; by which, though not mentioned in the specific character, the plant is more familiarly distinguished, and from which it has derived its title *nodosus*. Boys

* Thomson's *Annals of Philosophy for April* 1814.

† *Communications to the Board of Agriculture*, vol. 1. p. 219.

Fuci.

amuse themselves by cutting them transversely near the end, and making whistles of them: hence the name *sea-whistles* sometimes bestowed on the plant. The seeds are contained in elliptico-spherical receptacles, which proceed, on short flat peduncles, from the sides of the branches. These receptacles acquire a yellow colour, and give occasion to the name of *yellow tang*, by which this species is known in Orkney. Like the last species, it is much used by the kelp-makers, and it often gets the name of *kelp wrack*. Zoophytes are seldom found attached to this fucus; but dense tufts of the dark-coloured Conferva polymorpha are frequently to be observed on it, and indeed this species of Conferva is scarcely ever to be detected in any other habitat.

F. serratus. F. *serratus*: "The frond coriaceous, flat, mid-ribbed, linear, dichotomous, serrated at the margins; receptacles solitary, terminal, flat, linear, serrated, sharpish." It is sometimes called *black wrack*, or *prickly tang*, sometimes simply *ware*. It is distinguished at first sight by the edges being serrated, and by the absence of air-vesicles. It is only uncovered at ebb tide, growing, as already remarked, in deeper water than F. vesiculosus, or nodosus. In its mode of growth, it forms a pulvillum or circular tuft, spreading out on every side from a central point of attachment. When fresh, the frond is of a dark olive green colour; when cast ashore and dried on the beach, it is almost black. It is very frequently overrun by the small coralline called Sertularia pumila, or sea-tamarisk. Serpula spirorbis, and spirillum, are also frequent on it. The black wrack is preferred for covering lobsters, or other shell-fish, that are to be kept alive during land carriage, being less apt to run into fermentation than some others which abound with mucus. According to Gmelin, 6 ounces only of lixivial salt are procured from 16 ounces of the ashes; and Turner mentions, that he was told that it is but little used for making kelp in the Western Islands, "because it shrinks so much in drying, and contains so little marine salt," meaning soda. In Norway, it is called *bred tang*; and Gunner states, that in some parts of that country, the inhabitants sprinkle it over with meal, and give it to their cattle.

F. loreus. F. *loreus*: "The substance of the frond is between cartilaginous and coriaceous, compressed, linear, nerveless, entire at the margins, dichotomous, expanded at its base into a bell-shaped cup; tubercles immersed in every part, and on both sides of the frond." This species is well known by the name of *sea-thongs*. In Orkney it is called *drew*,—a name which would seem to be etymologically related to the *badreux* of the Straits of Magellan. It is pretty common in the north of Scotland and its islands, particularly on shelving sandstone rocks. When in a young state, before the *thongs* have grown, it forms a concave disc or cup, and gives to the rocks the appearance of being covered with some sort of mushroom, or rather peziza, as mentioned in the specific character. From this circumstance, it is described by some old writers as *Fucus fungis affinis*; and it is perhaps the *Fungus phasganoides* of others. The extended strap-shaped fronds, generally two in number, arise from the centre of the cup. They are dichotomous, or divide into two at intervals. They are generally three, often six, or even ten feet in length. Borlase, indeed, in his *History of Cornwall*, mentions that on that coast, they are sometimes found twenty feet long. The colour is olive green, with a tinge of brown. The plant is pulpy and succulent, and a good deal of excellent kelp is made from it in Orkney; for instance in the island of Westray, on an estate belonging to Dr Traill of Liverpool. It is a perennial species, or at least the plants require two years to come to perfection. Wahlenberg therefore is in a mistake when he says that it is an annual; but it must be considered, that he describes from observations made on the most stormy shores of Norway, where, as he tells us, not a vestige of it survives the winter, where the discs appear only in May, and where the plant never attains a greater length than eight or twelve inches. The same author gives it as his opinion, that the cup-shaped disc is the only part analogous to a frond, the *thongs* being merely seminiferous spikes. To this notion he has been led, partly by the imperfect growth of the specimens he was acquainted with, and perhaps partly by the inaccurate description of the fructification given by Dr Roth. This was first correctly described and delineated by Mr Turner, (*Hist. Fuc.* t. 196.) Elliptical tubercles are everywhere immersed through the strap-shaped fronds, containing masses of minute dark brown seeds.

F. filum. F. *filum*: "The frond cartilaginous, slimy, cylindrical, filiform, attenuated at both ends, jointed internally, spirally twisted when old." This species is frequently called *sea-lace*. In Orkney, it gets the name of *cat-gut*, and in Shetland *lucky minny's lines*. The length to which it grows is amazing, not less than from twenty to forty feet. Lightfoot mentions, that the stalks, skinned when half dry and twisted, acquire such strength and toughness, as to be used for fishing line, like *Indian grass*, (which last, although it has got this vegetable name, is an animal substance, attached to the ovaries of some of the small foreign sharks.) The plant consists of a simple frond, without branches. It is of a deep olive colour. In the interior, the stem is divided by horizontal partitions, which Lamouroux says form a spiral when the plant becomes bent or twisted. The Bishop of Carlisle, and Mr Woodward, had previously remarked (in *Lin. Trans.* vol. iii.) that the whole frond is composed of two equal longitudinal threads, coiled spirally round each other; this structure becoming evident when the plant has received an injury. It floats about in the manner of Sparganium natans, following the course of the waves; but, as remarked by Linnæus, it lies immediately under the surface of the water, not on it. In Scalpa Bay, near Kirkwall in Orkney, we have sailed through meadows of it in a pinnace not without some difficulty, where the water was between three and four fathoms deep, and where of course the waving weeds must at least have been from twenty to thirty feet long. This, too, was the growth of one season; for the storms of winter completely sweep it from the bay every season. The plant, however, may not, strictly speaking, be an annual; and Lamouroux observes, that its duration depends very much on the nature of the place where it grows. In Orkney, a considerable quantity of kelp is occasionally made from this species; and the kelp-makers remark, that "it falls small in burning, and washes like soap." * It is common in all the friths of Norway, as far as the North Cape; and Bishop Gunner adds, that it furnishes a grateful and nutritious food to the Norwegian cattle. The fructification of this species has long been a problem to the naturalist. Roth considered it as placed in a glandular capsule at the extremity of the plant. Stackhouse thought he found it hid in the substance of the plant,

* *Tour in Orkney and Shetland*, 1806, p. 29.

Fuci.

in the form of naked grains. Lamouroux is of opinion, that it is to be sought in certain tubercular excrescences sometimes to be observed near the base or root of the plant. Turner has lately ascertained, that the seeds, or perhaps capsules containing seeds, are situated in the substance of the frond; that they are of a pyriform shape, and crowded together; and that they escape as the epidermis melts away.

F. digitatus.

F. *digitatus:* "The root fibrous; stipes or stem woody, cylindrical, expanded at its apex into a single cartilaginous, flat, nerveless, roundish leaf, quite entire at its margins, deeply cleft into numerous ensiform, mostly simple segments."—This species has in England received the appellation of *sea girdles and hangers,* and in Scotland it is very generally known by the name of *tangle:* in Orkney it is called *red-ware.* It is the *Skalmetare* of the Norwegians, and the *slat-mhara* or sea-wand of the Scots Highlanders. It is one of the largest native species, having a stem often three feet in length, and a large divided frond; and was denominated *phycodendron* or *Fucus arboreus* by some of the older writers. It is very abundant on all our rocky shores, growing chiefly on rocks which are only partially uncovered at the lowest ebbs, so that in neap tides the fronds are scarcely perceptible. The root consists of a congeries of thick horny fibres, often covered with Balanus striatus, and the interstices inhabited by asterias sphærulata and other vermes. In deep water, exposed to a moderate current, but protected from the heavy action of the waves, it attains a great size, the stalk becoming as thick as one's wrist, from three to four feet long, and the fronds of corresponding length, perhaps from ten to twelve feet. Both Turner and Wahlenberg seem to doubt whether F. saccharinus (next described) and this, be specifically distinct. Wahlenberg observes, that, near the shore, the winds and waves prevent a large growth, or the copious production of mucilage, and that in this way the appearance of F. digitatus is so much changed, that a new name (saccharinus) is applied to it. We must be excused for remarking, however, that we have seen specimens of Fucus saccharinus cast ashore from the Frith of Forth, which measured fifteen feet in length; and for adding, that the Fucus digitatus which grows at the Black Rocks near Leith exposed to winds and waves, is uniformly possessed of the distinctive characters of F. digitatus as described by Turner. In Scotland, the very young stalks and leaves are eaten along with dulse, or F. palmatus. Old Gerrard indites, that being boiled tender, and eaten with butter, pepper and vinegar, it makes good food. But at present it is employed only in the raw state. On the shores of some of the Orkney islands, particularly Westray, it is cut by means of long knives or scythes, managed by men in boats at low water; it is tied in large bundles, and being floated ashore, is burned into kelp in reverberatory furnaces. Captain Richan of Rapness has considerable merit in forming a very pure kelp by these means. It may be stated, that Dr Traill of Liverpool, from a series of experiments made by him while resident in the northern islands, found that its fronds yielded more kelp than equal portions of F. vesiculosus, or any of the other species generally used in the manufacture.

In Scotland the stems are sometimes put to rather an unexpected use,—the making of knive-handles. A pretty thick stem is selected, and cut into pieces about four inches long. Into these, while fresh, are stuck blades of knives, such as gardeners use for pruning and grafting. As the stem dries it contracts and hardens, closely and firmly embracing the hilt of the blade. In the course of some months the handles become quite firm, and very hard and shrivelled, so that, when tipt with metal, they are hardly to be distinguished from hartshorn. In the north of Scotland, and especially in the Orkney and Shetland islands, the large stalks are dried and used as fuel. This is likewise done in Norway, and on some of the shores of France, where fuel is nearly equally scarce, but much less needed. The stems are generally invested with many parasitic fuci and confervæ, and not unfrequently with the shell-fish called anomia ephippium and scala.

A curious fact may be mentioned relative to this species. Dr Yule of Edinburgh being engaged in some experiments, in order to ascertain the state in which the saline matter exists naturally in the fuci, had some thick stems of F. digitatus hung up in his cellar. From different parts of one of these, young shoots of frondlets germinated,—of great delicacy and beauty, being nearly transparent. Do the fuci, then, produce buds from their stems, like most land plants; or did these germs originate from seeds accidentally attached to the stem, when in its native element? On being brought into a warm room, the young shoots speedily decayed.

F. bulbosus.

F. *bulbosus:* "The root hollow, swollen into a bulb, rough all over; stipes coriaceous, flat, twisted once at its origin, its margins undulated in the lower part; its apex expanded into a single, cartilaginous, flat, nerveless leaf, entire at its margins, deeply cleft into numerous ensiform, mostly simple segments. The fructification consists in oblong seeds immersed in the margins of the stipes."—This is the Fucus polyschides of the *Flora Scotica,* sometimes called *sea furbelows.* In size it far exceeds any other sea-weed found on our shores, and is certainly not undeserving the titles of *giganteus* and *arboreus,* sometimes bestowed on it by the earlier botanists. It is very curious that, notwithstanding its size, Linnæus seems to have been unacquainted with it. It sometimes occurs twelve feet long; and it is of such a specimen in its wet state, that Lightfoot speaks, when he says, that a single plant is a sufficient load for a man's shoulders. It is plentiful in the Pentland Frith, and numbers of large specimens are frequently cast ashore in the bay of Thurso, as well as on the Orkneys. It is likewise pretty common among the Western Islands. It is found more sparingly on the east coast of Scotland. On the shores of the south of England, of France, and in the Mediterranean, it is very abundant. It is always found in deep water, occupying very commonly, in the southern seas of Europe, those kinds of habitat which F. digitatus generally fills in the north. It very often forms a constituent of the drift-ware collected on the Scottish shores after storms, and either burnt into kelp, or laid on corn lands as a manure.

Esculent species.

In treating of the kelp fuci, it has already been mentioned, that most of them yield a substitute for winter provender to cattle on the bleak shores of northern countries. Some others, which are frequently employed as articles of human sustenance, and which have sometimes saved the inhabitants of those countries from the horrors of famine, are now to be enumerated; with the addition of two or three which are occasionally employed as ingredients in salads and condiments.

F. saccharinus.

F. *saccharinus:* "The root fibrous; fibres long and branching; stipes almost woody, cylindrical, undivided, expanding at its apex into a single cartilaginous flat simple linear oblong nerveless leaf, entire at its margins; the fructification consists in scattered seeds immersed in the leaf."—This species is often called *sea-belt*. It is very common, and one of the largest of our fuci. The colour is a deep olive brown, sometimes partly green. Wahlenberg mentions that he ascertained by experiment that the plant contains no mucilage. An extraordinary circumstance in the history of this plant (already alluded to) was first correctly observed by Mr Bingham of Uxbridge. A contraction is observed to take place in the frond every year: this is occasioned by a new or secondary frond proceeding from the stem, and pushing the old or primary frond before it. Mr Turner was the first who correctly described the fructification. It is observable in the centre of the leaf, in the form of irregular spots, the frond being at these places much thickened, and the surface found, on applying a microscope, to be covered with innumerable extremely minute oblong brown seeds. Lightfoot mentions, that the common people on the coast of England sometimes boil this species as a pot-herb. The Icelanders, we are told by Anderson, boil it in milk to the consistence of pottage, and eat it with a spoon. They are also said to soak it in fresh water, dry it in the sun, and then lay it up in wooden vessels; it soon becomes covered with a white efflorescence of salt, which has a sweetish taste, and in this state they eat it with butter. Lastly, it is mentioned that they feed their cattle with the plant, both in its recent and dry state. There is, however, every reason to think that all this is more properly applicable to Fucus palmatus or dulse, than to the true F. saccharinus; for Mr Hooker informs us that the *alga saccharifera Islandica* is the Fucus palmatus. We are positively certain that the Fucus saccharinus of the Frith of Forth, prepared according to the usual methods of cookery, makes a wretched pot-herb, and that, in its unprepared state, it is of so harsh a nature that cattle cannot relish it. The Norwegians, we may add, on the authority of Wahlenberg, prize it so little, that their name for it, *Toll-tare*, implies that it is fit only for the devil. Very different, however, is the estimate of its merits in some parts of the East Indies. It is there so extensively used as human food, that it is well entitled to be placed at the head of the list of edible fuci. Thunberg, in his *Flora Japonica*, states that it is much used in Japan, and is there prepared in such a way as to be quite esculent. Barrow, in his *Voyage to Cochinchina*, confirms this statement, and mentions, that, when valuable presents are made by the Japanese, they are laid on pieces of this fucus, in testimony, as he thinks, of their regard for it as the general emblem of those sources of subsistence which the sea affords. He is further of opinion, that the famous chinchou jelly of China is in part made from this species. If further proof be wanted, it is furnished by Broughton, who informs us,* that in Volcano Bay, in the island of Matsmai, he saw a junk laden with sea-weed, which he affirms, without hesitation, to have been Fucus saccharinus. He says that it grows plentifully on the shores of Volcano Bay, and that the people were constantly engaged in cutting it, drying it in the sun, and making it up into bundles for exportation. He repeats, in three different places of his work, that the plant alluded to is Fucus saccharinus; and although neither Barrow nor Broughton seem to have any pretensions as botanists, they are supported in this instance by Thunberg, who ranks high as a botanical authority. It may therefore seem extravagant to surmise the possibility of all these writers being in a mistake concerning the identity of the species; yet to those best acquainted with this tribe of plants, it would be no great surprise hereafter to learn, that the Fucus saccharinus of the East is in reality a non-descript species, resembling the British plant. In the mean time, however, we must receive them as the same, and conclude, that the Fucus saccharinus of our shores is neglected and despised, merely because we are ignorant of the mode of preparing it; and that, from the want of this knowledge, a plant, capable of affording a useful article of food or even a nutritious delicacy, is of no use to us, but to swell the heap of drift-ware for the kelp furnace or the dunghil. For the former purpose, indeed, it is not much esteemed, as it is found to become bleached and saltless from even slight exposure to rain."

F. esculentus.

F. *esculentus*: "The frond membranaceous, flat, mid-ribbed, simple, ensiform, entire at its margins, supported upon a short, cylindrical, pinnated stipes; pinnæ fleshy, distichous, oblong, flat, nerveless, containing numerous, pyriform, immersed seeds."—This is called *Badderlocks* or *Hen-ware*, on the east coast of Scotland; and in the Orkney islands, *Honey-ware*. In Norway it is, by way of eminence, styled *tare* or ware. It grows on rocks in pretty deep water, commonly in places where the tips of the fronds can reach the surface at ebb-tide. The stalk is generally from six inches to a foot in length; and near its base occurs a whorl of pinnæ. The frond varies from six to twenty feet in length, with a mid-rib extending the whole way. The mid-rib, stripped of its membrane, is the part chiefly eaten; but in some places, particularly in Orkney, the pinnæ are also eaten, under the name of *mirkles*. Mr Turner mentions that these are likewise called *keys*, and are only brought to market when thick and fleshy, which is generally in August and September. In Norway the pinnæ do not in general appear till the second year. Wahlenberg states, that during the first year the stem is naked, but next year, while the greater part of the frond is destroyed, the stem swells in the middle; from which swelling the pinnæ proceed. At the Carr Rock in the Frith of Forth, the pinnæ were visible not only the first year, but in plants only a very few months old; and the rudiments of them were discernible in some which were only three or four inches long, and apparently but a few weeks sprung.

F. palmatus.

F. *palmatus*: "The frond is membranaceous, flat, nerveless, palmated, quite entire at the margin; segments oblong, mostly simple; seeds naked, collected into wide, irregularly shaped spots, scattered all over the frond."—This is the well-known *dulse* of the low-land Scots, and the *duilliosg* of the Highlanders. In Ireland it is called *dillesk*; and it is there first washed in fresh water, and then dried in the sun, before being used. In this state it is often made up into rolls, and chewed like tobacco. The Icelanders call it *sol*. The Norwegians name it *sou-soell* or sheep's-weed, and Bishop Gunner has therefore adopted the name Fucus *ovinus*, observing that sheep and goats betake themselves in great numbers eagerly to the shore at ebb-tide to obtain this pleasant food. "Buy dulse and tangle," is one of the Edinburgh cries, *tangle* meaning the tender stalks and very young fronds of Fucus digitatus. Both are eaten recent from the sea, commonly without any preparation; they are sometimes considered as forming a salad, but more generally are used as a whet. Dulse is now very seldom fried and brought to table. It is said, that the inhabitants of the Greek

* *Voyage to the North Pacific Ocean, in* 1795, &c. by W. R. Broughton, p. 273.

Fuci.

islands are fond of this species, adding it to ragouts and olios, to which it communicates a red colour, and at the same time imparts some of its rich and gelatinous qualities. The dried leaves infused in water exhale an odour somewhat resembling that of sweet violets, and they communicate that flavour to vegetables with which they are mixed. Lightfoot mentions, that in the Isle of Skye in Scotland, it is sometimes used in fevers, to promote perspiration, being boiled in water, with the addition of a little butter. Fucus palmatus grows not uncommonly on rocks which are barely uncovered at the ebb of the tide; but it is more frequent as a parasite on Fucus nodosus; and it occurs also on the stems of Fucus digitatus, attaining in this situation a considerable size, perhaps twelve or fifteen inches long, while in general it is only about six or eight inches. It is soft and limber, and does not become rigid by drying, being of a more loose texture than many other sea-weeds.

F. edulis. F. *edulis.* "The frond fleshy, flat, nerveless, simple, cuneiform, quite entire, rounded at the apex, attenuated at the base into a very short cylindrical petiolus; solitary seeds scattered all over the frond."—This is not uncommon in Scotland, and being thick and succulent when young, is frequently preferred to F. palmatus, especially for roasting in the frying-pan. Like that species, it gives out a smell somewhat resembling that of sweet violets. When fresh, it is of a deep opake blood-red colour; on maceration, it gives out a purple dye. Old fronds of a large size, perhaps two feet in circumference, are sometimes cast ashore near Leith; these are of a dark colour, and very full of holes. These holes are supposed by the fishermen to be made by crabs, which, they assert, are very fond of this species.

F. ciliatus. F. *ciliatus.* "The frond between membranaceous and cartilaginous, flat, nerveless, generally lanceolate, branched in a pinnated manner, ciliated at its margins and surface; cilia mostly simple, patent, subulate, producing tubercles at their apices."—This is not very common on our shores: it is sometimes, however, mixed with F. palmatus, and sold and eaten as dulse along with that species. It is distinguished not only by its cilia or fringes, but its fine red colour, and almost pellucid substance. It was formerly known by the names of F. lanceolatus, and holosetaceus.

F. pinnatifidus. F. *pinnatifidus.* "The frond compressed, cartilaginous, branched; branches mostly alternate, doubly pinnatifid; ramuli blunt, callous; capsules ovate, sessile, and naked seeds on the ramuli."—In Scotland, this is sometimes called *Pepper-dulse*, from its hot biting taste in the mouth. On account of this quality, although its smell is not very prepossessing, it is sometimes eaten along with the common dulse. In Iceland, it is believed, it is still used in place of a spice. It appears to be an annual, and its pungency is considered as greatest in the early part of the summer. It is very common on all our shelving rocky shores, growing along with F. palmatus and crispus, and Corallina officinalis. It is subject to considerable variations, particularly in colour; being frequently olive yellow, but sometimes tinged with red, or dark red approaching to purple. It is somewhat curious that this species, which is common to Scotland and Iceland, should be found also in the Red Sea, and on the shores of Egypt.

F. natans. In treating of the oceanic fields of sea-weed, some of the uses of Fucus *natans* (including F. natans, bacciferus, and several others of Turner) have already been hinted at. The most succulent fronds are selected, and prepared as a pickle, like samphire, and the young and tender shoots are eaten as a salad, seasoned with juice of lemons, pepper and ginger. This sort of sea-weed is also in some repute as a medicine, being accounted aperient and antiscorbutic, and employed by the native Americans to cure fevers.

Many of the Asiatic nations bordering on the sea, use different species as food. The superior orders employ them chiefly to give consistence to sauces, or to moderate the pungency of the hot spices which they use in such profusion.

F. lichenoides. In the East Indies, and particularly in Ceylon, F. *lichenoides* (*Turn.* t. 118.) is in high estimation for the table. The following is its character: "Frond subgelatinous, cylindrical, filiform, much and irregularly branched; branches patent, nearly of equal height, acuminated, generally forked at their apices, with short divaricated segments; tubercles hemispherical, sessile, scattered all over the frond." From the circumstance of its being used as an article of food, Gmelin, in his *History of Fuci*, gave it the title of F. *edulis*, a name now appropriated to a very different one, allied to the *palmatus*, and above described. F. lichenoides is completely of a gelatinous nature: it is washed in fresh water, and squeezed, so as to remove a considerable part of its mucilage and saltness; after which it is served up with a sauce prepared with lemon-juice and ginger. This is supposed to be one of the principal ingredients employed by the East Indian swallows in constructing those edible nests which are so much in repute not only in China, but throughout India, and in request even at the luxurious tables of London. The most pure and transparent nests are now generally believed to be almost entirely composed of the gelatinous fuci.

F. tenax. F. *tenax* is employed in the Chinese empire to serve all the purposes of our gum Arabic and glue. It is a small cylindrical filiform species, allied to F. acicularis. It was first described by Turner in *Annals of Botany*, vol. ii. and is figured in the *History of Fuci*, t. 125. It is gathered on the shores of the provinces of Fo-kien and Tche-kiang; and although of small size, it is found so plentifully, that about 27,000lbs. are annually imported at Canton, and sold at 6d. or 8d. per lb. As soon as gathered, it is dried in the sun; and being then compressed, it will keep good for several years. When it is to be used, the saline particles and impurities are washed off; it is then steeped in warm water, in which it dissolves, stiffening as it cools into a vegetable gluten, which again liquefies on exposure to heat. It seems probable that this is the principal ingredient in the celebrated gummy matter called *chin-chou*, or *hai-tsai*, in China and Japan. Large sheets of paper or of coarse gauze are besmeared with it; they thus acquire additional transparency, and are used in windows or lanterns. Windows made merely of slips of bamboo crossed diagonally, have frequently their lozenge-shaped interstices wholly filled with the transparent gluten of the hai-tsai.

It is remarked by Mr Turner, (*Hist. Fuc.* t. 216—218), that the common and well-known though very variable species, F. *crispus* and *mamillosus* of our own shores, are readily melted by boiling, and that they afterwards form a gelatine. This has not yet, however, been applied to any use, either by the cook or the artist. Unfortunately they are not only of small size, but could not easily be gathered in sufficient quantity.

It may be mentioned, on the authority of Mr Barrow, that at the Cape a kind of gelatinous fucus, very useful as food, is gathered, particularly from the shores of Roben Island. The leaves are described as sword-

Fuci.

shaped, serrated, and about six inches long. These being first washed clean, and sufficiently dried to resist putrefaction, are steeped in fresh water for about a week, changing it every day. After this, being boiled for a few hours in a little water, they form a clear transparent jelly; which being mixed with sugar, and the juice of a lemon or orange, affords a pleasant and refreshing dish.

According to Dr Olaus Swartz, F. *spinosus*, (muricatus of Gmelin) is eaten by the inhabitants of Sumatra. This species occurs at the Cape, but is there neglected.

Some of the gigantic species, particularly F. *potatorum* of Labillardiere, furnish various instruments and household vessels, as well as food, to the native inhabitants of New Holland.

A few of the smaller and more delicate kinds seem capable of affording colouring matter or paint. Ginanni describes one under the name of *Fuco tintorio*. This Mr Turner considers as probably F. purpureus, which is very common in the Mediterranean, and gives out a beautiful chocolate dye in fresh water.

It may be mentioned, that in the North of Scotland, a kind of sauce for fish or fowl, somewhat resembling ketchup, is made from sea-weeds; frequently from the cup-like frond or base of F. loreus.

Medicinal species.

The mucus from the vesicles of F. vesiculosus and similar species, has been recommended in diseases of the glands, by Dr Russell; and F. *helminthocortos*, (*Turn.* t. 233.) a small Mediterranean species, though little known in Britain, has long been employed by medical men on the continent as a vermifuge, under the name of Moss or Coralline of Corsica.

Ornamental species.

Some of the small red species are very ornamental when displayed in pictures; and are used not only to embellish the cabinet of the naturalist, but apartments in general. The foreign species chiefly employed for this purpose, is F. *cartilagineus*, which abounds at the Cape, and is remarkable for the regularity and elegance of its form, and the richness of its tints.

F. cartilagineus.

F. coccineus.

The native species most generally used for forming mimic trees or landscapes, is F. *coccineus*. The frond is compressed, in substance between membranaceous and cartilaginous, much and irregularly branched; the ramuli subulate, disposed in alternate parcels of three or four each. As formerly observed, two kinds of fructification are to be found on different individuals of this species; both spherical sessile capsules, and lanceolate siliquæ. It is beautifully figured by Turner (*Hist. Fuc.* t. 59.) and also by Stackhouse, in a frontispiece to one of the fasciculi of his *Nereis Britannica*, (p. 106.) It is singular that this species, though very common, escaped the notice of Linnæus. When it is dexterously expanded on very smooth white paper, or on the glossy interior of large flat shells, the effect is very beautiful. It is generally of a bright red colour, but sometimes tinged white or yellow. It grows about three or four inches long. In minuteness of ramification, it is excelled only by F. *asparagoides*, (*Turn.* t. 101.) a species of much less frequent occurrence.

F. plumosus.

F. *plumosus* is likewise very ornamental. The frond is compressed, cartilaginous, much and irregularly branched; the branches are repeatedly pinnated, producing the feather-like appearance, from which the name has been given. It is of a purple colour, often inclining to yellowish brown. It is generally from three to five inches long; but in the north of Scotland it reaches six or seven inches. Still farther to the north of Europe, as on the northern coast of Norway, it grows to yet a larger size; so that it may truly be reckoned a northern plant. It is generally found attached to old stems of fucus digitatus.

F. alatus.

F. *alatus* is the most abundant of all the small ornamental sea-weeds, being very common on stalks of F. digitatus. The frond is membranaceous, very tender, mid-ribbed, linear, subdichotomous; the segments alternately pinnated. It is three or four inches high, and of a fine purplish red colour.

Preserving of Sea-weeds.

Preserving of sea-weeds.

Many of the fuci, and particularly the Florideæ of Lamouroux, make a beautiful appearance when preserved in a herbarium or hortus siccus. All of them require to be soaked for some time in fresh water, and they are the better for being repeatedly rinsed in renewed basons of water, to cleanse away and extract as much as possible the sea-salt which adheres to them, or with which they are impregnated. The larger sort need no other preparation; but are to be dried between folds of bloating paper, and pressed in the manner of herbaceous plants. The finer leaved fuci must be treated in a different way. After being washed, as above directed, in repeated waters, till no impurities of any kind remain, they are to be separately floated out in a large shallow dish containing water, so that their most minute and delicate branches may be fully expanded. For disentangling the nice ramifications, a common pin, or a sharp-pointed pen, may be employed. A piece of stiff, but fine and smooth writing paper, is then to be gently introduced under the specimen, and the minute branchlets being again spread out where they may have been disordered, the paper is to be cautiously and slowly inclined, and at last drawn out, so as to contain on its surface the plant in its fully expanded state. After this, most of the delicate species, if carefully dried and pressed, adhere to the paper by their own gluten, and require no farther care. Mr Turner mentions that he fixes the non-adhesive kinds by means of a cement made from F. ciliatus and crispus of our shores. These are boiled in water over a quick fire, and soon become melted: on cooling, they form a gluten, not to be relied on as a strong cement, but which is well adapted for a herbarium, as it neither imparts a stain like glue, nor a glare like gum. If the paper be slightly rubbed over with the mucilage, and a delicate membranaceous plant afterwards placed on it, it will become sufficiently fixed merely by moderate pressure. Some collectors, finding that any kind of paper is apt to curl up, expand the delicate species over a plate of glass, and, after allowing the water to drip off, transfer the specimen carefully to the paper.

To inland collectors, who occasionally make an excursion to the shore, it may be useful to know, that all the preparation that is necessary at the sea side is to dry the specimens moderately in the free air, and tie them loosely up in strong brown paper. In this way they may be carried to a great distance, and kept for some days. On being immersed in fresh water, they in general expand as fully as before; but it must be confessed that the colour of some kinds is extremely apt to change. In the *vasculum*, or botanic box, which serves so well for preserving herbaceous land plants, specimens of marine plants very rapidly undergo the putrefactive fermentation. (P. N.)

Fuego.

FUEGO, or TIERRA DEL FUEGO, "the land of fire," was so denominated by Magellan, because he perceived many fires during the night, supposed to have been volcanoes in the mountains, but probably nothing more than the numerous fires kindled by the natives on account of the cold. It is a large island, or rather group of islands, bounded on the north by the straits of Magellan, and on all other sides by the sea; situated between 52½° and 56° South Latitude, and between 65° 10′ and 75° 30′ West Longitude from Greenwich. It is divided by narrow straits into eleven or more islands of considerable size, and extends about 300 miles from east to west, and from 100 to 200 in breadth. From Charlotte promontory, which is the north-east extremity, the coast extends west north-west, to a large promontory, that forms the mouth of the first narrow passage in the strait; and then, in a south south-west direction, forming a circular basin, which terminates at the promontory of Sweep-stakes on the south side of the second narrow channel. The inhabitants on this part of the coast behaved with great humanity to the crew of the Spanish ship Conception, which was wrecked on their shores in 1765; assisting them in saving part of their cargo, and in erecting sheds to shelter them from the weather; and discovered so little of the cruelty common to most savages, that the Spaniards of South America projected a missionary establishment among them. The coast next inclines southward, forming an arch of a great circle, cut by Cape Monmouth, and the inlet of St Sebastian, on to Savage bay, from which a mountainous country stretches south-west, exhibiting the appearance of several narrow straits. Beyond these is Swallow harbour, a well sheltered bay, where there is good landing and a sufficient supply of wood and water; but the surrounding mountains have a dreary aspect, and seem to be deserted by every thing that has life. The coast continues now in a north-west direction, forming many bays and inflexions, inclosed by barren rocks without any appearance of soil, having their summits covered with snow, and their deep vallies filled with immense masses of ice. To this part of the country Sir John Narborough gave the name of "the land of Desolation;" and nothing more dreadful, says Bougainville, can be imagined. It is still high and steep, and terminates in Cape Pillar, the north-west extremity, where the Pacific Ocean opens to the view. This cape is a great mass of rocks, which rise into two huge cliffs resembling towers; and round it are several small islands or rocks named the Twelve Apostles, reaching several miles into the sea. Two leagues south of Cape Pillar is Cape Desire, from which the coast takes a south-east direction, and is broken into various inlets, or rather composed of a number of islands, beyond which appear barren and rocky mountains, spotted with tufts of wood and patches of snow. From Cape Gloucester, which is about 23 leagues from Cape Desire, the coast turns south-south-east for ten leagues, to Black Cape, a steep and high rock, shaped like a sugar loaf; a little towards the east from which is the great bay of St Barbara, supposed to communicate with the Straits of Magellan. Beyond this bay, the country is entirely composed of rocky mountains without the least appearance of vegetation, terminating in dreadful precipices, and raising their craggy summits to an immense height. About 23 leagues from Barbara Bay, appears Cape York Minster, a lofty promontory, terminating in two high towers, with a conical hill between them. To the east of this opens Christmas Sound, in the bottom of which is a deep and secure harbour, named Devil's Bason, so completely encompassed by lofty rocks as to be entirely excluded from the rays of the sun. To the south-east of Christmas Sound is a group of rocks, called the Isles of Ildefonso, nearly east from which is Nassau Bay, whose west point is the most southerly extremity of Tierra del Fuego, and is sometimes denominated False Cape Horn. In front of Nassau Bay lie the Hermit Islands, the south point of which is the True Cape Horn, known at a distance by a round hill over it, and situated in 55° 58′ South Latitude, and in 67° 46′ West Longitude. The coast stretching north-east from Nassau Bay is little known for the space of 30 leagues, to Valentine's Bay, which forms the south-west entrance of the Strait of Le Maire. About the middle of this strait, on the Tierra del Fuego side, is the Bay of Good Success; and on the south-east extremity are two low promontories, called Cape Diego and Cape Vincent, where the strait opens to the east. From these capes to Charlotte Promontory, the eastern coast of Tierra del Fuego is more level, woody, and verdant, than any other part. The soil here in the vallies is rich and deep; and a stream of a reddish hue, but of good water, runs at the bottom of almost every hill.

Interior of the country.

The interior parts of Tierra del Fuego have never been explored, but appeared to consist of continued mountains of immense height and irregular surface. About one-fourth of their ascent is frequently covered with trees of a considerable size. Towards the middle, nothing but withered shrubs appear: next succeed patches of snow and fragments of rock; while the summits, composed of huge crags piled upon each other, and towering above the clouds, are devoted to everlasting sterility. Many of them are nothing but immeasurable masses of rock, naked from the base to the summit, without a single shrub or one blade of grass to be seen upon them; and the intermediate vallies, equally destitute of verdure, are filled with beds of snow, or masses of ice. The climate is intensely cold and stormy; and, even in the midst of summer, the ground is frequently covered with snow. Its severity is fatally exemplified by an accident mentioned in Captain Cook's first voyage, a part of whose crew having attended Sir Joseph Banks and Dr Solander on shore, and having been obliged to pass the night in the open air, though it was upon the most temperate part of the coast, and about the season of midsummer, two of them expired of cold; and Dr Solander himself, a native of Sweden, was saved with great difficulty. Even in this barren soil and dreary climate is found a great variety of plants unknown in Europe. The trees chiefly noticed were, beech, birch, winter-bark or spice laurel, and the holly-leaved barberry. The plains are covered with a kind of spongy moss; and nettles, wild celery, and scurvy-grass, are generally found close to the beech. Cranberries, red and white, are produced in great abundance. Fish may be procured with great facility on every part of the coast, and particularly on the Straits of Magellan. Whales, seals, and sea-lions, are seen in great numbers along the shores, particularly in the Straits of Le Maire. There are great quantities of shell fish, limpets, clams, and especially mussels, some of which are five or six inches in length. Few insects have been observed in the country, and none that were either hurtful or troublesome. Of land-birds there are few varieties: and none have been seen larger than an English blackbird, except a few hawks and vultures. But there is plenty of water-fowl, sea-pies, shags, and the kind of gull generally called Port Egmont hen;

Climate.

Productions.

geese, resembling bustards, smaller than the tame geese of England, but well tasted; and ducks of several kinds, the most remarkable of which, called by the sailors race-horses, are unable to fly on account of the shortness of their wings, but run upon the water with amazing swiftness. Almost the only quadrupeds observed by navigators were dogs in a domestic state, which differed from others of their species bred in America, in possessing the faculty of barking. The traces of larger animals were indeed noticed in some places: but their species could not be ascertained.

The natives of Tierra del Fuego are the most deplorable in appearance, and the most destitute in resources, of the human race,—inhabiting the most inhospitable climate in the world, and possessing no sagacity to provide themselves with those few conveniences, which even their dreary land might supply. They are a little, ugly, meagre, and beardless race, * with long black hair, and the colour of their skin like the rust of iron mixed with oil. Their whole apparel consists of the stinking skin of a seal, sometimes of a guanicoe, thrown over their shoulders, exactly in the state in which it was taken from the back of the animal. A piece of the same skin is sometimes drawn over their feet, and gathered about the ancles like a purse; and a small flap is worn by the women as a fig-leaf. They appeared very fond, however, of ornament, and paint their faces in various forms, generally with horizontal streaks of black and red, with a white ring round the eyes. They wear upon their wrists and ancles bracelets of beads formed of small shells or bones, and delight particularly in every thing that is of a red colour. Their food consists chiefly of cranberries and shell-fish, and sometimes the flesh of whales or seals, which they devour with the greatest relish in a raw and rotten state. Some of Captain Wallis's people gave to one of them a fish, as it was taken alive out of the water: the Indian snatched it hastily as a dog would take a bone; and, instantly killing it, by giving it a bite near the gills, proceeded to eat it, beginning with the head, and going on to the tail, without rejecting either the bones, fins, scales, or entrails. They ate readily whatever food was given to them by European voyagers, but could not be persuaded to take any other drink than water. They appear to have no fixed residence, but to move from one place to another, after having exhausted the supplies of shell-fish around their habitations. Their huts are constructed in the most rude and inartificial manner imaginable, and are merely a few poles set up inclining towards one another, and forming a cone at the top like a bee-hive. They are covered on the weather-side with a few boughs and a little grass, yet not so as to exclude the snow or rain; and, on the lee, nearly an eighth part of the circumference is left open, both as a door and a chimney. Within these wretched hovels no kind of furniture is seen; and a little grass laid round the inside of the stakes, serves the purposes of chairs and beds. The only utensils observed among them were a satchel to hang on the back, a basket to carry in the hand, and a bladder to hold water. Wherever they halt, though only for a short time, in the open air, they always kindle a fire; and are generally affected with sore eyes, from sitting so much over the smoke of their fires. Even in their canoes, they have a fire placed on a heap of sand in the midst of the vessel, around which they huddle themselves as close as possible; and which they seem thus to carry about with them, not only for the sake of immediate warmth, but in order also to have fire ready kindled wherever they may land. Their canoes are extremely slight made, sometimes of planks, but generally of pieces of bark sewed together either with the sinews of some wild beast, or with thongs cut from a hide. A kind of rush is laid into the seams; and the outside is smeared with a resin or gum, to prevent the water from soaking through the bark. About fifteen slender branches, each bent into an arch, are sewed transversely to the bottom and sides; and some straight pieces are placed across the top from one gunwale to the other, and fastened securely at each end. These vessels are about fifteen feet long, three broad, and three deep, are steered with paddles, and have only a seal-skin as a sail. The only appearance of ingenuity among them was in their weapons, which consisted of bows, arrows, and javelins. Some of the bows were neatly made, with strings of gut; and the arrows were formed of wood, very highly polished, with a point of glass or flint, barbed, and fitted to the shaft with wonderful skill. In the use of these weapons they discovered great dexterity, and seldom failed to hit a mark at a considerable distance. They have also a kind of harpoon, which they use in fishing, formed of a fish bone about a foot in length, sharpened at the end, toothed on one side, and fixed to a long pole. No appearance of subordination or government has been observed among them, and no one is respected more than another; yet they seemed to live together in the utmost harmony. Neither do they discover any notions of religion, unless a vehement vociferation addressed to every new object, may be considered as a species of exorcism, and as implying a belief in evil spirits. Both those who were seen by Bougainville and by Cook, though on different parts of the coast, gave themselves the name of Pecheray; and they do not seem to be a numerous people. Their language in general is guttural, and some of their words are expressed by a sound resembling that which is made by clearing the throat; but other expressions are sufficiently soft, such as *hallĕcă*, beads, and *oodâ*, water. They are harmless, and friendly towards strangers; and, either from a contented disposition, or from stupidity of mind, discover no desire for additional possessions and gratifications. When carried on board of European ships, they testified no emotions of surprise, satisfaction, or curiosity; regarded every object, except looking-glasses, and the clothes of the people, with utter indifference; and expressed no wish for any thing whatever but beads. One of their women even offered her sucking child to an officer of Byron's ship; and their whole aspect and manners declared them to be among the lowest and most wretched of human beings. See Byron's, Wallis's, Bougainville's *Voyages*, and Cook's *First and Second Voyages Round the World*. (*q*)

FULCRUM. See Mechanics.

FULDA, a town of Germany, in the circle of the Upper Rhine, and capital of the bishopric of the same name, but lately transferred to the Grand Duchy of Frankfort, is situated nearly in the centre of the bishopric, on the banks of the river Fulda. The principal objects of interest at Fulda, are the palace, with its pleasure gardens, where the bishop formerly resided, containing an apartment of optical glasses; the cathedral and its

* A few of the men on the coast of the Straits of Le Maire were larger, and more clumsily made.

Fulda, Fullers Earth.

treasury; the church of St Boniface; the church of St Michael, which is said to have some resemblance to the temple of Jerusalem; and the convent of Franciscans, finely situated out of the town. The University of Fulda was founded in 1739; and in the ancient library are to be found many rare and valuable MSS. Here is a manufactory of porcelain. In the neighbourhood of Fulda are the baths of Bruckenau, which are celebrated for their romantic situation, and for the good society which is to be met with. The celebrated Jesuit, Athanasius Kircher, was a native of this town. Population 12,000. Its position, according to trigonometrical observations, is East Long. 9° 44′ 0″, and North Lat. 50° 33′ 57″. (*w*)

FULDA, Bishopric of, the name of an ancient principality in Germany, which was included by Bonaparte in the Grand Duchy of Frankfort. The extent of this principality was formerly 37 square German miles; its annual revenue 35,000 rixdollars, and its population 900,000. The principality contained many well-wooded mountains, some rich arable land, and several important salt springs. See Confederation *of the Rhine*, Germany, and Catteau de Calleville's *Voyage en Allemagne et en Suede*, tom. i. p. 259, 260, where the reader will find an account of the origin of the town of Fulda.

FULGORA. See Entomology, *Index*.

FULLERS Earth. Two sorts of argillaceous earths are described under the name of *cimolia*, in catalogues of the Materia Medica, *cimolia alba, seu argilla alba*, Pharm. Edinb. the pure white strong clay, called, from the use to which it is principally applied, tobacco-pipe-clay; and *cimolia purpurascens*, (Pharm. Edin.) a compact bolar earth, commonly of a greyish brown colour, called from its use fullers earth. These have been both since expunged, and the name *cimolia* would appear to have been given from Cimolus, the ancient name of an island in the sea of Crete, opposite to the promontory Zephyrus, having the same kind of soil; hence *terra cimolia*, Κιμωλια γη, chalk, or fullers earth, and *Cretosaque rura Cimoli*, Ovid; it is now called *Sicandro*.

Among the useful researches for which we are indebted to the illustrious Bergman, we find one upon lithomarge, or stone marl, which seems to differ from common marl in its composition, chiefly in possessing a much larger portion of siliceous, and less of calcareous earth; the general characters of which are, 1*st*, When dry, it is smooth and slippery, like hard soap: 2*dly*, It is not perfectly diffusible in water; but when immersed in that fluid, it falls into pieces of greater or less magnitude, or in such a manner as to assume the appearance of curds: 3*dly*, In the fire it easily melts into a white or reddish frothy slag, which is considerably larger than before, in consequence of its porosity: 4*thly*, Its fracture is irregularly convex, or concave. Fullers earth is one of the most useful varieties of lithomarge. Its particular characters are, that the colour is greenish white, greenish grey, olive, oil green, greyish ash coloured, brown in all degrees from very pale to almost black; light yellowish green, or yellowish grey, passing into pale ochre yellow; its colours are sometimes disposed in spots or stripes, it occurs only in mass, and is without lustre; it is very hard and firm, of a compact texture, of a rough and somewhat dusty surface; its fracture is uneven, passing into large conchoidal and slaty or fine-grained; it breaks by force into indeterminate, blunt-edged, or slaty fragments; it is unctuous to the touch, not staining the hands, nor breaking easily between the fingers. It has a little harshness between the teeth, melts freely in the mouth, adheres slightly to the tongue. It is opake, and sufficiently soft to be scratched by the nail. It takes a polish by friction, is moderately heavy; but its specific gravity has not been accurately ascertained: thrown into water, it makes no ebullition, or hissing, but swells gradually in bulk, and falls into a fine soft powder, especially when the water is warm: it does not effervesce with acids; before the blow-pipe it melts into a brown spongy scoria. The fullers earth of Hampshire was analyzed by Bergman, from which he obtained the following results:—

Silex	51.8
Alumine	25.0
Lime	3.3
Magnesia	0.7
Oxide of iron	3.7
Water, or moist volatile matter . .	15.5
	100.0

The analysis of other earths included in lithomarge will be found below, under *Substitutes*. There appears to be two distinct formations of fullers earth; or rather two different minerals seem to be confounded under the same name. The fullers earth of Saxony belongs to the primitive rocks, being found under strata of slaty *grunstein*, and passing by degrees into this very mineral; hence it consists of the same materials, either originally deposited in this loose state, or having acquired this consistence from decomposition. The English fullers earth, on the other hand, is always found in beds covered by, and resting upon, that peculiar and hitherto undescribed sand-stone formation, which accompanies and serves as the foundation to chalk.

Fullers earth is found in several counties of England; but in greatest abundance in Bedfordshire, Berkshire, Hampshire, and Surry. For some account of this mineral in Surry, see the article England, vol. viii. p. 713. As a more particular account will naturally be expected under the present article, we shall consider the subject under the following heads: 1*st*, Particulars with regard to the counties of England in which it has been found; 2*dly*, The mode of treatment adopted by manufacturers; 3*dly*, Its various uses; 4*thly*, Legal restraints; 5*thly*, *Substitutes* used either at home or abroad.

Account of the fullers earth in Surry.

In the county of Surry there are great quantities of fullers earth found about Nutfield, Riegate, and Blechingley, to the south of the Downs, and some, but of inferior quality, near Sutton and Croydon, to the north of them. The most considerable pits are near Nutfield, between which place and Riegate, particularly on Redhill, about a mile to the east of Riegate, it lies so near the surface, as frequently to be turned up by the wheels of the waggons. The fullers earth to the north of the road between Redhill and Nutfield, and about a quarter of a mile from the latter place, is very thin; the seam in general is thickest on the swell of the hill to the south of the road. It is not known how long this earth has been dug in Surry; the oldest pit now wrought is said to have lasted between fifty and sixty years, but it is fast wearing out. The seam of fullers earth dips in different directions. In one, if not in more cases, it inclines to the west with a considerable angle. There are two kinds of it, the blue and the yellow: the former, on the eastern side of the pit, is frequently within a yard of the surface, being covered merely with the soil,—a tough, wet, clayey loam. A few yards to the west, the blue kind appears with an irony sand stone, Fullers Earth.

of nearly two yards in thickness, between it and the soil. The blue earth in this pit is nearly 16 feet deep. In some places the yellow kind is found lying upon the blue; there seems, indeed, to be no regularity either in the position or inclination of the strata where the fullers earth is found, nor any mark by which its presence could be detected. It seems rather thrown in patches, than laid in any continued or regular vein. In the midst of the fullers earth are often found large pieces of stone of a yellow colour, translucent, and remarkably heavy, which have been found to be sulphate of barytes, encrusted with quartzose crystals. These are carefully removed from the fullers earth, as the workmen say they often spoil many tons of it which lie about them. There is also found with the yellow fullers earth a dark brown crust, which the workmen consider as injurious also. In Surry, the price of fullers earth seems to have varied very little, at least for these last 80 years. In 1730, the price at the pit was 6d. a sack, and 6s. per load or ton. In 1744, it was nearly the same. It is carried in waggons, each drawing from three to four tons, to the beginning of the iron rail-way near Westham, along which it is taken to the banks of the Thames, where it is sold at the different wharfs for about 25s. or 26s. per ton. It is thence shipped off either to the north or west of England. A considerable quantity is also taken down into Wiltshire by the waggoners, especially when they happen not to have a full load of goods.

The workmen are paid at the rate of 2s. 6d. per ton; this includes the expence of clearing away the upper soil, as well as that of raising the fullers earth. They can work on the *earth* only when the weather is dry; it is then weighed as it is dug out, by means of a rude scale suspended over that part of the pit where they happen to be working, on three or four poles fastened together at the top, and spread out at their lower ends, (an instrument called provincially a triangle). The earth that is not immediately carted off by the waggons, is put under cover in an adjoining shed, in order to preserve it from the rain. During rainy weather, and after it till the earth is pretty well dried, the workmen employ themselves in uncovering the upper soil. The sandstone that lies over the blue fullers earth is broken into pieces; the larger pieces are used for building, and the smaller for the roads; the first brings 4s. 6d. the waggon load, the second 3s. 3d.; of each of which the workmen receive about one half. In the heart of the sandstone, pieces of petrified wood, of considerable size, and sometimes of a very grotesque shape, are often found. The workmen complain, that since the iron rail-way was brought to Westham, the demand for this earth, though equally great, is not nearly so *regular* as it used to be. It is thought that the demand for the Surry fullers earth will be lessened by the recent discovery of a pit of the yellow, or better sort, near Maidstone in Kent. Fullers earth does not appear to hasten or impede, to injure or to benefit, vegetation. See Stevenson's *Surry*, p. 50—53.

In Derbyshire.

The next characteristic stratum, owing to its forming a ridge of conspicuous hills through the country, is the Woburn land, a thick ferruginous stratum, which below its middle contains a stratum of fullers earth, which is thicker and more pure in Aspley and Hogstye End, two miles north-west of Woburn, than in any known place. The upper parts of this land are frequently cemented by the oxidated iron into car stone, and the lower parts contain fragments of silicified wood. See Farey's *Derbyshire*, p. 112.

No stratum of this mineral occurs in Derbyshire; but lumps of it of considerable size, very pure, and much like that of Bedfordshire, are frequently found in the marshy gravel pit one-third of a mile east of Bretby church. Similar lumps occur in the hard gravel rock under Masham town, and smaller ones in the alluvial covering of the gypsum quarries south-east of Chellaston. In Brassington a clay is dug with which cloths are scoured; and at Brathwell, north-west of Tickhill in Yorkshire, considerable quantities of fullers earth are got, probably alluvia on the yellow lime. See Farey's *Derbyshire*, p. 465.

In Herefordshire.

Of the more rare kinds of earths and clays, there have been found red and yellow ochres, fullers earth, and tobacco pipe-clay; but probably from the want of an adequate supply, or some imperfection in their qualities, they are now generally procured from other places. Fullers earth is, however, still dug occasionally for sale in small quantities, on the estates of the late honourable Edward Foley, of Stoke Edith. See Dunscomb's *Herefordshire*.

In Sussex.

Fullers earth is found at Tillington, and consumed in the neighbouring fulling mills. See Young's *Sussex*.

In Middlesex.

Mr Little and Mr Brown, in sinking a well at Paddington in the year 1802, near the one mile stone on the Edgeware-road, discovered a stratum of fullers earth at a considerable depth, but so thin as not to be of any importance. See Middleton's *Middlesex*.

Mode of preparing fullers earth.

The above seems to be nearly all the places in England where this mineral is best found. We have now to give an account of its preparation by manufacturers, for their peculiar purposes. We have seen in the chemical account of this mineral, that it is not perfectly diffusible in water; but when immersed in that fluid, it falls into pieces of greater or less magnitude, or in such a manner as to assume the appearance of curds. Of this the manufacturers are fully aware; but as it is necessary for them that the coarse and fine should be minutely separated, they pursue the following method. That they may effect a complete solution, they bake it for one or two hours, according to the degree of heat. To accomplish greater regularity in the baking, and to make it dissolve much sooner, the large lumps are broken into pieces of a quarter or a half pound each. After baking it is thrown into cold water, when it falls into powder; and the separation of the coarse from the fine effectually accomplished, by a simple method used in the dry colour manufactories, called *washing over*. It is done in the following manner: Three or four tubs are connected in a line by spouts from their tops; in the first the earth is beat and stirred, and the water, which is continually running from the first to the last through intermediate ones, carries with it and deposits the fine, whilst the coarse settles in the first. The advantages to be derived from this operation are, that the two kinds will be much fitter for their respective purposes of cleansing coarse or fine cloth; and without baking the earth would be unfit, as before noticed, to incorporate so minutely with the water in its native state; it would neither so readily dissolve, nor so easily be divided into different qualities, without the process of washing over. When fuel is scarce for baking the earth, it is broken into pieces of the same size, as mentioned above, and then exposed to the heat of the sun.

Uses of fullers earth.

The various uses of fullers earth may be shortly explained. According to the above method, the coarse and fine of one pit are separated; and the first is used for cloths of an inferior, and the second for those of a superior quality. The yellow and the blue earths of Surry are of

Fullers Earth.

different qualities naturally, and are like the above, obtained artificially, and used for different purposes. The former, which is deemed the best, is employed in fulling the kerseymeres and finer cloths of Wiltshire and Gloucestershire, whilst the blue is principally sent into Yorkshire for the coarser cloths. Its effects on these cloths, is owing to the affinity which alumine has for greasy substances; it unites readily with them, and forms combinations which easily attach themselves to different stuffs, and thereby serve the purpose of mordants to some colours; as is the case in the Turkey red. The fullers generally apply it before they use the soap. It may be used also instead of soap on board of ship, to wash linen or the hands with salt water, with which it is well known soap does not unite.

Uses of fullers earth.

Legal restraints.

The legal restrictions on the exportation of fullers earth, may be found in the 12 Car. II. 13 and 14 Car. II.; 9 and 10 William III. c. 40; 6 Geo. I. c. 21. § 22. The penalties are so enormous, that foreign chemists turned their attention to discover substitutes for fullers earth. Cronstedt describes only the lithomarge of Osmund, Tartary, and Lemnos; the Hampshire fullers earth not having come to his hands, probably on account of the severe penalties imposed by the English legislature on its exportation. Bergman examined them all except the second, which is the keffekil of the Crim Tartars, who are said to use it instead of soap, and which he was not provided with a sample. Wiegleb, in Crell's *Journal*, quoted by Kirwan, found that it consists of equal parts of magnesia and silex.

Substitutes for fullers earth.

Lemnian earth.

The Lemnian earth, so called as being found in Lemnos, was highly esteemed for many centuries, for its supposed medical virtues, and till lately sold in Europe under the seal of the grand signior, (hence called *terra sigillata*,) has the external appearance of clay, with a smooth surface, resembling agate, especially in its recent fractures, which are usually either concave or convex. It may be scraped with the nail, is composed of impalpable particles, though a little gritty between the teeth, under which it feels like tallow. When immersed in water, it is spontaneously divided into small pieces, with a slight crackling noise, but they do not become so small as to be invisible or impalpable; pulverization and boiling in water diffuse it in the fluid, which passes almost perfectly clear through double filtering paper. This earth removes impurities like soap, though it affords no froth.

Osmundic earth.

The Osmundic earth comes from Osmund, in the parish of Rutwick, in East Dalecarlia. It colour is grey like cinders; its surface rough, and as if greased; it is harder than the Lemnian earth, breaks into angular pieces, adheres strongly to the lip, and is more gritty between the teeth than that earth: in water it separates into smaller particles, and is detergent. By the humid analysis, Bergman found the constituent parts of the two foregoing earths as follows:

Lemnian earth.

Silex	47
Carbonate of lime	5.4
Magnesia	6.2
Alumine	10
Oxide of iron	5.4
Moist volatile matter capable of being expelled by drying	26
	100

Osmundic earth.

White siliceous powder	60
Lime	5.7
Magnesia	0.5
Alumine	11.1
Oxide of iron	4.7
Moist volatile matter	18
	100

Fullers earth of Saxony.

Amongst the foreign varieties of lithomarge, the fullers earth of Saxony ought not to be forgotten, particularly in this place, where substitutes are treated of: For this, however, we must refer to the beginning of the article, and this head will be concluded by introducing a substance that is very generally found both in Great Britain and abroad. Fullers earth, we have seen, from the general results, is alumine, combined with very fine silex; it is essential to this earth that the particles of silica should be very fine, otherwise they would cut the fine cloth; hence the object in washing over the fullers earth mentioned in a preceding paragraph. It is owing to the strong affinity, as noted before, which alumine has for greasy substances, that it is so useful in scouring cloth; hence pipe clay, the cimolian earth mentioned in the beginning of this article, is frequently used for the same purpose; and it may also be concluded, that *any clay* possessed of this property may be considered, in its uses, as fullers earth; for it is the alumine alone which acts upon the grease in the cloth.

The properties required in good fullers earth are, that it should contribute to the washing away all impurities, and promote that curling and intermixture of the hairs of the woollen cloth, which thicken its texture, and give it the desired firmness. Both probably depend on its detergent quality, that clears away all the unctuous matter of the wool, and renders its parts capable of becoming more perfectly entangled by the mechanical action of fulling; an effect not so likely to take place where the fibres or hairs are disposed by grease to slide easily over each other. The detergent power resides in all clays, but is doubtless greatly increased by the siliceous earth, which may be considered as the brush, while the clay serves as the soap. This is familiarly shewn by the common practice of adding sand to soap, which renders it much more detergent, but, at the same time more capable of injuring the substances to which it is applied, and that more especially when the sand is course. Fullers earth is bad if the sand be not exceedingly fine, and the superior excellence of the Hampshire earth seems to depend more on the fineness of its parts, than on their proportions, as is shewn by the experiment of boiling it in water, after which it passes more plentifully through the filter than any of the other kinds of lithomarge. (s)

FULMINATING POWDERS is a name given to those chemical compounds which are decomposed with such rapidity as to produce a report, with other signs of violence. The most conspicuous of these bodies are the ammoniurets of gold, silver, and mercury; the precipitate formed by alcohol from nitrate of mercury, which has been called *fulminating mercury*, and the powder formed with potash, nitre, and sulphur, called *pulvis fulminans*.

Fulminating gold.

The first of these compounds, viz. ammoniuret of gold, is prepared by dissolving gold in a mixture of equal parts of nitric and muriatic acids; dilute the so-

Fulminating Powders.

lution with three times its volume of water; and add pure aqua ammonia by a little at a time, so long as any precipitate is thrown down. Beyond this point, more ammonia would redissolve the precipitate, which is the substance to be obtained.

In this process, the ammonia combines with the oxide of gold, forming an insoluble yellowish powder. This is to be separated from the liquid, washed with pure water, and dried at a low heat upon filtering paper. When dry, it must be cautiously put into a clean bottle, the mouth of which must not be corked, but slightly covered with paper. Fulminating gold thus prepared has the following properties. It explodes by a smart blow from a hammer, or when sharply triturated in a mortar. It is also decomposed with sudden violence when heated to about 250°. By all these means, the explosion is accompanied with a loud report, and the disengagement of elastic fluids, and is accompanied with light and heat. The hydrogen of the ammonia combines with the oxygen of the oxide of gold, forming water, which is dispersed in the form of highly elastic steam. The azote of the ammonia, at the same time, is evolved, acquiring great expansive force by the disengaged caloric.

Fulminating silver.

Fulminating silver is prepared by first dissolving pure silver in nitric acid. By adding lime water to this solution, the oxide of silver is precipitated; this oxide is now separated by filtering and washing. Pure ammonia is now to be poured upon the oxide, and allowed to remain upon it twelve hours. The liquid part is now to be carefully decanted off, and a black powder remains, which is the ammoniuret of silver, the substance in question. It is now to be transferred with great caution, and by a little at a time, into as many portions of clean filtering paper. This powder is even capable of exploding, while moist, by a blow. When dry, it becomes so susceptible of decomposition as to explode by the slightest touch. The liquid separated from the powder, on being heated in a glass retort, affords azotic gas; and small opaque crystals soon begin to appear, of great brilliancy, having metallic lustre. These crystals are doubtless the true compound of ammonia with oxide of silver, owing their production in the crystalline form to their solubility in water. On being touched, they detonate even when covered with the liquid in which they are formed.

The same explanation which has been applied to the fulminating gold will apply to the substance in question, although the reason is not very obvious why the fulminating silver should be more easily decomposed. Perhaps it will be found, that the silver contains twice the quantity of oxygen with the gold, and that the oxide of the former combines with twice the quantity of ammonia.

Fulminating glass balls.

Fulminating silver has been lately used in making what have been called fulminating balls. These consist of small bubbles of glass a little larger than a pea. A small portion of this compound is introduced at a little opening left for the purpose. The glass is then covered with paper. Any force capable of breaking the bubble produces the explosion.

Fulminating mercury.

Mercury, from its weak affinity for oxygen, forms a detonating compound with ammonia, and other bodies containing much hydrogen. The first of these compounds is formed, by digesting strong aqua ammonia upon the red oxide of mercury for ten or twelve days. At the end of this time, the oxide assumes a white colour in crystals, having the form of small scales. In this form, it fulminates by heat similar to fulminating gold. Its effects, however, are not so strongly marked as the two former, and it gradually loses its fulminating property by keeping. The ammonia is separated, leaving the red oxide unchanged.

Fulminating Powders, Fumigation.

Howard's fulminating mercury.

Another fulminating compound with mercury, was discovered by Mr Howard. It is prepared, by dissolving 100 grains of mercury in one ounce and a half of nitric acid of the common strength. When the solution is cold, add to it two ounces of alcohol. Heat the mixture gradually till effervescence takes place. A greyish white precipitate will now be formed, which must be separated by the filtre, washed with distilled water, and dried at a heat not exceeding 212°.

This powder fulminates with great violence. A few grains laid upon an anvil, and struck with a hammer, gives a report as loud as a pistol. The same effect takes place, by triturating it in a mortar.

It produces a much greater quantity of light than any other of the fulminating compounds, but very little heat. When it is mixed with gunpowder, and a train of the fulminating mercury be laid into the mixture, and fired by the lighted paper, the whole of the fulminating mercury will be consumed without firing the gunpowder.

Whether fulminating mercury be exploded by heat or by percussion, the surface of the bodies near to it become covered with the vapour of mercury.

This compound is said to consist of the oxide of mercury, combined with oxalic acid, and a large quantity of nitrous etherized gas. The explosive effect is to be attributed to the oxygen of the mercury combining with hydrogen in the etherized gas.

Common fulminating powder.

The fulminating compound, composed of three parts nitre, two parts potash, and one of sulphur, has been long known. When a little of this mixture is laid upon an iron shovel, and held over the fire, or placed upon burning coals, or even held over the flame of a candle, it first melts, and then very suddenly explodes with a report equal to that of a musket. Equal parts of sulphuret of potash and nitre form the most perfect compound. Hence it is evident, that during the melting of the first preparation, the sulphur unites with the potash, forming a sulphuret, which at the same moment acts upon the nitre. The explosive effects are to be attributed to the formation and rapid evolution of sulphureted hydrogen and sulphurous acid gases, the disengagement of azotic gas, and the highly elastic steam from the water in the nitre and potash. (c. s.)

FUMIGATION, in medicine, signifies the mutation of different fumes, for the relief of catarrhs, coughs, sore throats, &c. The term is also applied to the process of fumigating rooms during the prevalence of contagious disease. This has been long practised, but perhaps with little success, till the discovery of the method proposed by Dr Carmichael Smith. We cannot expect much benefit to have been derived from the fumes of pitch, nor even from vinegar, which is more modern.

If it be true that contagious diseases are derived from the presence of some elastic fluid existing in the atmosphere, which has been called *miasma*, and since these, of which there must be varieties, as well as the disagreeable odours resulting from putridity, in all probability are inflammable matter, having hydrogen for their basis, it seems highly reasonable, that good effects may result from fumigating the places where they prevail, with substances which easily combine with hydrogen. Hence we are to attribute the good effects which were produced on board ships, and other places where contagious disease prevailed, by the use of the fumes

Fumigation, Functions.

of nitric acid as practised by Dr Smith, who, for this discovery, received a premium from parliament.

After the discovery of the oxymuriatic acid, Guyton Morveau, the French chemist, tried the effects of this gas in the hospitals of France, with such decided success, as to put its efficacy in destroying the contagious matter beyond all doubt. The mixture which furnishes the oxymuriatic acid consists of three parts of common salt, one part of black oxide of manganese, and two parts of sulphuric acid. The salt and manganese are first mixed together, and placed in vessels of stone-ware or glass, in the various rooms. The sulphuric acid is to be added by a little at once, from time to time, observing that the whole must not exceed the proportion above stated. The gas should never be evolved in a quantity, to excite coughing, nor to be otherwise disagreeable to the lungs. When we consider the beneficial effects of this gas, we cannot fail to see the necessity for using some of its liquid preparations for washing the hands and other bodies employed in cases of contagious diseases. These may be the oxymuriate of lime used in bleaching, or simple water impregnated with the gas. (C. S.)

FUNCHAL. See MADEIRA.

FUNCTION, in analysis, is an expression of calculation, formed in any manner whatever from one or several quantities on which its value depends. Thus, if x denote a variable quantity, and $a, b, c, d,$ constant quantities, then $\frac{ax^3+b}{c+dx}$ is a function of x. Again, if x and y are variable quantities, and a and b constant quantities, the expression $axy+by^2$ is a function of x and y. For other distinctions between functions, see FLUXIONS, Sect. I. Art. 2. The term *function* was first introduced into analysis by John Bernoulli.

CALCULUS OF FUNCTIONS.

Sir Isaac Newton, the inventor of the method of fluxions, made its principles depend on the properties of motion, (see FLUXIONS, Art. 20—23); and Leibnitz founded its equivalent, the differential calculus, on the nature of quantities, which might be regarded as infinitely small in respect of others. At first, mathematicians were more eager to explore the rich mine which these philosophers had opened, than to call in question the principles which had led to its discovery. But when these came to be critically examined, it was observed, that as motion was an idea foreign to pure analysis, it could not legitimately be made the foundation of one of its most important theories. Also, that the notion of a quantity infinitely little, was too vague to form the basis of a branch of the most precise of all the sciences. Hence it was thought desirable, that the calculus should have an origin purely analytical, and should depend entirely on the properties of finite quantities.

To accomplish this reform, the late M. Lagrange attempted to model anew the principles of the calculus. He gave his ideas in the Berlin Memoirs for 1772, also in his *Theorie des Fonctions Analytiques*, (1797,) which, he says, " contains the principles of the differential calculus, disengaged from all considerations of infinitely small or vanishing quantities, or of limits or fluxions;" and again in his *Leçons sur le Calcul des Fonctions.*

In the calculus of functions, the variable quantities are denoted by the last letters of the alphabet $z, y,$ &c. and the constant quantities by the first letters $a, b,$ &c. A function of a single quantity, is expressed by placing the characteristic letter f or F before it. Thus fx, or Fx, means any function of x. To denote a function of a quantity, that is itself composed of a variable quantity x, for example x^2, or $a+bx+cx^2$, &c. the compound quantity is included in a parenthesis, thus $f(x^2)$, or $f(a+bx+cx^2)$. A function of two independent variable quantities x and y is expressed thus $f\ (x, y)$; and so of others.

If two functions of two variable quantities x and y are composed exactly in the same manner, and with the same constant quantities, for example ax^2+bx+c, and ay^2+by+c, these are like functions, and may be expressed in the same calculation thus, fx and fy; but if the constant quantities are not the same in both, they cannot be represented by the same characteristic in the same calculation. However, if the constant quantities enter alike into both functions, and only differ in their absolute values, as in ax^2 and by^2, these in the same calculation may be denoted by $f\,(x, a)$ and $f\ (y, b.)$ The general notation we have used in FLUXIONS, art. 18, 23, 28, 45, &c. and in art. 193, Prob. 4. is almost the very same as that of Lagrange.

The theory of functions depends on the change which takes place in the value of a function, when its variable quantity is increased by some indefinite increment, and on the form of the developement of its new value. In the function $fx=x^2$, when x is augmented by the quantity i, then fx becomes $f\,(x+i)=(x+i)^2=x^2+2xi+i^2$, and in the function $fx=x^3$, when x becomes $x+i$, then fx becomes $f\,(x+i)=(x+i)^3=x^3+3x^2i+3xi^2+i^3$, and again, in the function $fx=\frac{a}{x}$, when x becomes $x+i, fx$ becomes $f\,(x+i)=\frac{a}{x+i}=\frac{a}{x}-\frac{a}{x^2}i+\frac{a}{x^3}i^2-\frac{a}{x^4}i^3+$ &c. By an examination of any number of particular cases, it will appear that they have a common property, which consists in the developement of $f\,(x+i)$ the new value of the function having always the form $fx+ip+i^2q+i^3r+$ &c. an expression in which the first term is fx, the original function, and the remaining terms are the successive positive integer powers of i, the increment, multiplied by a series of quantities $p, q, r,$ &c. functions of x, which are entirely independent of i, and which have a determinate form, that depends upon the nature of the original function. The truth of this analytic theorem, first particularly noticed by Euler, may be inferred from induction: As however it must result from the principles of analysis, Lagrange has endeavoured to demonstrate, that if the function $f\,(x+i)$ be developed into a series of the form

$$fx+ip+i^2q+i^3r+\text{\&c.}$$

the terms of which consist each of a single power of i multiplied by a function of x, that is entirely independent of i, the developement shall contain only the positive integer powers of i, and cannot by any means contain either a negative or fractional power of that quantity, provided that the value of x be altogether indeterminate. If, however, particular values be given to x, then the proposition will not be *universally* true. Our limits oblige us to refer to Lagrange's work for the demonstration (*Theorie des Fonctions*), which has in some respects been rendered more complete by Poisson, *Correspondence sur L'Ecole Polytechniques*, No. 3.

It being ascertained that the developement of $f(x+i)$ has in general the form

$$fx+ip+i^2q+i^3r+\text{\&c.}$$

in which p, q, r &c. are new functions of x, which derive their origin from the original function fx, the next thing to be considered is the law of relation which connects these quantities with each other. To determine this, Lagrange supposes x to change its value, and become $x + o$, o being any indeterminate quantity which is independent of i. It is evident that the function $f(x+i)$ will then become $f(x+i+o)$, and it appears also that the same result will be had if in $f(x+i)$ we put $i+o$ instead of i. Therefore also the result must be the same, whether we put $i+o$ instead of i, or $x+o$ in place of x in the developement

$$fx + ip + i^2 q + i^3 r + \&c.$$

By the substitution of $i+o$ instead of i in the series, it becomes

$$fx + (i+o)p + (i+o)^2 q + (i+o)^3 r + \&c.$$

which, by expanding the powers of $i+o$, and writing, for the sake of brevity, only the two first terms of each power, because the comparison of these terms is sufficient for the object in view, is transformed to

(A)

$$\begin{array}{l} fx + ip + i^2 q + i^3 r + i^4 s + \&c. \\ \quad + op + 2ioq + 3i^2 or + 4i^3 os + \&c. \end{array}$$

In order to affect the substitution of $x+o$ instead of x in the same series, we must consider, that seeing the function fx becomes $fx + ip + i^2 q + i^3 r +$ &c. when x is changed into $x+i$, it will become $fx + op + o^2 q + o^3 r$, &c. when x is changed into $x+o$. In like manner, if $p + ip' +$ &c. $q + iq' +$ &c. $r + ir' +$ &c. are what the functions p, q, r, &c. become when $x+i$ is substituted in them in place of x, and they are developed according to the powers of i, we shall have by changing i into o,

$$p + op' + \&c. \quad q + oq' + \&c. \quad r + or' + \&c.$$

for the developements of the same functions, when $x+o$ is substituted in them instead of x. Therefore, by this substitution, the series $fx + ip + i^2 q +$ &c. will become, by omitting the terms which contain the second and higher powers of o,

(B)

$$\begin{array}{l} fx + ip + i^2 q + i^3 r + i^4 s + \&c. \\ \quad + op + iop' + i^2 oq' + i^3 or' + \&c. \end{array}$$

This result ought to be identical with the other, independently of the values of i and o, which may be any quantities whatever. Now, by the theory of indeterminate quantities, this can only be true when the coefficients of like powers, and products of i and o, are identical; hence, by comparing the developements (A) and (B), we get these identical equations,

$$2q = p', \; 3r = q', \; 4s = r', \; \&c.$$

from which again we find

$$q = \tfrac{1}{2} p', \; r = \tfrac{1}{3} q', \; s = \tfrac{1}{4} r', \; \&c.$$

Remarking now that p is deduced from the original function fx, by first substituting $x+i$ for x, then developing the result $f(x+i)$ into a series, proceeding according to the powers of i, and lastly, taking for the value of p that function which is the coefficient of the simple power of i; its origin, and the series of operations by which it has been found, may be indicated by an appropriate symbol. We have already put p', q', r', &c. to denote quantities deduced from the functions p, q, r, &c. exactly as p is deduced from x; we may similarly denote the quantity p by $f'x$, that is, by the symbol for the function from which it has been derived, with the addition of an accent over the characteristic letter. As the function p or $f'x$ is derived from the function fx, so from the function $f'x$, a new function may be, in like manner, derived, which may be indicated by $f''x$; from this last again another function, which may be represented by $f'''x$, may be found, and so on: So that, in fact, the functions $f'x$, $f''x$, $f'''x$, &c. are the co-efficients of i, in the first terms of the developements of the functions $f(x+i)$, $f'(x+i)$, $f''(x+i)$, &c.

We have therefore $p = f'x$, and as p' is the function derived from p, as p was from fx, we have $p' = f''x$, and therefore $q = \frac{1}{2} f''x$. Again, q' being derived from q exactly as p' was from p, or p from fx, we have $q' = \frac{1}{2} f'''x$, and consequently $r = \dfrac{1}{2.3} f'''x$, and so on.

Therefore, substituting these expressions in the series

$$fx + ip + i^2 q + i^3 r + \&c.$$

which is the developement of $f(x+i)$, we find

$$f(x+i) = fx + if'x + \frac{i^2}{2} f''x + \frac{i^3}{2.3} f'''x + \frac{i^4}{2.3.4} f^{\text{iv}} x + \&c.$$

This beautiful analytical theorem was in substance originaly discovered by Dr Brook Taylor (*Methodus Incrementorum.*) Lagrange first demonstrated it independently of the fluxional or differential calculus, and made it the foundation of his theory of functions. The form under which he has given it shews clearly how the terms of the series depend on each other, and, in particular, how the functions which are the coefficients of i may be derived one from another, when the manner of forming the first $f'x$ from the original function fx is known.

Lagrange calls the function fx the *primitive function*, in respect of the functions $f'x$, $f''x$, &c. These, again, in respect of the primitive function, he calls *derivative functions* (*fonctions derivées.*) The function $f'x$ is called *the first derivative function*, or *derivative function of the first order*, or simply the *prime function*; the function $f''x$, derived from it, is called the *second derivative function*, or *derivative function of the second order*, or simply the *second function*; and again, $f'''x$, derived from the preceding, is the *third derivative function*, or *derivative function of the third order*, or *third function*, and so on.

Any function whatever, in respect to that from which it is derived, is its *derivative function*, and this last is the *primitive function* of the other.

Sometimes, instead of using the characteristic letter f, a function of x may be denoted by a single letter y; then, y being used instead of the symbol fx, the symbols y', y'', y''', &c. may represent the characters $f'x$, $f''x$, $f'''x$, &c. According to this notation, y being any function of x, when x becomes $x+h$, then y will become

$$y + iy' + \frac{i^2}{2} y'' + \frac{i^3}{2.3} y''' + \&c.$$

Since every derivative function of the first order is merely the co-efficient of i in the developement of the primitive function fx, when $x+i$ is substituted instead of x, the determination of the derivative function of any power whatever x^n is in fact the same thing as the determination of the term that contains the first power of i in the developement of $(x+i)^n$, according to the powers of i. Now it may be demonstrated by the elementary operations of algebra, that whether n be positive or negative, whole or fractional, the two first terms of the developement of $(x+i)^n$ are $x^n + nx^{n-1}i$, (See ALGEBRA, art. 319; also FLUXIONS, art. 7.); therefore, the first derivative function of x^n is nx^{n-1}. It is now easy to find all the terms of the developement of $f(x+i) = (x+i)^n$. For since from $fx = x^n$, we have $f'x = nx^{n-1}$, from this last we derive

$$f''x = n(n-1)\,x^{n-2},$$

and hence again $f'''x = n(n-1)(n-2)x^{n-1}$, &c. So that from the series

$$f(x+i) = fx + if'x + \frac{i}{2}f''x^2 + \text{\&c.}$$

we get

$$(x+i)^n = x^n + nx^{n-1}i + \frac{n(n-1)}{2}x^{n-2}i^2 + \text{\&c.}$$

which is Newton's binomial theorem.

Next let the function be $fx = a^x$, a being supposed constant, and x variable; then $f(x+i) = a^{x+i}$. Now the common principles of analysis are sufficient to prove that the two first terms of the developement of a^{x+i} are $a^x + \mathrm{A}a^x i$; here A is the Napierian log. of a, (see ALGEBRA, art. 355; also FLUXIONS, art. 14. and 19.) Therefore the first derivative function of a^x is $\mathrm{A}a^x$, that is, $f'x = \mathrm{A}a^x$; hence again $f''x = \mathrm{A}^2a^x$, $f'''x = \mathrm{A}^3ax$ &c. These values substituted in the developement of $f(x+i)$ give

$$a^{x+i} = a^x + \mathrm{A}a^x i + \frac{\mathrm{A}^2}{2}a^x i^2 + \frac{\mathrm{A}^3}{2.3}a^x i^3 + \text{\&c.}$$

Let the function be $fx = \log. x$, then $f(x+i) = \log.(x+i)$; but it may be proved, as in the former cases, that the two first terms of $\log.(x+i)$ are $\log. x + \frac{1}{\mathrm{B}x}i$, B being put for the Napierian log. of the basis of the system; (see FLUXIONS, art. 18. and 19.) Therefore the first derivative function of $\log. x$ is $\frac{1}{\mathrm{B}x}$; and, because $f'x = \frac{1}{\mathrm{B}}x^{-1}$ by the rule for the derivative function of a power, we hence find $f''x = -\frac{1}{\mathrm{B}}x^{-2} = -\frac{1}{\mathrm{B}x^2}$; and again $f'''x = \frac{2}{\mathrm{B}x^3}$, &c. These substitutions being made in the general developement of $f(x+i)$, we get

$$\log.(x+i) = \log. x + \frac{i}{\mathrm{B}x} + \frac{i^2}{2\mathrm{B}x^2} + \frac{i^3}{3\mathrm{B}x^3}\ \text{\&c.}$$

It has been shewn, (FLUXIONS, art. 17, and 19,) that the two first terms of the developements of the sine and cosine of $x+i$ are

$$\sin.(x+i) = \sin. x + i\cos. x + \text{\&c.}$$
$$\cos.(x+i) = \cos. x - i\sin. x + \text{\&c.}$$

Hence it appears that the first derivative function of $\sin. x$ is $\cos. x$, and that the first derivative function of $\cos. x$ is $-\sin. x$: Since therefore in the case of $fx = \sin. x$, we have $f'x = \cos. x$, it follows that $f''x = -\sin. x$, $f'''x = -\cos. x$, &c. and since when $\mathrm{F}x = \cos. x$, we have $\mathrm{F}'x = -\sin. x$, it follows that $\mathrm{F}''x = -\cos. x$, $\mathrm{F}'''x = \sin. x$, &c. These expressions substituted in the developement of $f(x+i)$ and $\mathrm{F}(x+i)$ give

$$\sin.(x+i) = \sin. x + i\cos. x - \frac{i^2}{2}\sin. x - \frac{i^3}{2.3}\cos. x + \text{\&c.}$$

$$\cos.(x+i) = \cos. x - i\sin. x - \frac{i^2}{2}\cos. x + \frac{i^3}{2.3}\sin. x + \text{\&c.}$$

From the brief view we have given of this calculus, its intimate analogy with the method of fluxions, or differential calculus, must be evident. In fact, they all rest upon the same analytical principles, and, the object presented to the mind in each is the same; for the different orders of derivative functions in Lagrange's calculus are identical with the successive differentials, or rather differential coefficients in that of Leibnitz, and with the different orders of fluxions in Newton's theory. The peculiarity of each calculus, as delivered originally by the inventor, consists in that relation between the original function and its prime function, or differential, or fluxion, which the mind selects as a subject of contemplation. We have seen that it is a fundamental proposition in analysis, that if $x+i$ be substituted for x in any function fx, its new value $f(x+i)$ has always the form $fx + ip + i^2q + i^3r +$ &c. p, q, r, &c. being functions of x, which are independent of i. Newton observed, that if x and fx are represented by two lines generated by motion, and if i be the velocity of the point which generates x, then ip, the second term of the developement, will be the velocity of the point that generates fx; (FLUXIONS, art. 20—22.) hence he called ip the *fluxion* of the function fx. Leibnitz again considered, that if x was increased by the quantity i, then fx was augmented by the increment $ip + i^2q + i^3r +$ &c. But supposing i indefinitely small, the first term of this series is indefinitely greater than the sum of all the following terms; therefore rejecting these, and retaining the term ip alone, he called it the *differential* of the function fx. (FLUXIONS, art. 107—110.) Lagrange, regarding the generation of algebraic quantities by motion as incompatible with the principles of pure analysis, and also considering the doctrine of infinitely small quantities, as too slippery a foundation for so sublime an edifice, he rejected both views of the subject, and deduced its principles from the theory of the developement of functions into series.

It is in general admitted, that *the Theory of Analytic Functions* has fulfilled the promise of its illustrious author, "to deliver the principles of the differential calculus disengaged from the consideration of infinitely small or vanishing quantities, also limits and fluxions." We think, however, that he has under-rated the value of the theory of *limits*, as delivered by Maclaurin and D'Alembert, when he says that the kind of *metaphysique* that must be employed in it is, if not contrary, at least foreign to the spirit of analysis, which ought not to have any other *metaphysique* than that which consists in the first principles, and the first fundamental operations of algebra.

The ingenious author, in the discussion of his theory, has adopted a new notation. This has been matter of regret, (Lacroix *Cal. Dif.* vol. i. art. 82, 83.) because the notation of the differential calculus was quite sufficient. In the comparison of methods and formulæ, different notations are perplexing, and the number of arbitrary characters already employed in analysis is a considerable and increasing evil. This, however, is but a small defect, when the luminous views and original methods which the work contains are taken into account.

Functions ‖ Funen.

many of the French mathematicians regard the publication of the *Theory of Functions* as an era in analysis: Indeed, all the works of the differential calculus that have since appeared, have more or less adopted its views See, in particular, Garnier, *Leçons de Cal. Differentiel.* The mathematical reader will of course study the *Theorie des Fonctions* itself; and it may be useful to know that the author published a second and improved edition of the work in 1813, a short time before his death. (ξ)

FUNCTIONS. See PHYSIOLOGY.

FUND, SINKING. See DEBT *National*, and SINKING *Fund.*

FUNDI, or FONDI, the name of a town and lake in Lavora, situated near the confines of the Roman and Neapolitan territories. The town, which is situated in the fertile valley of the same name, is very small, consisting of one street on the Via Appia, which still retains here its ancient form, being composed of large flags, fitted together with great skill, and without any cement. Fundi, which has a gloomy appearance, stands on a plain, surrounded on one side with hills, most of which are covered with olive trees. The whole plain is adorned with orange and citron trees, interspersed with cypress and poplars. The wines of this district were formerly celebrated, and still enjoy some reputation. At the extremity of the town, there is an old castle of little strength.

The lake of Fundi, *Lacus Fundanus*, or *Amyclanus*, which lies between the road and the sea, is a fine expanse of water, formed by several streams which fall from the mountains. Towards the road, its margin is covered with myrtles poplars, and luxuriant shrubs and flowers. The exhalations which arise from the lake and from the marshes, which are produced when it overflows, greatly affect the salubrity of this fertile valley. Mount Cæcubus is seen a little to the right, in going out of Fundi to Itri. Distance from Capua, 40 miles west, and from Rome 56 east. East Long. 13° 30′, and North Lat. 41° 20′. See Eustace's *Travels*, vol. i. p. 472. (*j*)

FUNDI, BAY OF, is the name of a large arm of the sea, extending principally between NEW BRUNSWICK and NOVA SCOTIA. See these articles.

FUNEN, FYON, or FIONIA, is the name of an island and province of Denmark, situated near the entrance of the Baltic, and separated from the continent by the strait called the Little Belt. The island is of an oval form, and is about 35 miles long from north to south, and 30 from east to west. The coasts are in general flat and sandy, and the country is open, with a gently undulating surface. There are several lakes and rivers in the island, but none of them are navigable. This province is more fertile, and produces more grain, than any other in Denmark. The soil is less argillaceous than that of Zealand, but is more susceptible of all kinds of culture. Its principal productions are barley, oats, rye, and pease; and about 10,000 barrels of corn are exported annually to Norway and Sweden. Funen is almost the only place in Denmark where bees are reared with success. Much wax, and honey of a superior quality, is produced, and mead is made in great quantities.

The orchards of Funen supply the kingdom with fruit. There is very little wood in the island, and the inhabitants make use principally of turf for fuel. Many of the Danish nobility have country seats in the island. Odensee, which is the capital of the island, communicates with the sea by a river, the navigation of which is facilitated by a canal. There are about 35 small vessels belonging to the town, but the commerce of the island occupies about 200 or 300. The principal trade of Odensee consists in the exportation of grain and skins. See Catteau de Calleville's *Tableau de la Mer Baltique*, tom. ii. p. 324: and Coxe's *Travels*, vol. v. p. 233. (*w*)

Funeral.

FUNERAL. The disposal of the dead has chiefly been accomplished by inhumation and cremation, the lifeless body being for ever removed from the sight of the survivors. Some nations, however, unwilling to part with it, or actuated by certain religious principles, have preserved it entire; and men have been able to contemplate their forefathers, who existed many generations previous to themselves.

Different modes of disposing of the dead.

The more rude and uncivilized tribes do not possess the same facilities of disposing of their dead that are possessed by cultivated nations. In high and frozen latitudes, they are compelled to abandon them on the snow, which throughout the year is impenetrable, as towards the Lake of Athapuscow, and among the Chipawayan Indians; or they cover them with branches in the woods where they expire. The ancient Colchians, Herodotus affirms, did not bury their dead, but suspended them on trees; a custom witnessed among the Ilinois and Aleutian islanders. And the Tungoose, a Siberian tribe, having dressed the body in its best apparel, inclosed it in a strong coffin, which is suspended between two trees, while the arms or implements of the deceased are buried under it. Others, as the Parsees, or Gabres of Persia and Bombay, are accustomed to expose the bodies of their deceased in an open edifice, where they are devoured by birds of prey; and in Thibet it is usual to deposit them in walled areas, inaccessible alike to wild beasts from below, and the fowls of the air from above. The Parsees, who constitute a large proportion of the population of Bombay, deposit their dead in a hollow tower of large diameter, mostly built up within, and having a sink or well in the centre. When the vultures, which always hover around, have cleaned the bones of their flesh, they are precipitated into the well, which has subterraneous communications. Those of the inhabitants of Thibet who are unwilling to consign their relatives to the ordinary cemeteries, cut their bodies into quarters, and carry them up to the hills, where they may be devoured by birds: but inhumation never takes place. Amidst all these customs, however, few examples occur, in which the dead are committed to the waters: nay, it is not known to be practised by the rudest modern tribes, to whom the disposal of them otherwise must always prove difficult and laborious.

By inhumation.

Inhumations are generally such that the deceased may lie upon his back, or sometimes rest on one side; and the remains of Christians may frequently be recognized in the preceding position, from the arms being crossed on the breast. But the ancient Nasomenes, according to Herodotus, were so averse to this mode of inhumation, that they not only interred the body in a sitting posture, as is done by the modern natives of Hudson's Bay, but prevented an expiring person from thus breathing his last. Some, though not many, inter their dead standing.

Customs of the Greeks and Romans.

Inhumation has been practised alike by savage and civilized nations: either simply in the ground, or in subterraneous structures; in the vicinity, or at a distance from the dwelling of the deceased, or the habitations of the living. Near Sierra Leone in Africa, children are frequently buried in the houses of their parents;

Customs of the Greeks and Romans.

and the Soosoos, an African tribe, often inter the dead in the streets of their villages; but most commonly the place of sepulture is at some distance. The Jews buried their dead; and the same was done by the Greeks and Romans their contemporaries, who practised superstitious ceremonies on the occasion. So intimate a resemblance was observed by the two latter, the one of which derived the greater part of their customs from the other, that the same illustrations may explain the funerals of both. The Romans, however, improved several of those known among the Greeks; and from the greater number of historians which have been preserved, we are better acquainted with them. When a person expired, his body was washed with warm water, anointed with aromatic substances, or embalmed; and each of the members had a particular unguent. It was shrouded in fine linen, which was white with the Greeks, and black with the Romans; or the latter employed a common white toga. If the deceased was a distinguished person, he was clothed in his costume of ceremony, kept seven days during the necessary preparations for the funeral, and exposed on a state couch in the vestibule of the house, with his feet towards the door, at which were placed branches of the cypress or pine, according to his rank. In this we are able to trace the origin of the mutes at modern funerals, stationed at the door, with black plumes mounted on poles. A guard was always placed beside the body, to prevent the commission of any theft; but if it was that of a person of the first consequence, there were only young boys to drive away the flies. The seven days being elapsed, a herald publicly announced that the time of the funeral had arrived, and invited the attendance of all those who chose to assist. None, however, except the friends or relatives of private individuals did so; but public officers, or the people at large, attended, if the deceased had rendered services to the state. The body, according to a law ascribed to Solon, was carried out by the Greeks before sunrise, which was particularly adhered to in the obsequies of the young, in order that the luminary of day might not throw his light on such a melancholy spectacle as their untimely end. The deceased reposed on a bier, ornamented in proportion to his rank, crowned with a wreath of flowers, and having his face exposed, unless when it had been distorted in death. The custom of crowning with flowers, however, was not peculiar to the Romans. Several nations have been profuse in the use of them, and have also employed many varieties. Among the earlier Christians, it was customary to carry evergreens before the deceased to his grave: and even so late as the 17th century, cypress garlands were in great estimation at the funerals of the higher ranks, and rosemary and bay at those of the lower. Dionysius Halicarnassus relates, that at the death of the daughter of Virginius, the women and virgins left their houses, deploring her fate, and some threw flowers and garlands on her couch. A parade and procession followed, of torchbearers, musicians, and the attendant relatives, and among the Romans there was a mimic, whose province it was to wear the same habit, and represent the same manners as the deceased. His own bust, along with the bust of his relations, was carried on an elevated platform, and his spoils in war or insignia of honour were likewise exhibited. Busts, however, were not borne before persons of low origin, nor before those who had been condemned for any crime, though they had been invested with dignities. Next followed hired mourners, women whose employment was to lament the deceased, and who lavishly intermingled his praises with their wailings. His friends and relatives, all clothed in black, joined in the procession; and also his sons with their heads veiled from public view, and his daughters bareheaded, with dishevelled hair, and barefooted, attired in white. Thus the body was conveyed to the place of sepulture, or to the funeral pile, for inhumation and cremation were equally practised both by the Greeks and Romans: only the latter, being a much more expensive ceremony, was particularly reserved for wealthier persons. The original spot of interment was probably not far from their usual dwelling; but afterwards the Greeks selected one at a distance, which is invariably done by tribes removing from their primitive state. Plato says, the bodies of persons deceased should be conveyed to situations useless for other purposes, "because the natural fertility of the earth is not to be impaired either by the dead or the living." But they were careful always to lay the head towards the east, while other nations are indifferent about the position; and the Christians uniformly lay it to the west. Thus in the accidental discovery of cemeteries in Britain, of which no memorial remains, we can ascertain whether they have been used anterior to the introduction of Christianity, by the head lying to the west or otherwise. The laws of the twelve tables prohibited interment within the city of Rome; and therefore cemeteries were prepared in the fields, or near the high-ways, and often consisted of brick or stone buildings, with a number of niches, whence they were called *Columbarium*. Many minor ceremonies took place with these two nations, such as inhaling the dying breath of the deceased, as if to receive his soul; the nearest relation first closing and again opening his eyes, and putting a coin in his mouth, to pay the freight to Charon across the Stygian ferry. These customs are now universally abrogated, from Greece being occupied by Mahometans and Christians, who practise very different ceremonies; and from the Roman territories being inhabited by Roman Catholics only.

Customs of Mahometans.

A greater portion of the surface of the globe is probably possessed by those who profess the religion of Mahomet, than by those who entertain any other tenets. Their funerals are conducted with much solemnity by their priests or Imams, and are attended by the friends and relations of the deceased; but in general, the body of males is accompanied by males only, and those of females by their own sex. The extinction of life is followed by immediate preparations for interment; and this proceeds from an idea, that if the bliss which awaits the true believer is merited by the deceased, not an instant should be lost in conveying him to the cemetery; should it be otherwise, it is incumbent on every good Mussulman to discharge himself as speedily as possible from the service of the wicked. This precipitation, though not common, occurs among other nations: in some, it originates from the necessity of immediate interment in hot climates; in others, it is an established custom, which cannot be traced to any certain source; but it is so great, as to admit of very little doubt, that many persons are committed to the earth before life has fled. A few hours after dissolution, the body, having been previously washed with milk and water, or with water only, is placed on a bier with the face uncovered, and carried with hasty steps to the grave. As Mahomet has declared that whoever shall carry a dead body forty paces towards the place of sepulture will thereby expiate a deadly sin, it is usual for all ranks to tender their assistance on meeting a funeral procession. Being predestinarians in the strictest acceptation, no dread of danger or injury deters them from it; whence a devout Mahometan, even while the plague rages, offers his assistance, and supports, without apprehension, the body of one who has died of it. The interment being finished, and the deceased placed on his right side, and turned towards Mecca, the Imam repeats a prayer, and calls him three times by his name, mentioning also that of his mother, but without the smallest allusion to the name of his father; and when in ignorance of her name, it is not unusual to substitute that of the Virgin Mary. This part of the ceremony bears some analogy to the *Conclamatio* of the Romans, among whom it was customary to call the deceased with a loud voice, after he was laid on the funeral pile, or when he was a person of distinguished rank, to use horns or trumpets. It has likewise been common with many nations of the world, and is so with the lower classes of people in Ireland, to call loudly on the deceased, to interrogate him why he died, and whether he had not every thing in this world that he could desire. With the Romans it has been supposed, but without any rational foundation, as designed to ascertain whether or not the body is inanimate; because instances are given of persons rising from the pile prepared to burn them, and returning in health to their homes. The name of the deceased Mahometan and his mother being pronounced, another ejaculation or prayer follows, and the party returns home. No weeping, or symptoms of distress, are seen at a funeral; all profess unlimited resignation to the will of Providence: Whatever happens is deemed a wise dispensation, which it would be impious to lament. Their cemeteries are of considerable extent, and the graves shallow and separate; for the modern European custom of interring numbers in the same grave is unknown. However, it has not been universally so in Europe; for the canons of the Council of Auxerre declare, *non licet mortuum super mortuum mitti.* The grave is covered with a slab, which, instead of being plain and flat, is perforated in the centre, so as to admit of cypress trees being planted immediately over the body. A hollow square stone is occasionally preferred, which, being filled with earth, admits of the cultivation of trees or herbs within it. Relations frequently visit the cemeteries, and pray on the graves of the deceased; and it is peculiarly interesting to see widows and orphans occupied in this pious vocation.

Some eastern nations preserve the body a long time unburied.

An opposite custom is presented in many respects by the Chinese and Tunquinese, whose numbers far exceed the inhabitants of all the European states combined, and vie with the numbers which are under the sway of the Mussulman doctrines; while they have subsisted under a regular form of administration, and preserved the same ceremonies for the lapse of thousands of years. With the latter, instead of hasty and precipitate interment, the body of a person deceased is preserved a long time, sometimes two years, in order to admit of sufficient preparation for his obsequies. A splendid funeral is the utmost object of ambition. Individuals are content to labour their whole lives, and subsist in penury, that the funeral pomp at their death may be the greater. When this is conducted with uncommon magnificence, it forms an epoch in the history of a family, of which the remembrance is transmitted to successive generations; and nothing can be a more serious reproach than an heir having omitted this essential means of doing honour to his predecessor. Unlike the customs of the western world, a Chinese or a Tunquinese prepares his coffin a long time before he expects that, in the course of nature, it shall receive his earthly remains. Its splendour is the primary consideration, and the wealthy frequently expend a great portion of their property in obtaining one made of some valuable wood, adorned with sculpture or painting, and decorated with inscriptions. It is not unusual for the children of a family, by contributing among themselves, to get an elegant coffin privately made for their father, or for any other near relation, and endeavour to give him an agreeable surprise, by conveying it unexpectedly into his apartment: this mode of presenting a coffin to a parent is a filial act of piety. Its place is in the banqueting chamber, as an ornamental piece of furniture, to be admired by the guests of the owner, who do not fail to compliment him on its beauty. But when the period for its occupation does arrive, and a person breathes his last, the byestanders cover his face with a handkerchief, to which they believe his soul attaches itself, and it is carefully preserved. His body is put into the coffin, which still retains its original place, and along with it clothes, goods, and rice, to serve for his use in the next world. Men are clothed in seven of their best habits; women in nine. The coffin is not nailed, but joined with a very adhesive pitch, and then entirely varnished over, which precludes the escape of any emanations. Meantime regular visits are paid to the deceased, and whatever be the rank of the visitor, on this occasion, he always holds himself inferior, at no time approaching the coffin without four prostrations. At every meal of the family, different kinds of food are offered to the deceased, of which he is entreated to partake; and the principal person of the house, in pronouncing an eulogium on his character, deplores his loss to the survivors, and offers unlimited rewards to heaven for his restoration. The splendour of the funeral is all this time in contemplation. Should the tangible funds of the deceased be inadequate, his lands are sold; and should something still be wanting, his children dispose of their own property, or the friends and relations contribute; and as a record of the greater donations is kept, he who is thus liberal is entitled to singular honour. Particular solemnity is observed in transporting the body to the place of sepulture: the eldest son, or nearest relative, precedes it, having his head wrapped in a faggot of straw, and throwing himself on the ground at repeated intervals, as if to interrupt its passage; and the procession is slow and long, and interrupted by many pauses. Much importance is attached to the place of sepulture; priests are consulted on the subject, and 40 or 50 times greater price is paid for what is judged the most suitable, than for any other spot of land. It is such as is supposed to be most satisfactory to the dead, and favourable to the living. Children who experienced misfortune, after the death of their father, have been known to dig up the body, and deposit it in a preferable place, in order to avert the influence of destiny. One singular ceremony, in Tunquinese funerals, consists in carrying a vase full of water on the coffin, which, if accomplished without spilling a drop, is judged a happy presage, and the bearers are liberally recompensed.

The Jews still preserve some of the ancient ceremonies practised in the burial of their dead, when they were masters of Jerusalem. The thumb is bent into a particular position: the bearers of the corpse wear no sandals, lest the breaking of a latchet should interrupt the procession; they rend their garments; and throw dust on their heads. But they had a pomp and solemnity equal to those of the other nations, which they gradually rose to rival or excel. Josephus relates, that the bier of Herod consisted of gold, ornamented with precious stones, and a purple couch, whereon the body lay, covered with purple; there was a crown of gold on the head, and a sceptre in the right hand; the army marched in solemn procession, and five hundred of the royal domestics and freedmen followed, bearing sweet spices in their hands.

Cremation practised both by the ancients and moderns.

Inhumation is practised universally in Europe, throughout Africa, and in most parts of America; while cremation, though an unusual custom, is a common mode of disposing of the dead in Asia. This has prevailed from remote antiquity, for many years antecedent to the Christian era, and, as well as another ceremony closely connected with it, and to which we shall soon advert, has undergone little alteration. The ancient Greeks and Romans burnt their more illustrious dead. The body, clothed in its best attire, was deposited on a pile, formed of combustible wood, with a piece of money in the mouth, to pay, as before observed, the freight to Charon. The whole pile was environed by boughs of the cypress tree, liquids fit to disseminate an agreeable odour were poured on it, and the nearest relative applied a lighted torch. The arms of the deceased, and other things most regarded by him, were thrown into the pile and consumed; and to do him honour, the byestanders contributed their offerings in the same manner. But in order to preserve some remains of the body, it was enclosed in an envelope of incombustible cloth, and the ashes being collected along with the fragments of bones unconsumed, were washed with milk and wine, placed in an urn, and along with lachrymatories containing the tears shed for the deceased, consigned to a tomb wherein were frequently deposited sepulchral lamps. No custom has been more widely practised than that of burning the dead; we find it among the most polished nations of antiquity, and among the rudest modern tribes. It was practised in Britain, in Gaul, and many other countries whose names are transmitted to us by history. At this day, the Tshutchi, a nation inhabiting a rigorous climate at the north-eastern extremity of the Asiatic continent, burn their dead, and the spot where it is done is marked by stones laid in such order, as to bear some resemblance to the figure of the human body. A large stone is placed at the head, which is anointed with marrow and fat, and a small pile of deer's horns, heaped up at a little distance, which receives a yearly accession when the place is visited by the relatives of the deceased, who recapitulate his feats and qualities. In the island of Japan, and in the kingdoms of Ava, Siam, Thibet, and throughout many parts of Hindostan, cremation is not uncommon. But in the former countries it is chiefly the bodies of the wealthy which are treated with that distinction. What proves an affliction to other nations of the earth, is the source of rejoicing among the natives of Ava; the dead seem to excite no regret, or, to use the words of a modern author, much ingenuity is shewn in the means of abating it. At the same time there is great semblance of grief, for the widow and her friends repair to the spot where the pile was erected, and with loud lamentations collect the half-calcined bones and ashes; some days being previously occupied in dancing and festivity. The Siamese display particular funereal pomp in the cremation of their dead. The intestines are previously removed; perfumes and wax lights are burnt around it, and it is carried forth on a gilt wooden bier. All the family and friends dressed in white, attend the pile, which is kindled amidst the sound of instruments. But the honour of cremation is not conferred on every one indiscriminately; those who have suffered a capital sentence of the law; all who have been exposed to a violent death; and women who have died in parturition, are consigned to the earth, which is regarded as disrespectful to the dead. The pile is composed of precious woods, generally erected near some temple; and the ceremony is embellished by fetes and theatrical exhibitions. But we shall afterwards speak of the remarkable ceremonies adopted on such occasions in further detail.

The Chinese do not always consign the coffin to the earth, nor do all those nations, which remove the body from view without destroying it, practise interment. The poor of Aracan, who have none to pay the expence of a funeral, are carried to the side of a river, to be washed away as it flows. Some tribes in the neighbourhood of Caffraria, sew up the corpse in skins, and carry it to a distant thicket. The Araucanians, on losing a relation, seat themselves on the ground around him, and weep during a long time. The body, clothed in its best attire, is then exposed on a high bier, remaining there during the night, which is either employed in lamenting with those who come to offer consolation, or in eating with them; and this meeting is called *curicahuin*, or the black entertainment, from the symbol of mourning. One, two, or three days after death, the body is carried in procession to the cemetery, surrounded by women bewailing the deceased, and accompanied by another woman, who strews ashes on the road. It is now laid on the ground along with weapons if it is the body of a man, or feminine implements if it is the body of a woman, and with a quantity of provisions for subsistence during the passage to the other world. The spectators take leave of the deceased, and wishing him a prosperous journey, raise a pyramid of earth or stones above the body, on which a quantity of the country beverage is poured. Perhaps the Highland cairns, the *carnedds* of Wales, and *tumuli* of other regions, have all a similar origin, and may have originated without actual inhumation.

The bones preserved for the cemetery.

Several of the North American tribes testify a very great solicitude concerning the bones of the deceased. Nor is this confined to the inhabitants of the North; for the same is seen among those towards the opposite extremity of the continent; and the historians who consider the inhabitants of America as descended from the Jews, think that they find some analogy here. The Choktahs, or Chactaws, after three months previous inhumation, dig up the body, and place it on a scaffold opposite to the hut of the deceased, around which the family and friends convene, jointly participating in great lamentation, and a subsequent feast. A person, whose particular office it is, despoils the bones of their flesh, which are then carefully collected, and being placed in their natural order in a small chest, are carried in solemn procession to the bone-house. This resembles a shade elevated on posts, open at both ends, and those of the different tribes are kept separate. It is even judged impious to mix the bones of strangers with those of their own kindred; and therefore, if necessity compels them to deposit the bones of different tribes under one roof, they are still kept separate. Sometimes the skull, on these occasions, is painted red, and if the deceased has been a man of note, the chest is taken down a year after, when the friends weep once more over the bones, and the red colour being refreshed, the whole is consigned to everlasting oblivion. Should a party of Indians, engaged in war or hunting, lose any of its number, the body is elevated on a scaffold, and covered with logs of wood. The survivors return when the flesh is supposed to be consumed, and the bones thoroughly dried, and carry them home to be solemnly deposited. An author well acquainted with their customs, observed "some Indians return with the bones of nine of their people, who had been two months before killed by the enemy. They were tied in white deer skins separately, and when carried by the door of one of the houses of their family, they were laid down opposite to it, till the female relations convened with flowing hair, and wept over them half an hour, and then buried them with their usual solemnities." The Abipons, a nomadic South American race, immediately strip the flesh from the bones of those killed in a foreign country, and carry them to their proper cemeteries. Dobrizhoffer, a German missionary, relates, that he saw seven skeletons thus brought to a village, and kept nine days in a hut previous to interment. The Pampas and Moluches, other South American tribes, and also the Serranos, entrust some of their most distinguished women with removing the flesh from the bones of the dead, and burying them until the remaining fibres decay, or with bleaching them in the sun. While the work of dissection is going on, the Indians walk round the tent covered with long mantles, their faces blackened, singing a mournful tune, and striking the ground with their spears, to drive away the evil spirits. This anxiety is shewn by different nations: in beating on kettles, and most likely the ringing of bells has originally had the same object. The bones being prepared, are packed up in a hide, and conveyed on a favourite horse of the deceased to the cemetery of the family, sometimes 300 miles distant. Being disposed in their natural order and tied together, they are clothed with the deceased's best attire, and ornamented with beads and feathers, which are cleaned once a year. Different members of the family are thus placed in a sitting posture in a pit or excavation, with their weapons and other implements, and the pit is covered over. But it is farther the office of some matron of the tribe to open the pit every year, and to clean and clothe the skeletons. The carcasses of horses killed on the occasion, that the deceased may ride on them in the next world, are placed around the mouth of the pit, supported on stakes.

Exposure of the dead to animals of prey.

Among the Gabres or Parsees of India, the body is left exposed on the ground, and a dog enticed to take some certain morsel out of the mouth, which, on being accomplished, is deemed a favourable omen. But it is otherwise should the animal refuse; and during this period of expectation, prayers are pronounced by the priests. The body is then consigned to the sepulchre, which is described to be "an object of the most dreadful and of the most horrid prospect in the world; and much more frightful than a field of slaughtered men." Bodies are seen in all different stages of decay; either undergoing the decomposing process of nature, or bleeding and mangled by the vultures surrounding the walls, some of them so gorged with human flesh as almost to be incapable of taking flight. A day or two after being deposited there, the relatives are said to examine which eye has been lost, and should it prove to be the right one, a period of unexampled felicity is anticipated. See Gabres.

It has been the general practice of most nations of the globe, to burn or inter along with persons deceased those things that were most useful or interesting to them in life. The ruder tribes, as well as the more civilized, have entertained an infinity of vague and contradictory sentiments regarding the state of the soul after death; some believing that it hovers long around the body; that it is immediately transferred to regions of bliss; that it has a long journey to accomplish; or that it subsists in an intermediate condition, uncertain of reward or punishment, until all mankind shall be judged. Ancient nations often buried treasures of great value in the tomb of royal or opulent persons. Thirteen hundred years after the decease of David, we read that a high priest of Jerusalem took three thousand talents from his sepulchre, to bribe Antiochus to raise the siege of the city. Now there are sometimes found in the tombs of the ancient Tartars, whole sheets and plates of solid gold.

Sacrifices of mankind and animals to the dead.

The Jukati of Siberia inclose provisions in the coffin, expressly "that the deceased may not hunger on the road to the dwelling of souls." His favourite riding horse is accoutred, and led to the place of interment along with a mare. Two holes are dug under a tree, in one of which the deceased is deposited, and his horse being killed is buried in the other, while the mare is also killed, but is devoured by the guests. The arms, domestic implements, and feminine articles of the deceased, have been either interred in the same grave, or consumed on the same funeral pile. But by a more barbarous custom, as if the destruction of inanimate substances, or the preservation of them for the use of the deceased, were alike inadequate, the sacrifice of living animals, as we have seen, and even of human beings, has been in general practised. Slaves and captives were murdered at the foot of the funeral pile of the ancients, and consumed by the same fire that reduced the body to ashes; and wives were mercilessly put to death, that they might accompany the souls of their husbands to those regions, which were supposed ready to receive them. But so remarkable and unnatural a ceremony in funeral rites demands further illustration, especially as, instead of expiring with the name of the Greeks and Romans, we find it still existing at the present day.

Mankind, in the early stages of society, have inferred, that a future state bears an intimate resemblance to their condition in the world they inhabit; that they have the same necessities, and the same propensities and enjoyments. Hence the horse is killed, and the slave or the wife murdered, that their souls, transferred along with his own, might contribute to the use of the owner. By certain refinements, however, which can only be discovered in the sanguinary disposition of man, a sacrifice was deemed requisite, to appease the manes of the dead; and in this mixed character, the shedding of the blood of man and animals must be viewed. As the sentiments of a nation changed, the actual immolation ceased; but, as happened among the Romans, the combats of gladiators at a funeral pile were substituted, wherein one or both commonly perished. And with the Chinese there is a figurative sacrifice, in the images of men and animals consumed at the time of the obsequies. Yet it is not long since this was introduced; for an emperor of that nation, whose reign terminated in 1661, ordered 30 persons to be sacrificed to the manes of a favourite queen, and directed that her body, deposited in a valuable coffin, should be burnt, along with a prodigious quantity of precious materials.

Voluntary sacrifice.

Likewise, when an empress of the same people died in 1718, four youthful females, her attendants, proposed to sacrifice themselves on her tomb, which the emperor her son, a wise and politic prince, Funeral.

humanely prohibited. Sometimes the slaves and friends of the ancients voluntarily sacrificed themselves on the pile of the deceased; and those wives, who were not dragged to be murdered at the tomb, or by a horrible solemnity buried alive in the same grave, sometimes perished by voluntary immolation. It is recorded in history, that one of the earlier kings of Sweden having, in the heat of battle, vowed to sacrifice himself in ten years to the gods, should they then propitiate his cause; his queen accidentally discovered the fact, and, to anticipate the necessity of being buried alive when the event should happen, separated from him during life. The northern nations believed in a kind of elysium, or ethereal palace, where their resurrection would take place amidst their usual earthly enjoyments; and slaves conceived, that admission would be denied them, unless they accompanied their masters, whence a contempt of death, unknown to posterity, was inspired. Among the ancient Thracians, it appears that the favourite wife was put to death by her nearest relations at the tomb of her deceased husband, and interred along with him; and if he had more than one wife, a contest arose for permission to offer this token of affection. Diodorus the Sicilian relates, that about eight years subsequent to the death of Alexander the Great, the two wives of an Indian commander, who had fallen in battle, contended for the honour of being burnt along with his body; a singular custom introduced, as Strabo affirms, from the women of those climes being wont to become enamoured of young men, and poison their husbands. The elder being pregnant at the time, preference was given to the younger, and preparations were made for the ceremony. The widow approached the pile, and divesting herself of her numerous personal ornaments, as rings, necklaces, and jewels among her hair, distributed them as tokens of remembrance to her friends and attendants. Having taken leave of all, she was placed by her own brother on the pile, while the army of Eumenes, then contending for the Macedonian empire, marched three times solemnly around it with their arms. Meantime, without betraying the smallest apprehension at the crackling of the flames, she turned towards her husband's body, and heroically closed her earthly career to the great admiration of the spectators.

It is remarkable that now, after the lapse of thousands of years, the most intimate coincidence is witnessed in this voluntary sacrifice of the Hindoo females on the funeral pile of their departed husbands; we say voluntary, but it can scarcely be called so, for although there is no compulsion, it is not creditable to evade it. When a Hindoo expires, it is of no importance whether a person of rank or otherwise, his widow, if belonging to that particular cast, enforcing it, declares her resolution to perish; it not only entails credit on her memory, but aids her husband in obtaining celestial privileges. Attended by her friends and relatives, she approaches a consecrated spot, where a pile is erected by Bramins, generally near a river, wherein she sometimes bathes. No apprehension is ever betrayed by the youngest; she walks with a firm step thrice around the pile; mounts it unassisted, and sits down by the body of the deceased; then taking off her personal ornaments, she distributes them, with great composure and precision, to her female attendants, and gently reclining towards her husband, draws a cloth over her face. Meantime the Bramins perform certain ceremonies, and continue building up the pile several feet above both the bodies: they supply combustible substances; and pouring oil upon it, the whole is kindled by the nearest relation, and blazes forth amidst the shouts of the multitude. There are examples of the torch being applied by the children of the widow while almost in infancy, and it is thus that by common consent of nations the last offices are committed to the nearest relative. Although this horrible and barbarous custom is established among the Hindoos, it is unquestionably on the decline, and, in those places to which Europeans have common access, it is now of rare occurrence.

In other countries there are sanguinary scenes of an analogous description, practised to appease the manes of the dead. Formerly, in North America, a number of wives were strangled at once, with a single cord, on the decease of a husband. In Kodiak, an island on the northwest of that continent, when a chief is interred, some of his most confidential labourers are sacrificed and buried along with him. In the kingdom of Assam, several wives of a rajah or sovereign, a number of servants, and a quantity of oil and provisions, were all wont to be enclosed in the pit which received his body, and either instantaneously destroyed, or left to die a lingering death. In the island of Nukahiwa, if a priest dies, three human victims must immediately be offered up for the repose of his soul; and those whose province it is to procure them, lie in ambush where the unsuspecting natives resort in their canoes for food, and are soon enabled to fulfil their bloody mission. Yet all this is inconsiderable when compared with what are called the *Customs*, an annual ceremony in Dahomy, an African state. There the king "waters the graves of his ancestors," with the blood of victims in thousands; pyramids are absolutely constructed of human heads. Most of those unhappy beings are prisoners of war, who are mercilessly sacrificed. On the decease of the king himself, his women immediately begin to break and destroy every thing around them, and then to massacre each other, which continues until a successor is named, who takes possession of the palace and interrupts the carnage. On an occasion of this kind in 1774, 285 women perished, besides six said to have been buried alive with the king; and more recently, in the year 1789, when a king died, the number amounted to no less than 595. There is still another waste of human life at the funeral of some of the African and Australasian tribes. If a mother dies while suckling her child, it is buried alive in the same grave along with her. This, however, is not to be viewed in the light of a sacrifice; it originates in a different principle, which seems to be that among savages the care of their own children is all that they can accomplish; the infant, therefore, is doomed to destruction, from the belief that no female can be found willing to preserve it. Modern example therefore proves, that we may safely credit what is recorded of the immolation of human victims at the tomb or the funeral pile of the ancients.

Festivals at funerals.

It seldom happens that the assistants at a funeral simply dispose of the dead with the ceremonies now alluded to, as a greater or lesser festival almost always follows. This has already been partly illustrated. In our own country, we know that the obsequies of those, even in the most humble station, are always attended with the distribution of bread and wine, or less costly liquors. In some places it is preparatory to a more ample feast, in such profusion, as to prove of serious inconvenience to the successor: it lasts whole days, and, as among savage nations, resembles a rejoicing for the liberation of the deceased from his earthly tenement, more than a lamentation for his loss. Mirth and merriment prevail; and, in the Highlands of Scotland it has been carried to such an extent, that when given before the funeral, where the successor always presides, examples have occurred of the party setting out for the place of interment, and leaving the corpse behind them. This is identically the *Silicernum* of the Romans, at which certain viands were served up, or distributed to the people. In the north of England, the entertainment is called *arvil*, and the bread employed *arvil bread*—names of uncertain etymology; and, in Scotland, the subsequent carousals are said to be drinking the *dirge* of the deceased. The origin of these ceremonies is doubtful. A feast wherein much lavishness and extravagance are displayed, is given by the Washington islanders, on washing and laying out the body; and twelve months afterwards another, equally profuse, is given to thank the gods for having permitted the deceased to arrive safe in the other world. These throw considerable light on the purpose of the entertainment, which is perhaps jointly for oblation and commemoration. It is repeated successively for years by various nations; by the Tunquinese it is considered disgraceful to be sparing; and the South Americans, in pouring some of their first made beverage yearly on the graves, drink to the good health of the dead. The inhabitants of Thibet have an annual festival in honour of the dead, which takes place at night, and then innumerable lamps are lighted up, amidst the sound of mournful music. We shall abstain from speaking of the festival of souls, said to have been practised by certain American tribes, from being ignorant whether it is not entirely discontinued; but at intervals of ten or twelve years, the dead were dug up, and carried on the backs of their relatives to their huts, where great entertainments ensued; after which, they were, in like manner, replaced. The Greeks and Romans performed the obsequies of the great with uncommon splendour: Races, games, and theatrical entertainments, were all exhibited; and at present, with some Eastern nations, whole fleets and armies are put in action, for the greater pomp, on the funeral of an emperor.

In many countries, independent of the natural lamentations by the relatives of one deceased, it has been customary to employ hired mourners, whose shrieks and despair might enhance the display of grief. In scripture, it is said, "wailing shall be in all the streets: and they shall say in all the high ways, alas! alas! and they shall call the husbandman to mourning, and such as are skilful in lamentation to wailing." At the modern funerals of the lower classes of Ireland, the women collect, and utter hideous outcries, emphatically called the *Hoolaloo*, mixed with the praises of the dead, and with the questions, "Why did he die? Had he not a wife and family? Had he not every thing he could wish? Why did he leave this world?" and the like: a savage custom, characteristic of a barbarous state of society.

A funeral hymn has been prevalent, as well as the performance of music, at the obsequies of persons deceased, as also an eulogium or oration upon them. The funerals of the Greeks and Romans were attended by the sounding of pipes, and sometimes of trumpets and horns; but the lyre, being consecrated to Apollo, was prohibited; and a hymn, song, or dirge, called *Nænia*, was sung by girls or adults. The singing of psalms at modern funerals is part of these customs preserved; and a solemn requiem takes place among Roman Catholics for the repose of the soul. Frequently the most celebrated composers are entrusted with the composition of this piece of music; and it has been said of Mozart, that the requiem he composed for a German prince was first performed for himself. A musical solemnity sometimes attends the funeral of celebrated musicians, as of Rameau in Paris in the year 1764; and there was a commemoration of Handel in 1786, in Westminster Abbey, 27 years after his decease. The music composed or performed on these occasions in more humble life, is called a dirge or lament, as in the Highlands of Scotland, ; and there is yet known a lament composed and performed by some freebooter for himself, while leading to the gallows. Solemn music is an invariable concomitant of military funerals; that of our officers being attended by a full band, and that of a private soldier by fifes and drums. But in marching from the place of interment, a lively air always succeeds the mournful tune.

Funeral hymn or dirge.

A number of minor ceremonies preceding interment, are in use in different countries, and in different districts of the same country. Of this number are ringing the passing bell for a person expiring—wakes or watching with the dead, often rendered a scene of the grossest debauchery—placing a platter of salt on the corpse, or candles around it, and the like. Sometimes it is the custom to have funerals by day, sometimes by night. The colour of the fringes of the pall, and the gloves worn by mourners in Britain, denote that the deceased was unmarried if white; and it was lately the custom of some parts of England, for six maidens to bear the pall of a young man, and six youths to bear that of a young woman. In Wales, the graves of the deceased are adorned with flowers: The white rose always decorates that of a virgin: Those of persons distinguished by piety and benevolence are planted with red roses. The road to the grave of unmarried persons is also strewed with evergreens and sweet-scented flowers. In Scotland, the body is lowered into the grave by the nearest relatives; no funeral service is performed, and but rarely a funeral sermon on the subsequent Sabbath, in commemoration of the virtues of the deceased. Suicides are denied the right of interment in consecrated ground; and infants dying before baptism, are interred on its confines. But these rules are not strictly enforced.

Ceremonies in Britain.

Commission of suicide has generally been viewed as a criminal act: By the usages of Britain, the body should be buried in the highway, and a stake driven through it; of which recent examples are to be found. In the later periods of the Jewish history, when despair prompted the miserable objects of conquest to self-destruction, their leaders endeavoured to avert their intentions, by representing the ignominy to which their bodies would be exposed, by the privation of sepulture. The Fantees, a modern African tribe, testify their abhorrence of the deed, by refusing to pay the accustomed rites to the bodies of suicides.

A great variety of customs has been practised among nations, in respect to the remembrance of the dead. By some, the ashes have been scattered in the air, and all memorials of them consigned to oblivion. By the Abipons of South America, every thing that may recal the image of a person deceased is destroyed; his cattle are killed, all his implements burnt, and his hut is overthrown; his wife and family migrate elsewhere, and his name never is again repeated. The

Funeral.

Knisteneaux of North America destroy all that belong to him; and the Chipewyans never employ what has served for his use.

Mourning.

Mourning is a ceremonial also much diversified by the custom of nations. In general, it is more rigid on the widow of the deceased, than on the rest of his relatives. The Theodosian code adjudged a woman to be infamous who married ten months or a year from the decease of her husband. In Britain, it is rather understood that second nuptials should not take place within a year; and the period of mourning extends to two. The women of some North American tribes must live three or even four years in a state of widowhood: and in eastern countries, the eldest son cannot marry during the time of mourning for a parent, which is two years; and he should all the while sleep along with the rest on mattresses, not in beds, and subsist on very simple fare. Wearing particular colours, as white, black, or purple, is emblematic of mourning in different countries; and shaving the hair close is a particular mode of testifying grief for one deceased. But sometimes only half the head is shaved; or the hair, if generally worn long, is simply shortened. A more decided mark of sorrow consists in severe lacerations of the persons of the survivors, their faces are disfigured, they slash their limbs with knives, or sharp-pointed bones; and some, to shew a more indelible testimony of affection, are successively deprived of a joint of one of their fingers for every relation whom they lose. See *Herodotus*, lib. iv. *Strabo*, lib. xv. *Dionysius Halicarnassus*, lib. xi. Nicolaus Damascenus *Apud Excerpta Valerii*, p. 520. FUNFKIRCEN, or Five Churches, is the name of a town in Hungary, situated in a fertile country between the Drave and the Danube. It is principally celebrated for its university, which was founded by Louis I. and which was at one time attended by about 2000 students. It was ruined, however, by the capture of the place by the Turks. Population about 12,000. East Long. 18° 9′, North Lat. 46° 61′. (w)

FUNGI.

Fungi.

Character of the Fungi.

The most conspicuous of the plants to which we propose to direct the attention of the reader in this article, are, in general termed by the English *Mushrooms* or *Toad-stools*, and by the Scots *Paddock-stools.* By the Greeks they were called Μυκῆτες; and they are now known to botanists under the general appellation of *Fungi*, a term sufficiently expressive of their soft, spongy, coriaceous texture. They constitute the first link of the great chain of vegetable life, and serve to connect organised bodies with inorganic matter. In simplicity of form and structure, they differ widely from the other vegetable tribes, as they present neither leaves nor flowers. Destined to spring up in the midst of corruption, and to draw their nourishment from putrefaction, the fastidious observer turns from them with disgust; and the true naturalist, while aware of their importance in the scale of being, finding them too perishable in their nature to be easily preserved in his cabinet, too capricious in their growth to be cultivated in his garden, and too sportive in their forms to be successfully delineated with his pencil, leaves them with regret to rot on the dunghill and to wither in the wood. Hence they are fancifully characterised by Linnæus as *Nomades, autumnales, barbari, denudati, putridi, voraces. Hi flora reducente plantas hyematum, legunt, relictas earum quisquilias sordesque.*

The botanists of the first age, such as Theophrastus, Dioscorides, and Pliny, attributed the origin of mushrooms to a certain viscosity arising from putrefying vegetables. This notion very generally prevailed, until the immortal Harvey unfolded his second grand discovery, *omne animal ex ovo.* After this period, the germination of plants was investigated with greater care, and many able botanists applied themselves to the elucidation of the obscure physiology of the fungi. Clusius had long before maintained that mushrooms spring from seeds; but it was reserved for Boccone, Mentzel, and Tournefort, to establish the truth of the assertion. These eminent botanists were soon followed in the same track by Battarra, Micheli, Dillenius, Gleditsch, Linnæus, and Hedwig; and more recently by Bulliard and Persoon. It is now demonstrated that mushrooms are as regularly organised vegetables as the phenogamous plants; that they consist of fibres, vessels, and roots; that they have peculiar organs appropriated for the production of the seeds; and that without these seeds, no regeneration can take place. In short, they spring up, flourish, and decay, like other organised beings, after having transmitted the principles of that vitality which they possess, to a new race, exactly similar to themselves.

Seeds.

In order to obtain the seeds of mushrooms, it is in general only necessary to place them in a fresh state upon a plate of glass, the surface of which will soon be copiously covered with them. These seeds differ widely, like other vegetables, as to size, shape, and colour, and still more as to situation, insertion, and number. Some can easily be seen by the naked eye, while others can with difficulty be detected by the highest magnifiers. These seeds are many of them so light as to be dispersed through the air, from whence they are precipitated upon the ground and upon plants by rain and snow. They seem in fact to be everywhere. They are the constant attendants on decaying vegetable and animal matter. Is an apple rotting in a damp place, it is speedily covered with a mucor, sending forth its slender diverging stems, and forming a glory round it? Is even the dead hoof of a horse exposed for any time to the weather, it also will become covered with a fungus peculiar to itself? These plants cover the damp walls of cellars and caves, and seem formed to flourish in those places which are unfit for the support of the more perfect vegetables. If we take these circumstances in connection with the infinite multitude of animalculæ, which seem equally profusely distributed, we will be irresistibly led to the conclusion, that the earth itself is a mere re-

Fungi. ceptacle of germs, each of which is ready to expand into vegetable or animal forms, upon the occurrence of circumstances favourable for its developement. In the early stages of the earth's existence, the germs of a few zoophytes only were unfolded, afterwards those of the testaceous mollusca expanded, and finally those of the mammiferous animals. In the course of these changes, one generation succeeded another, but the generation which followed was not the unaltered progeny of the preceding. The zoophytes of the first period differ from those of the last; no living proofs of their existence remain, their memorials only are to be found imbedded in the solid rocks. It has happened to plants as to animals. At first the germs of the filices and the palms expanded into leaves; and finally the surface of the earth became covered with the stameniferous vegetables. But the ferns of the first period no longer exist; the circumstances which favoured their growth are no more; and their place is occupied by other ferns, the germs of which have expanded under a new arrangement. In this survey, the mind is astonished when it considers the infinite number of those germs, prevented by the absence of favourable circumstances from ever expanding into maturity. Here the followers of Harvey are bewildered; and here the theory of equivocal generation, which suggested itself to the inhabitants of the banks of the Nile, and to which Aristotle gave form and currency, seems calculated to soothe a reflecting and philosophical mind. The history of the earth countenances such a theory, and the phenomena of the mineral kingdom yields it many powerful analogies, we had almost said direct proofs. It does not consider the generation of plants as the result of chance, any more than philosophers do the production of lightning, of rain, or of snow. All result from those laws which Omnipotence has imposed on the material and intellectual world.

Those grains which are considered as the seeds of mushrooms, are by some supposed to be merely buds or germs. This opinion, which was first proposed by Gaertner, and since that time maintained by many able botanists, is considered as supported by the analogy of the zoophytes. To us this seems to be a mere dispute about words. It is unwarrantable to expect a close resemblance between the seeds of mushrooms and the seeds of stameniferous plants when they differ so widely in their general form. The seeds of the former may, for aught we know, resemble the parent plant in miniature; and by the simple enlargement of their parts, without the production of any new organs, arrive at maturity. But experiments are still wanting to determine this point.

Classification. If the examination of the mode of growth of the fungi be involved in such obscurity, in what condition may we expect to find their systematic classification? In the system of Linnæus, they constitute the last order of the class Cryptogamia; and were distributed by him into the following genera: Agaricus, Boletus, Hydnum, Phallus, Clathrus, Helvella, Peziza, Clavaria, Lycoperdon, and Mucor. Since his days, the species have been investigated with great care, and many curious facts in their history have been ascertained; yet still they have not obtained from botanists that attention to which they seem entitled, on account of the curious forms which they exhibit, the substances which enter into their composition, and the economical uses to which they have been applied. In this department of botany, no one is deserving of higher praise than M. Bulliard. This author has contributed, more perhaps than any other, to the illustration of this intricate tribe, in his work entitled, *Champignons de la France*. This work, besides containing accurate descriptions of the different fungi of France, exhibits at the same time faithful delineations of their form. In the same rank we must place the *British Fungi* of Mr Sowerby, the most splendid botanical publication which has appeared, in reference to our native plants. But here we must observe, that although the figures are admirable, the accompanying descriptions are extremely imperfect. This deficiency, however, we trust, will soon be amply supplied by the learned President of the Linnæan Society, in the fourth volume of that classical work, the *Flora Britannica*, which for the space of ten years has been anxiously wished for by the British botanist. But it is to Persoon that the world is indebted for the most judicious and systematic arrangement of the Fungi. It was necessary to take a comprehensive view of this tribe of plants as a whole, to overlook the old genera, and to form anew the various species into natural groups or genera, characterised by permanent differences in habit, form, and structure. This task Persoon has in a great measure accomplished, and has published the result of his labours, in two works entitled, *Tentamen Dispositionis Methodicæ Fungorum*, and *Observationes Mycologicæ*.

In the Natural Method of Jussieu, the *fungi* form one of the orders of the acotyledonous division of plants. They do not admit of generic arrangement according to the parts of fructification, so conveniently as the phenogamous plants, yet still the position of the seed-vessel furnishes the means of the more general classification; while their form, colour, and consistence, aid us in the discrimination of the species. By Persoon they are divided into two great tribes, according as the capsule is situated on the outside or in the interior of the plant.

The Gymnocarpi have their capsules or seed-vessels situated on the external surface. In form as well as in structure, the plants of this tribe present very remarkable differences, and even the parts destined for the production of the seed, exhibit very various appearances. These differences, however, are not without their use, as they enable us to combine the various genera under different families, and thus assist the student, by diminishing the labour of investigation. This tribe is accordingly divided into five families, and contains twenty-one genera.

The Angiocarpi have the capsule placed internally; and in some it is contained in a receptacle which is closed on all sides, at least in the young stages of the plant. To this receptacle Persoon has given the name of *peridium*. This tribe is divided into four families, and includes twenty-five genera.

We now propose to consider more minutely these various genera, and to explain the characters upon which their existence depends. That their number will surprise the Linnæan student accustomed to refer to Hudson, Withering, and Lightfoot, we are prepared to expect; but we request his attention to the following circumstances. Accurate observers of nature are become numerous; botanists are now in possession of more powerful instruments, and better methods of analysis; and their studies are greatly facilitated by accurate representations. Hence it is that new species are daily brought to light; the history of old species elucidated;

and new genera formed by almost every observer, in consequence of the discovery of new relations. The formation of new genera, is the necessary consequence of the enlargement of the science. Linnæus was not acquainted with an hundred species of fungi; now, their number has increased more than ten-fold. To us therefore the Linnæan genera have become useless. They mark the former state of the science, and they have contributed their share to the advancement of the study; our systems and our genera, must, in like manner, yield to the more extensive and accurate information of future observers. While we approve of the formation of new genera, therefore, where the state of the subject demands it, we condemn that zeal so conspicuously displayed by some, in the frittering down of the old genera into as many new ones almost as there are species. Such naturalists mistake the object and the end of these subdivisions, imprudently attempt to pass beyond the bounds which limit the present state of the science, and endeavour to anticipate those changes which other discoveries and more enlarged views will render necessary. In this account of the genera, we have confined ourselves to those which are sanctioned by high authority. These are principally derived from the works of French naturalists, who, unrestrained by the fastidious reserve of the British character, and possessed of more ample means through national munificence, have of late contributed materially to the enlargement of systematic botany and zoology. The description of one species at least will be subjoined to each genus, together with a reference to those works where faithful representations of them may be found.

TRIBE I. GYMNOCARPI.

FAMILY I. *Composed of Filaments.*

1. BYSSUS. GENUS I. BYSSUS. The plants which are now referred to this genus, exhibit the appearance of fine down or velvet, and consist of small filaments, which are simple, branched, anastamosing, or interwoven. They occur of various colours, as white, yellow, red, or brown. Almost all the species included in the first section of the genus Byssus of Linnæus still remain under this title.

As an example of this genus, we may mention the *Byssus candida*, (Dill. *Musc.* tab. 1. fig. 15. A.) Its substance is tender, woolly, of a white colour, and closely pressed to the substance on which it grows. From its broad and mucilaginous base arise many slender branches, spreading more in breadth than height, elegantly subdivided, the extremities ending in capillary fibres variously branched, or in a thin expanded surface like fine paper. It grows upon dead leaves and rotten wood. It is the *Himantia candida* of Persoon.

Every person must have observed in the beginning of summer a greenish scum, floating on the surface of small ponds, rendering the water greenish, turbid, and hardly drinkable. This substance was considered by Linnæus as belonging to the present genus; but subsequent naturalists have referred it to the genus Conferva. Be that as it may, it often proves a great nuisance in wells; and the discovery of any method of destroying it must necessarily be acceptable. In the spring of 1815, when the workmen were engaged in the erection of the new light-house on the Isle of May, under the inspection of that eminent engineer Robert Stevenson, Esq. they were much incommoded by the appearance of this substance on all the wells and pools of the island. Quicklime in considerable quantity was thrown into the wells, without retarding or destroying the growth of this vegetable. At last the wells were enclosed with walls sufficiently high to exclude the light from the water, and this contrivance fortunately succeeded in the extermination of a plant which at one time threatened to prove a very serious evil.

2. MONILIA. GENUS II. MONILIA. The plants of this genus are composed of slender stalks, which are either simple or branched, and resemble the filaments of the preceding genus. These stalks bear on their summits small articulated threads composed of spherical globules, which separate when the plant grows ripe. The species of this genus bear a very near resemblance to those included in the genus Mucor; but their naked capsules, joined to the want of a vesicular peridium, forbid such a union as the incorporation of the two genera.

Monilia glauca, (Mich. gen. 212. t. 91. f. 1.) This is the Mucor glaucus of Linnæus. Its stalks are white, simple, and slender; the capsules are agglutinated, the one before the other, in diverging lines, representing little tufts of feathers, of a spherical form. The capsules are round and diaphanous; white at first, but turning green as the plant reaches maturity, at which period they separate from one another. This plant grows in tufts, and sometimes scattered, on fruits which are in a putrefying state. Another species of this genus, Monilia digitata, the Mucor crustaceus of Linnæus, is found on corrupting meat, but it differs from the preceding in having the seeds disposed in an umbel.

3. BOTRYTIS. GENUS III. BOTRYTIS. In this genus, the stalks are straight and branched, bearing upon their summits naked capsules, in a head, or in clusters, the one not agglutinated to the summit of the other. They closely resemble the genera Manilia, Mucor, and Ægerita. They possess an evanescent existence. They are distributed into two sections, the first comprehending those with upright branched fibres, and the second those which form a sort of bed from which the upright stalks proceed.

Botrytis lignifraga. Sowerby, tab. 378. fig. 14. may be mentioned as an example of the first. It grows upon the bark of trees, but especially on the birch, imbedded in the external layers of the bark, piercing the epidermis, and forming on the outside small tubercular masses. These are at first white, and resemble cotton; but they afterwards change to a deep green, and become powdery. The stalks are slender, crowded, upright, and interwoven. The capsules are rounded, and very small. Mr Sowerby considers this species and Monilia glauca as varieties of the same plant, and as constituting the much-esteemed blue mould in rotten cheese.

Botrytis rosea may be given as an example of the second section. It is the Mucor roseus of Sowerby, Tab. 178. fig. 11. This forms small knobs, which are at first white, round, and of a hairy aspect; afterwards they lengthen out, become of a vermilion colour, and emit a reddish powder: the base consists of strong, straight fibres, from which proceed, at right angles, upright, simple, slender stalks, bearing at their summits from two to five oval capsules. It grows chiefly on the bark of trees, especially the Alder, also on the decayed kernel of nuts and on rotten wood. When growing upon trees, this plant usually appears at the opening of the glands, or near the place where some insect has made a puncture.

4. AEGERITA. GENUS IV. AEGERITA. To the naked eye, the plants

Fungi. of this genus present nothing but a tubercle or convex crust; under the microscope, however, they exhibit a number of separate spherical capsules, attached to branched and extremely slender fibres, which form the base. They resemble the plants of the preceding genera in form, but their aspect is glabrous and fleshy, the others being hairy or fibrous.

Aegerita aurantia, the Mucor aurantius of Withering. Bulliard's *Champ.* p. 103. tab. 504. fig. 5. The filaments are slender, branched and creeping, supporting without order minute rounded seeds. This plant forms little plates of a golden yellow colour on the bark of decayed wood, the hoops of casks, and the corks of bottles.

Conoplea. GENUS V. CONOPLEA. This genus contains plants, which are composed of branched filaments, resembling the Byssi, bearing, here and there, the capsules, which are nearly globular, and easily detached like powder.

Conoplea puccinioides. This species grows on the dead leaves of the carices, forming very minute black tubercles, which are easily destroyed. These, when examined with a microscope, are found to be composed of branched pellucid filaments, bearing upon their whole surface, opake, angular globules, which are large when compared with the size of the stalk.

Erineum. GENUS VI. ERINEUM. This genus consists of tubes, frequently cylindrical, and truncated at the summit. They grow in numerous groups on the leaves of living plants. It is not as yet ascertained whether the capsules are internal or external.

Erineum vitis. This plant grows on the inferior surface of the leaves of the vine, where it forms numerous irregular patches of a red, or rather of a rust colour. Under the microscope, it appears to be composed of a multitude of simple, crisped, cylindrical tubes, truncated at the summit.

Stilbum. GENUS VII. STILBUM. In consistence this genus resembles the Mucor, but is somewhat firmer. The stem supports a rounded head, which is solid; at first watery or gelatinous, afterwards compact and opake; and which, according to Tode, bears the seeds at the external surface.

Stilbum rigidum. Pers. *Syn.* 680. The stem of this plant is stiff, cylindrical, permanent, and of a black colour. The head is globular, at first watery, of a white colour, or slightly yellow; it afterwards becomes grey, and separates from the stem at maturity. It is found on rotten wood in the spring.

FAMILY II. *Fungi which do not decay into a pulp, and in which the fertile surface is united or continuous.*

Helotium. GENUS VIII. HELOTIUM. The plants included in this genus have a regularly convex pileus, or cap, supported on a stalk, and smooth on both sides. The capsules are produced on the upper surface, and are disposed in the same manner as in the following genus.

Helotium agariciformis. Helvella agariciformis of Withering. Sower. tab. 57. The stem is cylindrical, about the thickness of a pin; the cap is thin and hemispherical, with a regularly rounded margin. The whole plant is very small, of a white colour, and resembles an Agaric in its appearance. It is found on rotten wood in moist and shaded places.

Peziza. GENUS IX. PEZIZA. The Pezizæ consist of a cup-shaped receptacle, either concave or hemispherical; the superior surface is smooth, and the seeds which it bears escape in the form of a fine powder. According to Hedwig, the seeds are contained in membranaceous capsules, each of which contains in general eight seeds. These fungi vary very much in their general appearance. Some are supported on footstalks, while others are destitute of them. They live upon the ground, on rotten wood, and even in water. As to substance, they are either coriaceous, fleshy, or waxy; characters which serve to distribute the species of the genus into the three following sections.

SECT. 1. *Coriaceous. Peziza coriacea.* Bull. p. 258. tab. 438. fig. 1. This plant is glabrous and ash-coloured, the skin is thick and coriaceous, the inferior part produced into a slender stem contracted at the base. Above it is salver-shaped, ferruginous towards the centre, and plentifully covered with a grey powder. It is found on the dung of the stag, the horse, and the ass.

SECT. 2. *Fleshy. Peziza fructigena.* Sower. tab. 117. This species is about half an inch in height, with a slender stalk tapering downwards. The upper part is more or less concave, opake, leathery, and fleshy. It is often found on coriaceous fruits, and, after Withering, we have found it in clusters on rotten sticks.

SECT. 3. *Waxy. Peziza acetabulum.* Sower. tab. 59. This is among the largest of the genus. The stalk is woody, short, and brown, branching up the base of the cap. The cap is upwards of two inches in diameter, and at first bell-shaped; afterwards it becomes more shallow, waved at the edges, reddish brown within, and paler without. It is found on rotten wood, and also on the ground.

GENUS X. TREMELLA. The Tremellæ consist of a gelatinous substance of various forms, containing the seeds scattered over their surface. The genus Tremella of Linnæus has undergone a considerable revolution. The green coloured species inclosing a gelatinous mass, containing filaments, now rank with the ALGÆ in the genus *Nostoch* of Vaucher; others are inserted among the *Aegeritæ*, and a few will be found with the *Gymnosporangiæ*. 10. Tremella.

Tremella amethystea. Bull. tab. 499. fig. 5. The substance of this species is gelatinous, and divided at the base into variously shaped lobes; the colour is purple, more or less deep; the surface glabrous, often furrowed. It is only found on rotten wood.

GENUS XI. HELVELLA. The fungi of this genus are furnished with a stem, terminated by an irregular cap, smooth on both sides, and throwing out the seeds at the inferior surfaces only. In appearance they resemble the Merulii, but the want of veins or gills beneath, form a sufficient mark of distinction. 11. Helvella.

Helvella mitra. Sower. tab. 39. The stalk is two or three inches high, a finger thick or more, irregular, hollow, deeply furrowed, often full of holes, or sinuses, and generally of a white colour. The cap is deflexed, and commonly divided into curled or folded lobes, which adhere to the stalk, but is extremely irregular and variable, and has neither gills nor pores. Its colour is generally a yellowish white, sometimes fuscous, livid, or black purple; the substance is waxlike and friable, the surface soft like sattin. The seeds are oval, and are thrown out by sudden jerks.

GENUS XII. SPATHULARIA. This genus contains such fungi as possess a stalk, with a cap, compressed vertically on each side of the stem. They make the nearest approach to the *Clavariæ*. 12. Spathularia.

Spathularia flavida. Helvella spathula of Sower. tab. 35. This plant is of a yellowish colour; the stalk is cylindrical, wrinkled, and compressed towards the top, which bears a vertical cap, obtuse at the summit, and produced on each side of the stalk. Hence it resembles a spathula. It is found in autumn in pine groves. When in perfection, if the heads are touched, a smoke arises from the edges, which is thrown out with considerable force, and continues to rise for some time, glittering in the sun like particles of silver.

13. Clavaria. Genus XIII. Clavaria. The fungi of this genus consist of simple or branched expansions, generally fleshy, sometimes coriaceous, destitute of a cap, and emitting the seeds from all parts of the surface. They are, in general, club-shaped, and have been divided by Persoon into several genera. The present genus excludes those Linnæan species which are known to possess distinct receptacles for the seed.

Sect. 1. *Fleshy, simple. Clavaria pistillaris.* Sower. tab. 237. This is the largest and thickest species of the genus. It is from one to two inches high, simple, glabrous, and club-shaped. The skin is very close and filamentous at the summit, which is at first rounded, and afterwards parts lengthwise into fungous threads. It grows upon the ground and among moss, is of a yellow or straw colour, and of a friable substance like suet.

Sect. 2. *Fleshy, branched. Clavaria coralloides.* Sower. tab. 278. This plant is brittle and plump, simple, or in two or three divisions, each of these subdivided into a number of smaller branches, like some species of coral. These branches are round, or slightly compressed, and often waved at the edges. The colour is in general yellowish, rarely reddish, sometimes white. The flesh, or internal substance, is white. It grows upon the ground, and is subject to great variation in form and colour. It is admitted to the table, and esteemed one of the best of the esculent fungi.

Sect. 3. *Coriaceous, simple. Clavaria ophioglossoides.* Sower. tab. 83. This plant is readily distinguished by the blackness of its colour, and softness to the touch. It is about two inches high, and half an inch over at the broadest part. The stalk is club-shaped at the summit, sometimes divided into two parts, generally grooved, and often twisted. The surface is glabrous, and covered with a very fine black powder. It is white within, and hollow when old. It grows upon the ground in moist situations.

Sect. 4. *Coriaceous, branched. Clavaria laciniata.* Sower. tab. 158. This forms at first a shapeless crust, which, as it grows old, divides into flat expanded branches, jagged at the ends. It varies much in its appearance. Its colour is white or grey, but the extremities of the branches are often tipt with reddish brown. The substance is solid and tough. It grows upon the ground.

14. Thelephora. Genus XIV. Thelephora. The Thelephoræ possess a coriaceous cap, of an irregular form, sessile, and adhering to other bodies by the side or the back; the outer surface is smooth, or covered with a few papillæ, and bears the seeds. They are found attached to the stems of trees, by their barren surface; afterwards they lose in part their attachment, and become horizontal, thus placing the fertile surface beneath. They constitute several very well marked and natural sections.

Sect. 1. *Cap entire, funnel-shaped, adhering by the centre. Thelephora caryophyllea, Auricularia caryoph.* Sower. tab. 213. This plant is fleshy, thick, and soft. The upper surface is beautifully zoned; the under side is smooth and waved, and covered with globules disposed in fours, which are visible with a microscope. It is sometimes simple, at other times divided into many parts, covering each other like the tiles of a house. The margin is frequently torn. In some cases it adheres by the side, and in others appears to be furnished with a short peduncle. It varies greatly in colour, through different shades of brown. It is annual, and grows upon the ground, and upon putrid wood.

Sect. 2. *Cap semicircular and attached by the truncated side. Thelephora reflexa.* Sower. tab. 27. This is a very common plant, growing on decayed trees, pales, and gates. The upper surface is zoned and hairy; the under surface close, and sometimes variegated. In colour and shape it is subject to much variation. The substance, when young, must be gelatinous, as it is often pierced by blades of grass, but when old it is tough and coriaceous. The under surface has always a reddish hue.

Sect. 3. *Cap attached by the barren surface. Thelephora papyrina.* Sower. tab. 349. This is slender, soft zoned, and hairy above. The inferior surface is at first united, afterwards it is zoned and pitted with pores of various sizes. The prevailing colour is yellow or red. It grows on the trunks of trees.

Genus XV. Hydnum. The inferior surface, and sometimes the superior, of this fungus, is hedge-hogged, with awl-shaped substances, pointing to the earth. These prickles are soft, solid, cylindrical or conical, emitting seeds from near their extremities. The plants are either fleshy or coriaceous, and grow upon the ground or upon the trunks of trees. 15. Hydnum.

Sect. 1. *Without a distinct cap, branched. Hydnum coralloides.* Sower. tab. 252. This is the largest species of the genus. It is sessile, at first white, and afterwards yellow. The base, which is fleshy and brittle, sends out a number of branches, whose under surface is beset with prickles. The last divisions of the branches form imbricated bushes, each bearing a tuft of long, awl-shaped, crooked and parallel prickles. When young it is very like a cauliflower. It grows upon dead stumps and aged trees.

Sect. 2. *Without a distinct cap, base spreading on the trunks of trees. Hydnum barba Jovis.* Sower. tab. 328. This fungus is coriaceous, sessile, membranaceous, and applied to the substance upon which it grows by all the points of its superior surface. When young, it is of a white colour, becoming afterwards of a yellowish red. The inferior surface is covered with numerous white simple mammellar protuberances; from the summit of these, yellow simple or branched filaments proceed; and in the latter stage of the plant, others are protruded, which are of an orange colour, and covered with hairy spiculæ.

Sect. 3. *Pileus distinct, prickles cylindrical or conical. Hydnum auriscalpum.* Sower. tab. 267. This plant is coriaceous, tan-coloured at first, afterwards becoming of a dark brown. The stalk is thick, short and solid, supporting a rounded, zoned, and sometimes downy cap, which is at first vaulted and smooth above; afterwards the cap becomes funnel-shaped, and the inferior surface studded with small cylindrical prickles. It grows upon old rotten cones, and decayed branches of the fir tree, lying half buried in the ground.

Sect. 4. *Cap more or less distinct, prickles lamellar. Hydnum sublamellosum.* Sower. tab. 112. This Hydnum is tender, white, and furnished with a short, solid, cylindrical stem. The cap is very thick, and the prickles are formed into small straight plates, variously waved. It grows on the ground, either singly or in groups.

Fungi.

Family III. *Fungi having the fertile surface furnished with tubes.*

16. Fistulina. Genus XVI. Fistulina. Cap with separate tubes underneath, containing the seeds. The plants now included in this genus were formerly ranked with the Boleti, from which they seem sufficiently distinct.

Fistulina hepatica. Sower. tab. 58. This plant is very plentiful in autumn among oak trees, growing on their trunks or spreading roots. Its vegetation is most rapid in wet weather. When very young, it resembles a strawberry; and, advancing in growth, it becomes hispid, with tubular protuberances, shaped like florets. By degrees it acquires a distinct underside of a pale yellow, with similar protuberances, and as these become more distinct, the upper ones lose their form. At length the under surface becomes covered with distinct and separate tubes, entire at their orifice, turning brown, and emitting seeds at their edges, which often hang in festoons, or little cobwebs formed by spiders. The fungus afterwards either rots, or turns black in decay. It varies in shape and size, but commonly resembles liver, being saturated with a blood-coloured fluid, which adds to the resemblance. Its taste is like that of the common mushroom, and some persons reckon it nearly as good.

17. Boletus. Genus XVII. Boletus. In this genus the cap has tubes underneath, which are united, and contain the seeds. It is indispensably necessary, in so extensive a genus as this, to subdivide the species into sections. Linnæus was acquainted with but few species of Boletus, and was satisfied with distributing them into two sections, the first containing such as are parasitical and destitute of a stem, and such as are furnished with a stem. In the *Flore Francaise*, they are divided into four sections; the first comprehending the Fistulinæ; the second such as have an imperfect cap, with the tubes scattered over different parts of the plant; the third, with the tubes united together, and inseparable from the flesh of the pileus, is subdivided into those without stems, those with lateral stems, and those with central stems; and the fourth having the tubes united, but easily separated from the flesh. The arrangement of Withering, however, appears both the most obvious and the most natural. It is founded on the condition of the stalk; the plants being either without a stem, having a central stem, or a lateral one. The subdivisions of his sections, founded on the colour of the tubes, is more artificial and inadmissible, as it is a character in the Boleti which is liable to many changes.

Sect. 1. *Stemless. Boletus ungulatus. Bol. igniarius* of Sower. tab. 132. This plant is coriaceous, attached by the side, and shaped like a horse's hoof. The cap is hard, rubbing to a polish, marked with concentric bands or ridges, each broad ridge indicating the growth of the year, and three or four small ones that of the different seasons of the year. The tubes are very slender, equal, the colour of tanned leather, in old plants stratified, a fresh layer being added every year. It grows on various kinds of trees, and subsists for several years. It is the *Agaricus Chirurgorum* of Pharmacopœias.

Sect. 2. *Stem central. Boletus piperatus.* Sower. tab. 34. The stem is cylindrical, greenish yellow, and nearly two inches high. The cap is yellow, flat, smooth, thin, at the edge, and about three inches over. Flesh thick, tinged with yellow. Tubes decurrent, short, deep orange, or earthy red; pores brown and irregular. This species grows upon the ground, and has a pungent effect upon the throat like that of a capsicum.

Sect. 3. *Stem lateral. Boletus betulinus.* Sower. tab. 212. This stem is nearly two inches in length, and half an inch in diameter, of a black colour. The cap is pink, brown, oblong, convex, curled at the edge, thin and flexible, and often divided into tongue-shaped lobes. The flesh is white; the tubes white and short; the pores very minute. It grows upon the trunks of old trees.

Family IV. *Fungi, having the fertile surface furnished with gills or prominent ridges.*

Genus XVIII. Merulius. The plants of this genus are fleshy or membranaceous; the cap is furnished with gills or veins underneath, of the same substance with the plant. 18. Merulius.

Sect. 1. *With a stem and gills underneath. Merulius umbelliferus.* Bull. tab. 519, fig. 1. A. The stem is whitish, smooth and hollow, not thicker than a horse hair in the smaller plants. The cap is white, thin, convex, a little bossed with the sides, and plaited. The gills are white, fixed mostly in pairs in the small, and in fours in the larger plants, the long ones being about 18 in number. The delicate structure of this plant causes it to tremble when held in the hand. The cap is so delicately transparent, that the edges of the gills appear plainly on the upper side, and have caused it to be described as striated. It is common in the autumn months at hedge bottoms, and amongst moss, adhering to dead leaves and half rotten sticks.

Sect. 2. *With a stem and veins underneath. Merulius infundibuliformis.* Bull. tab. 465, fig. 2. The stem in this plant is fluted, hollow, running insensibly into the pileus, which is also hollow. The gills are silvery grey, and branched like nerves. The whole plant is tough, elastic, and of a greyish mouse colour.

Sect. 3. *Stemless. Merulius membranaceus.* Sower. tab. 348. The whole plant is somewhat like wet parchment, lobed and waved irregularly. It grows in a vertical direction, the one side containing fibrils by which it adheres to other bodies, and the other side is furnished with fine branched anastomosing veins. It grows on moss in damp places, and on thatched houses.

Genus XIX. Agaricus. The agarics are fleshy and membranaceous; the cap is furnished with gills underneath, of a different substance from the rest of the plant, and composed of two plates containing the seeds. 19. Agaricus.

When Linnæus published his *Systema Naturæ*, he was acquainted with only 27 species of agarics, which he subdivided into two sections, Stipitati, pileo orbiculato, and Parasitici, acaules demidiati. Since the days of the illustrious Swede, the number of species has increased prodigiously; so that in Britain alone, nearly 300 are known as native plants. Various attempts have accordingly been made to introduce accurate divisions into so extensive a genus. But difficulties nearly insurmountable have hitherto rendered such efforts abortive. All that the generality of naturalists observe, is the last state of the existence of the plant; impregnation has probably taken place before it rises above the surface of the ground, so that nature exhibits to us the ripening and dispersion of the seeds only, and the final dissolution of the individual. Since we are not permitted to inspect those organs which, among the phenogamous plants, serve so admirably for their artificial, we had almost said for their natural division, all that remains for us is, to examine with care those characters which are least liable to change, even although these should be but remotely connected with any of the primary functions of their nature. Among the French writers, many subdivisions have been adopted, but almost all of them are artificial, founded upon characters either difficult of detection, or inconstant and fugacious. This will be better illustrated, by stating the characters of those subdivisions, as they appear, for example, in the *Flore Francaise*, which are as follows: 1. *Pleuropus.* Destitute of a wrapper or volva, stem wanting, or lateral, or eccentric. The sessile species are usually coriaceous; those having a stem are fleshy, with an irregular pileus. As an example, we may refer to the *Agaricus quercinus* of Sowerby, tab. 181. 2. *Russula.* Destitute of a wrapper, stem central, gills equal among themselves, and not terminating in a collar surrounding the stem, as *Agaricus pertinaceus*, Flor. Fran. No. 369. 3. *Lactarius.* Destitute of a wrapper, stem central, gills unequal, juice milky, generally white, sometimes yellow or red, *e.g. Agaricus deliciosus.* Sower. tab. 222. 4. *Coprinus.* Destitute of a wrapper, stem central, naked or furnished with a ring; gills unequal, dissolving into an inky fluid when old; cap membranaceous, *e. g. Agaricus cylindricus.* Sower. tab. 189. 5. *Pratella.* Destitute of a wrapper, stem central, naked, or furnished with a ring; gills turning black, but not dissolving as they grow old; cap fleshy. *e. g. Agaricus cyaneus* of Withering. 6. *Rotula.* Destitute of a wrapper, stem central, gills equal, ending in a collar surrounding the stem, *e.g. Agaricus rotula.* Sower. tab. 95. 7. *Mycena.* Destitute of a wrapper, stem central, hollow, gills not blackening with age, cap not umbilicated, *e.g. Agaricus pratensis.* Sower. tab. 247. 8. *Omphalia.* Destitute of a wrapper and ring, stem hollow or solid, cap umbilicated, gills generally decurrent, and not blackening with age, *e. g. Agaricus dryophilus.* Sower. tab. 127. 9. *Gymnopus.* Destitute of a wrapper and ring, stem solid, cap fleshy, gills not blackening with age, and either decurrent on the stem, as *Agaricus miniatus,* Sower. tab. 141, or adhering to the stem, as *Agaricus roseus,* Sower. tab. 72, or having the gills loose, as *Agaricus aurantius.* Sower. tab. 381. 10. *Cortinaria.* Destitute of a wrapper, stem central, gills not blackening with age, but covered when young with an incomplete curtain, which leaves upon the stem a filamentous ring, *e. g. Agaricus collinitus.* Sower. tab. 9. 11. *Lepiota.* Destitute of a wrapper, stem central, gills not blackening with age, covered when young with a curtain, which rends, and leaves on the stem a ring, *e. g. Agaricus cepestipes.* Sower. tab. 2. 12. *Amanita.* Furnished with a wrapper or membranaceous covering, which envelopes the mushroom when young, afterwards rending, and sometimes leaving its remains upon the cap. Of these, some have the wrapper imperfect, as *Agaricus verrucosus* of Bulliard, tab. 316; while in others it is complete, as *Agaricus bulbosus.* Sower. tab. 130.

With regard to the *wrapper,* the *volva* of some authors, but not of Linnæus, it appears to belong but to a very few species; and even in these, to be sometimes so imperfect as to lead authors to deny its existence. It seems to be confined to the plants with solid stems only; nor has it been found attendant even upon these when the gills are decurrent. It envelopes the whole plant in its early stage, and afterwards bursts asunder, leaving its remains in the form of warts upon the cap in some instances, and in others disappearing entirely. On a character so uncertain, is the genus *Amanita* of Persoon founded.

The *cap,* or *pileus* as it is called, is the most obvious part of the mushroom; but it is apt to vary both in shape and colour. The last character is very uncertain; the former is a little more permanent. The cap is either conical, convex, flat, or concave and funnel-shaped. It is constantly varying in the same plant, but is pretty uniformly the same in the same species, when the plant is in perfection; that is, when fully or nearly expanded, and before it exhibits symptoms of decay. In some mushrooms, both the cap and the stem exhibit a viscidity or clamminess on the surface. This character, however, is not much to be depended on, as in dry weather some of the viscid spaces shew no symptoms of a moist or even adhesive substance; and in a moist atmosphere, many, at other times dry to the feel, become more or less viscid.

The *stem* is less variable than the cap. Its shape, the proportion of its length to its breadth, and of both to the cap, afford tolerable distinctive marks; and its colours, though subject to change, are perhaps rather more fixed than those of the cap. But the most permanent characters afforded by the stem, depend upon its position and internal structure. The Agarics are either destitute of a stem, the cap sitting close upon the root, or the stems are central or lateral. When the stem is cut across with a sharp knife, it appears hollow or tubular in some species. The tube is not always proportioned to the size of the stem, though it is uniform throughout its whole length. It is sometimes entirely empty, sometimes loosely filled with a pithy substance; but its regularity is not affected by that circumstance. In many species, the stem when cut appears solid, varying greatly, however, in the degree of solidity. It may be as solid as the flesh of an apple, or as spongy as the pith of elder; but still it is solid, that is, there is no regular hollow pervading its whole length, though the more spongy and larger stems sometime show irregular and partial hollow places from the shrinking of the pithy substance as the plant grows old; but this can never be mistaken for a regular, uniform, and native hollowness.

The *gills* are the flat thin plates found on the under side of the cap, and attached to it. They are of a texture evidently different from that of the stem or the cap, and vary much in their respective lengths. Each gill consists of two membranaceous plates, between which the seeds are formed. They are always attached to the pileus, and sometimes to that only. They often also adhere to the stem, and frequently extend along it downwards. These fixed and decurrent gills are attached to the stem by their ends, which are next the centre of the cap, and not by their edges, as is sometimes the case in some of those species whose caps are nearly cylindrical. Among those which have loose gills, (or not attached to the stem), there are a few species in which these organs terminate in a collar, not unaptly compared to the nave of a wheel, the hollow centre receiving the stem like an axle. The number of gills varies even in the same species. Sometimes they are all equal in length, at other times there are between the primary gills which extend from the margin to the centre of the cap, a few secondary ones, reaching from the circumference a short way inwards. Those gills which have four in a set, are by far the most common; but in those which have four in a set when young, the gills very often increase to eight when fully expanded, some of the longer gills bearing from the stem. Characters taken from the number of the gills, are therefore very uncertain and variable. The *colour of the gills* is an obvious, and fortunately, at the same time, a permanent circumstance; and when we reflect that their colour is principally, if not solely, caused by that of the fructification or seeds within them, we might *a priori* have expected what experience has taught in this case, that it is the most fixed, the most certain characteristic on which to found the distinctions of the species; and that this, together with the structure, will be at all times sufficient to afford permanent specific distinctions. It is allowed, that these colours change when the plant begins to decay, but no botanist would complain that the characters are wanting, in a subject collected in a rotten state. The colour of the flat sides of the gills is what ought to be attended to, because the colour at the edge in some plants is different through all the stages of its growth, and in others it changes sooner than that of the sides, evidently from the discharge of the seeds when ripe. The colour of the whole of the gills being sometimes influenced by the ripened seeds, it is clear that this colour ought to be described where it is liable to such a change, not only in the perfect and vigorous state of the plant, but also in its mature and nearly decaying state, taking its character from the former. Thus, in several of the deliquescent agarics, especially such as dissolve in decay to an inky liquor, the plants, when very young, have white gills; these become grey when the seeds are formed, and black when quite ripe, and dissolve in decay. These circumstances may be properly noticed in the history of the plant, but no one would think of taking its character from its yet but half unfolded state, any more than from its state of decay; such a plant, therefore, must be placed amongst others whose gills are grey.

Some of the agarics have a *curtain*, the *volva* of Linnæus, extending from the stem to the edge of the pileus. This curtain is torn as the pileus expands, and soon vanishes; but the part attached to the stem often remains, forming a *ring* round it. This ring is more or less permanent as its substance is more or less tender; but some of the species appear some years with, and other years without, a ring; so that though it forms a very obvious character, it cannot be admitted as the ground of specific distinction. Major Velley, when speaking of *Agaricus æruginosus*, says, "in the autumn of 1788, in several hundred specimens, I never found one that had a ring on the stem; but the following year, almost every one that occurred had this distinguishing mark."

Many of the agarics, when wounded, pour out a milky juice; but this circumstance is by no means uniform in the same species. Some plants, apparently healthy and vigorous, shew no signs of milk when wounded, while others of the same species, on the same spot, and at the same time, pour out their milk in abundance. This frequently happens with the *Agaricus exampelinus.*

Taking all these characters in connection, and allotting to each a conspicuous place, in proportion to its permanency, our countryman, Dr Withering, in his "*Arrangement of British Plants*," presented to the public a classification of the agarics, more simple, obvious, and applicable, than any of those subdivisions which have hitherto appeared. Without venturing to give a description of any of the species belonging to the different divisions, we content ourselves with presenting an outline of the whole.

A. Stem central.

I. Solid and Decurrent.

1. Gills white. 2. Gills brown.
3. Gills red. 4. Gills buff.
5. Gills yellow. 6. Gills purple.

II. Solid and Fixed.

1. Gills white. 2. Gills brown. 3. Gills purplish.
4. Gills buff. 5. Gills yellow. 6. Gills grey.

III. Solid and Loose.

1. Gills white. 2. Gills brown. 3. Gills red.
4. Gills buff. 5. Gills yellow. 6. Gills grey.

IV. Hollow and Decurrent.

1. Gills white. 2. Gills red.
3. Gills yellow.

V. Hollow and Fixed.

1. Gills white. 2. Gills brown. 3. Gills red. 4. Gills purple.
5. Gills yellow. 6. Gills buff. 7. Gills green. 8. Gills grey.

VI. Hollow and Loose.

1. Gills white. 2. Gills brown. 3. Gills red.
4. Gills buff. 5. Gills yellow. 6. Gills grey.

B. Stems Lateral.

1. Gills white 2. Gills brown.
3. Gills buff.

C. Stemless.

GENUS XX. MORCHELLA. The plants of this genus have no wrapper; their ovoid cap is supported by a cylindrical stem, not perforated at the summit, but raised below into anastamosing nerves, forming polygonal cells, in which the seeds are concealed. These plants were formerly associated with the genus Phallus, but in consequence of their want of a wrapper, and the seeds not being enveloped in a slimy liquor, they have been disjoined by Jussieu, Lamarck, and Persoon. 20. MORCHELLA.

Morchella esculenta. Phallus esculentus of Linnæus, Sower. tab. 51. The stem is cylindrical, solid, or hollow; white and smooth; the cap is hollow within, ovoid, adhering to the stem by its base, and latticed on the surface with irregular sinuses: the height is about four inches. This plant is well known in Britain by the name of Morel, and is eaten with safety.

FAMILY V. *Fungi in which the fertile surface decays into a pulp, the plant issuing from a wrapper.*

GENUS XXI. PHALLUS. Stem enveloped by a wrapper at the base, supporting a cap, which is perforated at the top, marked with a network of cells, and furnished with a slimy liquor, in which the seeds are lodged. 21. PHALLUS.

Phallus impudicus. Sower. tab. 329. This is one of the most singular productions of the whole tribe. It arises from the earth under a wrapper, shaped exactly like a hen's egg, of the same colour, having a long fibrous radicle at the base. This wrapper is composed of two coats or membranes, the space between which is full of a thick, viscid, transparent matter, which, when dry, glues the coats together, and shines like varnish. In the next stage of growth, the wrapper suddenly bursts into several lacerated permanent segments, from the centre of which arises an erect, white, cellular hollow

Fungi.

stalk, about five or six inches high and one thick, of a wax-like friable substance, and most fœtid cadaverous smell; conic at each end, the base inserted in a white, concave, membranaceous, turbinated cup, and the summit crowned with a hollow conical cap, an inch long, having a reticulated cellular surface, its base detached from the stalk, and its summit umbilicated, and either perforated or closed. The under side of this cap is covered with a clear, viscid, gelatinous matter, similar to that found between the membranes of the wrapper; and under this viscid matter, concealed in reticulated receptacles, are found the seeds; which, when magnified, appear spherical. As soon as the wrapper bursts, the plant begins to diffuse its intolerable odours, which are so powerful, and widely expanded, that it may be readily discovered by the scent only, before it appears to the sight. At this time, the viscid matter between the coats of the wrapper grows turbid and fuscous; and when the plant arrives at its full maturity, the clear viscid substance in the cap becomes gradually discoloured, putrid, and extremely fœtid, and soon afterwards turns blackish, and, together with the internal part of the cap, melts away. It is common in woods and hedges.

22. Clathrus. Genus XXII. Clathrus. The receptacle for the seeds in this genus is formed of fleshy, arched, anastamosing branches, which form a kind of vault. The branches emit, on all sides, a viscous liquor, concealing the seeds; the receptacle is inclosed in a wrapper in the young state of the plant.

Clathrus cancellatus. Bull. p. 190, tab. 441. This plant is sessile, globular, and white. The wrapper soon breaks from the summit, and discloses the receptacle or cap, which is often of a red colour. The branches of the receptacle form an ovoid vault. The seeds are mixed with a stinking liquor. It is found on sandy grounds, and in dry woods, in the middle parts of Europe.

TRIBE II. ANGIOCARPI.

Family I. *No peridium, the plants parasitical, protected, when young, by the epidermis of the plant upon which they grow.*

23. Gymnosporangium. Genus XXIII. Gymnosporangium. The plants of this genus exhibit a gelatinous mass, at the surface of which seed vessels are found, composed of two conical cells, joined at the base, and separating at maturity. These capsules are placed at the summit of weak slender filaments, which proceed from the base, and traverse the gelatinous mass. All the plants of this genus are parasitical on the different species of junipers.

Gymnosporangium fuscum. Tremella sabinæ. *Dicks. Crypt.* i. p. 14. This is of a reddish or brown colour, issuing from beneath the epidermis on which it grows. It is somewhat narrow at the base, almost cylindrical, obtuse, sometimes marked by a longitudinal groove. Its consistence is a little gelatinous. The microscope discovers, on the surface, numerous seed vessels, supported by slender filaments, proceeding from the base of the plant. It grows upon the *Juniperus sabina*, &c.

24. Puccinia. Genus XXIV. Puccinia. The plants of this genus present themselves under the form of compact gelatinous tubercles, upon which the seed vessels are raised; these are supported upon stiff stems, are in general divided into two or more cells, by transverse partitions, and emit the seeds by the summit or by the sides. They grow upon the leaves and young shoots of plants, sometimes under the epidermis, which they pierce in order to reach the air, and sometimes upon the epidermis itself. In autumn there is scarcely a plant that is not infected with these parasites. They are divided into three sections.

Sect. 1. *With three or four cells. Puccinia rubi.* Sower. tab. 400, fig. 9. This is a very common plant, growing on the under side of the leaves of the common bramble in autumn, spotting their backs with little sooty-looking clusters; which, when magnified, are found to consist of a number of transparent stems, tapering upwards, each with three or four oval heads, resembling little black beads placed on each other, the uppermost somewhat acute at the apex.

Sect. 2. *With two cells. Puccinia graminis.* The *Uredo frumenti* of Sower. tab. 140. This species, too well known in this country by the name of *blight*, grows on the leaves and stalks of various species of gramina, thereby stinting and weakening the plant. It forms linear patches, which are at first yellowish brown, and afterwards become black; the seed vessels are supported on short stems, somewhat clavate; the cells are two in number, the one at the extremity somewhat larger than the other. It is common on wheat, in low grounds, or where too closely sown, especially after rain in the early part of autumn.

Sect. 3. *With one cell. Puccinia pisi.* Sower. tab. 393, fig. 8. This parasite attacks the stems, leaves, and tendrils, of the common pea. It grows in brown pustules, which are a little prominent, and scattered oblong on the stem, but rounded on the leaves. The epidermis is first raised, and afterwards bursts and forms a border around the pustules. It consists of unilocular ovoid capsules, supported on very short stems.

Genus XXV. Bullaria. These grow in groups, under the epidermis of dead stalks, which they raise, and afterwards burst, each group consisting of a multitude of articulated and sessile capsules. These differ from the genera Puccinia and Uredo, in growing upon dead stalks, and not upon living leaves. 25. Bullaria.

Bullaria umbelliferarum. Persoon's *Obs. Myc.* tab. 2. fig. 5. This species is common on the dead stalks of umbelliferous plants, growing under the epidermis, which it raises up in the form of an oval greyish bladder, and then pierces it longitudinally; a reddish-brown mass may then be distinguished, almost pulverulent, which presents, under the microscope, sessile capsules, separated into two cells by a partition, or rather a transverse stricture, giving them the form of the figure 8.

Genus XXVI. Uredo. This genus exhibits merely a naked powder growing under the epidermis of living leaves, which it bursts, and issues by the orifice, the torn margin resembling a small receptacle; the seeds or capsules are ovoid or globular, without transverse partitions. In autumn these fungi are to be found on almost every leaf. Several species infest the willows. 26. Uredo.

Sect. 1. *Powder black, brown, or red. Uredo segetum.* Bull. page 90, tab. 472, fig. 2. It is painful for us to record the name of another parasitical fungus, as destructive to our crops as the blight, but known by the name of *Smut*, and attacking the ears of wheat, oats, and barley. It consists of small spherical globules, a little adhering together, and of a brown or blackish colour. It grows under the epidermis, and sometimes destroys the whole parenchyma of the ear.

Fungi. The epidermis which remains in shreds, and the fibres, which, on account of their hardness, resist the devastation, were formerly supposed to be the seed-vessel, and the proper filaments of the parasitical plant.

SECT. 2. *Powder yellow. Uredo linearis.* Sower. tab. 139. This species grows on the leaves of many of the grasses, forming linear patches visible on both sides, rising under the epidermis, which at last bursts in the direction of the nerves. The powder is at first yellow, afterwards brown, composed of ovoid globules.

SECT. 3. *Powder white. Uredo tragopogi.* This is found on the leaves of the goat's-beard, in the form of a white powder.

FAMILY II. *Peridium membranaceous, filled with Powder not intermingled with Filaments.*

27. Ecidium. GENUS XXVII. ECIDIUM. The fungi of this genus appear at first as simple tubercles, which soon open at the summits into a circular orifice, more or less deeply toothed. The inside contains a farinaceous powder. They are all parasitical, growing upon the leaves of living plants.

SECT. 1. *Tubercles scattered. Ecidium anemones.* Lycoperdon anemones, Pultn. *Lin. Trans.* vol. ii. p. 311. This grows on the inferior surface of the leaves of the *Anemone nemorosa*, in the form of scattered tubercles. They appear at first under the cuticle, and afterwards burst forth like white buds, with a pore in the summit, and then expand into a cup with a laciniated border. The powder is white, and composed of ovoid globules, scarcely cohering. This plant can scarcely be mistaken for any of the other parasitical fungi with which this anemone is infested, as the Ecidium punctatum, in which the powder is brown, the Uredo anemones, and the Puccinia anemones.

SECT. 2. *Tubercles closing into a circular ring. Ecidium tussilaginis.* Sower. tab. 397, fig. 1. This grows upon the under surface of the leaves of several species of tussilago. The leaf appears with a reddish-white spot on the upper surface, and below the receptacles are disposed in spots, rounded and serrated, or often formed into a ring. Powder orange, sometimes white.

SECT. 3. *Branched in irregular clusters. Ecidium berberidis.* Sower. tab. 397, fig. 5. This grows upon the back of the foliage of the common barberry, in rounded convex tufts, the space of each appearing on the upper surface like a red spot. The common base is reddish, supporting small yellow tubercles, which divide at the summit into a circular opening, the margin furnished with fine teeth. Powder yellowish-orange. Found principally in the spring.

28. Mucor. GENUS XXVIII. MUCOR. The plants of this genus have a membranaceous globular or tufted receptacle, seated on a stem, at first watery and transparent, afterwards opake, and full of naked powder, not mixed with filaments, and but little cohering.

Mucor mucedo. Sower. tab. 378, fig. 6. This species, which every one knows, is common on all fermenting and decaying vegetable or animal matter. The stalks are simple and slender, bearing upon their summits a globular seed-vessel, at first white and transparent, afterwards brown and opake. The seeds are numerous, round, and greenish while inclosed in the seed-vessel. This seed-vessel bursts with an elastic force, as may be seen when viewing it under the microscope.

GENUS XXIX. LICEA. The fungi here referred to have a sessile, membranaceous, brittle peridium, bursting in various ways, and containing a powder without filaments. They are destitute of a membranaceous base. 29. Licea.

Licea circumsissa. Sower. tab. 258. This plant is sessile, rounded, and a little flattened. It opens irregularly across, and contains a golden yellow powder, among which one or two filaments may be discerned with difficulty. It grows at the end of autumn on dead wood.

GENUS XXX. TUBULINA. The plants of this genus possess a membrane which supports many sessile peridiums, which are generally cylindrical. The powder is destitute of filaments. 30. Tubulina.

Tubulina cylindracea. Bull. tab. 470, fig. 3. The peridiums are sessile, and rest upon a white obvious membrane: They are cylindrical and lengthened, and terminate in an obtuse point, of a rusty brown colour, with a white point. These burst irregularly towards the upper end, and allow the rusty brown powder to escape. This plant grows upon moist dead wood.

FAMILY III. *Peridium membranaceous, filled with Powder, intermingled with Seeds.*

GENUS XXXI. TRICHIA. The peridiums of this genus are sessile or pedunculated, supported upon a membrane which is very apparent in the young state of the plant. These inclose the filaments, which are attached to a stem, or to the partitions of the peridium, and support numerous pulverulent globules. They are divided into several sections, which might with propriety be constituted into genera. 31. Trichia.

SECT. 1. *Peridium ovoid, spherical, sessile, or pedunculated, bursting irregularly. These form the Spherocarpus of Bulliard. Trichia turbinata.* Bull. tab. 481, fig. 1. The base is white, membranaceous, and very apparent; the stems are simple, smooth, slender, lengthened, cylindrical, terminating in an orange-coloured peridium, at first in the form of a rounded tuft, afterwards as if truncated, and finally concave at the summit; at which time it might be taken for a Peziza, if the interior of the peridium were not filled with long-haired network, covered with a greyish-red powder. It grows on dead wood.

SECT. 2. *Peridium bursting in such a manner as to form a persisting calyx on the summit of the stalk. This is the Arcyria of Persoon. Trichia nutans.* Sower. tab. 260. The base consists of a white coriaceous membrane, supporting the little fungi; the peridium is lengthened, becoming cylindrical, and at the same time decaying at the top, leaving at liberty the powder and the filaments. It grows upon dead wood.

SECT. 3. *Peridium destroyed in whole or in part, in such a manner as to leave anastamosing nerves, through which the powder issues.* The *Crebraria* of Persoon. *Trichia semi-cancellata.* Sower. tab. 400. fig. 5. The base is a coriaceous white membrane, supporting numerous stalks, which are simple, striated, of a brownish-black colour, tapering towards the summit, straight, or leaning in old age. The peridium is globular at first, opake, of a fine yellow before and reddish after the emission of the seeds. The lower part is membranaceous, and persisting in the form of a denticulated calyx; the upper part is formed of fibres, disposed in a net-work, vanishing after the emission of the powder, which is yellow.

Fungi.

32. Stemonites. Genus XXXII. Stemonites. The plants of this genus are usually inserted upon a membrane in groups; the peridiums are pedunculated, and traversed by an axis, which consists of a lengthening of the peduncle.

Stemonites typhoides. Sower. tab. 50. The white membrane of the common base supports a number of slender stalks, which traverse the peridium, and remain after the escape of the powder. The peridium is cylindrical, soft, of a milk-white colour when young, but becoming black afterwards. It bursts laterally in many places, and throws out a brown powder. It grows during the summer on rotten trunks of trees.

33. Diderma. Genus XXXIII. Diderma. In this genus many individuals arise from a common membrane, having a peridium with a double covering, containing powder intermingled with filaments. This genus bears the same relation to the Trichia as the Geastrum does to the Lycoperdon.

Diderma floriforme. Bull. tab. 371. This plant is altogether of a coriaceous consistence, and of a pale yellow colour. The base consists of a thick obvious membrane, supporting many slender, smooth, cylindrical stalks, with a globular smooth head. At length the outer bark opens into five or six unequal rays, exposing a true peridium, pear-shaped, wrinkled, and permanent, bursting irregularly, and emitting a brownish-coloured powder.

34. Reticularia. Genus XXXIV. Reticularia. This genus consists of plants, which are at first pulpy, shapeless, and soft. Internally they present cells full of powder, forming a kind of slender net-work; finally, they are reduced into a fine powder.

Reticularia hortensis. Sower. tab. 399. This is common on tan in hot-houses. It at first appears to ferment as it were in a kind of whitish froth, in a few hours becoming yellowish, and seemingly mixed with a powder; at length it grows fragile, flattens, and assumes a lightish brown colour on the outside, being replete with dark powder, or seeds in irregular divisions within; after which it soon falls to pieces. In the fresh state it smells not unlike rotten cheese.

35. Spumaria. Genus XXXV. Spumaria. The plants of this genus resemble the preceding, but their pulp conceals coriaceous and membranaceous cases, inclosing the seeds.

Spumaria mucilago. Sower. tab. 280. This plant is of a white colour, soft, and flaky like scum. Internally the coriaceous cases are shaped like coral, and inclose a black powder. It dries up quickly, and by the touch is reduced to powder, nothing remaining but the black cases. It grows upon the stalks and leaves of dead and living plants.

36. Leucogalia. Genus XXXVI. Leucogalia. In this genus the peridium is membranaceous, rounded, and filled while young with a liquid pulpy mass, afterwards changed into a powder mixed with a few filaments. This peridium opens in a regular manner at the sides, or on the summit.

Leucogalia argentea. Sower. tab. 272. This plant is sessile, or prolonged at the base into a very short peduncle. Its form approaches to spherical; its colour is white when young, afterwards it turns red or brown. The pulp changes into a powder, at first grey, afterwards rust coloured, and at last brown. The seed-vessel bursts at the side. This species grows solitary, on putrid trunks, in autumn.

37. Lycoperdon. Genus XXXVII. Lycoperdon. The plants of this genus are composed of a peridium generally globular, solid when young, with whitish close flesh, changing into a powder intermingled with filaments. At maturity it opens at the summit, in a manner more or less regular. Several species of this genus are so well known in this country by the name of *Puff-balls*, as to render any farther description unnecessary.

Fungi.

38. Geastrum. Genus XXXVIII. Geastrum. The plants of this genus are globular at first, then the external covering opens at the top, and divides into many rays, curling backwards, and raising the peridium on a vaulted pedestal. The peridium is globular, and opens at the summit by an orifice bordered by fading hairs. The inside is full of brown powder, intermingled with filaments, dispersed, and indistinct. The external covering is coriaceous and thick, the internal is membranaceous; between these there is sometimes found a fugaceous wrapper.

Geastrum hygrometricum. Sower. tab. 80. The external covering is of a chesnut colour, divided into five or six nearly equal rays, which are bent backwards. The peridium is spherical and sessile, mouth ciliated, and usually bordered with a circle of a paler colour. For a more minute account of the species of this genus, the reader is referred to an excellent paper of Mr Woodward's, on the stellated Lycoperdons, in the *Linn. Trans.* vol. ii. p. 32—62.

39. Tulostoma. Genus XXXIX. Tulostoma. The peridium is solid, globular, fleshy, white, and becomes converted into a fine powder, intermingled with fine filaments. It is supported on a cylindrical stalk, hollow throughout, having an opening at the top, with a cartilaginous border.

Tulostoma brumale. Bull. tab. 294, and 471. fig. 2. This plant is of a white colour, the stem is cylindrical, generally glabrous, sometimes imbricated; peridium globular, opening at the summit by a round orifice which is flat, or a little prominent. It grows in sandy grounds in winter, and in the beginning of spring.

Family IV. *Peridium membranaceous or fleshy, and without powder.*

40. Cyathus. Genus XL. Cyathus. The fungi of this genus consist of little cups, the orifice of which, at first, is vested with a membrane, and the inside filled with a viscid limpid juice; afterwards the membrane bursts, the liquid evaporates, and there remain in the bottom of the cup from three to five lenticular capsules, adhering to the base by a slender filament, and filled with jelly, in which grains are observed supposed to be seeds.

Cyathus striatus. *Nidularia striata* of Sower. tab. 29. This plant is conical, woolly on the outside, and scored within. The capsules are smooth above and woolly beneath. It grows on the ground, and on rotten wood.

41. Stictis. Genus XLI. Stictis. This genus exhibits little membranaceous cups, half way inserted into the barks of trees, full of a substance not powdery, inclosing the seeds; these are closed when young, but open afterwards into a cup.

Stictis immersa. *Peziza immersa* of Sower. tab. 369. fig. 9. This little fungus is wholly black, sometimes a little woolly on the underside. It forms holes in the wood on which it grows.

42. Pilobolus. Genus XLII. Pilobolus. In this genus the receptacle is thread-like, widening at top into a vesicle filled with water, at the summit of which there is found a fleshy substance, supposed to contain the seeds in the inside.

Fungi.

Pilobolus urceolatus. Sower. 300. This curious production may be found on horse dung, in damp or dewy mornings or evenings almost all the year. At first it is cylindrical, with a small yellow head. In a few hours the stipes inflates towards the top, and becomes pitcher-shaped, and at the same time the head gradually changes brown, by degrees becoming totally black. The plant being arrived at perfection by its inflation or expansion, it bursts and projects the head to the distance of three or more inches, probably to disperse the seed.

43. Thelebolus. Genus XLIII. Thelebolus. Receptacle cortical, globular, entire at the margin, when young inclosing a vesicle, which afterwards pushes out, containing a great many loose capsules, lengthened, pointed, and filled with seeds.

Thelebolus hirsutus. This species grows upon the bark of living trees, forming a greyish membranaceous base supporting many small globular heads, with a rounded orifice at the top, by which the internal matter containing the seeds escapes.

44. Erysiphe. Genus XLIV. Erysiphe. The fungi here referred to have a fleshy receptacle, containing many oval acute seed-vessels, and surrounded with a white pulp prolonged into many articulated simple or branched rays. These grow upon the living leaves. The receptacles of all the known species are at first yellow, then red, and at last black; the extension of the base is always white, often covering the leaves with a retiform membrane or powder.

Erysiphe fraxini. Mucor erysiphe of Linn. This plant grows on the inferior surface of the leaves of the common ash, forming at first a thin white crust, which afterwards supports small tubercles, at first yellow, then orange, brown, and at last black; these are bordered with seven or eight pointed hairs, swollen at the base. These hairs are at first upright, then they become horizontal, and finally are obliterated.

45. Tubercularia. Genus XLV. Tubercularia. The plants of this genus present merely a fleshy sessile tubercle, simple or composite, the seeds contained in a thick liquid in the inside. They grow upon the bark of trees and certain plants, and are all remarkable for their red colour.

Tubercularia vulgaris. Bull. tab. 284. This plant is not absolutely without a stem, but the stem is very short, and nearly as thick at the top, entering into the substance of the bark on which it grows. In some specimens the top part is of a full vermilion, and the lower part of a yellowish colour. In other specimens this order of colour is reversed. It is common in this latter variety to find young shoots growing up close to the stem of the older plants, the heads of which have the full vermilion colour. It varies from the size of a pin's head to that of hemp-seed. It is found plentifully on pieces of half rotten sticks in the autumn.

46. Sclerotium. Genus XLVI. Sclerotium. The sclerotia present merely a hard bark or covering of a more or less compact fleshy substance, without visible veins, in which the seeds are supposed to be nestled. They differ from the genus Tuber in the absence of veins, and from Tubercularia in the flesh being firmer, and the bark more coriaceous. They are the productions of spring.

Sclerotium durum. Pers. *Syn.* 121. This grows between the bark and the wood, upon the dry stalks of herbs and shrubs. It is oblong or oval, a little flattened, and of a black colour. The substance is firm and hard, and in the interior the flesh is white and coriaceous.

47. Tuber. Genus XLVII. Tuber. The plants of this genus are fleshy, round, subterraneous, solid, not becoming powdery, nor opening at the top, but containing veins in various directions. By Linnæus they were united with the lycoperdons.

Fungi.

Tuber cibarium. Sower. tab. 309. *Truffles,* as the plants of this species are called in England, are globular, seldom the size of a hen's-egg, without any root, and of a dark colour approaching to blackness. The surface is uneven and rough; the flesh firm, white while young, but when old it becomes black with whitish veins.

Having thus concluded our proposed review of the different genera of Fungi, it may be proper here to remark, that, under the term Hypoxyla, which we have added as an Appendix to the present article, the reader will find some of those genera described, which he probably expected to meet with under the title Fungi. Such as the genus Rhizomorpha of Rothes, and that extensive genus, or rather tribe of plants, the Sphæria of Linnæus.

Preservation of the Fungi.

Before proceeding to offer some remarks on the physiology of the Fungi, it may be proper to state the methods which have been employed for the purpose of preserving them in a fit state for subsequent inspection and comparison. The difficulty, indeed, of preserving such soft and perishable objects has always been found one of the most formidable obstacles to the study. Dr Withering, to whom the British botanist lies under so many obligations, after a long continued attention to the subject, discovered the following method, which he found to answer the purpose. Take two ounces of vitriol of copper, (sulphat of copper,) reduced to powder; pour upon it about a tea cup of cold water, stir them with a piece of stick or quill for about a minute, then pour off the water and throw it away. On the remaining vitriol pour a pint of boiling water, and when the whole is dissolved and grown cool, add to it half a pint of rectified spirit of wine; filtre it through paper; keep it in a bottle closely corked, and call it the *pickle.* To eight pints of pure spring water, add a pint and a half of rectified spirit of wine; keep this in corked bottles, and call it the *stronger* liquor. To eight pints more water, add one pint of spirit of wine, and call it the *weaker* liquor. Be provided with a number of wide-mouthed glass jars of various sizes, capable of holding from two ounces to two pints, all very well fitted with corks.

Whatever fungus, whether Agaric or Boletus, &c. you wish to preserve, should be suffered to lie upon your table as long as it can be trusted without danger of its decaying, so as to allow some part of its moisture to evaporate; the thick and fleshy plants should lie the longest, but the deliquescent ones, and those which are very thin and delicate, should be put into pickle almost immediately after they are gathered.

Pour some of the pickle into a square jar, and into this immerse the specimens to be preserved. The specimens should remain in the pickle from three hours to three days, according to their bulk and fleshiness. Then remove each specimen into the jar in which it is to be kept, suiting the size of the jars to the size of the specimens. If they are of the large juicy and fleshy kind, fill up the jar with the *stronger* liquor, but the weaker will suffice for the smaller and thinner plants. Whichever liquor be used, the jar must be quite filled with it, and immediately corked very tight. Cover the cork and the top of the jar with Venice turpentine, by means of a painter's brush, and then tie a piece of wetted bladder very tight over the top of the jar. These

Fungi.

precautions are necessary to prevent the access of air and the evaporation of the liquor, because, if either of these happen, the specimens will soon be spoiled. The Boleti are in general more difficult to preserve than the Agarics, and such of either as abound with a milky juice are apt to foul the liquor, which must then be changed. Mosses and Lichens may be preserved in great perfection by this method of pickling. But we must add, that a collection formed in this manner will be both bulky and expensive.

Another method, still more simple, has sometimes been practised, namely, to dry them in a stove of clean sand moderately heated. Almost all the coriaceous agarics may in this manner be preserved with ease, so as to exhibit not only their form, but also in a great degree their colour. The sand must be fine, clean, and dry, and poured into the dish with care, observing to fill the spaces between the gills gently with the sand, without bruising them or altering their position.

But a vast number of the fungi noticed above cannot be preserved by any of those methods which we have detailed. Many of them consist almost entirely of water, so as to be incapable of drying without total destruction, while the characters of others depend so much upon the colour, and at the same time are of a substance so fugaceous, that no liquor can preserve their delicate tints, or their still frailer forms. Hence the mycologist must employ his pen to describe, and his pencil to copy these productions, whose characters he investigates, otherwise his conceptions of the species will be both obscure and indeterminate.

In addition we may mention, that agarics may be transported to almost any distance with little damage by the following method. Put them into an earthen jar upon a layer of moss a little pressed down; cover them with more moss, carefully filling up the interstices; and then go on stratifying them until the jar be quite full; pour in the pickle above described as long as the moss will continue to imbibe any, then stop the mouth of the jar securely. It may be useful to observe, that when several species are put into one jar, they may be labelled with slips of card paper written with a black lead pencil.

Physiology.

In attending to the physiology of this intricate class of vegetables, there is no circumstance in their history more surprising than the rapidity of their growth. The space which intervenes between their germination and maturity is seldom more than a few days, or at most a few weeks, and in many cases a few hours only are required. Withering relates, that a young plant of the Agaricus cylindricus put into water, and covered with a glass bell, grew three inches and a quarter in twelve hours. Sowerby when describing the Phallus caninus, says, "I have often placed specimens by a window, over night, while in the egg form, and they have been fully grown by the morning," and he adds, "they have never grown with me in the day time. The absence of light, indeed, to this tribe of plants, does not seem so prejudicial, as it does to the stameniferous vegetables. Some of them live under the ground, others in the recesses of caves and in dark cellars.

In regard to situation, the fungi present many remarkable differences. A few grow upon the ground, and seem to derive their nourishment from the soil. Others spring up on the various putrid substances presented by nature or art. Rotten fruit, cheese, meat, dung, are all destined to support particular species of fungi. But these parasites are not confined to dead plants and putrid matters, otherwise we might consider them like the *Silphides* among the insects, and style them nature's scaffingers. But they likewise attack living vegetables. They presume not to infest animal matter until the spark of vitality has fled; but they prey upon the very juices of vegetables, seat themselves on the stalks, the leaves, and the flowers, and occasion their stinted growth and decay. Some are peculiar to one plant, while others infest the foliage of several plants, provided in general they belong to the same natural family. They make their appearance in pastures and corn-fields, on way sides, in marshes, and in woods. In one season, you may observe multitudes rising in a particular spot, where none will be found in the subsequent season. So uncertain are they in their growth, that it is not likely they will ever enter into the composition of ornamental gardening. We are told by Gleditsch, that morels are observed to grow in the woods of Germany in the greatest plenty, in those places where charcoal has been made. Hence the good women who collect them to sell, receiving a hint how to encourage their growth, have been accustomed to make fires in certain places of the woods, with heath, broom, and other materials, in order to obtain a more plentiful crop. This strange method of cultivating morels being, however, sometimes attended with dreadful consequences, large woods having been set on fire and destroyed by it, the magistrate thought fit to interpose his authority, and the practice is now interdicted. We may add, that the beautiful little moss called the Dicranum purpureum makes its appearance in precisely similar situations.

We cannot take leave of this part of the subject, without stating to our readers the following observations, which were made by that eminent naturalist, the late George Montagu, Esq. on a Scaup duck, which came into his possession, and which died a few days after.—"The cause of death" (says he) "appeared to be in the lungs, and in the membrane that separates them from the other viscera; this last was much thickened, and all the cavity within was covered with *mucor*, or blue mould. It is a most curious circumstance to find this vegetable production growing within a living animal, and shews that where air is pervious, mould will be found to obtain, if it meets with sufficient moisture, and a place congenial to vegetation. Now the fact is, that the part on which this vegetable was growing was decayed, and had no longer within itself a living principle; the dead part therefore became the proper pabulum of the invisible seeds of the *mucor* transmitted by the air in respiration; and thus nature carries on all her works immutably, under every possible variation of circumstance. It would indeed be impossible for such to vegetate on a living body, being incompatible with vitality; and we may be assured that decay must take place before this minute vegetable can make a lodgement to aid in the great change of decomposition. Even with inanimate bodies, the appearance of mould or any species of Fungi is a sure presage of partial decay and decomposition." *Ornith. Dict.* sup. Duck Scaup.

But the most uncommon circumstance in the mode of growth of the fungi remains to be mentioned, and is their disposition to grow in circles. Many of the Agarics, for example, are solitary, while others are uniformly gregarious. Those of the last kind frequently rise up in a somewhat regular manner, and form circles more or less complete. These circles for a long time perplexed the naturalist, ever more anxious to employ singular and uncommon agents in accounting for the

Fungi.

phenomena of nature, than to trace the various steps of the process by the slow but certain road of fact and observation. For an account of the various hypotheses which have been formed, in order to account for these circles, or fairy rings as they are called, see the article FAIRY RINGS. Before, however, dismissing the subject, we must remark, that the disposition to assume regular figures in the course of vegetation, does not seem peculiar to the fungi. Every person at all acquainted with the lichens, must have observed similar appearances of a circular growth in many of the crustaceous species. And no one who has ever traversed the sandy downs of a sea-shore, can have failed to remark the lineal growth of the Carex arenaria, running under the sand and protruding its stalk in a straight line, as if planted by a skilful gardener. How careful, therefore, should we be to prefer observation to conjecture, and fact to hypothesis.

The season of the year in which the fungi appear most numerous is towards the end of autumn and beginning of winter. They observe particular seasons of the year in which to rise with as much regularity as the more perfect plants, and hence some of the species naturally allied may with tolerable certainty be discriminated. The Agaricus Georgii, which is found in Essex in considerable quantities, and collected for the London market, is known by the name of St George's mushroom, because they usually spring up in greatest quantities about St George's day.

The fungi exhibit some of the finest colours of the vegetable kingdom. In the coloured drawings of the more perfect plants, the artist is sometimes too profuse in tints, and the figures exhibit a gaudy aspect; but in the colouring of figures of the fungi, he need be under little apprehension of committing excess. Nature having withheld from this portion of her plants those flowers which form the chief beauties of the higher orders, and even the leaves with which they are clothed, has profusely scattered her colours over the whole surface of the mushrooms, ornamenting the cap with one colour, the gills with a second, and the stem with a third. Let but the lover of natural beauty free his mind from prejudice, and then examine the forms and colouring of the fungi, and he will be compelled to admit, that many of them rival in symmetry and splendour, the rose and the lily, those gaudy ornaments of Flora.

In general the fungi emit scarcely any smell, and appear entirely destitute of any volatile particles; or they possess a cadaverous smell, which renders them exceedingly offensive. A few, however, emit effluvia by no means disagreeable, nay, in some instances remarkably pleasant. Thus the Agaricus pratensis diffuses an agreeable odour like almond kernels. The Agaricus fragrans powerfully sends forth the pleasant smell of new mown hay, similar to the Anthoxanthum odoratum. While these odours please the sense of smell, others are by no means so agreeable, as Agaricus murinus, which smells like mice; and in this respect resembles the Cynoglossum vulgare. It is impossible for us to determine what important purpose in the economy of the fungi the scent which they emit serves; but in some cases it is most destructive to the animal creation. Thus in the case of the Phallus impudicus, the fœtid cadaverous odour which it emits allures multitudes of flies to light upon its cap, where they are entangled by the slimy matter with which that organ is so plentifully supplied. In this case, it is probable that the plant obtains some nourishment from the decay of the flies to enable it to perfect its seeds. Similar arrangements in the economy of nature have been observed to prevail in the higher orders of vegetables, as in the Drosera rotundifolia, or common sundew, frequent on our turf bogs. The Laplanders burn some of the Boleti about their habitations: and the smoke, as they think, drives away a species of gadfly which is fatal to the young rein-deer.

In respect to taste, the mushrooms present as remarkable variations as they do in regard to smell. Many of them are vapid and tasteless. Others, though by no means unpleasant in the mouth, leave a disagreeable roughness in the throat. Thus the Agaricus aromaticus yields to the tongue the agreeable coolness of peppermint; but leaves on the throat a roughness which remains for a considerable time. This is remarkably the case with almost all the lactescent agarics.

Scarcely any two agarics agree in regard to substance. Some are replete with a watery fluid, while others are dry and coriaceous. Some decay and wither into a substance like leather; whereas others either deliquesce into a black atramentous liquor, or are changed into a powder easily dispersed.

The investigations of the chemist have scarcely been extended to this tribe of vegetables, although ample encouragement be given, by their external properties, to expect some new substances. When exposed to the destructive distillation, they yield the ordinary products of vegetables, together with a quantity of ammonia, indicating the existence of some ingredients nearly related to the animal kingdom. They leave but a scanty residuum of charcoal; and the earthy and saline contents of the ashes have never been examined with care. Dr Scott of Dublin was the first who detected oxalic acid in nearly a pure form, in a young plant of Boletus sulphureus, which he found about the middle of August, on the trunks of an old decaying cherry tree. Having preserved a specimen, he, after some time found a singular crystallization on the upper surface, and which he observed to have ruptured the investing coats of that surface. These needle-like crystals were formed on the fungus, in consequence of its drying only, as none were observable while it remained on the tree. That they were pure oxalic acid, or at least combined with a very small portion of vegetable fixed alkali, was evident from the taste, and by the tests of solutions of lime and barytes. This fungus, after being freed from the saline matter, was distilled in an earthen retort, during which a quantity of watery fluid came over, a thick tar-like extractive matter, carbonic acid gas, carbonated hydrogenous gas, and lastly hydrogenous gas. It was not observed whether azotic gas was among the first products; but it probably was, as the watery fluid which came over in distillation contained ammonia, which appeared by the odour, and the fumes that were exhibited on holding a paper moistened with diluted muriatic acid over a mixture of the former with quicklime. The coaly residuum, when burnt in the open air, afforded by lixiviation some vegetable fixed alkali. "That the oxalic acid" (says Dr Scott) "is produced or evolved in the course of vegetation, in many plants of the higher ranks, is well known; but that it should be found in any of the fungus tribe, (which have hitherto been supposed to produce only an ammoniacal salt, and on that account considered as a link between vegetables and animals,) is a curious and I believe an isolated fact. How far the production of oxalic acid in this fungus might depend on its place of growth, or soil as it may be termed, I cannot say, but it is worth while to repeat the observation on other fungi similarly situated." *Linn. Trans.* vol. viii. p. 262.

The odour of some of the fungi, particularly the Agaricus pratensis, would dispose us to expect to find prussic acid as a part of its composition; but the experiment has never been tried. We recommend it, however, to those who have leisure and favourable opportunities.

Few of the mushrooms have been subjected to a regular chemical analysis. Dr Lister, so far back as 1672, published in the Philosophical Transactions, an account of his experiments on the Agaricus piperatus. He found it to yield a milky juice with a taste hotter than pepper, not discoloured by exposure to the air, nor by the blade of a knife. This juice speedily coagulated when kept in a glass vessel, but did not lose its hot taste. Trommsdorf (*Ann. de Chim.* vol. xxii.) afterwards examined the same plant, and besides the acrid matter which Lister had observed, and which is well known, he found it to yield a considerable quantity of albumen. It also yielded by distillation a considerable quantity of carbonate of ammonia.

It is to Buillon la Grange that we are indebted for the most accurate set of experiments on three kinds of mushrooms, which may serve to give us a correct idea of the composition of the tribe.

The *Tuber cibarium,* which we have described above, well known in Britain by the name of *truffles,* was grated down small, and then washed with water upon a searce, till the liquid ceased to carry off any thing. A blackish fibrous matter remained upon the searce. The liquid let fall a brown coloured matter when left at rest. It produced no effect upon vegetable blues. The brown deposite does not resemble starch in its properties. Water produces but little effect upon truffles. Warm water, however, dissolves a portion, which possesses the characters of albumen.

When the plant was treated with nitric acid, a solution was accomplished; nitrous gas, carbonic acid, and azotic gas were disengaged; and the solution by distillation, yielded a liquor containing prussic acid. The residual liquid yielded bitter principle, an oily matter, and small crystals, which Buillon la Grange considered as a combination of oxalic acid and bitter principle. He suspected also the presence of malic acid.

Alcohol dissolves a small portion of a brownish bitter matter, which acquires the properties of resin by exposure to the atmosphere. When truffles are left in the state of a paste with water, they acquire the smell of cheese. When mixed with sugar and water, they undergo fermentation, carbonic acid is disengaged, and alcohol formed.

When distilled, truffles are found to yield an acid liquid, a black oil, carbonate of ammonia, carbonic acid, and carbonated hydrogen. The charcoal contains magnesia, phosphate of lime, iron and silica. See *Ann. de Chim.* vol. xlvi.

Boletus laricis. This plant in a dry state is used on the continent as a medicine, and sold under the name of Agaric. It is in pieces which are white, light and friable. The outer skin is leathery, and dark coloured. Its taste is at first sweetish, but leaves a bitter and acrid impression in the mouth. When steeped in water, it communicates a yellowish colour and a sweetish taste to the liquid. The infusion reddens vegetable blues; and holds in solution sulphate of potash, sulphate of lime, and muriate of potash.

When this substance is boiled in water, the liquid acquires a gelatinous form as it cools. Evaporated to dryness, and treated with lime, the odour of ammonia becomes perceptible. Alcohol boiled upon the boletus acquires a red colour, and when mixed with water lets fall a copious precipitate, which exhibits the properties of a resin. This resin has a yellow colour, is brittle, semitransparent, and has a sour and bitter taste. When treated with lime, and the solution afterwards decomposed with muriatic acid, a quantity of benzoic acid is obtained from it. From these experiments, it is evident that this substance contains resin, benzoic acid, different salts, some extractive, and some animal matter, to which the gelatinous form of the decoction must be ascribed.

Sulphuric acid dissolves and rapidly chars the boletus. Nitric acid acts with energy, nitrous gas is disengaged, and the boletus becomes brown. By continuing the action of the acid, crystals of oxalic acid are obtained; malic acid is likewise formed, together with some resin, and a substance which approaches the nature of wax in its properties. The fixed alkalies give it a red colour, render it gelatinous, and a great quantity of ammonia is disengaged. See *Ann. de Chim.* vol. li.

Boletus igniarius of British authors, is not uncommon in this country on the trunks of trees. When boiled in water, the liquid acquires a deep brown colour, and a slightly astringent taste. It holds in solution sulphate of lime and muriate of potash. When evaporated to dryness, it leaves a brown coloured extract, which attracts moisture from the atmosphere. This substance when incinerated left a white ash, containing a considerable portion of potash; and when dissolved in water, exhibited by re-agents the presence of lime and of muriatic and sulphuric acids. The residual portion of the boletus being calcined, was found to contain phosphates of lime and magnesia, and some iron.

Alcohol has scarcely any action on this boletus; but when assisted by heat, it dissolves a small portion of resin. Nitric acid dissolves it readily; malic and oxalic acids are formed, and probably also a portion of bitter principle, while carbonic acid and nitrous gas are disengaged. Alkaline leys dissolve it with difficulty, forming however a soapy liquid, and separating a small portion of ammonia. From these experiments we learn, that this boletus differs in many respects from the preceding. It contains much less resin, and a much smaller proportion of animal matter, and yields no traces of benzoic acid. See *Ann. de Chim.* vol. liv.

Little more was done by chemists towards bringing into notice the composition of mushrooms, until M. Braconnot directed his attention to this curious tribe of plants, and succeeded in making us acquainted with the properties of two new combinations; to the one he gave the name of *fungin,* and the other he called *boletic acid.* The one is represented by the solid matter of the plants, the other constitutes the chief ingredient of its juices.

Fungin may be obtained pure, by boiling it in a weak alkaline solution. In that state it is whitish, soft, insipid, possesses little elasticity, and readily yields to the teeth. It would appear, that fungin thus purified may be used as an article of food, from what mushroom soever it has been obtained. The poisonous qualities of mushrooms it would seem reside in the juices, not in the fungin. This substance when dried burns with considerable splendour, emitting an odour similar to that of burning bread, and leaving behind it a white ash. Dried fungin, when distilled in a retort, yields about half its weight of a liquid product, consisting partly of a brown oil, and partly of water, holding a good deal of ammonia in solution. It yields no acid, which distinguishes it very much from wood. The charcoal remaining in the retort, amounts to rather more than one-fourth of the dried fungin subjected to distillation. This charcoal exhibited traces of sulphureted hydrogen, and contained sand, phosphate of lime, and traces of carbonate of lime, and phosphate of alumina.

Fungin does not dissolve in alkaline solutions, in which respect it differs essentially from lignin, which is readily dissolved by a weak alkali; but if fungin be boiled in a very strong alkaline ley, it is partly dissolved, and a saponaceous product obtained. Ammonia dissolves a small portion of fungin, and lets it fall again in white flocks, when exposed to the air.

Weak sulphuric acid has no action on fungin; but when concentrated this acid chars it, and at the same time sulphurous acid and vinegar are formed. Muriatic acid dissolves it very slowly, and converts it into a gelatinous matter. It is thrown down in flocks, by the addition of potash to the acid. Chlorine passed over dry fungin suspended in water, converts it into a yellow matter, having at first an acrid taste, which it gradually loses by exposure to the air.

When digested in diluted nitric acid, azotic gas is disengaged. Heated with concentrated nitric acid, it swells and effervesces at first violently, but the action soon subsides. When the acid is driven off, there remains a liquor containing oxalate of lime, some prussic acid, and two fatty matters, the most abundant similar to tallow, the other to wax. By evaporating the liquid, a considerable quantity of oxalic acid in crystals was obtained. The mother water still contained oxalic acid, and a portion of the bitter principle from indigo.

When fungin is steeped in an infusion of nut galls, it imbibes a considerable portion of the tannin, and acquires a fawn colour. When left to putrefy spontaneously in water, it emitted first the odour of putrefying gluten, then that of putrid meat. Neither acid nor ammonia was found in the water; but it contained a portion of mucilage, which gave it viscosity, and the property of precipitating with acetate of lead. The fungin itself assumed the aspect of gluten, without however possessing its properties.

The other substance which we have to notice is the *boletic acid*, which M. Braconnot obtained from the juice of the Boletus pseudo-igniarius, by the following process. The juice was boiled, filtered, and evaporated cautiously to the consistence of a syrup. This syrup was repeatedly digested in alcohol, the insoluble portion was dissolved in water, and precipitated by nitrate of lead. The white precipitate thus obtained was mixed with water, and decomposed by sulphureted hydrogen gas. The water being now evaporated, yields numerous crystals, which constitute *boletic acid*, the properties of which are as follow:

When purified by solution in alcohol and crystallization, it is white, not altered by exposure to the air, and consists in irregular four-sided prisms. Its taste is similar to that of tartar. It requires 180 times its weight of water to dissolve it at the temperature of 68°. It is soluble in 45 times its weight of alcohol.

The aqueous solution reddens vegetable blues. Nitrate of lead occasions a precipitate in it, which is redissolved by agitation. It precipitates the red oxide of iron completely from its solutions in the form of rust coloured flocks; but it does not throw down the black oxide of this metal. It precipitates nitrate of silver in the state of a white powder, which is soluble in nitric acid. Nitrate of mercury is precipitated in the same state, but the solution dissolves with difficulty in nitric acid. Neither lime nor barytes water produce any effect upon the aqueous solution of this acid. When boletic acid is heated, it rises in white vapours, which irritate the throat, and condense on surrounding bodies in the form of a farinaceous powder. When distilled, the greatest part of it sublimes unaltered, excepting that it afterwards crystallizes more regularly. At the same time a little liquid appears, having a strong smell of acetic acid.

Boletate of ammonia, is a salt which crystallizes in flat four-sided prisms, and is soluble in 26 times its weight of water at the temperature of 68°. Its taste is cooling, saline, and somewhat sharp. When heated it melts, swells, and sublimes. It precipitates red oxide of iron; but does not alter sulphates of lime, alumina, or manganese. It slowly precipitates nitrate of copper in blue silky needles. *Boletate of potash* is very soluble in water, and crystallizes with difficulty. Acids precipitate the boletic acid from it. When boletic acid is heated with carbonate of lime, it dissolves it with effervescence. The *boletate of lime* crystallizes in flat four-sided prisms. This salt has little taste, and requires at least 110 times its weight of water, at the temperature of 72.5°, to dissolve it. It is decomposed by oxalic and sulphuric acids. *Boletate of barytes* is an acidulous salt in white plates, little soluble in water or nitric acid. When thrown on a red hot iron it burns rapidly, with a red flame and striking scintillations, leaving for residue carbonate of barytes. When boletic acid is heated with iron filings and water, hydrogen gas is emitted, and a yellow liquor is obtained with an inky taste. See *Ann. de Chim.* vol. lxxx.

From the preceding account of the composition of mushrooms, it must strike the most careless reader, that in their nature the fungi hold a middle rank between animals and vegetables, or, in other words, that they partake of the nature of both. It was necessary to be acquainted with this circumstance, before noticing an opinion concerning the animal nature of mushrooms, which has been sanctioned by the authority of very respectable names.

It is well known that the zoophytes, or the various kinds of corals, and corallines, and sponges, were, by the older botanists, considered as belonging to the vegetable kingdom. Scarcely had the conjectures of Peyssonell been rendered probable by Trembley, and demonstrated as true by that ornament of our country Ellis, and the animal nature of those bodies established, than botanists began to suspect, that they were swaying the sceptre over tribes which were aliens in their kingdom. The zoophytes were thus removed from them, and they anticipated a still farther reduction of their subjects, in consequence of the mixed nature of the fungi. A circumstance now took place in botanical opinion, which we have often witnessed happen to other creeds. Destroy the validity of one tenet, and you pave the way for suspicions as to the soundness of the remainder. One class of bodies formerly considered as plants, were now demonstrated to be of an animal nature; and, led away by false or imperfect analogies, other tribes of reputed vegetables were considered as having equally strong claims to advancement in the scale of being. In particular, the *fungi* were considered as having so near a resemblance to the zoophytes in many respects, that Butner, Weiss, Muller, and Scopoli, gave it as their opinion, that they possessed animality. This opinion has been generally rejected by botanists, as well as by zoologists. We pretend not to decide the important question; but we venture to assert, that the claims of the fungi (many of them at least) to rank as

Fungi.

zoophytes, have never been substantially invalidated, and we deem it an act of justice to state these claims.

By the aid of chemistry, the composition of the fungi has in part been ascertained. The existence of albumen has been demonstrated, and in their ashes the phosphoric salts seem to prevail. When burnt, they emit the odour of burnt animal matter, and ammonia is disengaged. When they decay, they emit a fetid cadaverous scent, unlike the putrescent remains of any other tribe of vegetable. Hence it is that in the last stages of their existence they are fed upon by those insects, which at other times resort to putrid carcases. These are points of resemblance which we consider as very remarkable. They lead us not to any positive general conclusion, although well calculated to raise curiosity, and excite suspicion. But we have even more to say upon this subject. In form and appearance, the resemblance between some of the zoophytes and the fungi is complete. Compare, for example, the figure of the "Mucor botrytes" of Sowerby, tab. 359, with the "Corallina omnium minima, vesiculis nunc ramorum, nunc racematum, dense dispositis" of Ellis: *Coral.* tab. 13. no. 22. B. So closely do they agree in form, that one drawing may serve for both. Who is there acquainted with both classes of beings, that does not perceive a resemblance between the Pezizæ and the cup-shaped sponges, and the Boleti and Milleporæ? But to conclude; upon what claim is the genus Corallina admitted to rank as a zoophyte? Its calcareous substance causes it to approach the millepores, and upon this ground it ranks with the zoophytes. Why is a sponge placed in the animal kingdom? It contains albumen, so do the fungi; when burnt it exhales an ammoniacal odour, so do the fungi. In short, the points of resemblance are so numerous, that the opinion of the animal nature of mushrooms, though not proven, is still plausible. Nature employs the zoophytes as the connecting link on the one side, and the fungi on the other, for the purpose of forming a union between the two kingdoms; but it is impossible for us to ascertain with accuracy, the precise point where animal life ends, and where vegetable life begins. There is probably no such point, both kingdoms being merely parts of one great whole.

Uses of the fungi.

It now remains that we consider the uses to which the plants of this tribe have been applied, and the important purposes which they serve in the economy of nature.

The Boletus igniarius of Withering has been highly recommended as a styptic, and various trials of its efficacy have been made, both in Britain and on the continent. It is beaten out into soft square pieces, and is well known to surgeons by the name of *Agaric*, or Agaric of the oak. It has been much celebrated for stopping the bleeding of arteries in amputations and wounds. But It has by no means proved so successful as Brossard and some of its admirers anticipated.

An excellent touch-wood is made from the same fungus, in Germany. The upper rind is first pared off; it is then boiled in a solution of saltpetre, and afterwards dried and pounded with a hammer; it is then boiled a second time in the same solution, and, after being dried, it is fit for use.

But the same Boletus is employed in a still more extraordinary way in Franconia. In that circle of Germany, as we are informed by Gleditsch, the inhabitants beat this fungus into square pieces, which resemble the softest leather, and sew them together in a curious manner into garments.

Fungi.

The Agaricus muscarius has been applied to as many useful purposes nearly as the touchwood Boletus. In Kamtschatka, the inhabitants prepare a liquor from an infusion of this agaric, and the runners of the *Epilobium angustifolium*, which, taken in a small quantity, exhilarates the spirits, but in a larger doze brings on trembling of the nerves, intoxication, delirium and melancholy. When mixed with milk, it kills flies, according to Linnæus; and the same author also tells us, that the expressed juice rubbed on walls and bedsteads, effectually expels bugs. The same plant administered in dozes of from ten to thirty grains in vinegar, is prescribed by Swediaur in cases of epilepsy and palsy, subsequent to the drying up of eruptions. It is also recommended to be sprinkled in powder on bad ulcers and gangrenes.

There is a species of Boletus termed by Linnæus *suaveolens*, which, as that author informs us, the Lapland beaux carry in their pouches by way of perfume, and to render their persons agreeable to their mistresses. It is strange that among so simple a people, such a recommendation should be found necessary, and it is equally surprising that a mushroom in a lover's pouch should secure success.

Mr Sowerby, in his Preface to the *British Fungi*, after stating the uses to which this tribe of plants has been applied, has the following observations: "The Lycoperdons afford, in their ripe state, different browns, very copiously, in a fine impalpable powder, fit for immediate drawing, when mixed with a little gum arabic water. I intend, when I figure some of the Lycoperdons, to use their own powder to represent itself." This pledge he has redeemed in the case of the Leucogala argentia, tab. 272. the lowermost figure of that plate being coloured with the powder of the plant itself.

The fumes of the Lycoperdon proteus, when burnt, have a narcotic quality, and hence they are sometimes employed to produce stupor in bees, in order to obtain the honey without destroying the hive.

These are a few of the uses to which this tribe of plants has been applied. Some of them may excite a sneer, while others will provoke a smile. The time may come when the fungi shall hold a more conspicuous place among the useful vegetables than they now occupy. Not above half a dozen of species have as yet been chemically examined. Yet these analyses have brought to light several important facts, and even furnished us with two new vegetable principles. The history of the one may throw some light upon their respective merits as articles of human food, while the other appears to furnish the chemist with a new instrument of analysis.

Mushrooms have long been employed as articles of human food, and as the basis of several sauces. In this country, a very few species only are made use of, but on the continent very many kinds are employed. By the Russians in particular, few are rejected. Even the most acrid and suspicious of the whole tribe, as the Agaricus piperatus, is eaten in great quantity. Nay, so fond are they of this mushroom, which in this country is deemed poisonous, that they fill large vessels with it in the autumn season, or pickle it with salt, and reserve it for winter food. The kinds which are held in the highest estimation are, however, few in number. The truffle seems to hold a most conspicuous place in the estimation of the epicure. It is found from two inches to two feet under the surface. It is chiefly found in a light sandy soil, although it also inhabits rich loam, open pasture ground, and woods of oak and chesnut. Its scent is so penetrating, that dogs and swine smell it at a distance. The former of these animals are taught to hunt it out, and when they come to the place, they bark a little, and begin to scratch up the earth with their feet. Sometimes the herds attentively watch the swine when rutting up the ground, and deprive them of their hard-earned morsel by appropriating it to themselves. Truffles are found in various parts of England and Scotland. They are regularly sold in Covent Garden market, and are principally employed to thicken soups and sauces, and to give them a fine flavour. Morels are used for the same purpose, and are reckoned but little inferior.

But the most common mushroom in use at our tables, is the *Agaricus campestris*. In this species the cap is white, changing to a brown when old, and becoming scurfy; regularly convex, with the margin inflected, becoming flat with age. Flesh white, firm, and solid. The stem is short, white, and solid, nearly cylindrical, about a finger thick, and surrounded with a membranaceous ring, the remains of the curtain which at first covers the gills. The gills are loose, pinky red, changing with age into a liver colour, in contact with but not united to the stem; very thick set, irregular in disposition, some forked near the stem, some next the edge of the pileus, some at both ends, and generally in that case excluding the intermediate smaller gills. They differ very much in size, the head varying from two to nine inches in diameter. It is principally found in rich dry old pastures, where the turf has not been ploughed up for many years. In such situations it may be found in abundance during the months of August and September, of a much finer flavour, and firmer in the flesh than those which are raised by gardeners. Several other agarics are also in use, as the *Oreades*, which is rather tough, but of a fine flavour; the *Mouceron*, which is held in very high estimation in France; the *Deliciosus*, which the ancient Romans esteemed as one of the greatest luxuries of the table, and which is still brought to the markets of Italy for sale: it occurs also in this country, but is here seldom employed.

These mushrooms are either eaten while fresh, stewed or boiled, or preserved when pickled or pulverised. For these purposes, both the skin, the gills, and the stem are taken away, and the fleshy part which remains, termed the button, is employed. When sprinkled with salt, and allowed to remain for some time, a considerable quantity of juice is obtained, which, when boiled up with various kinds of spiceries, forms the well known sauce called *ketchup*. This sauce is often very successfully counterfeited with bullock's liver, which is said to produce a liquor equally savoury and agreeable, at least in stews.

Stone which produces mushrooms.

Since these vegetable bodies are in such request, we need not be surprised to find, in books of gardening, various directions concerning the culture of mushrooms. The most simple and easy method of raising these curious productions is mentioned in the *Trans. Swedish Acad.* 1797, where we are informed that there is a stone used in Italy for producing mushrooms, by keeping it moistened with water in a cellar. There appear to be two kinds of it; one found in the chalk hills near Naples, resembling a white stalactite, intermixed with fine roots of shrubs; the other is a hardened turf from some volcanic mountains near Florence. This loses by calcination about 15 per cent. and the residuum gives .46 silica, .23 alumina, .07 lime, .20 oxide of iron, with some traces of magnesia and potash. To render these stones more productive, and prevent their quality of producing mushrooms from being exhausted, it is necessary, we are told, to water them with water in which mushrooms have been washed! thus furnishing them, no doubt, with a store of the minute seeds of the plant.

Method of forming mushroom beds.

Gardeners contrive other methods of propagating mushrooms, so as to produce them at all seasons of the year. These plants do not require light during their vegetation, so that they may be raised on beds made on purpose, within doors, under sheds, in lofts, stables, or cellars. These beds should be made of the best warm stable dung, which ought to be first mixed up in a heap, that the whole may ferment together equally; and after the first great heat is over, it may then be employed in the formation of the bed. But before proceeding to this part of the process, it is necessary to obtain a sufficient quantity of good *mushroom spawn*, as it is called. The *natural spawn*, as it is termed, and which consists of white fibrous radicles, is frequently found in the dung of old cucumber or melon beds; it is also often to be met with in old heaps of horse dung, which have lain for two or three months. It is frequently to be found in pasture grounds, in stable yards, and in mill tracks. In all these situations it is in lumps of dry rotten dung or mould, of a white fibrous substance, and possessing the smell of a mushroom. Such spawn is sold by the market gardeners, and may be conveyed with safety to any distance. Having obtained a supply of spawn, the next part of the process is to prepare the bed. Choose a dry lying place, and having levelled the surface, make the fermented dung into a bed from 3 to 4 feet in height, and let the whole be finished in the form of the ridge of a house. The dung in this case must not be too closely pressed, and it must remain for a fortnight or three weeks before the spawn is put in, or until the heat is become quite moderate. If the spawn is put in when the bed is in its warmest state of fermentation, it would be entirely destroyed. When the bed has been brought into a proper state, let the spawn be divided into small lumps, and plant it in rows lengthwise of the bed, observing to begin the first row within about five or six inches of the bottom. Plant the spawn immediately under the surface of the dung in lines six inches distant, and leave the same space between the pieces in the rows. When this is done, let the surface of the bed be made smooth, and then let every part of the bed, from the bottom upward, be covered with some rich dry earth, about an inch and a half thick, making the surface smooth with the spade. When this is done, let the whole be covered with clean dry straw, a foot thick at least, to keep out the wet and cold. Such a bed, with proper care, will begin to produce mushrooms in five or six weeks, and will continue bearing for several months.

This mode of culture supposes that you have procured roots of the plants which you wish to cultivate; but, according to other methods, the use of this spawn is superseded, the seeds of the mushroom seeming to be everywhere, and merely requiring favourable circumstances to ensure their germination. According to this last method, a floor is laid of ashes or bricks, so as to keep the bed quite dry, and free from under damp. Upon this place a layer of horse droppings, six inches thick. These should be new from the stable, and must not be broken, and the drier they are so much the better. They may be collected every day, until the whole

Fungi. Method of forming mushroom beds.

floor be covered to the above thickness; but they must not be allowed to ferment or heat. During the formation of the bed, the materials should be as much exposed to the air as possible; and if out of doors it should be defended from rain. When this first course is quite dry, and judged to be past a state of fermentation, cover it to the thickness of two inches with light dry earth, if sandy so much the better. The use of the earth here is for the spawn to run in. After this lay another course of droppings, and earth them over as above, when past a state of fermentation; then a third course, which in like manner earth over. This finishes the bed, which will be a very strong and productive one if properly managed afterwards. But the tyro in gardening will naturally enquire from whence the plants are to spring in this bed. Where is the seed? The seeds are contained in the droppings of horses, which have been employed. These produce mushrooms more plentifully, and with greater certainty, than the dung of other animals. The digestive organs of horses seem to have less power to hurt the vegetative quality of these seeds, which must be collected along with their food, than the stomachs of other animals. Or it may be that the dung of horses is a better nidus for the seeds than other dungs, and that these seeds are very widely diffused. The droppings of hard fed horses only are useful. Those of horses fed with green food will of themselves produce few or no mushrooms. Hence the dung of carriage or saddle horses, fed entirely on corn and hay, is generally the most productive.

Whether the bed be in the open air or in a house, it must not be watered until the spawn begins to *run*. This may be known by thrusting in the hand into the bed a few inches deep, and examining the state of that which is brought up. It ought to smell exactly like mushrooms, and have the appearance of small bits of thread. But generally you will be forewarned of the spawn running, by a previous crop of spurious fungi, which rise more or less abundantly according to the fineness or grossness of the materials of which the bed is composed. These fungi have all a nauseous sickly smell; and although some of them belong to the genus Agaricus, they do not possess those salmon-coloured gills which characterise the cultivated species. When it is thus ascertained that the spawn is fully formed, give the bed two or three hearty waterings, in order to set it a growing, for otherwise it will lie dormant, and show no symptoms of vegetation. But beware not to damp the bed too much, as thereby the growth of the spawn would be greatly retarded. If a few old mushrooms be previously steeped and broken in the water, you sow innumerable seed at the time of watering, and thus ensure future crops.

When the bed is in full perfection, it should be examined two or three times a week to gather the produce, turning off the straw covering very carefully. Two methods are recommended by gardeners to be observed in collecting the mushrooms. According to the first, they are to be detached clean to the bottom by a gentle twist, as if the stump is left, it is apt to become maggoty, and infect the rest of the bed. According to the opinion of other gardeners, they ought never to be pulled, but always cut; as by pulling, many young ones might be destroyed, there being always a number of these forming or clustering about the roots of the old ones, which should not be disturbed. If the spawn be deeply situated in the beds, mushrooms will often form and come to maturity entirely under the ground. They may be easily recognised, however, as they are generally large, and push up small hills above their heads.

On the use of mushrooms as aliment.

Mushrooms, although eagerly sought after by many, are by no means a nourishing article of food. Their fibres are tough, and very difficult to digest, swelling in the stomach like a sponge; and there are instances on record of their remaining three days in that organ in an undigested state. So indigestible are some of the Boleti, for example, that they have been found as bezoars in the intestines of some of the inferior animals. Thus the Boletus igniarius has occurred disposed in layers, and cemented by an animal matter. (*Ann de Mus. d'Hist. Nat.* iv. 335.) But it would be fortunate if no objections could be urged against their being used in diet, but those which arise from their coriaceous indigestible nature, and their want of nourishing particles. All of them are a doubtful and suspicious food, and the most innocent of them have often proved prejudicial, nay *poisonous*.

It would be desirable if we could draw the line of distinction between the harmless and the noxious. But neither the eye of the botanist, nor the laboratory of the chemist, can render us assistance. No reliance can be placed on either taste, smell, or colour. The qualities of the same species are different when the plant grows in wet ground, from what they are when it obtains a dry situation. The same species is sometimes innocent when young, but noxious when old. From these considerations it has even been recommended, and with much propriety, to erase their names from the list of aliments. Not a year passes in which instances do not occur of the deleterious effects of mushrooms. The newspapers abound with such, and yet these warnings are not sufficient to deter the inexperienced from using them. The reason is obvious; they hear that some kinds are in common use at the tables of the great; and trusting to colour and shape, they too often gather the hurtful in place of the harmless.

The effects produced upon the constitution by the use of the noxious kinds, are of the most alarming nature. In cows and other cattle, they have been known to create bloody urine, nauseous milk, swellings of the abdomen, inflammations in the bowels, stoppages, diarrhœas, and death. In sheep, they bring on a scirrhous liver, a cough, a general wasting, and dropsy. In men, nearly the same symptoms have appeared, with vomitings, fainting, trembling, and death. In such cases, when persons have unhappily eaten deleterious kinds, vomiting ought to be excited as speedily as possible, and gentle laxatives administered; and after the first evacuation, a drachm of sulphuric ether, in a glass of water of marshmallows, may be given.

Some few attempts have been made for the purpose of ascertaining whether the poisonous matter resides in the substance or in the juice of the mushroom. M. Parmentier, in order to determine the matter, took some mushrooms of the deleterious kind, and distilled them with water in an alembic. The water which came over into the receiver was administered to a dog, without producing on the animal any visible effects. Having emptied the contents of the alembic in a vessel, and mixed with some food to disguise them, he administered these to a dog; but the residue differed widely in quality from the condensed vapour, for the poor animal expired in a few hours after. The same author informs us, that having administered some poisonous mushrooms along with some food to a dog, he observed the following symptoms: The dog first began to shew symptoms of uneasiness and stupidity, afterwards it

Fungi. vomited up the food and mushrooms which it had swallowed. After a short interval, it again began to vomit, and emitted a thick viscous matter. This continued until the death of the animal, which happened soon after. Upon opening up the stomach and intestines of the dog, no appearances of corrosion presented themselves, the inflammatory symptoms were merely those which might have arisen from violent vomiting.

Parasitical fungi noxious to plants. The fungi often appear as the formidable enemies of man, in his fields, his gardens, and his houses. The diseases called the *blight* and the *smut* are, as already noticed, both caused by parasitical fungi, whose history deserves to be attentively studied by every farmer. These little plants destroy the leaves, the stem, and the ear, and produce the most dismal havoc in the fields. No remedy has been discovered to impede or remove the disorder after it has once made its appearance. The pickling of the seed before sowing it, with salt, quicklime, or urine, and the frequent change of seed from different places, are the only known, though not always efficacious, preventives.

The parasitical fungi sometimes attack fruit trees. One species is figured by Mr Sowerby, tab. 379, as infesting the apple-tree leaves, covering them with a very fine white powder, with dark brown particles, scarcely visible to the naked eye. The form of these particles is somewhat ovate, but irregular. Mr Knight observes, that on shaking a leaf over a plate of glass, he detected little oval bodies, which shrivelled a little in drying. Some of these were transferred to other trees, and the disorder along with each, every one producing its own species.

The dry rot is another of those evils which have been supposed to be occasioned by a parasitical fungus of the genus Boletus. It is not our intention in this place to endeavour to ascertain the point, whether the fungus is the cause or the consequence of the disease, although we are rather inclined to suspect that decomposition has commenced before the fungus begins to grow. That the fungus may aid the process of destruction, we can easily suppose; but we also believe that wood in a fresh sound state would offer but a bad soil for the germination of such parasites.

Uses of fungi in the economy of nature. The fungi serve several important purposes in the economy of nature. They accelerate the process of dissolution, by converting the woody fibre of dead trees and branches into a softer and more deliquescent substance. They supply with a grateful food many insects which feed upon them, and even hatch their young in them. And lastly, they furnish, by their uncommon forms, an agreeable variety to the eye of the botanist, when contemplating the scenery of the vegetable kingdom, and lead him to adore that Being who is exhibited in all his works as powerful, kind, and wise.

In Plate LXXV. the reader will find figures of the four following species:

Agaricus campestris, or common mushroom.
Phallus esculentus, or morel.
Tuber cibarium, or truffle.

APPENDIX.

HYPOXYLA.

This order of the class Cryptogamia was first employed by Lamarck and Decandolle, in their arrangement of the native plants of France. It seems to connect the *Fungi* with the *Lichenes*, and consists of plants which have many of the characters of both these orders. The Hypoxyla are either of a coriaceous or corneous texture, or resemble cork in consistence. The receptacles, which are almost always of a black colour, sometimes comprehend the whole plant; in other instances they are inserted upon a stem, which is straight, solid, filamentous, or pulverulent. Whatever be their position, these receptacles are rounded or oblong, open at the summit by having a pore or slit, and filled with a mucilaginous pulp, which is more or less evident in some shape, until the period of maturity. This pulp encloses the seeds. Some species present here and there parcels of white fugaceous powder, which many naturalists consider as the male organs of the plant.

The plants of this order are chiefly found on the trunks of trees; some of them grow upon decaying leaves; and a small number have been observed on rocks, and on the ground. Unlike the more perfect plants, many species of this order give out no oxygen when exposed to the rays of the sun under water. In such circumstances, however, there are a few which yield hydrogen gas.

This order is naturally divided into two tribes, according as the mucilaginous pulp issues from the receptacle in an obvious or insensible manner. The first of these approaches the fungi in appearance and consistence; the second intimates its relation to the lichens, by the pulverulent base which surrounds the receptacle. It is not our intention, in presenting our readers with an account of this order, to describe all the species which it embraces, but merely to enumerate the characters of the genera. Under each genus there will be found the description of one species at least, for the purpose of illustrating the characters upon which it is founded.

TRIBE I. *In this tribe the seed-bearing pulp obviously issues from the receptacle when the plant has arrived at maturity.*

Genus I. Rhizomorpha. This genus, which was instituted by Rothes, consists of plants having a receptacle nearly globular and persistent, opening at the summit by an indistinct orifice, attached in the form of tubercles, to a stem which is simple or branched, and spongy within.

Rhizomorpha fragilis. Clavaria phosphorea of Sowerby's British Fungi, tab. 100. The bark of this species is black, brittle, glabrous, and shining; the inside is white and spongy. The stem is cylindrical, when it grows exposed to the air; but compressed when it creeps in the crevices of wood. It pushes forth a number of branches, which frequently anastamose. The fructification, which is but rarely seen, consists of tubercles scattered or in groups, spherical, black, a little shagreened, ending in an orifice which can scarcely be perceived. These tubercles are filled with a black pulp containing the seeds. This plant grows in subterraneous places, in the hollows of trees, in the chinks of wood, and between the wood and the bark. In some instances it has been observed to emit a phosphoric light, when fresh, at the ends of the shoots.

Genus II. Sphæria. This genus consists of plants which present one or more osseous rounded receptacles, opening at the top by an orifice usually of a lengthened shape, solitary, clustered, or inserted upon a corklike stalk, filled with a mucilaginous substance, containing the seeds, and which issues by the orifice of the receptacle. Almost all the species of this genus are of a black colour, and of a compact consistence; a few are red and fleshy. Several species, previous to the opening of the cells, exhibit a white fugacious powder, which has been accurately observed by Hoffman, Todé, and Bulliard, and which many naturalists consider as the male organs of the plant. Almost all the species of this genus, especially those which have no stems, grow under the epidermis of living trees, or decaying leaves, which they pierce at the time of the dispersion of the seeds. The genus is divided into the following sections.

Sect. 1. *Capsules supported on a lengthened fleshy or cork-like base.* (*Hypoxylon* of Jussieu.) Sphæria digitata, Sower. tab. 69. This plant commences its growth very early in the spring, and continues through the summer, ripening its capsules in autumn annually. Though at first somewhat pointed, and covered with a whitish dust or farina, as it advances it assumes a more conical form, and the farina is more on the top. It finally becomes blunter, and the head is covered with spherules copiously discharging a black soot-like powder. The inner substance is very white and solid, the fibres diverging from the centre upwards, and in breaking form a diverging cone. This plant, when exposed to the action of the sun under water, gives out air which contains seventy per cent. of hydrogen gas.

Sect. II. *Capsules placed upon an exposed base more or less apparent. Sphæria concentrica*, Sower. tab. 160. The general shape of this curious parasite is hemispherical, though often very uneven. It forms whitish farinaceous threads, and black spherules in alternate order around the whole surface, which having fructified, remain in striæ, concentrating from the root or base. The white threads destitute of farina becoming greyer, and the appearance of capsules in the black striæ being totally lost, give it the exact resemblance of the grain of the wood in some charcoal. This plant is found on ash, hornbeam, willow, and other trees, and often grows to three inches diameter, in some situations continuing to grow many months.

Sect. 3. *Capsules not united by a common receptacle, but joined the one to the other in bundles or clusters. Sphæria coronata*, Hoffm. *Crypt.* i. p. 26. tab. 5. f. 2. This species presents five or six cells disposed in a circular ring, black, somewhat globular, of the size of a pin head; their openings are lengthened, cylindrical, and inclined in such a manner as to unite at the summit. These cells are placed in the bark; their orifices pierce the epidermis, and appear a little on the outside. This species grows upon the birch.

Sect. 4. *Capsules distinct, approaching, or solitary. Sphæria gnomon*, Sower. tab. 373. fig. 6. This species is found at the beginning of spring upon the leaves of the hazel tree, forming, in general, rounded or annular patches. The capsules are distinct from one another. On the upper part of the leaf, a black somewhat convex tubercle may be perceived, beneath are found lengthened blackened knobs; a concave orifice may be observed at their summit, furnished with a bristle resembling a style.

Genus III. Næmaspora. The plants of this genus differ from those of the preceding, in consequence of the fertile pulp containing the capsule issuing from the orifice of a semi-compact consistence, and lengthening out into a capillary appendage, soluble in water.

Næmaspora carpina, Sower. tab. 376. This is not uncommon on the hornbean; the spherules are lodged under the bark, and are compressed, irregular, and waxy, and throwing out black twisted tendrils; afterwards they become brittle, and like charcoal.

Genus IV. Xyloma. The capsules are hard, of various forms, filled with fleshy jelly; they remain firm, and burst in different places to allow the escape of the jelly. The plants of this genus grow upon dead or living leaves, where they form black and frequently bright spots. They prefer the upper surface of the leaves, while the greater number of the parasitical fungi which grow upon living leaves, prefer the under surface.

Xyloma punctatum. Every one is acquainted with the appearance of this plant. It grows upon the upper surface of the common sycamore, in the form of black patches, approaching to a circular form. It consists at first of rounded distinct wrinkled flat points.

Genus V. Hypoderma. The plants of this genus have an oblong receptacle opening by a longitudinal slit, and emitting a substance, which is nearly pulverulent, containing the seeds. They differ from the plants of the last genus in aspect, and by the oblong slit of the receptacle.

Hypoderma quercinum, Sower. tab. 373. 3. This plant is frequent on the dried branches of the oak in lengthened spots, waved, and for the most part transverse. When the seeds are about to be dispersed, the epidermis of the bark opens, and the capsule splits in the same direction, affording a passage to the seeds, and vanishing itself soon after: the seeds are black.

TRIBE II. *In this tribe, the seed bearing pulp remains in the receptacle, or escapes in a gradual and insensible manner.* The former tribe connects the hypoxyla with the fungi, and this tribe establishes their relation to the lichens.

Genus VI. Hysterium. The receptacle is oblong, and opens by a longitudinal slit. It encloses the seeds, which are enveloped in a gelatinous liquor, thus forming a capsule constituting the whole plant. The hysteria live on fallen trunks, and not under the epidermis.

Hysterium pulicare. Lichen marmoreus of English Bot. 739. This plant presents convex tubercles, which are black, compact, oblong or rounded, opening at the top by a longitudinal slit. It grows in groups on the bark of the oak, and various other trees.

Genus VII. Opegrapha. The receptacles of this genus are linear, sessile, simple or branched, marked above by a longitudinal slit containing the seeds. These are situated in an interrupted crust. This genus, named and characterised by Humboldt and Persoon, consists of numerous species, confounded under the names Lichen rugosus and scriptus of Linnæus. Some of the species grow upon trees, others upon stones. In all of them the receptacles are black.

Opegrapha denigrata, E. Bot. 1753. The crust is white, and sometimes so thin that one would be disposed to consider it a simple alteration of the colour of the epidermis of the bark. The receptacles are black, often shining, waved, simple or branched, prominent, marked by a distinct groove, clustered in rounded spots. Common on the oak and various other trees.

Genus VIII. Verrucaria. The plants of this genus have a thin crust, bearing the receptacles sometimes buried in it, sometimes prominent, somewhat globular, closed at first, afterwards pierced by a pore at the summit. They differ from the former genus in the receptacles opening by a rounded pore, and not by

Hypoxyla.

a longitudinal groove: These, in all the species of the genus, are of a black colour. Some grow on wood, or the bark of trees, while others prefer rocks or walls. They are arranged with the lichens by different authors.

Verrucaria sanguinularia, E. Bot. 155. The crust is ash-coloured, with a tinge of green, granular, wrinkled, thin, and irregular. The receptacles are scattered, hemispherical, black on the outisde, bright red within. When magnified, a small pore may be observed at the summit of the receptacles.

Genus IX. Pertusaria. The plants of this genus have an indistinct crust supporting their receptacles, which are pierced by many pores, corresponding to as many internal capsules; the pores sometimes unite, and form an irregular cup during the old age of the plant. They differ from the preceding genus in aspect, in the number of capsules, and in the receptacles being of the same colour with the crust.

Pertusaria communis. Lichen pertusus of En. Bot. 677. The crust is smooth, of a greenish ash colour when moist, cinereous when dry, and covered with numerous, crowded, smooth, angular warts, of the same colour as the crust. Upon the head of each wart are small black impressed punctures, from one to ten in number, as if made with the point of a pin, under each of which punctures, if the wart be cut transversely, will be found a hollow, spherical cell. In the old specimens, the punctures open of themselves, and discover the cell. It is found on the trunks of trees, and also upon rocks.

Fungus ‖ Furnace.

FUNGUS. See Surgery.

FUR. See Darfur.

FUR Trade. See Peltry.

FURNACE is the name given to an apparatus, which consists of a certain cavity containing combustible matter, with various means of supplying it with air to effect its combustion.

Furnaces may be divided into two general classes, viz. wind or air furnaces, and blast furnaces. In the first of these, the air is induced to pass through the fire by the draught of a funnel or chimney communicating with it. In the second, the air is supplied by the action of bellows, or other pneumatic apparatus. The term *furnace*, however, is more particularly applied to such as are used in the manufactures for the fusion and calcination of substances, and in the laboratory of the chemist.

The most simple and effective air furnace, would consist of a plain prismatic or cylindric column, the interior cavity of which is defended from the exterior air by some infusible substance, the least capable of conducting heat. That portion of the cavity which is occupied by the fuel, may be called the body of the furnace. This is separated from the lower portion, called the ash-pit, by a grate for the admission of air. The upper portion above the body is called the chimney. When the fire is kindled, all the air above the grate becomes specifically lighter than the outer air. This induces a current of air through the furnace, the velocity of which will be as the difference of temperature between the inner and outer air, and as the square root of height, reckoning from the grate to the summit of the column.

In a furnace so constructed, the air would meet with the least resistance from not being required to change its direction after it enters the grate, and its practical effect would come the nearest to the law above laid down. But for the sake of convenience, the body of the furnace is detached from the chimney, by a connecting cavity called the throat of the furnace. This will interrupt the free passage of the air, in proportion to the deviation of its direction from the perpendicular line, and inversely as the area of its section. The intensity of the heat of every furnace, will therefore be as the quantity of oxygen consumed in a given time, and inversely as the space in which the combustion is produced. This will therefore be as the velocity of the current and the density of the air, all other things being equal.

Furnace.

Let D = the density of the outer air,
d = the density of the air in the chimney,
h = the height of the chimney,
g = the velocity produced by gravity in a second of time,
i = the velocity of the ascending current;

then the velocity which the height h would give will be $= \sqrt{2hg}$, and the velocity of the current, or

$$i = \sqrt{2hg} \times \frac{D-d}{D}.$$

The practical effect, however, will fall short of this formula, from the interference of several causes, the principal of which is the interruption of the current, partly by the change of the direction of its motion, and partly by the roughness of the sides of the chimney.

The first of these may be in some measure obviated, by making the throat sufficiently wide, and as little out of the perpendicular as circumstances will admit. The friction upon the sides may be decreased considerably, by rubbing those sides of the bricks which have to form the interior surface, in order to make it as even as possible. It will also be advantageous that the walls of the chimney should conduct away the least possible quantity of heat. This will be effected, by first building an inner wall of one course of bricks, and then surrounding it with an outer wall, leaving a cavity between the two walls equal to the thickness of a brick, which cavity is to be closed firmly at the top. This will serve to keep the temperature of the air in the chimney hotter than it otherwise would be, and by that means increase the velocity of the current. The interior of the body of the furnace, the throat, and a small portion of the chimney, must be of fire brick.

It is difficult to give a maximum for the height of chimnies; although from the above theorem, the power of the furnace would increase as the square root of the height, to any extent. Yet in practice, it will be found to be limited by two causes. The one, the friction of the sides of the chimney; the other depends upon the gradual diminution of the temperature of the inner air as it ascends till it becomes equal to that of the external. This first will vary with the facility with which the heat is conducted away through the sides of the chimney. It will be obvious, however, under the most favourable circumstances, that the changes of power by altering the height will not be very conspicuous, from its being as the square root of the height.

Furnace.

For instance, if a chimney of one foot high produce an effect of 1, it will require the height to be 4 feet to produce twice, and one of 9 feet to produce three times the effect, and so on, increasing in the same ratio.

In reverberating furnaces, which are heated by the flame of pit coal, the maximum is much higher than in the melting furnace, which is heated with coak. This arises from the flame in the former heating the interior of the chimney. The melting furnace should have its chimney not less than 30 feet. The reverberatory furnace may with good effect be made much higher.

The chimney of a furnace should be perfectly distinct from every other, nor can it have any opening in its side without sustaining an injury proportionate to its size; but its effect will be less, as its height above the fire is greater.

Sound philosophy and experience will ever discard the practice of attempting to make one furnace perform two operations at the same time.

Melting furnace. Plate CCLXII. Figs. 1, 2.

Having given some account of the principles of furnaces, we shall now describe several at present used in the arts, and in the laboratory. Plate CCLXII. Fig. 1, is a section and side elevation of a melting furnace. B is the body of the furnace, containing a crucible upon its stand. The use of the stand is to raise the crucible above the grate *g*, so as to allow its bottom to receive the greatest heat of the fire. A is the ash-pit opening through the outer wall, or into a cellar below. This serves to prevent the cold air from annoying the operator. D is the damper, which when shut covers the under side of the grate. K is the cover, which is either formed by putting two fire bricks in an iron ring, or by moulding fire clay into proper form, and burning it afterwards. C is the chimney. Fig. 2. is a plan of the same furnace.

Furnace for heating a sand-bath. Figs. 3. 4.

Figures 3. and 4. are a section and plan of a furnace for heating a sand-bath. A is the ash-pit, B the body of the furnace, *d* the door for fuel, *g* the grate, W a wall, or one large fire-brick placed between the grate and the chimney, leaving no way for the smoke to pass but through the neck *n*. It then descends on the other side, and passes through the flue F into the chimney C. *p* is a plate of cast metal, formed of two plates ribbeting into each other, by which it is less liable to break by the heat than if the plate was in one. This plate covers the whole of the top of the furnace, so as not to allow the escape of smoke. I I is a frame of cast-iron lying loosely upon the plate, with as little touching surface as possible. Within this frame a wrought iron rim S is placed, for the purpose of enveloping the sand which constitutes the sand-bath. There are rims of different depths, according to the size of the vessels to be placed in the sand.

Reverberatory furnace, Plate CCLXII. Figs. 5, 6, 7.

Figs. 5, 6, and 7, are two sections and a plan of a reverberatory furnace. A is the ash-pit, B the fire place, *g* the grate; F, in the plan Fig. 7, is the opening for the introduction of fuel, which is pit-coal. The flame plays along the hearth H, and passes into the chimney C. O is an opening for the introduction of the substances to be entered or melted, which are placed upon the hearth. If the substance is to be melted, it runs down to the opening T, where it is taken out. D is the damper for regulating the fire. This furnace is more particularly adapted for melting than for calcining, on account of its inclining hearth, and the opening at T. The construction is a little varied for the latter purpose. The hearth is nearly horizontal, and there is generally but one opening, which is in the middle.

Enamelling furnace. Plate CCLXII. Figs. 8, 9.

Figs. 8 and 9, are two sections of an enamelling furnace. A is the ash-pit, *g* the grate, B the body-furnace, where the fuel is contained; M is the muffle, an earthen vessel, more plainly seen in Plate CXLIII. Fig. 9. It contains the substances to be operated upon, and is for the purpose of defending them from smoke or flame, and admitting a supply of fresh air; K is the cover, T the throat, and C the chimney. This furnace is also employed for assaying metals by cupellation.

Muffle furnace. Figs. 10, 11, 12.

Figs. 10, 11, and 12, contain a view and section of a muffle furnace, for producing very intense heats. The body of the furnace, shewn at AA, is in the form of an oblong coffer, swelling out in the middle. The grate is shewn at C, standing over the ash-pit F. The hole for the muffle is seen at E; and the dome, or upper part of the furnace, is seen at BB, having a very large door D, for the purpose of introducing the fuel. This furnace was employed by Pott, and afterwards by D'Arcet, in their experiments on the habitudes of earths and stones, when exposed to a violent and long continued heat. Figs. 13, 14, 15, 16. represent fire-tongs for various purposes.

Figs. 13, 14, 15,

A description of Dr Black's portable wind furnace will be found in our article on Chemistry, vol. vi. p. 189, and a perspective view and section of it in Plate CXLIII. Fig. 7. and 8.

A description of Mr Arthur Aikin's portable blast furnace is given in the article Chemistry, p. 160, and a perspective view and section of it in Plate CXLIII. Figs. 10, 11, 12, and 13.

Farther information on this subject will be found in our articles Glass-making, Iron, Stove, and in several other articles where furnaces are adapted to particular purposes in the arts. See also Lewis' *Philosophical Commerce of Arts*; Aikin's *Dictionary of Chemistry*, vol. ii.; Miche on Reverberatory Furnaces, in Rozier's *Journal*, vol. xxxii. p. 385. Perceval's Chamber Lamp Furnace, in the *Repertory of Arts*, vol. iii. p. 29; and in the *Transactions of the Royal Irish Academy*, vol. iv. p. 91; Watt's Patent Furnaces, in the *Repertory of Arts*, vol. iv. p. 226; Mr Edward Howard's Improved Air Furnace is described, in Tilloch's *Philosophical Magazine*, vol. v. p. 190—193, and represented in plate iv. of that work; Raley's Patent Furnaces, in the *Repertory of Arts*, vol. x. p. 155; Accum's Improved Universal Furnace of Dr Black, is described in his *System of Practical Chemistry*, vol. ii. p. 357, and in Nicholson's *Journal*, 8vo. vol. vi. p. 273; Curaudau's New Evaporating Furnace is described in the *Annales de Chimie*, No. 149. *An.* xii. and in Nicholson's *Journal*, 8vo. vol. ix. p. 204—207; and Lucas's furnace for cast-iron cutlery, in Parke's *Chemical Essays*, vol. iv. Ess. 15. A furnace for decomposing the sulphate of barytes, is described in the same work, vol. ii. Ess. 5. (c. s.)

Furneaux Islands.

FURNEAUX'S Islands. The great continent of New Holland is separated from Van Diemen's Land on the south, which was during centuries believed to be an integral part of it, by a considerable expanse of water lately discovered, called Bass Strait; and numerous islands, some towards the centre of the strait, and some on the respective coasts are interposed between the two territories. These have been classed into groups by successive navigators, though with little regard to order, and without any decided analogies. One of the principal and most comprehensive is Furneaux's Islands, divided by Bank's Strait 12 or 15 miles in width from the north-east extremity of Van Diemen's Land, stretching from about 40° 22′ to 41° 27′ of South Latitude, and situated, with respect to the centre of the group, in about 148° of East Longitude.

Furneaux Islands.

Neither the exact number of islands composing this group, nor their individual size, are completely ascertained: the principal are Great Island, Cape Barren Island, Clarke's, Preservation, Chappel, and Babel Islands, besides many rocks and islets. The first is not less than forty miles in length, and the second twenty. Almost all have good harbours for shipping; but the channels among some of them are narrow, and of dangerous navigation.

Mineralogy.

The basis of the greater part of these islands is a whitish granite, sometimes inclining to a reddish tinge, and full of small black specks, supposed to be tin, and communicating a deleterious quality to water, as several people died on drinking it. When exposed to heat, fumes escape strongly denoting the presence of arsenic. The hills rise to a considerable height; the highest is supposed to be 1200 feet. Those of Cape Barren Island are generally crowned with huge masses of granite; and immense detached blocks of the same substance are scattered about on the rest. The lower parts of the islands are commonly sandy, or they have swamps and pools, where the water is usually of a reddish hue; in other places, it is fresh and good, although transient visitors have denied its existence.

Trees.

The whole islands are overrun with brushwood, intermixed, in the more sheltered parts, with a few stunted trees, never exceeding twelve feet in height, and several low shrubs grow on the humid grounds, surrounding the margins of pools and swamps; but most of the brushwood assumes a depressed and creeping form, particularly on those sides of the islands exposed to the more prevalent winds. A very singular and unexampled feature is presented in some of the trees having undergone a partial petrifaction in Preservation Island. There, in a particular spot, none of them are thicker than a man's leg; all are decayed; but while the upper branches consist of wood, the roots at the surface, and the trunks to a certain height, are converted to a chalky substance. The interior central part is always circular, seldom of the same diameter or of the same composition; and rings of the brown wood sometimes appear, on breaking over the trunks, as if the petrifaction were still incomplete.

Vegetables.

The vegetable productions of Furneaux's Islands are scanty throughout; and it is to be observed, that although there are patches of rich and fertile soil, and the most luxuriant growth of numerous plants in the vast extent of New Holland and Van Diemen's Land, a very large proportion of the skirts, for the interior is yet unknown, consists of low sandy tracts, appearing as if recently reclaimed from the sea, and where nature is seen in her most barren aspect.

Animals.

Two species of seals, differing in structure and habits, frequent the shores of these islands, basking on steep declivities, from whence they can easily precipitate themselves into the sea; and they afford the three new genera of quadrupeds, the kanguroo, the wombat, and the duck-billed ant-eater, all strangers to the older naturalists, because none exist on the four great continents of the world. The first is of a reddish brown species, weighing 40 or 50 lib. now grown shy from incessant pursuit, and difficult to be caught on account of its impenetrable retreats of brushwood. The wombat, whose flesh is very acceptable food, where quadrupeds are so scarce, was first seen on Clarke's and Cape Barren Island. It has since been caught on the continent; but its instinct is visibly modified by the presence or absence of danger, for it here feeds at all times, often foraging among the refuse on the shore, while on the continent it never leaves the holes where it burrows like a badger until dark. The duck-billed ant-eater is esteemed a great delicacy. Speckled, yellow, and likewise black snakes, are seen on several islands on the confines of the brushwood; they have venomous fangs, but it is not reported that they have ever proved destructive. They frequently penetrate the burrows made by the sheer water or sooty petrel, amidst the sandy tufts of coarse grass, probably in quest of the young. These birds occur in surprising numbers, darkening the air at sun-set in their flight: they burrow exactly in the manner of rabbits, and breed in their holes, and, in spite of the disturbance and destruction which they experience, they pertinaciously resort to the same spot. Penguins and other birds burrow in the same manner, in places separate and distinct from the petrels; and as the latter always retire to the ground at night, the penguins, which have been sheltered there the whole day, then regularly leave it. It is extremely difficult, and sometimes dangerous, to walk amidst the excavations formed by them, as people suddenly sink knee deep. The most valuable birds are the goose and black swan; the former is numerous, it feeds on grass, and seldom takes to the water; the latter is rare, and frequents fresh water pools only, in the breeding season.

History.

Furneaux's islands were first explored by Mr Bass, surgeon of the Reliance, and Lieutenant, afterwards Captain Flinders, of the navy, in 1798. They were about the same time, and subsequently, resorted to by vessels from Botany Bay, in prosecuting the seal fishery, which was so profitable that a single ship captured 9000 seals. Some years later, the French expedition of discovery examined the principal islands, and their appearance and position have been further explained by the elegant charts of Captain Flinders, published in 1814. Previous to all these periods, however, one of them had afforded refuge to a shipwrecked crew, and it is not improbable that, during the frequent intercourse of the Dutch with their eastern possessions, the external islands may have been seen or visited. It must now be admitted, that an extensive portion of the coast of New Holland had, nearly two centuries ago, been surveyed by them, though all remembrance of the fact was lost. Yet the slight sketches, which only afforded scope for conjectures, are evidently the result of attentive investigation.

Furneaux's islands are probably of too little importance to become a permanent settlement. At present temporary establishments are formed upon them, by those engaged in the seal fishery, which is less productive than it was originally. Besides, fresh water is scarce in general, the navigation is intricate, and the shores are frequently covered with the wreck of vessels, which repeatedly perish in the neighbourhood. See Collin's *Account of New South Wales*, vol ii. Peron *Voyage aux Terres Australes*, p. 351. Flinders's *Voyage to Terra Australis*, vol. i. Introduct. p. 126. (c)

Furnes.

FURNES, *Furnæ*, a town of the Netherlands, situated about three miles from the sea, on the canal which leads from Bruges to Dunkirk. Its fortifications were demolished in the years 1792, 1793, and 1794. The town house, which is a good building, adorned with figures of kings and princes, has a handsome tower with musical chimes. The town carries on a considerable trade in corn, bees, cheese and butter. Its fairs are held on the 26th March, 5th May, and 3d October. Population of the town 3200. East Long. 2° 39′ 51″, and North Lat. 51° 4′ 23″, according to trigonometrical observations.

FURRUCKABAD, or the *Happy Abode*, is a town of Hindostan, in the district of the same name, and capital of the province of Agra. It is situated at a short distance from the west bank of the Ganges, and was built about 100 years ago by a Patan colony. The streets are wide, and the houses and open places are shaded with trees. In consequence of the vicinity of the British cantonments, the town is flourishing, and carries on a considerable trade. There is here a civil establishment for the administration of justice, and the collection of the revenue. Close to Furruckabad is the town of Futtygur, where a brigade of troops is usually cantoned. East Long. 79° 33′, and North Lat. 27° 23′. See Valentia's *Travels*, vol. i. p. 194.

FURNITURE STOP, on the organ, in music, is a double or triple, &c. range of pipes, sometimes called the mixture stop. The tune of these ranges of pipes are XXIV, XXVI, XXIX, &c. respectively, above the pitch of the diapasons. This stop is rarely used but with the sesquialtera and other compound stops; and this medley of sound to every note, is said by some to "enrich" the instrument: but whatever may prove to be their hitherto untried effect on a (Liston's) EUHARMONIC *Organ*, (see that article), the confusion of rattling loud *beats*, constantly heard on common organs using these stops, is not less offensive to good ears, than Dr Robert Smith has described in his *Harmonics*, 2d edit. pp. 80 and 227. (ϱ)

FURTH is a large and populous town of Germany, in the circle of Franconia, situated on the river Rednitz, some leagues from Nuremberg, on the road from that town to Franckfort. With the exception of the new parts of the town, Furth is very irregularly built, and is a mere mass of houses without order. Manufactures constitute the principal riches of this industrious town. Mirrors are made here to a great extent, and almost all those which bear the name of Nuremberg are manufactured at Furth. Each mirror, before it is finished, passes through the hands of more than twelve different workmen. Articles turned out of wood and metal, clocks, jewellery goods, chains of watches, needles, buckles, snuff-boxes, and a great many other similar articles, are manufactured here. There is here also a manufacture of tobacco, which is successfully cultivated in the neighbourhood. A considerable trade is carried on in wines, which are much esteemed, and which are made principally at Sommerhausen, Rundsuck, Sommerach, Westheim, &c. The commerce of this place is greatly facilitated by the junction of the Peignitz with the Rednitz, which are then navigable to Mein. The Jews, who form one half of the population, are permitted to have a synagogue, a school, and a printing-office. Population 16,000.

FURTHCOMING, or FORTHCOMING, in the law of Scotland, is that process by which an arrestment is followed up and made effectual. It is brought at the instance of the arresting creditor, who calls the common debtor before the judge to hear sentence given, ordering the debt to be paid, or the effects arrested to be delivered up.

The decree in an action of furthcoming operates as a legal assignation to the arrester, which cannot be defeated by the poinding of co-creditors. See ARRESTMENT. (z)

FUSEE. See TIMEKEEPER.

FUTTIPOOR, or FUTTEHPOOR, is a town or large village of Hindostan, in the province of Agra. It is encircled with a stone wall of great extent, built by the Emperor Akbar. The enclosed space does not seem to have been filled with buildings, and the inhabited part is an inconsiderable village. A hilly ridge of considerable height divides this space, and extends about 4 or 5 miles beyond the wall. The materials of which the houses are built comes from the neighbouring hills, which are composed of a greyish rock. On the highest part of the rock, near the centre of the enclosure, stands the tomb of Shah Selim Cheestee, in consequence of whose devotion the Empress of Akbar is supposed to have become pregnant after remaining several years barren. The approach to this mausoleum is extremely grand. An ancient palace of Akbar stands upon the same ridge. See Hunter in the *Asiatic Researches*, vol. vi. p. 75.

FUZE. See GUNNERY.

FYZABAD, or the *Beautiful Residence*, is a town of Hindostan, in the province of Oude, of which it was once the capital. It was founded by Sadalkhan, a Persian, who was forty years governor of the province. It is situated on the south side of the Goggra, or Dewals river. The town is of considerable extent, and contains many inhabitants, chiefly of the lower classes; the merchant-bankers, money-changers, and the great men, having removed to Lucknow when the son of Sujad ud Dowlah removed the seat of government to that town. The remains of a fortress and of Sujad ud Dowlah's palace, with its extensive gardens, are still to be seen. The ancient city of Oude, or Ayodha, the capital of the great Ram, adjoins Fyzabad. East Long. 82° 10′, and North Lat. 26° 46′. See Hodge's *Travels* and Foster's *Journey*.

G.

Gabres.

GABRES, GUEBRES, or GAURS, worshippers of fire, is the name of a religious sect which has subsisted in Asia from a very ancient period.

Mankind, in the most rude and barbarous state, are unavoidably sensible of the dissemination of light and heat by the sun. His presence announces the day, while his absence covers the earth with darkness. His emanations are a powerful source of vegetation; and summer, which enables them to provide alike for transient wants and future necessities, is denoted by his more protracted appearance. Hence it is not surprising, if, in gratitude for the benefits conferred by this luminary, some marks of adoration have followed. Men, in most ages and in most countries, have worshipped the sun; and fire, in his absence, has been substituted as a prototype, under different characters. Among the ancient nations following this practice, the Romans are most familiar to us, who preserved sacred fire, which was never to be extinguished, and which was guarded by the vestal virgins. But, anterior to their era, it appears that the worship of fire was widely spread over Persia, and reduced to an established form, acknowledged and received by a large proportion of the inhabitants long before the birth of Christ. A celebrated philosopher, Zoroaster, is reported to have either founded a sect distinguished from all others by the adoration of fire, or, which is more consonant with the customs of mankind, to have reduced the practice to systematic order. Miraculous events attended his origin; his life was, like that of all other lawgivers, a tissue of extraordinary occurrences; and, according to some of his followers, he was taken up into heaven, instead of dying a natural death. Zoroaster was born about 589 years before Christ, and his disciples subsisted in Persia until the overthrow of Jezdedjerd, king of that country, by the Mahometan Caliph Omar; whence historians date the era of the modern Gabres from the first year of the reign of this sovereign. Some months after the death of Jezdedjerd, the persecution of the Mahometans induced many of them to withdraw to Kohistan, a mountainous district in the present province of Khorassan, where they dwelt for an hundred years. They subsequently emigrated to the island of Ormuz, in the Persian Gulf, where they remained fifteen years stationary; and then, sailing for India, landed at Diu. But, on consulting certain oracular declarations in their sacred writings, they discovered that their residence was not auspicious here; and, again committing themselves to the sea, reached a fertile part of the coast, having experienced a frightful tempest on the voyage. The prince of this territory received them favourably; but observing them to be numerous and well armed, he engaged the observance of five separate conditions, before granting them permission to land; namely, that they should explain the mysteries of their faith, lay aside their arms, speak the language of India, and also that their women should appear unveiled, and that their nuptials, according to the custom of the country, should be performed at night. The Gabres, finding nothing in their books adverse to these conditions, gladly assented, and landed, professing their desire for peace and tranquillity.

[Or]igin of [th]e Gabres [in] Persia.

Gabres.

Account of their removal to India.

On the other hand, the Indians, discovering the analogy of some of their principles to their own, permitted them to settle where they chose; and a portion of ground being selected, they built a city on it, which was called Sanjan. Probably, in relation to the place from whence they had emigrated, they are more generally called Parsees, and have subsisted towards a thousand years in Guzerat and other parts of the coast of India. Soon after their arrival, they obtained a new grant of land, whereon they erected a temple dedicated to fire, in pursuance of a former vow, if they should escape the storm that had assailed them. Here they remained united for about three centuries after the death of Jezdedjerd, when they dispersed to Baroach, Surat, and other places, while, in the lapse of two more, their city was gradually depopulated. The sovereign of Guzerat, however, being threatened by an invasion of Mahometans, anxiously recalled them, on which occasion 1400 were found capable of bearing arms; but many of their number fell in an engagement with the enemy. Their city was pillaged, and the survivors fled, carrying the sacred fire along with them, in quest of another establishment, which they successively found and abandoned. The fire was conveyed from place to place during several centuries, and at last the Gabres found an asylum in Surat, Bombay, and various settlements on the coast of Malabar, where they enjoy the full and undisturbed exercise of their religion.

Account of the Gabres in Persia.

Part of the original stock remained in Persia, their native country, where they seem to have experienced even a harder fate than those who emigrated. In consequence of the oppressions of their conquerors, the arts known among them declined, they lost all knowledge of their own origin and history, and became a poor and degraded race. At present they are treated with the utmost rigour, and most of them have, in consequence, been compelled either to emigrate, or to abjure the religion of their ancestors. In addition to other oppressions, they are subjected to a capitation tax of twenty piastres by the Persian government. The greater proportion inhabit the shores of the Caspian; and the cities of Ispahan, no longer the capital of the empire, Yezd, and Kerman. The suburb of the first, which they occupy, is called Gaurabad, and in the same quarter is a bridge called the Gaurs Bridge. About a fourth part of the population of Yezd, which contains 20,000 houses, consists of Gabres. But the principal resort of old, though now exhibiting only a few scattered cottages, was a place in the neighbourhood of the city of Badku, on the peninsula Abscharon, on the Caspian Sea. Here a natural phenomenon has served to promote their faith, and rivet them in the adoration of fire. About 10 miles north-east of the city, is what is called Atash Kudda, or fire temple of the Gabres, a remarkable spot, something less than a mile in circumference, from the centre of which a bluish lambent flame is seen to arise. When the wind blows, it is elevated to about eight feet in height, but it is lower in still weather. All around this place an invisible vapour escapes on digging up two or three inches of the

Gabres.

Account of the fire temple of the Gabres.

earth, which is inflamed on the application of fire; nay, if a cane tube, or one of paper, be inserted so deep in the ground, and a light applied to the orifice, a flame resembling that of spirit of wine immediately bursts forth, which does not injure the tube, provided the edges be covered with clay. Several temples, apparently of simple construction, lately stood in this neighbourhood, and, among others, a small one, where a flame issued from a hollow cane near the altar. Devotees were to be seen, about forty or fifty in number at a time, who had made expiatory pilgrimages hither, and subsisted on wild celery, a kind of Jerusalem artichoke, and other roots, while they remained. They affirm that this fire has burned since the flood, and believe that it will last until the end of the world. So singular a phenomenon cannot but deeply impress the uncultivated minds of the Easterns, who would rather seek its origin in some supernatural cause, than endeavour to explain it by the combination and action of the different substances of inanimate matter.

According to the principles of the Gabres, their sacred fire should be found in every town or settlement, and ought never to be extinguished. If compelled by the pressure of circumstances to remove, it ought to be carried along with them; and it has thus been transferred from place to place in India, while preserved in vigour, during 800 or 900, or perhaps 1000 years. Some time ago, when from invasion, or another cause, the whole Gabres were obliged to fly, and their houses were burnt, the temple, or edifice containing the sacred fire, was preserved, which they ascribed to its innate powers of protection. Concerning this element they entertain the most extravagant ideas, though its worship be subservient to that of Hormusd, a divinity the source of all good. They maintain, that an original principle, analogous to eternity, (at least nothing more definite can be explained by it,) created light, water, fire, Hormusd the author of good, and Ariman the author of evil; but speech preceded all creation, for by its influence the formation of beings was effected: Hormusd is adored for his beneficence, and Ariman held in detestation on account of his malevolence. The sacred fire Behram, which is the guardian of the country, is the extract of 1001 fires, taken from 15 other fires. It must be preserved unextinguished in absolute purity; and many sacred offices are performed before it, either by priests in their temples, or by individuals in private. In the former it is kept up simply, we conceive, by a supply of wood. It is watched night and day by priests, and burns on a vase contained within a grating, which none other may approach. The light of the sun being brighter than fire, is excluded from their temples; and if any person of different tenets should approach, the priests consider themselves defiled, and have to undergo purification. Independent of this care of the sacred fire, they entertain a veneration for the element in general. When once kindled, they deem it sacrilege to extinguish it unless by a particular method: A candle must either burn to the end, or, if they wish to spare a portion, a small part next the wick is cut off, and, being carried to the hearth, is left to burn out. A light is blown out by the wind of a fan or the hand, but never with the breath, for that is impure; and should their houses take fire, instead of extinguishing the flame with water, the surrounding parts are pulled down, or removed, in order that it may go out of itself. In short, their general principle is, to allow it to come naturally to a close, and not abbreviate it by violence. The Gabres keep different festivals, continuing six days, as at the beginning of the year; six particular festivals afterwards, each of five days; and a festival the last ten days of the year, during which they believe that the souls of the virtuous descend to within three bow shots of the earth. They also observe the anniversaries of their own birth, and that of their children. But these festivals are different in different places, and some in Persia are unknown in India. Their prayers are numerous; they are offered up not only after natural operations, but on cutting their hair or nails, the fragments of which are preserved to be laid in their cemeteries.

Marriage ceremonies.

Marriage is a favourite condition among the Gabres, and sterility a reproach. A man is entitled to have only one wife, but should she have no offspring, he may, with her consent, take another, the first still continuing to dwell along with him. But the same privilege is not allowed to a wife. In Persia, it has been affirmed that a man might marry five wives, though only the first was to be considered the true and legitimate one, and hence a preference over the rest. The husband was entitled, however, to repudiate her at the end of seven years if she remained sterile; as also for adultery, or apostacy from her own religion. It is added, that if the wife repented of her offence within a year, and did penance during three years, the parties might be reunited. Perhaps these points are not sufficiently established, and the authors who have treated of some of them are not aware that marriage is considered to be of five different kinds. When a young female has attained maturity, she may demand that her parents shall provide a husband for her; and if they disregard her request, it is a culpable neglect; but if she, on her part, refuses marriage, and dies a virgin at eighteen, her soul is believed to remain in hell until the resurrection. The marriages of the Gabres are performed with great pomp and solemnity, 2000 guests being sometimes invited in India, while all the friends and relatives of the parties are clothed in their most splendid attire. A prodigious display of lighted torches appears, and a numerous procession is attended by noisy musical instruments. The ceremony is then performed by a priest, and the wedded pair occupy their own proper residence. By a special regulation, which has prevailed nearly 150 years, the Gabres of India never present any thing at the great entertainments which embellish their marriages that has had life in it, because there are always numbers of Indians invited to participate.

Mode of disposing of their dead.

But amidst the most singular customs which have ever been witnessed among mankind, is the conduct of these people in the disposal of their dead. They are neither interred nor burned, but exposed to be devoured by beasts of prey. Perhaps there is no custom of the present day, however extraordinary, that we cannot trace in the records of antiquity; and few which were practised in the most remote ages, are altogether extirpated among modern nations. Herodotus, and after him Strabo, acquaint us that the Magi, who were the original race now described in these pages, did not inter the bodies of their dead, but exposed them to beasts of prey. The Hyrcanians, or natives of Irak, as we denominate it, had dogs trained, if they could require any training, to devour the dead; and the Bactrians were so tenacious of this fashion, that when Nicanor, governor for Alexander, wished to abolish it, he was very nearly losing the whole province. According to Justin, the Parthians exposed the dead to be devoured by dogs and birds, and afterwards buried the naked bones. The ancient inhabitants of India left the bodies of their deceased relatives to be devoured by vultures, which were possibly viewed as sacred birds. Ælian speaks of a nation or tribe, the Barcæi, which burnt those who died by the course of nature, but others who fell in battle were exposed to be devoured by vultures, because these birds were held to be sacred. The modern Gabres, or Parsees, the worshippers of fire, expose their deceased relatives as a prey to vultures, whether in Persia or in India. When a person is about to expire, a prayer is whispered in his ear, and a dog presented before him; but it is important that the animal should look in his face, which is obtained by placing some meat in that direction. Two dogs must be brought for a pregant woman; or if no dogs can be procured, means should be used to attract the attention of the bird that is to prey on the body. It appears that this part of the ceremony may be postponed until carrying forth the body to be deposited in the sepulchre, which is either done in silence attended by a numerous assemblage, or while women chaunt a kind of requiem. The repository of the dead is a circular edifice, or low tower, open above, with a stone floor, elevated from the ground to receive the bodies, and inclining towards the centre. By the letter of the law, this sepulchre, which is called Dakhme, should stand only on a hill, and be demolished every 50 years, to expose the earth to the light of the sun; but probably neither of these conditions are fulfilled, and we only know that they are apart from towns. Several are seen at Bombay and Surat; the largest about 55 feet in diameter, and 25 feet in height, built up to within five feet of the top, and having a well or sink of 15 feet diameter in the center. There are three concentric grooves or compartments around the sink for receiving the bodies, which are loosely wrapped in cloth, the outer for the men, the next for women, and the interior compartment for the bodies of children, all with connecting channels to drain off the fluids, into which they are partly resolving by the progress of decay. Nothing can be more horrible than the spectacle presented here, whether in the various stages of putrefaction in its most unsightly form, in the disjointed and mangled fragments of the human frame, the overpowering fœtor emanating from the corpses, the presence of the vultures greedily devouring their prey, or glutted with human flesh scarcely able to take wing, altogether forming such a combination, as the strength of living man can with difficulty resist. But the natives have no such feelings; on the contrary, they look for auspicious omens in the very eye which shall be first torn from its socket. After a certain interval, the bones are collected towards the sink with iron rakes, and the communication of subterraneous channels prevent it from being choked up. The body first interred in a new-constructed Dakhme ought to be that of an infant, the child of a priest.

The Gabres nourish a strong predilection for some animals, and entertain a corresponding aversion for others. Cows and dogs are in great estimation. They have an antipathy to cats, insects, and reptiles, from believing them created by Ariman, the source of evil; and Tavernier says, that in Persia the women destroy all the frogs on a certain day, because a prophet whom they principally venerate, was once disturbed by these animals. But the zeal of this author for the Catholic faith has led him, according to his own acknowledgement, to expose only what is most absurd in the religion of the Gabres; hence his accounts, which in some things are manifestly erroneous, must be read with caution.

This sect seems to exist in much greater purity in India than in Persia. Their ceremonies, even some of the most important, are extremely different; and those of the Persian Gabres are compounded of the principles of the Christians and Mahometans along with their own. The earlier doctrines of Christianity, and many points of Jewish history, are especially to be recognized in the baptism of their children, the history of their prophets, the escape of the sacred fire in the semblance of a white dove, and the like. Probably these have been introduced by the decline of learning, and from the influence of their priests being unable to preserve their original faith in its purity. But the reverse has succeeded in India, where the Gabres practise their worship undisturbed, and have preserved some of their books of the law, written in a peculiar character, until the present era.

The moral character of these people is universally esteemed. They are qniet, inoffensive, and industrious. At Bombay and Surat, but especially the former, where they are best known, they are highly respected, and one of the most wealthy some years ago charitably maintained 2000 persons of all different tribes at his own expence, during a time of famine. They are among the richest inhabitants of the island, and are accustomed to give the most magnificent entertainments to Europeans, while no one of their own sect is left destitute, so much are they distinguished for munificence and liberality.

(c)

GABS, the name of a town of Africa, situated on the south-east part of Tunis, in a bay of the Mediterranean. It was the *Epichus* of Scylax, and the *Tacape* of Ptolemy and Pliny. Dr Shaw informs us, that the ruins of this ancient city are still to be seen upon a rising ground, at the distance of half a mile from Gabs, having been formerly washed by the sea, which here formed a bay nearly half a mile in diameter. The greater part, however, of this bay is now filled up and gained from the sea. Among these ruins are some beautiful granite pillars, about twelve feet long, and all of them square: a form which Dr Shaw had never seen in any other part of Africa. There are several extensive plantations of palm trees at Gabs, but the dates are much inferior both in taste and size to those of Jireed. The principal trade of the place consists of the al-hennah, which is cultivated to a great extent in all the gardens. "This beautiful odoriferous plant," says Dr Shaw, "if it is not annually cut and kept low, as it is usually in other places, grows ten or twelve feet high, putting out its flowers in clusters, which yield a most grateful smell, like camphor. The leaves of this plant, after they are dried and powdered, are disposed of to good advantage in all the markets of this kingdom: For with this all the African ladies that can purchase it, tinge their lips, hair, hands, and feet, rendering them thereby of a tawny saffron colour, which, with them, is reckoned a great beauty. The al-hennah, no less than the palm, requires to be frequently watered; for which purpose, the river that runs through these plantations is cantoned out, as it seems to have been in the time of Pliny, into a number of channels. Distance from Tunis 57 leagues south, from Wood-riffe three leagues, and from Ellamaite 12 leagues. The baths of Gabs, or the *Aquas Tacapitanas*, are situated at Elhammah, about four leagues to the westward of Gabs, and are described by Shaw. East Long. 10° 2′, North Lat. 34°. See Scylax, *Perip.* p. 46; *Ptolemy*, lib. iv. cap. 3; *Pliny*, lib. v. cap. 4; lib. xviii. cap. 22; *Strabo*, lib. xvii. p. 1188; and Shaw's *Travels in Barbary and the Levant*, chap. iv. p. 213.

GAERTNER. See *History of* BOTANY, p. 34.

GAETA, or GAIETA, the *Cajeta* of the ancients, is the name of a sea port town of Italy, in the kingdom of Naples, and province of Lavora. It is situated on a peninsula, which is joined to the mainland by a narrow isthmus. The fortress, which was erected by Ferdinand II. of Arragon, stands upon the rocky promontory; and when seen from Mola, it forms a very striking object, with its white ramparts presenting to the eye, one above the other, its stages of angles and batteries. The sea floats into its moats, which are both broad and deep. Its harbour, which is well described by Homer, still exhibits the same character. It was anciently repaired by Antoninus Pius. The streets of the town are neatly built and well paved; the houses are built on porticos; and the general appearance of the town is lively within, and picturesque without. "The cathedral," says Mr Eustace, "though not large, nor highly decorated, is well proportioned, well lighted, and, by the elevation of the choir, admirably calculated for public worship. The font is a fine antique vase of white marble, with basso relievos, representing Athamas, Ino with a child in her arms, and a group of Bacchantes. The sculptor was an Athenian; but such a vase is better calculated for a gallery of antiques than for the place where it now stands. Opposite the great portal of the cathedral rises an antique column, marked with the names of the winds in Greek and Latin.

The tomb of Munatius Plancus stands upon a bold eminence, on the neck of land which joins the peninsula to the continent. Like that of Adrian, it is round, stripped of its marble casing, and converted into a tower with battlements. The gulf abounds with fish, particularly sturgeon, from which caviar is made. Gaeta is the see of a bishop, suffragan of Capua. Distance from Naples 40 miles north west; from Mola four miles by land and two by water. East Long. 13° 28′, North Lat. 41° 15′. See Homer *Odyss.* x. 107; and Eustace's *Travels*, vol. i. p. 475.

GAGE. See PNEUMATICS.

GAINSBOROUGH, a town of England, in the county of Lincoln, is pleasantly situated on the eastern bank of the Trent, which here separates Lincolnshire from Nottinghamshire. The town is clean, well paved and lighted, and consists chiefly of one long street parallel to the river. The principal public buildings are the church, the town-hall, the old hall or palace, the theatre, and the bridge. The church, which is an irregular building, in a very bad style of architecture, was lately rebuilt at the expence of the inhabitants. The pulpit cloth and cushions are made of crimson brocade velvet, trimmed with gold; and they are made of materials which were taken in 1743 at the battle of Dettingen. The town-hall, which is situated in the market-place, is a brick edifice, with shops below it and the jail: it is used occasionally as an assembly room. The old hall or palace is a Gothic mansion, situated at the north-west end of the town. It consists principally of oak timber framing, and forms three sides of a quadrangle, open to the south. It has a tower 78 feet high, and the whole building was about 600 feet square. The moats with which it was once surrounded are still visible. It is now converted into apartments for families. The theatre is a small but very handsome modern building. The bridge, which is very elegant, consists of three elliptical arches. It was completed in 1791; and, being private property, a toll is exacted. There are several meeting-houses in the town, and some good charity schools. This town has a small share in the Baltic trade, and it carries on a considerable trade in corn and other commodities to and from the coast. Vessels of 150 tons burden can come to the town with the tide. The trade of Gainsborough is greatly facilitated by the Readley Canal, which opens a communication with Yorkshire; and by the Chesterfield Canal a communication is opened with the counties of Nottingham and Derby.

About five miles to the south-east of Gainsborough are vestiges of the city of Sidnacester. On a ridge along the banks of the Trent, about half a mile to the north of Gainsborough, are some embankments called the *Castle Hills*. The central encampment contains an area of 510 feet in circuit, and is surrounded by a double fosse and vallum. The circular part appears to have been a Roman work, and the rest is Danish. Horse races are annually held at Gainsborough.

The following is the statistical abstract for the town and parish in 1811:

Inhabited houses	1159
Number of families	1227
Families employed in agriculture	49
Ditto in trade and manufactures	628
Males	2446
Females	2726
Total population	5172

See the *Beauties of England and Wales*, vol. ix. p. 671.

GALANGAL is the name of a medicinal root, and the produce of a plant of the same name. There are two kinds of galangal, the great and the small; the last of which is generally held in the greatest estimation. The *great galangal* is a tough woody root, about $1\frac{1}{2}$ inch thick. It is whitish within and brown without, and has a thin bark, covered with rings or circles about one-fourth of an inch distant. It has a bitterish and a somewhat aromatic taste. The *small galangal*, which is superior in all its qualities to the great galangal, is a much shorter and smaller root, of an irregular form. It is commonly the size of the little finger, being seldom more than half an inch thick, and two inches long. It is of a pale red colour, with a small admixture of brown on the inside, and of a brownish-red colour on the outside, and is surrounded with many circular rings, that project a little beyond the rest of the surface. It is not heavy, but its texture is firm and compact. It cuts with difficulty with a knife, and leaves a polished surface. Small galangals must be chosen full and plump, of a bright colour, compact and sound, and leaving an acrid and unsupportably hot taste.

The permanent duty upon galangals is £1, 8s. per cwt. and the war duty 9s. 4d.; amounting in all to £1 : 17 : 4.

The following Table shews the quantity of this root imported and sold by the East India Company, from the years 1804 to 1806 inclusive:

Years.	March Sale.		September Sale.		Average Price per Cwt.
	Cwt.	Price.	Cwt.	Price.	£ s. d.
1804	896	£1810	..	....	2 0 5
1805	..	....	104	£264	2 10 9
1806	..	....	10	18	1 16 0

Twelve cwt. of galangal are allowed to a ton. See Lewis's *Materia Medica;* and Milburn's *Oriental Commerce.*

GALAPAGOS, or TORTOISE, or ENCHANTED ISLANDS, are the names which have been given to a cluster of desert islands situated in the Pacific Ocean, in East Long. 268° 18′, and South Lat. 1° 22′. They were first discovered by the Spaniards, and have been since visited by Dampier and Vancouver. The southernmost island is about 4 miles in circumference, and the northernmost about 1½ mile. Most of these islands are flat, and tolerably high. Four or five of the most eastern are rocky, hilly, and barren, producing nothing but some shrubs on the shore. Others of this cluster produce trees of different sorts; and in some of the most western of the group, which are 9 or 10 leagues long, and six or seven broad, large and tall trees, especially mammee trees, grow in extensive forests. In these large islands, the rivers are of a tolerable size. See Dampier's *Voyage round the World*, vol. i. and Vancouver's *Voyage.*

GALASHIELS. See ROXBURGHSHIRE.

GALAXY, or MILKY WAY. See ASTRONOMY.

GALBA. See ROME.

GALBANUM is the name of a gum which exudes naturally from the joints, or is obtained by incision from the stem of an evergreen plant, which is found in Persia, Arabia, and some parts of Africa. The following excellent account of this gum, as an article of commerce, is given by Mr Milburn.

"Galbanum is a gummy, resinous, rather unctuous substance, sometimes in the natural drops or tears, but more frequently in masses composed of a number of these blended together. The drops, when perfect, approach near to a roundish or oblong figure; but they commonly lose their form in the masses. These are pale coloured, semi-transparent, soft, and tenacious. In the best specimens, they appear composed of clear whitish tears, often intermixed with stalks and seeds of the plant. When fresh, the masses and tears are white, and with age change to yellow or brown.

"When the tears can be procured, they are to be preferred to the masses or cakes. These tears should be fattish, moderately viscous, and glossy on the surface; such as are too fat, of a dark brown colour, and mixed with sticks and other foreign substances, are to be rejected. The best cakes are those of a light yellow colour, of a strong, piercing, and, to most persons, a disagreeable smell, of a bitterish warm taste, not very humid, nor yet quite dry, being of a nature between a gum and a resin, flaming in the fire, and with difficulty dissolved in oil. The fewer chips, dirt, stalks, or other impurities, the better. A mixture of two parts of rectified spirits of wine, and one of water, will best shew its quality, by dissolving all the pure galbanum, and leaving the impurities. When its foulness renders it of little value, it is best purified by enclosing it in a bladder, and keeping it in boiling water till it melts or becomes soft enough to be strained by pressure through a hempen cloth. If this process be skilfully managed, the galbanum loses but little of the essential oil, some of which is generally carried off in evaporation."

The following is an account of the quantities imported and sold at the East India sales in the years 1804 to 1808 inclusive, with the sale amount and average price per cwt.

Years.	March Sale.		Sept. Sale.		Total.		Average per Cwt.
	Cwt.	Price.	Cwt.	Price.	Cwt.	Price.	£ s. d.
1804	..	..	15	£241	15	£241	16 1 4
1805	24	£199	42	399	66	598	9 1 2
1806	..	..	57	238	57	238	4 3 6
1807	..	..	..	..	..	..	.. .. ..
1808	..	..	..	..	..	..	.. .. ..

Sixteen cwt. of gum galbanum is allowed to the ton. The permanent duty is £2, 4s. per cwt. and the temporary or war duty £1, 8s. per cwt.; making in the whole £5, 12s. per cwt.

GALEN, one of the most celebrated physicians of antiquity, and singular for the unbounded sway which his opinions long maintained over the medical world. He was born in the 131st year of the Christian era, in Pergamos, a city of Asia Minor, of which Esculapius, the god of medicine, was considered as the protector. This circumstance, and the consequent attention which its priests paid to the medical art, probably rendered it a place well fitted to cherish in an ardent mind a zeal for medical pursuits. He flourished in the reigns of M. Aurelius, Commodus, Lucius, and Severus. He enjoyed great advantages from the literary and scientific attainments of his father Nico, a man of considerable wealth, and highly respected for his exemplary temper and virtue, as well as for his eminent knowledge in literature, geometry, astronomy, and architecture. His mother is described by him as a woman of strict virtue, and an excellent economist, but unhappy in her temper, often quarrelling with her husband, and even biting her domestics.

His preliminary education, consisting in grammar, arithmetic, geometry, and astronomy, was continued till he was fifteen years of age. In these branches he discovered a ready capacity and a retentive memory, and his attainments far exceeded those of his fellow scholars. He then turned his attention to logic and philosophy. He studied the system of the Stoics, by attending the prelections of Philopator, and reading the works of Chrysippus. On the latter he wrote a comment during his early studies. From the Stoical discipline he is considered as having greatly profited, by acquiring principles of rigid self-government, which armed him against the licentious manners of that age. He studied the Platonic philosophy under Caius, a fellow citizen, a man of singular worth and incorruptibility of character. To these studies he was probably indebted for the elegant direction which was given to the natural fervour of his mind. His father also gave him an opportunity of learning the Epicurean philosophy, under an Athenian who had settled in Pergamos. On the various systems of the day, he so far made up his mind, as to write dissertations on their merits. In these he gave a share of praise to each, with the exception of the Epicurean, which he rejected and opposed. His early studies were not undertaken with any view of rising in the world, but purely as conducive to the improvement of his own mind, and the rational enjoyment of life. But a resolution to cultivate a philosophy which excludes all exterior glory, very often proves unsteady, especially where prospects of utility to mankind seem to exact from an accomplished mind a devotedness to a public life. The destinies of Galen were widely different from these original views. In his seventeenth year, he was determined, by a superstitious regard to a dream of his father's, to apply to the study of medicine. His previous liberal education had so far enlarged his mind, as to impress him with the propriety of combining with his new pursuits the prosecution of his philosophical studies. Natural philosophy, in a particular manner, appeared necessary, for the purpose of cultivating a thorough knowledge of the physical qualities of those objects which medicine comprehends. He carefully weighed the merits of the various medical as well as philosophical systems, and made himself a complete master in the art of reasoning, as practised by the ancients. Possessed of judgment to guide in some measure his own studies, he changed his teachers whenever he perceived that no improvement was to be derived from them. Hence it was an honour to have him for a pupil, and to the sophists of the day he was not a little formidable. Some of his studies were prosecuted at Corinth, others at Smyrna. Afterwards he went to Rome, where he embraced an opportunity of studying with the teachers belonging to the three medical sects, the Rational or Dogmatic, the Methodic, and the Empiric. He maintained a uniform respect and attachment to all his teachers, but in none did he ever repose blind admiration or implicit confidence. Determined to take nothing on mere report, which it was possible for him to examine with his own eyes, he travelled for the express purpose of seeing the different articles of the materia medica in their native country. He went to Palestine to see the opobalsamum and bitumen, and to Lemnos to see the celebrated Lemnian earth. He reviewed the metallic productions of Cyprus, and brought home, for the use of his countrymen, quantities of the mineral substances which went under the names of Cadmia, Pompholyx, Diphryges, and Chalcanthus. He also examined the articles of diet used in different countries, and pointed out those which he considered as most proper for the sick.

After a long residence in Alexandria, and a course of travels which he had performed in Egypt, he returned at the age of 28 to practise medicine at Pergamos. He communicated to the medical men of that city the information which he had collected, and directed them in a variety of experiments on the virtues of medicinal plants. He was honoured with the medical charge of the gladiators, and gained no small credit by the success with which he treated their wounds.

A sedition arising in Pergamos, he repaired to Rome, where he soon acquired very high celebrity by his professional success in the diseases of some conspicuous individuals. He cured Eudemus the philosopher of an intermittent fever, which had been previously mismanaged. He gave remarkably accurate predictions of the future course of various cases of disease, and displayed great address in tracing some instances of indisposition to maladies of the mind. When called to the wife of Justus, he declared her illness to have originated in an amorous affection, and discovered the individual who was the object of her languishing attachment. He found that the disease of a servant to whom he was called, proceeded from the depressing influence of fear; and it appeared, on enquiry, that this person was unable to give a proper account of some property which had been committed to his charge. In short, Galen seems to have shone as an accurate student of the phenomena of disease, and to have applied to professional uses a general and ready knowledge of the human heart.

At Rome he was intimate with the first characters in the literary world, such as Eudemus and Alexander Damascenus, two celebrated Peripatetic teachers, and Sergius Paulus the prætor, a man of consular dignity, the most eminent man in Rome for intellectual accomplishments, and for ability in the management of state affairs. The great success of Galen, his growing character, and the high remunerations which he sometimes received, excited the hostility of his competitors, most particularly among the sect of the Methodics whom he opposed, and who at that time were in high credit. They represented his success in practice, and the accuracy of his predictions in disease, as entirely the effect of accident. The latter was sometimes ascribed by them to the art of magic. The annoyance which he sustained from this opposition, and the breaking out of a plague in the city of Rome, determined him, in the 37th year of his age, to leave that city, and return to his native country. But he had not remained long there, when he was invited to attend the Emperor M. Aurelius in Aquileia, and in the train of this emperor he returned to Rome. Aurelius gave him the charge of his two sons, Commodus and Sextus, during his absence in the German war. Galen ingratiated himself at court, by performing some successful cures on Commodus, and by showing the accuracy of his judgment in the prognosis which he pronounced of an acute disorder with which Sextus was affected. When the emperor himself was afterwards seized with sickness, Galen told him that it was entirely the effect of an overloaded stomach, and gave him relief by a suitable prescription. This benignant emperor was no less pleased with the philosophic spirit and the virtuous habits of Galen, than with his professional ability. On the death of Demetrius, Galen was appointed to succeed him as the sole compounder of the famous preparation called *theriaca*, a distinction which served to mark him as the first physician of his day. It does not appear that Galen continued stationary in Rome till his death. Several years of his life, though we know not how many, seem to have been again spent in his native city. Galen died at the age of 70. The place of his death is unknown. Some say that he lived to the age of 87, and a fabulous story was at one time circulated that he lived 140 years.

The biographers of this celebrated man have delighted to recount the virtues for which he was eminent, such as fortitude, inflexible justice, and piety. He appears to have held the creed of the unity of the Deity. A zealous writer has laboured to show that he died on his way to Judea, on a journey which he was led to undertake by the claims of the Christian miracles. From this a hope is suggested that he had submitted to the rite of Christian baptism, and died within the bosom of the Catholic church. These facts, however, Galen.

are but ill authenticated. His dutiful sentiments towards his father, his devotedness to his native country, (the interests of which he often cultivated to the neglect of his own fortunes at Rome,) the grateful veneration which he entertained for his teachers, the sedateness of his manners, the correctness of his conversation, which was equally remote from obscenity and ridicule, the mildness of his temper, his gentle behaviour towards his servants and all around him, and the cheerful animating tone of his discourse with the sick, are virtues which, though not uncommon, it is pleasant to find adorning the character of this great physician.

In his reasonings he was reckoned solid and close, in every argument confounding his adversaries, and coming off triumphant. The most unbecoming quality betrayed in his writings, is a disposition to boast of his own ability, and to treat other writers with contempt.

He wrote several treatises which have not reached our day, among which are his books on philosophy and grammar. Five hundred treatises on medicine are ascribed to him, and half that number on other subjects.

Galen, though possessed of a mind too independent to submit implicitly to any of his predecessors, unconsciously forged chains which enthralled the medical opinions of many succeeding ages. The contending errors of ancient systems, produced a very powerful effect on his inquiring mind. He entertained the plausible opinion, which was so universal among the ancients, that all particular truths in philosophy are to be deduced from general or first principles. The specimens of philosophical truth, however, which he found thus substantiated in the various schools, were so unsatisfactory, and so often at variance with the phenomena of nature, that at one time he was strongly disposed to embrace that philosophy, which declares the universal uncertainty of human knowledge, a system which, under the name of Pyrrhonism, was at that time very prevalent. From this he was preserved, by contemplating the satisfactory results which mathematical science afforded in the problems of geometry and astronomy, and, in a particular manner, the calculation of eclipses, and the undoubted utility of dials and other mathematical instruments. On comparing the proofs of the certainty of science, with the numerous specimens of its errors, he was not induced to abate his exclusive confidence in synthetic reasoning, but drew the inference, that the true data or first principles, which were the foundations of natural science, had not yet been discovered. He conceived that he himself was destined to lead the way in the investigation of medical truth. To this object accordingly all his efforts were powerfully directed. If he had not laboured under the error now mentioned, which was derived from Aristotle, an error common to him with other men of learning in that age, and which never indeed lost its dominion over science till the appearance of the *Novum Organon* of Bacon, Galen would have produced a work as conspicuous for solidity and minute information, as for genius and comprehensiveness of thought. Future ages would then have approved while they wondered. His system, though defective, and often rendered illusory by the intermixture of the subtile doctrines of Aristotle, was ingenious and well connected. His talents enabled him to stop the spirit of improvement for fifteen centuries; but now, when emancipated from his illegitimate dominion, we are enabled to profit by his labours, and to contemplate in his writings a mighty monument of genius and industry, fitted at once to animate exertion, and to repress presumption. For an account of his opinions, see the *History of* ANATOMY, and the *History of* MEDICINE.

Galen wrote with elegance in the ordinary dialect of the Greek language, inclining to the Attic.

The Greek editions of his works are those of Aldus and Aud. Asulanus, printed at Venice in 1525, in five folio volumes; and that of Hieron Gemusæus at Basle, in 1538, in the same form.

The editions of Latin translations of his works are more numerous, and were published at Paris, Venice, and Basle. René Chartrier published his works in Greek and Latin, along with those of Hippocrates at Paris. See Eloy's *Dict. Hist*; Le Clerc's *Hist. de Medicine*; and the prefatory dissertations to the different editions of Galen's works. (n. n.)

Galicia.

GALICIA, a province of Spain, situated in the north-west angle of that kingdom; is bounded on the south by Portugal, on the north and west by the Atlantic Ocean, and on the east by Asturias and Leon. It lies between 41° 50′ and 43° 46′ North Latitude, and between 6° 10′ and 9° 10′ West Longitude, forming a very irregular kind of square, extending about 40 leagues from east to west, and 46 from north to south. It takes its name from its ancient inhabitants the Callaici, or Gallæci, and formerly comprehended a part of Old Castile. In its mountainous districts, as well as in those of Asturias and Biscay, the Cantabrians resisted all the power of the Roman armies; and in 714, presented the strongest barriers to the invasion of the Moors. Galicia was constituted a kingdom in the year 1060, by Ferdinand the Great, king of Leon and Castile, and was assigned as a province to his son Don Garcias; but till the reign of Ferdinand and Isabellá, in 1474, the inhabitants maintained, amidst their mountains and rivers, much of their original independence. The nobility, without paying great regard to the royal authority, acted as sovereigns in their respective territories, and encouraged their vassals in their marauding practices. But, by the exertions of Ferdinand and Isabella, these disorders were repressed, the country civilized, and the inhabitants attached to the Castilian monarchy.

Boundaries.

History.

The country is in general covered with mountains, most of which are well wooded, and very abundant in game. An extensive mountainous chain, which proceeds from the Pyrenees near Roncevallos, traverses Galicia from Leon, till it terminates at Cape Finisterre, the most westerly point of land in the province. The most considerable part of this branch is occupied by the mountains of the Sierra de Mondonedo, which occupy the whole of the north-eastern extremity, and extends northwards as far as Cape Ortegal. The principal rivers in the province are, the Eo, Eu, or Rio de Miranda, which runs from south to north along the common boundaries of Galicia and Asturias, and falls into the Northern Ocean above Ribadeo; the Sil, which rises in the mountains to the west of Leon, and proceeding westwards in a very circuitous course of 33 leagues, joins the Mino a few leagues north of Orense; the Mino or Minho, (in Latin *Minius*, so named from the vermilion which is found in abundance in its vicinity,) which rises in the east of the Sierra Mondonedo, and, after a course of 52 leagues in a south-west direction, falls into the Atlantic near the port of Guardia; the Tambra or Tamaris, which gives the name of Tamaricians to the people on its banks, and runs for the space of 20 leagues from the north-east to the south-west; the Ulla, which originates in the interior of the country,

Aspect, mountains, and rivers.

Galicia.

and has a course of 23 leagues in a south-east direction; the Mandeo, the Eume, and a number of others to the amount of seventy, besides an immense number of small streams.

Minerals.

The province of Galicia is said to have been formerly celebrated for rich mines of gold and silver; but its metallic productions at present are chiefly copper, lead, and tin. Between Corunna and Betanzos, there are quarries of jasper and white marble; and in other places there are found also marcassite, vitriol, sulphur, &c. The country abounds in mineral waters, and especially in hot springs, many of which are well frequented for the purpose of bathing. One part of the town of Orense, in consequence of the number of these thermal waters, which warm the air by their vapours, enjoys all the mildness of spring, while the opposite part is experiencing all the rigours of winter. There is one wonderful spring called Lousana, at the source of the river Lours, on the mountain of Cebret, which, though 20 leagues distant from the sea, and raised considerably above its level, is obserevd to ebb and flow with the tide. Its waters also are at one time as cold as ice, and at another extremely warm, in which latter state they are always most copious. In the forests and mountainous districts are found a variety of wild animals, particularly roebucks, hinds, stags, boars, and a great quantity of game. In its numerous rivers and extensive coasts, immense quantities of fish are taken, particularly salmon, sardin herrings, shad, trout, lampreys, skate, eels of all kinds, and above all the hog-fish, which has no bones, and being caught in the months of November and December, are frequently sent quite fresh into the provinces of Castile and Leon.

Climate and productions.

There may be said to be three different temperatures in the different districts of the province; that of the coast, which is generally mild and gentle; that of the mountains toward the north-east, which is cold, damp, and rainy; and that of the valleys towards the south-west, which is warm, dry, and pleasant. It is indeed of all parts in Spain the most subject to frequent rains and a cloudy atmosphere; but it is every where salubrious, and generally productive. There are vast quantities of lofty trees, especially oak, walnut, chesnut, and hazel; and in many places are seen mulberry, orange, and lemon trees, vines, apples, and a great variety of other excellent fruits. Though in some parts the soil is not very fertile by nature, the industry of the inhabitants has done much for its improvement. The lands frequently bear wheat, barley, rye and oats; and great quantities of maize, millet, flax, hemp, pulse, and excellent vegetables. The farmers fatten great numbers of cattle, besides raising some good horses, mnles, and a fine breed of asses and hogs. Numerous flocks of sheep and goats are seen upon the ridges of the mountains; and in many places abundance of excellent poultry is reared.

Manufactures.

There are fewer manufactures in Galicia than in the other provinces of Spain; and, though the inhabitants are remarkably industrious, they seem to have little inclination for the more mechanical arts, or the occupations of commerce. There are at Corunna and Ferrol rope-works and manufactories of sail-cloth, chiefly for the use of the Spanish navy. In the province of Lugo, woollen stuffs, hosiery, and coarse cloths, are made. In the territory of Monforté, in the county of Lemos, there are manufactories of silk, which produce a considerable revenue. There are also made in the province leather, tapes, soap, some printed calicoes, tolerably good table linen, a considerable number of hats, and great quantities of knit stockings, of which last article it is calculated that 25,000 pairs are annually sent to the neighbouring provinces, and double that number to America. Its principal articles of commerce are cattle, mules, horses, fish, cloth, wool, and wine, which are sent into the other provinces; salt provisions, particularly salted fish, which goes to foreign countries; leather, skins, hides, hats, soap, table-cloths, napkins, stockings, to America. Its exportations are made from the port of Corunna, and its imports, excepting those from America, are received by Vigo.

Articles of commerce.

Cities.

Galicia contains seven cities, 74 towns, 3434 villages, and 3683 parishes. The principal inland towns are San Jago de Compostella, the capital of the province, and residence of the archbishop, Lugo, Orense, Mondonedo and Tuy, each the seat of a bishop, Porto-Marin, Portvelezar, Torbeo, Velezar, Salvatierra, Monforté de Lemos, Viana, Monterey, Ponte vedra, &c. On the coast are forty sea-ports, but the greater part are very small, and the most worthy of notice are Corunna, Finisterra, Bayona, Gondomar, Muroz, Rivaldeo, Ferrol, Betanzos, Vigo, &c. The population of the province, in proportion to its extent, is greater than that of any other in Spain; and is estimated at nearly one million and a half. The people are chiefly employed in agriculture and fishing; and are distinguished by their simplicity of manners, hospitality of disposition, and general disregard of the arts of luxury. They are large and robust in their persons, commonly barefooted, and capable of supporting every kind of fatigue. The women are fair and tolerably handsome, with fine teeth, and very regular, but not very expressive features. The Galicians are naturally of a martial spirit, and great numbers of the young men enter the army even at fifteen years of age. They pique themselves upon their descent from the old Christians, who have never intermarried with converted Jews or Moors; and they are equally noted for their regard to religion, and their loyalty to the king. They are serious, grave, sober, rather solitary and retired in their habits, but uniformly distinguished by probity and courage. Their language is a mixture of the ancient Castilian and of the Portuguese, with several expressions of the Latin. They are said to have been the first poets in Spain; and a few of their ancient verses are still retained by tradition. But the chief characteristic of the Galicians is their inclination to emigrate to other provinces in quest of employment, though they can neither be said to be very poor or in want of subsistence at home. It is supposed that not less than 100,000 annually leave the province in this view, many of whom never return. They are uniformly employed as labourers in the time of vintage and harvest, in the two Castiles, and Portugal; and, when they do not appear to assist in these countries, much of their valuable produce, from the slovenly manner in which it is gathered, is actually trodden under foot. The great proportion of servants in all the principal towns of Spain are either Galicians or Asturians, who are generally preferred on account of their fidelity and obedience. They are ready to perform any kind of occupation, however servile, sweeping chimneys, or cleaning shoes; and the porters and water carriers in Madrid, Cadiz, and even at Lisbon, are commonly Galicians: at the same time it must be observed, that the name Gallego, which properly signifies a Galician, is now applied to the occupation as well as to the country; and is given to a person from any other province, exercising the employment of a porter. These Galicians are everywhere remarkable for their submissive dispo-

Population.

Galicia.

sition, and are too often treated like slaves; but their patient endurance is said to proceed from a fear of displeasing rather than from any meanness of spirit; and, in their native country, their character is found to be sufficiently decided. As a proof of the general honesty of the Galicians, it is worthy of notice, that in many parts of the province, but particularly in the vicinity of Orense, where much excellent wine is made, every proprietor deposits the produce of his vintage in vaults, at a little distance from the villages; and, though these cellars are neither guarded by any watchmen, nor even in many cases secured by shut doors, there is no instance of a theft being committed upon the property, thus in a manner delivered over to the public faith. See Laborde's *View of Spain*, vol. ii. (*q*)

GALICIA, or GALLITZIA, is the name given to the southern part of the possessions which the House of Austria acquired at the partition of Poland in 1772. The northern part, called Lodemeria, was an ancient dependance of the kingdom of Hungary. Galicia is separated from Hungary by the Carpathian mountains; and, including Lodemeria, it contains 1280 square German miles, or nearly 3555 square leagues.

The following Table will shew the agricultural state of this province. It contains in metzens, a German measure equal to nearly 5½ French bushels, the annual produce of the province.

Rye	1,148,123	Metzens.
Wheat	415,001	
Barley	793,372	
Oats	1,656,155	
Pease	98,323	
Millet	76,370	
Lentils	76,370	
Forage	3,130,177	Cart loads.
Number of horses in 1780	35,079	
Number of horned cattle	1,556,276	
Draught cattle	38,234	
Farms	3,253	

The following Table will shew the state of its manufacturing industry at the same period of 1780.

Water-mills	4694
Wind-mills	57
Saw-mills	259
Oil-mills	472
Powder-mills	11
Paper-mills	41
Iron forges	40
Manufactories of potash	25
Glass-works	21
Salt-works of various kinds	232

The trade which Galicia carries on with Poland, Hungary, &c. consists principally of grain, cattle, hides, wax, honey, salt, and other productions of its territory.

The following is the number of towns and population of Galicia and Lodemeria in 1780, according to M. Schloetzer.

	Towns	199
	Bourgs	111
	Villages	5575
	Houses	408,447
Christians	Males	1,112,442
	Females	1,093,311
Jews	Males	68,601
	Females	70,472
Total population		2,344,826

Galicia is watered by the Dniester, the San, and several other rivers. Lemberg is the capital of the province.

Galileo.

GALILEO GALILEI, an eminent Italian astronomer and natural philosopher, was born at Pisa, in Italy, on the 15th February 1564, and was the son of Guilia Ammanati di Pescia, and Michelagnolo Vincenzio Galileo, a Florentine nobleman, who distinguished himself by his writings on musical subjects. The earlier years of Galileo were occupied with the study of music and, drawing, in both of which he made singular progress, but as the limited fortune of his father did not permit him to settle his son in a state of comfortable independence, he resolved to educate him as a physician, and after going through the usual course of instruction at Florence, he was entered in 1582, at the university of Pisa as a student of philosophy and medicine. The doctrines of Aristotle, which were then taught in the public schools of Italy, were not congenial to a mind like Galileo's, and he was equally disappointed in the pleasure which he anticipated from the study of physic. He therefore abandoned for ever the medical profession, and devoted himself with unremitting ardour and proportionate success to the study of mathematics. Without the aid of a master he studied the different books of Euclid, and made himself master of the writings of Archimedes, and the other ancient geometers. His fame as a mathematician was soon widely extended; and in the year 1589, before he had reached his 26th year, the Duke of Tuscany appointed him to the mathematical chair in the university of Pisa. In the discharge of his duties as a professor, he incurred the resentment of some of the more violent Aristotelians, whose doctrines he did not scruple to oppose; and his tranquillity and his studies were frequently disturbed by the hostility of his metaphysical enemies. He resolved therefore to change the place of his residence, and he gladly accepted of an invitation which he received to fill the mathematical chair in the university of Padua. He left Pisa in 1592, and continued in his new situation at Padua for 18 years, raising the reputation of the university by the brilliancy of his talents, and diffusing a taste for science through the whole of Tuscany. His affection for his own country, however, induced him to accept, in 1611, the mathematical chair at Pisa, from Cosmo II. Grand Duke of Tuscany, who annexed to it a very handsome pension. The same nobleman afterwards invited him to Florence, with the title of principal mathematician and philosopher to his highness, and continued his former pension, without any obligation to discharge the duties of the professorship.

In these various situations, Galileo's attention was particularly occupied with the subjects of optics and mechanics. During his first residence at Pisa, he was led to the idea of measuring time by the pendulum, by observing the motion of a lamp in the cathedral of Pisa. From reading the treatise of Archimedes, *De his quæ vehuntur in aqua*, he was led to the invention of his *Balance* for determining the proportion of the ingredients in mixed metals. He constructed a glass thermometer, which contained water or air; and in 1597 he invented his geometrical and military compass, of which he published a description at Padua in 1606. In April or May 1609, when he was on a visit to Venice, he was accidentally informed that a Dutchman, of the name of Jansens, had invented an instrument through which distant objects had the same appearance as if they were brought near the eye. Galileo reflected deeply on the subject of this contrivance, and, from his thorough knowledge of the properties of lenses, he was soon enabled not only to discover the principle of its construction, but to complete one of the instruments for his own use. He immediately applied his telescope to the heavens, and made those splendid discoveries of which we have already given a full account in our History of ASTRONOMY, vol. ii. p. 597, and p. 612, 613.

It was during these observations that he was invited to Florence, where he enjoyed the fullest leisure to pursue them with diligence, and to carry on a correspondence with the principal philosophers of Germany, respecting the discoveries which he had made, and the great truth of the earth's motion, which they tended to establish. Galileo had scarcely enjoyed four years of tranquillity at Florence, when the fame of his discoveries, and his sentiments respecting the stability of the sun, reached the ears of the holy inquisition. Formal complaints were laid before that vigilant body; and Galileo was summoned to appear at Rome, in 1615, to answer for the heretical doctrines which he had taught. He was accused of maintaining the motion of the earth, and the stability of the sun; of teaching the same doctrine to several of his disciples; of carrying on a correspondence on the subject with several German mathematicians; and of having published it, and attempted to reconcile it to Scripture in his epistles to Marc Velser, in 1612. A meeting of the inquisition was held on the 25th of February 1616, and they decreed that Galileo should be enjoined by Cardinal Bellarmine, to renounce the doctrines which he taught, and to promise neither to teach, nor defend, nor publish them; and that, if he refused to acquiesce in this sentence, he should be thrown into prison.* On the following day, the 26th of February, Galileo appeared before Cardinal Bellarmine; and having declared that he would abandon the doctrine of the earth's motion, and would neither defend it nor teach it, either in his conversation or in his writings, he was dismissed from the inquisition. The mildness of this sentence was no doubt owing to the interposition of the Grand Duke of Tuscany, and other persons of great rank and influence at the papal court, who took a warm interest in the fate of Galileo. The inquisition, however, was not satisfied with this abjuration. They issued a decree, declaring the new opinions to be heretical and contrary to scripture, and prohibited the sale of every book in which they should be taught.

Galileo returned to Florence, and prosecuted his studies with his usual ardour and success. The opinions which he had disavowed, acquired additional strength from every new discovery. He resolved, therefore, to publish them to the world, but in such an indirect manner as to prevent, if possible, any interference on the part of the inquisition. He accordingly published at Florence, in 1632, his great work, entitled, *Dialogo di Galileo Galilei delle duo massime Sisteme del Monde, Tolemaico e Copernicano.* The subject of the Ptolemaic and Copernican system is here discussed by three speakers, Sagredo, Salviatus, and Simplicius, a Peripatetic philosopher, who defends the Ptolemaic system with much ingenuity against the overwhelming arguments of the other speakers.†

The church of Rome again took alarm at the publication of this work, and Galileo was a second time summoned to appear before the holy inquisition in the year 1633. Although he had now entered the 70th year of his age, yet he was compelled to repair to Rome; and upon his arrival in that city, he was confined to the apartments of the fiscal of the inquisitorial tribunal. By the intercession of the Grand Duke, however, he was permitted to reside in the house of his ambassador during the trial, which lasted about two months. At the end of this period he was brought up to receive the sentence of the court, which was signed by seven cardinals. This sentence, which is one of the most remarkable documents which the history of superstition can present, begins by recounting the former heresies of Galileo, and reminding him of the gentle punishment which had been inflicted. It accuses him of having obtained dishonourably a license for printing his book at Florence, and ordains that he shall, in the most solemn manner, abjure the Copernican system, as contrary to the scriptures; and bind himself by oath never to maintain or support it, either in his conversation or his writings. In order that this great heresy should not pass altogether without punishment, the court also ordained that the sale of his Dialogues thould be prohibited by a public edict; that he should be detained in the prison of the inquisition; and that he should for three years recite once in the week the seven penitentiary psalms, the court reserving to itself the power of modifying or removing this sentence.

The abjuration of Galileo, a copy of which we have given below,‡ was signed on the 22d June 1633, and exhibits a mortifying picture of human imbecility. If

* On the authority of many distinguished writers, we have stated, in our history of ASTRONOMY, that Galileo was thrown into solitary confinement. This, however, is a mistake, as there is abundance of evidence to prove that he was merely threatened with confinement, if he should refuse to acquiesce in the sentence of the inquisition.

† Sagredo, a learned Venetian, and Salviatus, a learned Florentine, were two of Galileo's intimate friends, but were both dead when he published his Dialogues. They had often discussed the same subject with Galileo at Venice, and their names were introduced as a mark of respect to their memory.

‡ "Ego Galilæus Galilæi filius quondam Vincentii Galilæi Florentinus ætatis meæ annorum 70 constitutus personaliter in judicio, et genuflexus coram vobis Eminentissimus et Reverendissimus Dominis Cardinalibus universæ Christianæ Reipublicæ contra hæreticam pravitatem generalibus inquisitoribus, habens ante oculos meos Sacrosancta Evangelia, quæ tango propriis manibus, juro me semper credidisse et nunc credere, et Deo adjuvante in posterum crediturum omne id, quod tenet, prædicat et docet S. Catholica et Apostolica Romana Ecclesia. Sed quia ab hoc S. Officio, eo quod postquam mihi cum præcepto fuerat ab eodem juridici injunctum, ut omnino desererem falsam opinionem, quæ tenet solem esse centrum ac moveri, nec possem tenere, defendere aut docere quovis modo vel scripto prædictam falsam doctrinam et postquam mihi notificatum fueral prædictam doctrinam repugnantem esse Sacræ Scripturæ: Scripsi et typis mandavi librum in quo eandem doctrinam jam damnatam tracto et adduco rationes cum magna efficacia in favorem ipsius, non afferendo ullam solutionem; idcirco judicatus sum vehementer suspectus de hæresi, videlicet quod tenuerim et crediderim, solem esse centrum mundi et immobilem, et terram non esse centrum ac moveri.

"Idcirco volens ego eximere a mentibus Eminentiarum Vestrarum et cujuscunque Christiani Catholici vehementem hanc suspicionem adversum me jure conceptam, corde sincero et fide non ficta abjuro, maledico, et detestor supra dictos errores et hæreses, et generaliter quemcunque alium errorem et sectam contrariam supradictæ S. Ecclesiæ, et juro me in posterum nunquam amplius dicturum, aut asserturum voce aut scripto quidquam, propter quod possit haberi de me similis suspicio; sed si cognovero aliquem hæreticum aut suspectum de hæresi, denuntiaturum illum huic S. Officio aut Inquisitori et ordinario loci, in quo fuero. Juro insuper ac promitto me impleturum et observaturum integre omnes pœnitentias quæ mihi impositæ sunt, aut imponentur ab hoc S. Officio. Quod si contingat me aliquibus ex dictis meis promissionibus, protestationibus, et juramentis (quod Deus avertat) contrarie, subjicio me omnibus poenis ac suppliciis, quæ a Sacris Canonibus et aliis constitutionibus generalibus et particularibus contra hujusmodi delinquentes statuta et promulgata fuerant: sic me Deus adjuvet et Sancta ipsius Evangelia, quæ tango propriis manibus.

"Ego Galileus Galilæi supradictus abjuravi, juravi, promisi et me obligavi ut supra et in horam fidem mea propria manu subscripsi præsenti chirographo meæ abjurationis, et recitavl de verbo ad verbum Romæ in Conventu Minervæ hac die 22 Junii anni 1633.

"Ego Galilæus Galilæi abjuravi ut supra manu propria."

the ignorant zeal of the assembly of cardinals has met with universal condemnation, what must we think of the conduct of a philosopher, who, for the sake of a few years of freedom, could solemnly abjure and renounce opinions which he implicitly believed, and which he had himself established by years of incessant labour? He who has the boldness to maintain opinions in opposition to the vulgar prejudices of the age in which he lives, should have also the fortitude to bear the consequences to which they may expose him. The fame of discovering and defending truth, is in no small degree tarnished by the meanness of afterwards abjuring it; and yet the history of persecution affords more than one example of science having exposed herself to this worst of indignities.

Had Galileo maintained with firmness the truth of his doctrines, he might even have succeeded in disarming the bigotry of his enemies; and if he failed in this, he would have at least secured the approbation of future ages. The truth of the Copernican system was at that time admitted by numerous distinguished and pious individuals, and there were many members even of the Catholic church who found no difculty in reconciling it with the apparently opposite language of scripture. It is a curious fact, which has not been noticed in any of the lives of Galileo which we have seen, that, during the first persecution of Galileo in 1615, or rather before it, an illustrious Neapolitan nobleman, Vincenzio Caraffa, had requested the opinion of Paul Antony Foscarinus, a learned Carmelite, respecting the Pythagorean and Copernican doctrine of the mobility of the earth. In his letter upon this subject, he reconciles the various passages of scripture with the new system, which he considers as well founded. He notices, with praise, the opinions of Galileo and Kepler; and he dedicates his epistle to the chief of the order of the Carmelites. This learned epistle was dated at Naples on the 6th January 1615, and was printed by permission at Florence on the 11th September 1630, three years before the second persecution of Galileo.

When we consider, therefore, that the new system had been promulgated more than a century before the time of Galileo, by Copernicus, who was himself a Roman Catholic clergyman; that the book which contained it was dedicated to the Pope himself; that the Copernican doctrines were embraced by Roman Catholic bishops and cardinals; and that they were maintained with impunity in Italy by some pious Catholics, at the very time when Galileo defended them; we can scarcely hesitate to believe, that Galileo had been a habitual and marked enemy of the Catholic faith, and that the inquisition had seized the opportunity of punishing him for his astronomical opinions, when they were irritated only at his irreligious sentiments.*

Through the influence of some distinguished individuals at Rome, Pope Urban VIII. softened the rigour of the sentence, and confined him for a while to the palace of the Garden de Medici at Rome. On account of his state of health, Galileo was allowed to leave Rome; and as the plague then raged at Florence, he was sent to the archiepiscopal palace at Sienna, the residence of the Archbishop Piccolomini, where he continued the prosecution of his studies, and demonstrated the propositions respecting the resistance of solids. After remaining about five months at Sienna, when the plague at Florence had disappeared, he was allowed to retire to his villa at Bellosguardo, and afterwards to that at Arcetri, in the neighbourhood of Florence, where he spent the remainder of his life.

In this tranquil spot, he observed the phenomena of the moon's libration, he continued his observations on the motions of Jupiter's satellites, and he proposed a new method of finding the longitude at sea, by observing on different meridians the frequent eclipses of these secondary planets. This important subject had occupied his attention before the year 1615, and the secretary of state to Cosmo Grand Duke of Tuscany, had communicated the invention to the Tuscan Ambassador at Madrid, for the information of Philip king of Spain; † but no attempt seems to have been made by the Spanish government to adopt it in their navy. Galileo, however, persuaded of its practicability, offered the use of his discovery to the States General of Holland, through Grotius ambassador to the Queen of Sweden, at Paris. The negociation with the States of Holland was carried on by M. Diodatus, a celebrated French lawyer. The States General eagerly embraced the proposal, and returned a polite letter in answer to Galileo's offer, accompanied with a golden chain as a testimony of their gratitude. Four of the most distinguished Dutch navigators, astronomers, and geographers, were appointed as a committee to examine both the theory of the new method, and the proposal which Galileo had made of a method of diminishing the agitation of a ship, for the purpose of observing the eclipses of Jupiter's satellites. Martin Hortensius, a mathematician at Amsterdam, and William Bleau, a geographer, and both members of the committee, were appointed commissioners to visit Galileo, and receive instructions from him respecting the theory and practice of his discovery. When they arrived at Arcetri, they had the mortification to find that Galileo had recently been deprived of his sight. He communicated to them, however, his views respecting the determination of the longitude, and occupied his hours of study in computing tables of the motions of the satellites of Jupiter. We are not distinctly informed what was the result of this interview; but astronomical instruments were then in an imperfect state, and Galileo's method, though admirable in itself, could be of no practical use, till the eclipses of the satellites could be computed from accurate Tables of their motions.

In the year 1636, when the Count de Noailles, the French ambassador at Rome, was returning to Paris, he paid a visit to Galileo at Arcetri, with whom he had formerly corresponded. Galileo presented him with a manuscript copy of his great work, entitled, *Discursus et Demonstrationes Mathematicæ circa duas novas Scientias pertinentes ad Mechanicam et Motum Localem.* The Count de Noailles shewed this work to several of the philosophers at Paris, and actually sent it to be printed by the Elzivirs at Leyden. Galileo was just preparing to send manuscript copies of the work into Germany, Flanders, England, Spain, and perhaps into some parts of Italy, ‡ when he received a letter from the Elzivirs, stating that the Count de Noailles had put the MS. into their hands, and requesting him to transmit a dedica-

* See our Life of Copernicus, where we have stated some additional reasons for this opinion.

† This correspondence is published in the *Opere di Galileo*, vol. ii. p. 435.

‡ Galileo mentions this fact in the dedication of this work to the Count of Noailles. His hesitation about sending MS. copies into Italy is curious: "et forsan," says he, "in loca quædam Italiæ."

Galileo.

tion as soon as possible. Galileo was delighted with this plan, and drew up, in the most flattering terms, a dedication to the Count, which is dated at Arcetri, March 6th, 1638. This work contains some of his finest discoveries. The doctrine of motion is treated ably and geometrically. The theory of equable motions, and of motions uniformly accelerated and retarded, and of these two combined, is correctly explained. Galileo had the honour of first demonstrating, that the spaces described by heavy bodies are as the squares of the times, and that all projectiles move in a parabolic orbit. He also laid the foundation of the subject of the strength of materials, and treated with much perspicuity the doctrine of the force of percussion.

The last days of Galileo's life were spent in the investigation of the force of percussion, and some other mechanical subjects; and, in consequence of the intensity of his application, he brought on a slow fever, and a palpitation of the heart, which carried him off on the 8th of January 1641, in the 77th year of his age. The death of this great man was universally regretted, and the sciences were considered as having sustained an irreparable loss. His body was carried from Arcetri to Florence, and at the desire of the Grand Duke of Tuscany, he was buried in the church of the Holy Cross, in the ancient sepulchre of the noble family of Galilei.

The most complete edition of Galileo's works, was published at Padua in 1744, in 4 vols. folio. This edition contains numerous annotations, and long commentaries, by several of his disciples. The following is a list of its contents, excluding the commentaries which we have mentioned:

Tom. I. Le Operazione del compasso Geometrico, e militare di Galileo.

Difesa di Galileo contro alle calunnie ed imposture de Baldassar Capra Milanese.

Discorso intorno alle cose, che stanno in su l'Acqua, o che in quella si muovono, di Galileo.

Lettera di Galileo al Sig. Tolomeo Nozzolini.

Della Scienza Meccanica, opera del Galileo con un frammento sopra la forza della Percossa.

La Bilancetta di Galileo.

Trattato del modo di misurar colla vista di Galileo.

Tom. II. Sidereus Nuncius.

Comtinuazione del Nunzio Sidereo.

Istoria e dimostrazioni intorno alle macchie solari, e loro accidenti, comprese in tre lettere scritte al Marco Velseri da Galileo.

Il Saggiatore di Galileo..

Lettera di Galileo al serenissimo principe Leopoldo di Toscana in proposito di quanto discorre Fortunio Liceti del candor Lunare nel cap. 50 del suo Liteosfero.

Lettera di Galileo al (P. Cristoforo Griemberger della Compagnia di Gesu in materia) della montuosita della Luna.

Lettera di Galileo a Monsignor Dini sopra l'uso del Canochiale, e di Pianeti Medicei.

Risposta di Galileo ad un problema propostogli dall' illustrissimo Sig. Pietro Bardi de'Conti di Vernio, *onde avvenga, che l'acqua a chi v'entra appaja prima fredda, e poi calda più dell'aria temperata.*

Lettere di Galileo in proposito de trovare le longitudini per via de Pianeti Medicei, coll'aggiunta d'altre lettere scritte al Galileo intorno alla medesima materia.

Operazioni Astronomiche di Galileo.

Trattato della Sfera, o cosmographia di Galileo.

Lettere di Galileo a Paolo Gualdo, &c.

Tom. III. Dialoghi delle Scienze Nuove, o sia discorsi e dimostrazioni intorno a due nuove scienze attenenti alla Meccanica ed ai movimenti locali di Galileo.

Galileo || Galls.

Lettere di Galileo circa le materie trattate nei dialoghi delle scienze nuove.

Lettere di Galileo, e del P. Castelli del modo di misurare le gocciole d'acqua cadenti sopra una data superficie.

Lettere di Galileo a Curzio Picchena, nelle quali tratta della Calamita.

Lettera di Galileo sopra il Fiume Bisenzio.

Lettere di Galileo, del P. Castelli, e del Nozzolini in proposita della stima d'un Cavallo.

Frammenti di Galileo.

Parere di Galileo intorno all angolo del Contatto.

Postille di Galileo al libro intitolato *Esercitazioni Filosofiche di Antonio Rocco.*

Considerazione di Galileo sopra il Gioco de'Dadi.

Problemi Vari di Galileo.

Pensieri Vari di Galileo.

Tom. IV. Diologo de Galileo delli due massime Sisteme del Mondo, Tolemaico e Copernicano.

For a particular account of the discoveries of Galileo, we must refer our readers to the articles Astronomy, p. 59, 612, 613; Carpentry, p. 500; Dynamics, p. 285; Epicycloid, p. 179; Mechanics, Optics, and Pneumatics. (β)

GALILEO's Temperament of the musical scale. In the Overend MS. works in the library of the Royal Institution in London, vol. i. p. 135, the temperaments of the principal notes in the scale, in fractions of the major comma, as mentioned in the second column of the subjoined Table, are ascribed to the above author, viz.

1	2	3	1	2	3
C	VIII		F※	IV	$-\frac{5}{7}c$
B	VII $-\frac{10}{7}c$	$-\frac{1}{7}c$	F	4 $+\frac{2}{7}c$	$+\frac{2}{7}c$
B♭	7	$+\frac{4}{7}c$	E	III $-\frac{8}{7}c$	$-\frac{1}{7}c$
A	VI $-\frac{6}{7}c$	$+\frac{1}{7}c$	E♭	3 $+\frac{6}{7}c$	$-\frac{1}{7}c$
G※	6 $+\frac{8}{7}c$	$-\frac{16}{7}\Sigma$	D	II $-\frac{4}{7}c$	$-\frac{4}{7}c$
G	V $+\frac{2}{7}c$	$-\frac{2}{7}c$	C※	I	$-\frac{7}{7}c$

But these would produce an extremely irregular douzeave, as appears from the third column, containing the temperaments of a regular douzeave, calculated by Mr Farey's theorems, *Philosophical Magazine*, vol. xxxvi. p. 51, and agreeing very nearly with Dr R. Smith's system of equal harmony. (ϱ)

GALLS, is the name given to morbid excrescences growing on different plants, in consequence of the attacks chiefly of hymenopterous insects. The egg of the insect is deposited in a puncture made with a sharp sting; and when it is hatched, the maggot causes a great degree of luxuriance in this part of the plant, which appears in various excrescences. Galls are found in the two British species of oak. The astringent galls brought from the Levant, and used in dyeing and making ink, are also the produce of a particular species of oak. The best Aleppo galls have generally a bluish, and sometimes a greyish and blackish colour, inclining to bluish. They are of a close compact texture, are difficult to break, and are unequal and warty on the surface. The small, white, and broken galls are by no means good. About 2000 cwt. of galls are annually used in Great Britain, the value of which, at £6 per cwt., is £12,000. The permanent duty upon them is 7s. and the war duty 2s. 4d.

The following Table, given by Mr Milburn, shews the quantity of galls sold at the East India Company's sales, from 1804 to 1808, with their prices.

Years.	March Sale.		Sept. Sale.		Total.		Aver. Price per Cwt.		
	Cwt.	Price.	Cwt.	Price.	Cwt.	Price.	L.	s.	d.
1804	330	£2006	51	£362	381	£2368	6	3	9
1805	71	559	594	3666	665	4225	6	7	0
1806	137	805	186	1167	323	1972	6	2	1
1807	1036	6611	131	665	1170	7276	6	4	4
1808	655	3673	321	1721	976	5394	5	10	6

Twenty cwt. of galls are allowed to the ton. See Olivier's *Travels in Persia*, and the articles Dyeing, p. 243; Ink, and Vegetable Physiology; and Milburn's *Oriental Commerce*, vol. i. p. 137.

GALLE, Point de, is a town in the island of Ceylon, being the third in point of size, built upon a long rocky promontory. The fort is about a mile and a half in circuit, and is situated upon a neck of land, and almost surrounded by the sea. The works are extensive and strong, but it is overlooked by some adjacent eminences. The rooms are large and bricked, the walls are thick, and the ceilings boarded. The houses in the fort are spacious and comfortably furnished. That of the commandant is very extensive. The Europeans live chiefly in the fort, but there are some good large houses built about it, and extending along the shore to the southward. The Cingalese live in cottages and hamlets scattered about in all directions. The houses both in the town and at the harbour are better than those of Trincomalee. The fort is garrisoned by two or three companies of Europeans; half a company of artillery, and a native battalion. The numerous batteries completely command the approach by water. They are in the old fashioned style, elevated on walls. The harbour, particularly the outer road, is spacious, and, excepting in a south-west wind, the inner harbour is secure. The entrance to it is narrow. The part of the bason which is land-locked is very small, but it secures a landing free from surf, which, according to Lord Valentia, beats with prodigious violence on the rocks that form the extreme end of the peninsula. On one of these rocks is erected the flag-staff, which therefore stands without the fort. A canal has been dug between the bay and a small river, for the purpose of conveying timber from the interior. It is, however, now in ruins. "We had here," says Lord Valentia, "excellent yams, good sallading, and cucumbers. The fruits were bad, mangoes, guavas, custard apples, cocoa nuts, varieties of oranges, some of which were black on the outside, and others the true mandarin, shaddocks, &c. The mutton is indifferent; but the beef, the poultry, the bread, and the fish are excellent. At Galle is a neat manufacture of tortoise shell." The coast and the surrounding country is very mountainous. The greatest quantity of rain falls between November and February. Arrack, oil, pepper, cotton, and cardamoms, are among its exports. East Long. 80° 20′, and North Lat. 6° 4′. See Percival's *Account of Ceylon*, and Valentia's *Travels*, vol. i. p. 266.

GALL, St, is the name of a town in Switzerland, and the capital of a canton of the same name. It derives its name from the ancient abbey of St Gall, situated within the walls of the town. The town is situated between two mountains, upon the small brook of Steinach. The seat of the cantonal government is in the chateau of the abbey. The Catholic clergy inhabit the monastery, which contains the library of the convent, now the library of the canton. It contains very valuable manuscripts relative to the history of the middle ages. The town library, which contains that of Vadianus, is kept in the college, which was founded in 1598. The collection of Vadianus contains many precious manuscripts, among which is a chronicle comprehending 13 folio volumes of letters of the most celebrated Swiss and German reformers. This library also possesses a cabinet of petrifactions, collected in the neighbouring country. There is a good collection of paintings and prints in the house of M. de Gonzenbach, and a cabinet of natural history in that of Doctor Zollikofer.

St Gall has always been celebrated as a manufacturing town. In the 13th century, great quantities of linen cloth were manufactured here, and at the epoch of the Council of Constance, 1414—1418, such crowds of workmen from that city settled in St Gall, that it became necessary to enlarge the town. The principal articles of manufacture, are linen goods, muslin, and cotton cloth. The inhabitants of Swabia, and of the mountains of Breghentz, were employed in spinning and embroidery by the manufacturers of St Gall; and towards the end of the 18th century, the number of embroiderers amounted to 30,000 or 40,000. The price of a piece of muslin richly embroidered in gold or silver, sometimes amounted to 60 Louis. The muslins embroidered in white are generally fabricated out of the town in the cottages of the forest of Breghentz. About the beginning of the present century, spinning machines, like those used in this country, were erected in St Gall, and in a few years a great number of these machines were in full activity, in consequence of the exclusion of English manufactures from the continent. All the environs of St Gall are covered with bleachfields.

The most interesting promenades and prospects at St Gall, are near the convent of Notkerseck; at Vogliseck, about a league from the town; at the Chateau of Warteck, from which there is a view of almost all the lake of Constance; and at the Chateau of Dottenwyl. The bridge of St Martin is well worthy of attention. It is built over a wild gorge upon the Goldach. It is the work of Hungewerk, and is constructed upon the same principle as the famous bridges of Schauffhausen, Wettingen, and Reichenau. Population of the town 9,000.

GALL, St, *Canton of*, one of the largest cantons of Switzerland, extends from the lake of Constance to that of Zurich, and almost to Kunkelsberg on the confines of the Grisons. It contains forty square geographical miles, or nearly 111 square leagues. Independently of the capital, it has nine towns and 15 convents, of which 11 are female ones. In the districts of *Sargans*, *Utznach*, *Upper Tockenbourg*, and *Rhinthal*, which contain mountains from 7000 to 8000 feet high, the people are principally employed in rearing cattle. In the other districts, viz. that of *St Gall*, *Gossau*, *Lower Tockenbourg*, and *Roschach*, there are many fine hills and cultivated mountains, with vallies covered with corn fields, vineyards and orchards. The canton of St Gall contains a small portion of the lakes of Zurich and Constance, the greater part of that of Wallenstadt, and some small lakes situated in the Alps. It has 10 rivers, viz. the Rhine, the Tamin, the Saar, the Seez, the Linth, the Thour, the Necker, the Glatt, the Sitter, and the Steinach. Population in 1803, 130,301, of whom nearly one half are Catholics.

GALLICIA. See Galicia.

GALLIC Acid. See Chemistry, p. 61.

GALLIPOLI, from καλλος *beautiful*, and πολις *a city*, a town of Italy, in the kingdom of Naples, and province of Otranto, is built upon a rock connected with the continent by a long bridge. It is situated at the heel of the boot, at the very extremity of the kingdom. The town, which is well built, is hollowed out below into subterraneous vaults for containing the oil, which forms the staple trade of this town. The country near Gallipoli furnishes enough of corn, wine and fruits, for the consumption of the inhabitants; and muslin and other articles are manufactured out of a species of cotton which is raised. The duty of export upon the oil is fully 40 per cent. as the king receives five carlins of oil out of every last, which consists of 12 or 13 carlins. The oil, when placed in the subterraneous vaults already mentioned, is purified and bettered in its quality by fermentation, which is occasioned during summer; but this produces in these vaults a heat which is almost unsupportable. In the year 1766, there was exported from Gallipoli to the other parts of the kingdom, 1395 lasts of oil, and out of the kingdom 17,323 lasts; besides 43 cantari of spun cotton, and 247 cantari of cotton wrought in different ways. Briganti reckons the average export of oil at 993,804 Neapolitan ducats. Population 8,000. East Long. 15° 58′, North Lat. 40° 29′.

GALLIPOLI, is the name of a seaport town of Turkey, in the province of Romania. It is situated on the Sea of Marmora, on a peninsula which has two harbours, one on the south and the other on the north. The Bazar is a fine edifice, with several domes covered with lead. The adjacent territory abounds in grain, wines, fruits, and particularly in excellent melons. There is plenty of deer, hares, patridges, and ducks. The cotton collected in the neighbourhood is inferior to that which comes from Smyrna and Salonica. Wool of different kinds, and excellent wax, brought from the different countries on the Black Sea, are shipped in the harbour of Gallipoli. Population about 10,000 Turks, 3,500 Christians, and a smaller number of Jews. East Long. 26° 37′ 30″, and North Lat. 40° 25′ 33″.

GALLON. See MEASURES.

GALLOWAY, the name of a district in Scotland, comprehending the shires of KIRKCUDBRIGHT and WIGTON, which see.

GALVANI, LEWIS, a physician and physiologist, whose name has obtained a very unusual degree of celebrity, in consequence of his having discovered the rudiments of a new branch of science, which was called after him, Galvanism. The history of this discovery will be detailed in the following article; at present we shall confine ourselves entirely to the biographical events of his life. He was born at Bologna in 1737, and was a member of a respectable family in that city, several of whom had distinguished themselves in the exercise of the professions of law and divinity. From his early youth he appears to have been of a serious and devout turn of mind, and it is said that he was so much attached to the discipline of the Romish church, as to have resolved to enter into one of the monastic orders. He was, however, dissuaded from this resolution, and he engaged in the study of medicine, and the collateral branches of natural philosophy. In the course of his education, he became a domestic pupil of Professor Galeazzi, and he so endeared himself to the family by his amiable disposition, that he formed a matrimonial connection with the professor's daughter. This lady seems, from all accounts, to have been distinguished both for her virtues and her talents; Galvani bore the tenderest regard for her; and when in the year 1790 she died, after a long series of ill health, it threw him into a state of melancholy from which he scarcely afterwards recovered. It appears that the discovery, which gave so much celebrity to his name, was, in some measure, due to the sagacity of Madam Galvani, for the original phenomena were noticed by her in the absence of the professor, and were reported to him as something that deserved his particular attention.

In the year 1762, he took his medical degree at Bologna, and wrote a thesis on the subject of the bones, shortly after which he was appointed a public lecturer both in the University and in the Institute of that city. He is said to have been particularly happy in his manner of lecturing, and to have acquired a high reputation as a diligent cultivator of the science of comparative anatomy. His reputation in these departments was, however, confined to his native country, and he was little known to the rest of Europe, when in the year 1792 he published a work which immediately brought him into general notice. It was entitled, *A Commentary on the Powers of Electricity in Muscular Motion*; it contained an account of his discoveries on the effects of electricity in producing the contraction of the muscular fibre, and the hypothesis which he adopted to explain its action. His opinion that the electricity in these cases was inherent in the animal body, and was excited without the aid of any external cause, is now generally thought to be incorrect, and indeed the discoveries that have been since made have so extended the science, that the original treatise can now be regarded as valuable, merely because it presents the first sketch of those facts, which have been since developed in so surprising a manner.

Galvani's philosophical pursuits do not appear to have engrossed all his time, for he continued to exercise his duties both as a public lecturer and a medical practitioner, with great assiduity; he also devoted a portion of his leisure to the society and correspondence of literary men, in which he appears to have taken much interest. His domestic happiness, as we have related above, received a very severe shock from the death of his wife, and he was afterwards called upon to exercise his fortitude in a different way, when he manifested a degree of firmness, which must be regarded as highly praiseworthy, even although we may conceive it to have been carried beyond the necessary limits. In the new division of Italy, which took place after the conquests of the French, the city of Bologna was included in the Cisalpine Republic; and all the public functionaries were required to take the oath of allegiance to the new government. This, however, he refused, as is supposed, in consequence of the irreligious character of the principal leaders in France at that time, and he was accordingly stripped of his offices and emoluments. In this emergency, much dejected in his spirits, and probably reduced to a state of pecuniary embarrassment, he was received into the house of a near relation, and fell into a state of extreme weakness. Upon these circumstances being made known to the government, they appear to have felt a degree of regret, for their harsh behaviour towards a man, who had so many claims to respect, both from his private virtues and his public labours, and a decree was passed for restoring him to his honours and emoluments. But his frame was too much exhausted to derive any benefit from this favourable change in his prospects, and he died towards the conclusion of the year 1798, in the 61st year of his age. See *Eloge de Galvani*, par Alibert. (α)

GALVANISM.

Introduction.

Galvanism is a branch of natural philosophy, which has originated within the last twenty-five years, and derives its name from Galvani, professor of anatomy at Bologna. He had the good fortune to make some observations on the electricity of the muscles of frogs, that appeared to him to depend upon a new power in the animal body; and although it is now generally admitted, that he drew an erroneous inference from his observations, yet they led to a train of experiments, which have associated his name with some of the most brilliant discoveries of modern science. To the supposed new power he gave the name of *animal electricity*; conceiving it to depend upon something inherent in the animal body itself; but we now regard these effects as produced by minute quantities of the electric fluid, set at liberty by a certain agency of substances upon each other.

Definition.

Galvanism may be defined, a series of electrical phenomena, in which the electricity is developed without the aid of friction, and where we perceive a chemical action to take place between some of the bodies employed.

Plan of the article.

In treating upon this subject, we shall arrange our materials into two divisions. We shall begin by an historical detail of the discoveries that have been successively made, from the time of Galvani's first observation, to the present period; and, in the second place, we shall give an account of the theories and hypotheses that have been formed to explain the phenomena of galvanism.

Part I. HISTORY.

History.

Sect. I. *Experiments before the Discovery of the Pile.*

Galvani's first discovery.

The original discovery, to which we have already alluded, took place from a singular accident. The wife of the philosopher, being in a declining state of health, employed as a restorative, according to the custom of the country, a soup made of frogs. A number of these animals, ready skinned for the purpose of cookery, chanced to lie in Galvani's laboratory, on a table near the electrical machine. While the machine was in action, an attendant happened to touch, with the point of a scalpel, the crural nerve of one of the frogs, that was not far from the prime conductor, when it was observed, that the muscles of the limb were instantly thrown into strong convulsions. This experiment was performed in the absence of the Professor, but it was noticed by his lady, who was much struck with the appearance, and communicated it to her husband. He repeated the experiment, varied it in different ways, and perceived that the convulsions only took place when a spark was drawn from the prime conductor, while the nerve was, at the same time, touched with a substance which was a conductor of electricity. At the time that this accidental discovery was made, Galvani was engaged in a set of experiments, the object of which was to prove, that muscular motion depends upon electricity; and it appeared, in a very remarkable manner, to confirm his hypothesis; so that he was induced to prosecute the inquiry with redoubled diligence. See *Eloge de Galvani*, par Alibert.

Prepared frog a very delicate electrometer.

When a frog was so placed as to form part of the electric circuit, it was found that an extremely minute quantity of electricity produced contractions in the muscles. If the hind legs were dissected from the body, the connection being kept up by the crural nerves only, and the electric fluid was passed through it in this state, a still more minute quantity was rendered visible; so that a frog, prepared in this manner, was capable of exhibiting very decisive marks of electricity, where none could be detected by Bennet's gold-leaf electrometer.

Discovery of proper galvanism.

After employing the electric fluid, as disengaged from the common machine, he next tried the atmospherical electricity; and it was in pursuance of this object, that he was first led to observe the effects of galvanism properly so called. Having suspended a number of frogs by metallic hooks to an iron railing, he found that the limbs were frequently thrown into convulsions, when it did not appear that there was any electricity in the atmosphere. Having duly considered this phenomenon, he discovered that it did not originate from an extraneous electricity, but that it depended upon the position of the animal, with respect to certain metallic bodies.

Action of two metals.

It appeared, that when the muscle and nerve of a frog were each in contact with metallic bodies, and these were also connected by a metal, the contractions were always produced. The effect was considerably increased by *arming* the nerve with a metallic coating, by which means a larger portion of it was brought into contact with the metal. But the most important of Galvani's discoveries was the effect produced by the combination of two metals. Of these combinations the most powerful was that of zinc and silver, and the most violent convulsions ensued when the nerve was coated with one of these metals, the muscle placed in contact with the other, and the two metals connected by a conductor of electricity.

Plate CCLXIII. Fig. 19.

General conclusions.

Galvani's general conclusion from his experiments was, that the animal body possesses an inherent electricity of a specific kind, which is connected with the nervous system, and conveyed by means of the metals into the muscles, so as to throw them into convulsions. He deduced a theory of muscular motion from his discoveries, according to which the body contains an apparatus analogous to the Leyden phial, the muscles and nerves being in different states of electricity, and the metals forming a connection between them, by which the electricity is equalized. In this application of the new phenomena, Galvani went beyond the limits of correct deduction; yet he deserves much commendation for the perseverance and ingenuity which he exhibited in prosecuting the inquiry. Although the discovery originated, in a considerable degree, from accident, still it must be remembered, that it is only men of ability who take advantage of such accidents. In the year 1792, he published an account of his discoveries and theories, under the title of *A Commentary on the Powers of Electricity in Muscular Motion.*

History.

Valli's letters, 1792.

Galvani had no sooner published an account of his discovery, than the philosophers, in different parts of Europe, entered with eagerness upon the examination of the new phenomena. The earliest writers on the subject were Valli, Fowler, and Volta. The principal object of Valli's letters, which appeared in the *Journal de Physique*, was to examine how far the opinion of Galvani was correct, respecting the dependence of the new influence upon the nervous fluid, and its identity with electricity. Although much of his reasoning must now be regarded as erroneous, yet still he displays considerable ingenuity and address in the contrivance of his experiments, and in the inferences which he deduced from them.

Fowler's Essay on Animal Electricity, 1793.

In the following year, Dr Fowler published an *Essay on Animal Electricity*, in which he displays an acute and sagacious mind, and may be considered, by his observations, to have paved the way for many of the discoveries of his successors. At the time when he wrote, the question was warmly agitated, whether the phenomena of galvanism could be referred to the electric fluid, or whether they do not depend upon some specific agent peculiar to the animal body. He commences by the inquiry, "Are the phenomena exhibited by the application of certain different metals to animals referable to electricity?" Although he conducts his train of reasoning with much ability, yet he drew the conclusion which we are now enabled to say is not correct. After examining minutely the circumstances which are necessary for the production of the galvanic influence, he finds that it is requisite that there should be two different metals, which are to communicate with each other and with the animal. He conceives it necessary that they should be in contact, one with the nerves, and the other with the muscles, and points out an error, into which Valli had fallen in his experiments, where he thought that the contact of the nerve only is sufficient to cause the contractions: he shews that, in this case, the moisture on the surface of the nerve acted as a conductor of the influence of one of the metals to the fibres of the muscle.

Are galvanism and electricity the same?

Dr Fowler concludes that the galvanic influence is not referrible to electricity, because for the production of the former, the presence of two different metals appears to be necessary, while electricity, as proceeding from the electrical machine, is excited by the action of an electric upon a conductor; an inference which was correct, according to the state of the science at the time when he wrote. He also endeavours to show that electricity and galvanism are not, in all cases, conducted by the same substances, and particularly adduces charcoal, which, although a conductor of electricity, is impervious to the galvanic influence. He afterwards made some curious observations upon the effect of galvanism on animals not furnished with distinct limbs, such as worms of various kinds. These animals could not be made to contract, yet by the nature of their motions, they seemed to be sensible to the impression of the two metals, when they were placed, partly on one, and partly on the other.

Effect on the voluntary and involuntary muscles.

Dr Fowler afterwards enters upon an interesting inquiry respecting the effect of galvanism on the different parts of the body. "What are the relations which subsist between the influence discovered by Galvani, and the muscles, the nervous, and the vascular systems of animals?" He found that the contractions were very readily excited in all the muscles which are subservient to the will, but that they were with great difficulty produced in the heart, and that they could not be rendered perceptible in the stomach and intestines. He observed that when a part is in a state of inflammation it acquires an additional sensibility to the galvanic stimulus, and he made the curious discovery of the flash of light, which is produced by placing the two metals in contact with the ball of the eye, and then causing them to communicate with each other. Sultzer, a German metaphysical writer, had mentioned several years before, the effect produced on the organ of taste, by applying two metals, one above and the other below the tongue, and then bringing them into contact; but the sensation was ascribed to a peculiar vibration excited by the metals, and conveyed to the tongue. The experiments with the two metals, upon the eye and the tongue, were varied in different ways by Professor Robison, an account of which is published at the end of Dr Fowler's *Essay*. Professor Robison mentions the sensation of taste which is excited, when the tongue is applied to the edges of a number of plates of zinc and silver, placed alternately upon each other; a construction which may be regarded as an approximation to the apparatus afterwards discovered by Volta.

Effect on the eye and tongue.

Robison's experiments.

Volta's letters, 1

In the same year in which Fowler's *Essay* was published, a very important communication appeared in the Philosophical Transactions of London, from the pen of Volta, in the form of letters to Cavallo. He gives a luminous account of Galvani's discovery, and adds many curious experiments and valuable remarks of his own. He attempted, and with complete success, to overthrow Galvani's opinion, that the animal body bears an analogy to the Leyden phial, the nerve and the muscle being in opposite states of electricity. He found that for the production of the effect it was essential to have two different metals, and hence he arrived at the important conclusion, which may be regarded as leading to all his future discoveries, that the muscular contractions are produced by small portions of electricity, that are liberated by the action of the metals upon each other. Another point which Volta established was, that the nerve is the organ on which the galvanic influence immediately acts; but he found that if a part of a muscle be laid upon two different metals, and these be made to communicate, a contraction is produced. This probably depends upon the nervous matter that is dispersed through the muscles, and also upon the moisture that is always present, and which serves to conduct the electricity to all parts of the body. Volta performed many experiments in order to discover, what circumstances are favourable to the excitation of the contractions, and upon the parts of the body which are the most easily called into action. His observations agree, in many respects, with Fowler's, although it is certain that their experiments must have been made without concert or communication. He found that snails and worms could not be made to contract, but that many of the insects, as butterflies and beetles, were subject to the influence of the metals. It appeared from his numerous trials, that those animals alone were sensible to galvanism, who are furnished with distinct limbs, having flexor and extensor muscles. In the animals of this description, it appeared that it was the voluntary muscles alone which are capable of being made to contract. Although the heart is a muscle which is easily thrown into powerful action, by chemical or mechanical stimuli, yet he could never produce any effect upon it by the action of the two metals. Volta made some of the same observations upon the effect of the two metals on the organs of sense, as have been mentioned in our abstract of Fowler's *Essay*.

History. Dr Wells's paper, 1795.

Dr Wells wrote an interesting paper on galvanism, which was also published in the Philosophical Transactions of London He proposed three distinct objects of inquiry, which, at the time when he wrote, embraced the points that were the most general subjects of discussion. He first inquires, whether the influence discovered by Galvani depends upon any property inherent in the animal body, or peculiar to it. In the second place, he inquires into the conditions that are necessary for its excitement: And lastly, he examines how far it ought to be considered as identical with electricity. Dr Wells coincides in opinion with Volta, that the contractions of the muscles depend upon electricity liberated by some cause, independent of the animal body, and that the moisture, which is present in all parts, is the immediate cause of the facility with which the effect is produced. He discovered the important fact, that charcoal may be employed, together with one of the metals, for exciting the influence; and also that the influence, when excited, may be conducted by charcoal. He argues at length against the hypothesis of Volta, respecting the production of the electricity by the contact of the two metals, and urges as a decisive objection to it, that the moisture which is attached to the animal, ought to serve as a conductor, and equalize their electrical condition, without their being absolutely brought into contact.

Dr Wells made some curious experiments upon the effects that were produced on the power of the metals and on charcoal by friction; after this operation he found that one of the substances alone was sufficient to produce the contractions. As it appeared that the friction did not immediately communicate electricity to the body that was rubbed, it must be supposed, that some change was brought about in its nature, by which its different parts were enabled to act upon each other, in the same manner with two distinct substances. He is decidedly of opinion, that galvanism is identical with electricity, because every substance which is a conductor of one of these principles, is also a conductor of the other.

Committee of the French Institute, 1798.

A very ample and elaborate memoir, on the subject of animal electricity, was drawn up by a committee of the French Institute, which, besides examining all the opinions and controversies that existed on the subject, contained an account of a great variety of original experiments. The committee was composed of some of the most celebrated chemists and natural philosophers of France; Guyton, Fourcroy, Vauquelin, Hallé, Coulomb, Sabbatier, Pelleton, and Charles. They arrange the materials of their report under six heads; 1. They examine the different circumstances which influence the nature of what they call the animal arc, by which they mean, that part of the galvanic circle which consists of the parts of the animal. They conceive that the animal arc may consist of nerve only, but in this opinion it is probable that they were mistaken. They found that cutting a nerve across did not prevent the passage of the influence, provided the cut ends were laid close together, and also that it was transmitted through different parts of the same animal, or even through parts of different animals, provided they were in perfect contact. They observe, that when a nerve is made part of the circle, those muscles are thrown into contractions to which the extremities of the nerve are distributed, not those which are contiguous to the trunk of the nerve. In the 2d place, they examine the nature and disposition of what is called the excitatory arc, or the metallic part of the circle. 3d, They inquire into the circumstances which enter into the action of the galvanic circle, and in any way influence its effect. The 4th head consists of the means which may be employed for varying, diminishing, or restoring the sensibility of the animal to the galvanic influence. In this part, they mention the effects of immersing the animal in a fluid, or in an unrespirable gas, so as to produce suffocation, when the susceptibility to the galvanic influence was either destroyed or much impaired; but the effects were very various, and difficult to account for in many cases. The 5th head consists of a comparison between electricity and galvanism; and the 6th contains a detail of some experiments which were performed by Humboldt, and subjected to the inspection of the committee. Many of Humboldt's experiments were curious and interesting; but they appear not to have been, in all cases, very accurate; for he concludes from them, that some substances, which were good conductors of electricity, would not conduct galvanism. See *Annales de Chimie*, xx. 51.

Humboldt's experiments.

Fabroni's paper, 1799.

An ingenious paper was about this time published by Fabroni, in which he discusses the question, whether the galvanic phenomena are immediately referrible to electricity, or whether they ought not rather to be attributed to chemical affinity? He relates many observations, that he made upon the chemical action of different metals on each other, when placed in contact, and shows, that they were then disposed to oxidate under the same circumstances, except that of being in contact, where, if separate, no effect would have been produced. He argues, that the facts stated by Galvani, Volta, and others, which were conceived by them to prove the electrical nature of the phenomena in question, only went so far as to shew, that electricity was concerned in the operation, but did not prove it to be the cause of them; and he is inclined to regard it rather as the effect.

Fabroni mentions among other facts, that mercury and tin when pure, and kept distinct from other metals, will remain a long time without tarnishing, but when alloyed, or kept in contact with other metals, they soon begin to exhibit signs of oxidation. He remarked, that coins composed of a pure metal were more durable than such as were composed of a mixture of metals. He mentions the corrosion which takes place, when copper roofs are soldered with another metal, and in the copper sheathing of ships when fastened with iron nails. These phenomena are supposed to depend upon a chemical affinity between the metals, by which their particles are individually attracted towards each other, while the separation of the particles of the solid metal, which is caused by their tendency to unite, permits the oxygen to act upon them. "These facts," he says, "as well as many others of the same nature, no less common than well known, ought to have proved to philosophers, that the metals, by exercising their mutual attractive force, must by the same energy diminish their respective powers of aggregation; that though neither of them separately may be able to attract oxygen from the atmosphere, or from water, they may acquire that power by simple mechanical touch as they pass to new combinations."

He then relates some experiments which he performed, in order to observe the comparative effect produced, by placing metals first in separate vessels of water, then in the same vessels, but not in contact; and lastly, in the same vessels, and also in contact. In the two former cases there was no change produced, while in the latter there was a considerable degree of oxidation. He afterwards entered upon some speculations

History.

on the source of the oxygen, and he found that, by covering the water with a stratum of oil, and thus excluding the atmosphere, the process of oxidation was retarded. This fact he adduces as a powerful argument in favour of the chemical hypothesis. He concludes, that the oxygen in these cases cannot be derived from the water, because were the water decomposed there would be a liberation of hydrogen. The effect that is produced on the senses of vision and of taste, he attributes to the formation of new chemical compounds, which act in a peculiar manner upon the organs; an opinion which may be true, to a certain extent, so far as respects the tongue, but it is not easy to conceive how it could cause the flash of light which is excited in the eye by the contact of the metals. See *Journal de Physique*, xlix. 348.

Fabroni's paper did not appear to excite much attention at the time when it was published, as it directly opposed the current of popular opinion. But many of the statements have been since verified by succeeding philosophers; and when we consider that it was written before the discovery of the pile, it must be regarded as displaying much sagacity and nice observation.

In this state, the science of galvanism remained until the year 1800. It was generally admitted, that the immediate agent in producing the phenomena was the electric fluid, and that the actions exhibited by the animal body depended merely upon its extreme sensibility to small quantities of this fluid. The experiments principally consisted in different combinations of conducting substances with parts of the animal body, composing what was called the galvanic arc or circle. The chemical effects had been little attended to, except by Fabroni; and his remarks, although truly ingenious, must be regarded rather as the first glance of a series of important facts, than as constituting their complete developement.

SECT. II. *Experiments from the Discovery of the Pile to the Decomposition of the Alkalies.*

Discovery of the pile by Volta, 1800.

The second period of the history of galvanism commences with the important discovery made by Volta, of the instrument which has been called the *galvanic* or *voltaic pile*. Volta, as we have seen above, adopted the idea, that the action excited by the two metals, depended upon an alteration in their respective states of electricity, or in a destruction of its equilibrium. The effect produced by one pair of plates could only be comparatively small; but he supposed that by interposing a conductor between several pairs of plates, it might be multiplied and concentrated in an indefinite degree.

Description.

PLATE CCLXIII. Fig. 1.

He accordingly provided a number of silver coins, and pieces of zinc of similar dimensions; these were disposed in pairs, and between each pair was placed a piece of card soaked in water; and thus a pile or column was formed, in which the three substances silver, zinc, and water, existed in regular rotation. The effect of the combination fully justified the expectations of the discoverer.

Effects.

All the phenomena that had been excited by a single pair of metals were far exceeded by those of the pile, while by touching the two ends of it at the same time, it was found that a distinct shock was felt in the arms. This fully established the opinion that had been formed, and was generally adopted, of the identity of electricity and galvanism; although there were still some circumstances connected with the latter, which appeared not to be completely analogous to the usual operations of the electric fluid.

Galvanic shock.

He found, that 40 pairs of the metallic discs, with the proper number of pieces of moistened card interposed, were sufficient to produce a shock, which was very distinctly felt in the hands and arms, and that by increasing the number of pairs, the power of the pile was proportionally augmented. In order to produce the full effect, it was found necessary that two pieces of metal, either composing the extremities of the instrument, or in contact with them, should be firmly grasped by the two hands; and the shock might, in this case, be repeated for any number of times, as long as the pasteboard between the two metals remained sufficiently moist. Volta conceived, that the newly invented apparatus was analogous in its action to the electrical organ of the torpedo. The experiments that he performed with it, were almost exclusively confined to the animal body; and he appears to have entertained no idea of the important use which would afterwards be made of the pile, as an instrument of chemical analysis. It is indeed a little remarkable, that after making so curious a discovery, he should have rested there, and not have proceeded with the farther prosecution of the subject. It would be unjust not to acknowledge, in the warmest terms, the obligation under which the scientific world was laid by the discovery of Volta; but, at the same time, it must be admitted, on the other hand, that the benefit of the discovery has been obtained by others. An account of the pile was written by Volta, in the form of two letters to Sir Joseph Banks, which were published in the Philosophical Transactions of London for the year 1800.

Nicholson and Carlisle's experiments.

No sooner was the discovery of the galvanic pile announced, than the English experimentalists began their operations with it, and almost at the first trial of its effects, made some important and interesting observations. Sir Joseph Banks, on the receipt of the letters, having communicated the information to his scientific friends, a pile was formed by Messrs Nicholson and Carlisle, with which they began to repeat the experiments of Volta. They arranged the substances in the order of silver, zinc, fluid; silver, zinc, fluid, &c.: an arrangement which it is necessary to attend to, in speaking of what have been called the silver and zinc ends of the apparatus. Volta, it appears, had satisfied himself that the action of the pile was electrical, because it produced the shock; but Messrs Nicholson and Carlisle applied to it the instrument called the revolving doubler, (See ELECTRICITY, p. 526), and by this means decidedly proved it to be the case: They found, that the silver end was in the minus, and the zinc end in the plus state of electricity.

Discover[y of] the + a[nd] — states

Decompo[si]tion of w[a]ter in th[e] interrupt[ed] circuit.

In the course of the experiments, a part of the circuit between the upper and lower ends of the pile was formed by water; and it was observed, that there was a disengagement of gas, at the part where the wire came in contact with the fluid. This gas was thought to have the odour of hydrogen; and it led them to notice, with more attention, the effect produced by causing the electricity to pass through a tube of water, into the two ends of which wires were inserted, which communicated with the extremities of the pile. We shall relate this very important experiment in Mr Nicholson's own words. "On the 2d of May we inserted a brass-wire through each of two cocks, inserted in a glass tube of half an inch internal diameter. The tube was filled with new river water, and the distance be-

History. tween the points of the wires in the water was one inch and three quarters. This compound discharger was applied, so that the external ends of its wire were in contact with the two extreme plates of a pile of 36 half-crowns, with the correspondent pieces of zinc and pasteboard. A fine stream of minute bubbles immediately began to flow from the point of the lower wire in the tube, which communicated with the silver, and the opposite point of the upper wire became tarnished, first deep orange, and then black. On reversing the tube, the gas came from the other point, which was now lowest, while the upper, in its turn, became tarnished and black."—"The product of gas, during two hours and a half, was two-thirtieths of a cubic inch. It was then mixed with an equal quantity of common air, and exploded by the application of a lighted waxed thread."

[...]l the body [...] the pile. They observed, that the same process of the decomposition of water is carried on in the body of the pile, as between the two ends of the wire in the interrupted circuit; the side of the zinc next to the fluid being covered with oxide in two or three days, and the apparatus then ceasing to act. Mr Nicholson found, that, by using metallic plates of considerably more extensive surface, no greater effect was produced in the decomposition of water, or in the violence of the shock; so that he concludes, "the repetition of the series is of more consequence to this action than the enlargement of the surface." It was now clearly ascertained, that the electricity of the silver or minus end was negative, that of the zinc or plus end positive. Although it appeared evident that there had been a decomposition of water effected by the copper wire, yet Mr Nicholson determined to render the operation more decisive, by employing a metal which was not oxidable. Platina was therefore substituted for the copper, and now gas was disengaged from both sides, and neither of the wires were tarnished. In a subsequent experiment, the wires were so managed, that the gases extricated from each side were kept distinct, and it was found that they consisted, the one of oxygen, and the other of hydrogen, and that in the proportion necessary to produce water. In some of these experiments the spark was visible (Nicholson's *Journal*, 4to, iv. 179.) Our readers will at once perceive the important views that were disclosed by the experiments related in this paper, in connexion with those performed by Mr Cruickshanks of Woolwich, of which we shall next give an account. They must be regarded as leading directly to the wonderful discoveries that have been made by means of the galvanic apparatus, as well as the theoretical deductions to which it has given rise, and which have produced almost a complete revolution in our ideas of the action of bodies upon each other.

[...]uick[...]anks's experiments.

Mr Cruickshanks confirmed the observations of Messrs Nicholson and Carlisle, respecting the actual appearance of sparks and the decomposition of water. This last process he varied in different ways. By employing the interrupted circuit with silver wires, and passing the influence through water tinged with litmus, he found, that the wire connected with the zinc end of the pile communicated a red tinge to the fluid contiguous to it; and afterwards, by employing water tinged with Brazil wood, he found that the wire connected with the silver end of the pile produced a deeper shade of colour in the surrounding fluid. Hence it appeared, that an acid was formed in the former, and an alkali in the latter case. The galvanic influence was passed through the interrupted circuit, in which the tube was filled with the solution of acetate of lead, when it was observed that the lead was separated in the metallic state, and deposited at the end of the *silver wire*, or the wire connected with the silver end of the pile, in the form of fine needles. Experiments were afterwards made upon the solutions of sulphate of copper and nitrate of silver: in this last case, he observes, "the metal shot into fine needles, like crystals articulated or jointed to each other, as in the *Arbor Dianæ*." He also succeeded in decomposing some of the neutral salts. See Nicholson's *Journal*, 4to, iv. 187.

[...]cid and [...]kali pro[...]ced in the [...]ter.

Metals revived from metallic solutions.

In a second memoir, Mr Cruickshanks paid more particular attention to the nature of the gases emitted in the interrupted circuit—to the effects of different kinds of wires—and to the influence of the fluid medium upon the decomposition of the water. Some of his most important conclusions are, that from the wire connected with the silver or copper end of the pile, whatever be its composition, if it terminate in water, the gas emitted is chiefly hydrogen; if it terminate in a metallic solution, the metal is reduced, and is deposited at the end of the wire. When the wire connected with the zinc end is formed of a perfect metal, nearly pure oxygen is disengaged; when of an oxidable metal, it is partly oxidated and partly dissolved, and only a small quantity of oxygen is liberated. When fluids contain no oxygen, they appear to be incapable of transmitting the galvanic influence; while, on the contrary, it would seem that it may be transmitted by every one which contains this element, (Nicholson's *Journal*, 4to, iv. 258.) These views of Mr Cruickshanks respecting the action of the pile were confirmed by some experiments that were performed, about the same time, by Colonel Haldane. He found that the apparatus ceased to act when it was immersed in water, or if it was placed in the vacuum of an air-pump. He found, on the contrary, that it acted more powerfully in oxygen gas, than when confined in an equal bulk of atmospheric air, while azote had the same effect as a vacuum. These circumstances led him to conceive that its action depended essentially upon the combination of oxygen, which it derives from the atmosphere. See Nicholson's *Journal*, 4to. iv. 242. 313.

Concludes that hydrogen is always emitted from one wire, from the other oxygen, or the wire oxidated.

Fluids without oxygen will not act.

Haldane's experiments.

Pile will not act without oxygen.

In the early part of his experiments, Mr Cruickshanks invented a new manner of disposing the apparatus, which has proved scarcely less important to the interests of science, than its original discovery by Volta. We allude to the method of placing the metals horizontally in a frame or trough, with proper intervals for containing the fluid which is intended to act upon them.

Trough apparatus. PLATE CCLXIII. Fig. 4.

The power of the pile in decomposing chemical substances being now established, by the experiments of Nicholson and Cruickshanks, a new field of investigation was opened, which was ardently entered upon, by some of the most distinguished among the English chemists. Dr Henry decomposed the sulphuric and nitric acids, and ammonia, and he reduced the oxymuriatic to the state of muriatic acid; but as gases do not conduct the galvanic influence, its decomposing power could not be applied to this last body. See Nicholson's *Journal*, 4to. iv. 223. 245.

Henry's experiments.

Decomposes acids and ammonia.

Sir H. Davy commenced his discoveries in galvanism at an early period of the investigation. He proposed, as a subject of experimental research, whether the ends of the wire, in the interrupted circuit, would discharge the two gases, if they were made to terminate in different portions of water. The ends of the wires were therefore placed in separate glasses, while the glasses

Davy's experiments.

Disengages the gases from two portions of water.

History.

were made to communicate by means of the fingers, or a moist substance, and it was found that the oxygen and hydrogen were evolved as usual. He next inquired whether it was necessary for the effect that the wires should be in contact with the ends of the pile; and in order to prove this point, slips of muscular fibre were interposed between the wires and the ends of the pile. The result of this disposition was that the gases were disengaged, but in a reverse order; the hydrogen now proceeding from the wire connected with the zinc end of the pile, and the oxygen from the silver or copper wire.

New combinations.

These experiments, which at the time when they were performed seemed most extraordinary, and almost inexplicable, were succeeded by others equally curious, in which Sir H. Davy produced the galvanic effect, by a new combination of substances. He found that charcoal was capable of conducting the influence and of decomposing water, the copper end giving out hydrogen, holding a little carbon in solution; the zinc end did not produce any considerable quantity of gas, the carbonic acid which was produced being absorbed by the water, in which the charcoal was immersed. He formed a pile of zinc and charcoal, which acted with considerable energy, and he afterwards discovered that a pile may be constructed of only one metal, with different fluids applied to its two surfaces, one of them capable of oxidating the metal, the other of preventing the effect of oxidation, the two fluids being separated from each other by water. The series which he employed was metal, diluted nitric acid, water, sulphuret of potash, and then again metal. In a subsequent train of experiments, he proceeded still farther, and composed a pile without any metal, but consisting solely of pieces of charcoal, having their different surfaces exposed to the action of different fluids.

Pile of one metal.

Pile of charcoal, without metal.

Pile will not act with pure water.

Sir H. Davy also made some very important observations on the nature of the fluid interposed between the plates of the pile. If the water that is employed be perfectly pure, containing no acid, salt, or gas, the apparatus is incapable of acting. He found that its energy was in proportion to the rapidity with which the oxidation of the metal advances, and consequently was most energetic when nitric acid was made use of. In pursuance of this opinion, he discovered, that the pile can act *in vacuo*, if an acid be interposed between the plates. See Nicholson's *Journal*, 4to. iv. 275. 326. 337. 344.; and v. 78. 341.

Wollaston's experiments.

About this period, Dr Wollaston began to investigate the subject of galvanism, and read a paper to the Royal Society of London, which displays great marks of sagacity and penetration. He observes that the energy of the apparatus seems to be in proportion to the tendency which one of the metals has to be acted upon by the interposed fluid. An experiment is related, not very unlike some of those which had been previously performed by Fabroni. If a plate of zinc and a plate of silver be immersed in diluted sulphuric acid, and kept asunder, the silver is not affected, but the zinc begins to decompose the water, and to evolve hydrogen. If the plates be now placed in contact, the silver discharges hydrogen, and the zinc continues as before to be dissolved. From these, and other analogous facts, he concludes, that whenever a metal is dissolved by an acid, electricity is disengaged. He extends this principle to the action of the electrical machine, which he conceives has its power increased by applying an amalgam to the cushion, into the composition of which a metal enters which is readily oxidated. As a farther illustration of the same principle, he found, that the machine will not act when immersed in carbonic acid gas.

Electricity disengaged by metals dissolved in acid.

History.

Electricity of the pile in large quantity, and of litt[le] intensity.

Mr Nicholson had suggested the opinion, that the electricity of the pile differs from that of the machine, in consequence of the latter being in a state of higher intensity, but in less quantity; the former of course being in greater quantity, but of low intensity. Dr Wollaston coincided in this idea, and supposed that it might explain the difference between the operation of the two instruments. It had been long known that water might be decomposed by the electric shock, but the effect differs from that of the pile, the two gases being separated promiscuously from both ends of the wire, not as when the pile is employed, the oxygen from one end, and the hydrogen from the other. But Dr Wollaston succeeded in producing the galvanic effect on water by common electricity, so as to keep the gases separate. This he acccomplished by coating two silver wires, so that the ends of them only were exposed. He then connected these wires with the two conductors of the electrical machine, and passed the spark, from one to the other, through a solution of a salt of copper; the negative wire was found to be covered with a metallic coating, as if it had been connected with the copper or silver end of the pile. See *Phil. Trans.* 1801, p. 427.

Decompose[s] water by electricity.

Trommsdorff burn[s] metallic leaves.

Professor Trommsdorff, about this time, discovered that the pile possesses a very powerful effect in burning metallic leaves. He formed an instrument of large plates of zinc and copper, and fixed gold leaf to the zinc end; then by bringing it in contact with the silver end, the leaf was rapidly consumed, the process being attended by a beautiful emission of coloured light. Silver, tin, and copper leaves were burned in the same manner, each giving out a brilliant flame tinged by its appropriate colour. (Nicholson's *Journal*, vol. v. p. 238.) The repetition of these experiments on the combustion of metals, led Fourcroy to a curious discovery, that the energy of the shock is not increased by the size of the plates, but by the number of the repetitions; while the same extent of surface, arranged in the form of a few large plates, readily consumed the metallic leaves, but had only a comparatively small effect on the sensations. (*Ann. de Chim.* xxxix. 103.) As the action of the pile was generally admitted to depend upon electricity, various attempts were made, by different experimentalists, to charge the Leyden phial, and Mr Cruickshanks at length accomplished it. It was now also generally agreed, that the extremity of the pile which gave out oxygen, was in the state of positive electricity, and the end which disengaged hydrogen in the negative state.

Fourcroy discovers the effect of large plates.

Cruickshanks charges th[e] Leyden phial.

Van Marum compares electricity and galvanism.

It became a curious subject of investigation to ascertain what was the precise difference between the electric fluid, as generated by the pile, and as disengaged by the common machine; and Dr Van Marum entered upon a series of experiments, in which the action of the pile was compared with that of the great Teylerian machine at Haarlem. He succeeded in charging, not only single jars, but whole batteries, by the pile; and they were always charged to the same degree of intensity with that which the pile itself indicated to an electrometer placed upon it. He found that the zinc end of the pile communicated positive electricity to the side of the jar or battery with which it was in contact, and the copper end the reverse. No perceptible difference could be experienced between shocks of the same intensity given by a jar or by the battery; whether they were charged by the pile or by the machine. He found that the intensity of the pile was always the same from

History.

the same number of plates, whatever was their size; but he perceived Fourcroy's observation to be correct, that it was necessary to employ large plates to burn the metals. He formed a pile of large plates of zinc and copper, and succeeded in fusing iron wires of considerable thickness; he at last even fused a wire of platina. He found that a battery, consisting of 137½ square feet of coated glass, was charged by a galvanic apparatus to an intensity equal to itself, in 1-20th of a second; a circumstance which proves the amazing velocity of the fluid. He conceived that the energy of the pile was much augmented when it was kept in an insulated state, and likewise when a solution of the muriate of ammonia was interposed between the copper and zinc plates. See *Ann. de Chim.* xl. 289.

ses iron al platina res.

tion of t pile deodates the a.

We have already noticed the discovery of Mr Cruickshanks, that the pile acted more powerfully in oxygen gas than in the air of the atmosphere; and an observation the converse of this, was made by Biot and Cuvier, which confirmed the relation between the action of the apparatus and the chemical state of the fluid in which it is immersed. When the pile was inclosed in a limited quantity of air, they found that, after some time, the air was sensibly deoxidated. See *Ann. de Chim.* xxxix. 242.

ste of opions in 01.

The discoveries that were made with the galvanic pile, especially by the English chemists, completely established some of the most important points which had previously been subjects of doubt or controversy. Animal electricity, as produced in the original experiments of Galvani, and afterwards in those of Valli, Fowler, Volta, and others, was now admitted to depend upon nothing adherent in, or attached to, the animal body, but upon an agent, called into action by external causes, and manifesting itself in consequence of the delicate sensibility of the nervous and muscular systems. This agent was now generally recognized as being identical with electricity, conducted by the same substances, possessing the same properties, and, in short, subject to the same physical laws. It was conjectured, that the apparent difference between electricity, as excited by the machine and by the pile, depended upon the different states of intensity in which they exist; the electricity of the machine being in a much higher state than that of the pile, although this latter is generally disengaged in greater quantity. This may be regarded as the state of the science in 1801; from this time, until the grand discovery of Sir H. Davy, which we have marked out as the third era, the attention of the different experimentalists, who devoted themselves to this department of natural philosophy, was partly directed to improving or modifying the apparatus, and partly to hypothetical discussions, respecting the nature of the action, and its connexion with chemical affinity. This latter topic, in conformity with the plan which we laid down, will be treated more at length in the Second Part of the Article. A number of new facts were, however, from time to time, discovered, which we shall proceed to detail; and in order to preserve the historical order, we shall also briefly touch upon those points of theory that are to be considered more fully hereafter.

ot's obrvations the size the tes.

A memoir appeared about this time from M. Biot, which contains some important observations on the relative effects of the different kinds of apparatus, especially with regard to the size of the plates that enter into their composition. Electricity is known to be discharged by points, and to be retained by extensive surfaces; and from this circumstance he conceives, that the smaller the plates are, the more rapid will be the circulation of the fluid; large plates furnish a greater quantity of the fluid, but it is less rapid in its motion; smaller plates, on the contrary, furnish less fluid, but it passes with more rapidity through the different parts of the apparatus. Hence what was spoken of by Nicholson and others, as constituting the intensity of the fluid, is resolved by Biot into the velocity of its motion. The different operations of the pile are differently affected by these two properties. The taste, the flash, and the shock, exist nearly in the same degree, and all depend principally upon the velocity; while the combustion of the metals is more influenced by the quantity of the electricity. The electrical attractions also depend upon the quantity of fluid, and are therefore more perceptible when large plates are used. It is observed that a pile composed of small plates affords very pungent shocks, but is more quickly exhausted. It was before stated, that Biot had perceived the pile to deoxidate a portion of air in which it was confined; and he now informs us, that the effect was produced more rapidly when the ends of the pile were made to communicate by intervening wires. The general conclusions with which he sums up this interesting paper, are, that the galvanic fluid resembles the electric in the repulsive property of its particles, and that the different phenomena depend upon variations in the quantity and velocity of the fluid. See *Journ. de Phys.* lii. 264.

Different velocity of the electricity.

Lehot's observations on the direction of the current.

An elaborate set of experiments was published about this period by Lehot, on the direction of the galvanic current. This subject had also occupied the attention of Biot, and it was generally admitted that its course was from the zinc plate, across the fluid, to the silver or copper plate. See *Journ. de Phys.* li. 135.

Erman's remark on the names of the extremities.

A circumstance of some importance in our view of the action of the pile, was pointed out by Erman of Berlin; he remarks, that the action takes place, not between the metals, but between the metal and the fluid; therefore, in designating the end of the pile, we should say that the zinc end is the negative, and the copper the positive. Nicholson and Cruickshanks supposed the apparatus to be constructed copper, zinc, fluid; but we should say, zinc, fluid, copper, as in this arrangement we have the complete circle. (*Journ. Phys.* liii. 121.) A similar remark was made by Dr Priestley, who was at this time performing experiments on galvanism in America: He says, that no alteration is produced in the apparatus by whatever metal is placed at the ends beyond the reach of the fluid. Most of the phenomena of common electricity had been imitated by the electricity of the pile, except that of attraction; and Gautherot now succeeded in contriving an apparatus for producing this effect. It consisted of two delicate wires, which hung loose from the extremities of the pile; when they were brought near together, a sensible approximation was perceived, and they were found to adhere with a degree of force. See *Ann. de Chim.* xxxix. 203.

Priestley's.

Gautherot on galvanic attraction.

Volta defends the electrical hypothesis.

It does not appear that Volta himself participated, in any degree, in the various discoveries that were made by means of his apparatus, or that he employed any means for improving or altering its original form. He seems to have interested himself solely in defending the hypothesis, which he had proposed to account for its operation, and which indeed may be considered as having led to its construction. His opinion, that the primary action was electrical, and that it depended upon a change in the distribution of the electric fluid, was

History.

now called in question by Mr Nicholson, Dr Wollaston, and other English chemists, who were more disposed to refer the effects to the chemical action of the fluid interposed between the plates in oxidating the metals. Volta, however, still adhered to his first opinion; and, in a paper written about this time, he lays it down as his decided conviction, that the action of one of the metals upon the other is the sole cause of the excitation of the electricity, and that the only use of the interposed water is to convey the excited electricity from one pair of plates to the other. (Nich. *Journ.* 8vo. 1. 135.)—Some remarks were, about this time, published on Volta's hypothesis, by Mr Cuthbertson and Dr Bostock; the former objecting to some of Volta's experiments, on which the electric hypothesis of the pile was attempted to be established, and the latter giving a more detailed account of the chemical hypothesis.

Pepys's galvanometer.

By an ingenious alteration in Bennett's electrometer, it was converted by Mr Pepys into a galvanometer. Mr Pepys also confirmed the facts to which we have already alluded, that oxygen is absorbed by the pile, that it will not act in azote or in hydrogen, and that it may be excited *in vacuo*, provided acid be interposed between the plates. (*Philosoph. Mag.* x. 38.) About this time, Ritter of Jena entered upon his investigation of the galvanic phenomena, and both performed many new experiments, and entered very zealously into theoretical discussions. He conceived that he had observed a connexion between galvanism and magnetism: He says, that if an iron wire be placed in the magnetic meridian, the north pole of the wire is more disposed to become oxidated than the south pole; when the magnetized wire is placed in water, the south pole, on the contrary, is most affected. If similar wires be employed, but not placed in the magnetic meridian, no difference is to be observed in the oxidation of the two extremities. See *Journ. de Phys.* lv. 235.

Ritter's experiments.

Supposed connection with magnetism.

Experiments on animals with warm blood.

In the experiments that had been performed on animals, those with cold blood had been generally employed, both on account of their being more convenient for the operation, and from the greater tenacity with which they retain their vitality. It was, however, ascertained, that animals with warm blood were equally susceptible of the influence; and Creve of Wurtzburg had produced strong contractions in a human leg after amputation. Vassali, in conjunction with his friends, Giulio and Rossi, performed a more ample set of experiments upon the bodies of some criminals that were beheaded at Turin. (*Journ. de Phys.* lv. 286.) They paid particular attention to the effect of the galvanic electricity upon the heart and the other involuntary muscles, a point which had been the subject of much controversy. Volta supposed that the involuntary muscles could not be made to contract. Fowler however asserts, that contractions were excited in the heart, although with difficulty; and Vassali confirmed the observations of Fowler, and extended them to the stomach and intestines; the same opinion was also maintained by Nysten. (*Journ. Phys.* lv. 465). On the other hand, Aldini, the nephew of Galvani, who now came into notice as an assiduous experimentalist, asserted that he was unable to act upon the heart.

By Vassali.

Nysten.

Aldini.

Circaud's experiments on fibrine.

Circaud announced a discovery, which, if it were fully confirmed, would prove of great importance in physiology, that the fibrine of the blood, immediately after it leaves the vessels, may be made to contract by the galvanic apparatus. Delametherie confirms the statement of Circaud, from his own observations; but we have been informed that the experiment has not succeeded in this country; and when we consider the difficulty and delicacy of the process, we may be allowed, without impeaching the veracity of the narrators, to entertain some doubts on the subject. See *Journ. Phys.* lv. 468; and lv. 161.

Aldini's experiments. Contraction in the human body by the pile, 1803.

In the year 1803, Aldini published his *Treatise on Galvanism*, a work which contains many curious experiments, and also some new theoretical opinions. The experiments which were the most calculated to produce an impression upon the spectators, were performed on the body of a criminal, who was hanged at Newgate, and also on the head and limbs of some of the larger warm-blooded animals. A powerful battery being applied, very strong contractions were excited, the limbs were violently agitated, the eyes opened and shut, the mouth and jaws worked about, and the whole face was thrown into frightful convulsions. These experiments, however, were principally remarkable from the subjects made use of, and the magnitude of the effect: there were others performed, really more curious, in which very considerable muscular contractions were excited, without the intervention of any metal, or other substance which could be supposed capable of disengaging the electric fluid. In some cases the effect was produced by bringing into contact the nerve of one animal with the muscle of another, and at other times by employing the nerves and muscles of the same animal. In some of the experiments, there appears to have been the most powerful contractions excited, by bringing the parts of a warm and a cold blooded animal into contact with each other. It does not appear, from any expressions in this treatise, whether Aldini considered the animal electricity, as he calls it, to be of a specifically different kind from that excited by the pile, or whether he supposes that the different parts of the animal body have the power of generating the same kind of electricity, without the aid of any external agent. He, however, deduces from his experiments an inference in favour of Galvani's hypothesis, of a proper animal electricity inherent in the body, and not requiring the assistance of any external agent for its developement.

Contractions produced without metal.

Remarks on Aldini's experiments.

There are some points respecting these experiments that require farther explanation. The most obvious conclusion that we should draw from them, would be that which was formed by Aldini himself, in favour of a proper animal electricity. But if this be the case, they must be regarded as essentially different from those of Galvani, where an electricity of the usual kind was certainly excited. Perhaps the most probable supposition is, that the parts of the body, in these experiments, acted in a manner analogous to the pile which was constructed by Sir H. Davy, in which electricity was developed by the action of two different fluids upon carbon. There are, however, many circumstances wanting to render this analogy complete.

Lagrave's animal pile.

An important experiment was announced by Lagrave: he stated, that by placing upon each other alternate layers of muscular fibre and of brain, separated by a porous body, soaked in salt water, a pile was formed which produced the usual effects of the galvanic apparatus: (*Journ. Phys.* lvi. 235.) The experiment must be of difficult execution, and we do not know that any one has since attempted to repeat it. Should it be confirmed, it would throw some light upon the experiments of Aldini, and would assist in the explanation of those facts, where animal electricity seemed to be developed, without the intervention of metallic bodies.

About this time galvanic electricity began to be ex-

History.

tensively employed in medicine, especially in those diseases where common electricity had been previously found useful. It might have been expected that much benefit would have been derived from so powerful an agent, and one which is so easy of application to any part of the body. Our expectations of advantage have, however, been generally disappointed. Flattering accounts of success were indeed published, in different nervous disorders, in paralytic affections, in deafness, in some kinds of blindness, in the recovery of persons apparently drowned or suffocated, and even in hydrophobia and insanity. But we believe that the practice is now very generally relinquished, from a conviction of its inutility.

…lvanism …ployed in …edicine.

…tter's …condary …le.

Ritter published an account of a curious appendage to Volta's pile, which he called the *secondary pile*, and which has been frequently called the *pile of Ritter*. It is a kind of electric apparatus, which may be charged by the voltaic pile, or may be made to retain the electricity that is perpetually flying off from this instrument. He perceived that a body, which had formed part of the galvanic circle in the pile of Volta, when the pile was removed, became itself electrical; but it exhibited an electricity opposite to that which it had previously possessed. Thus, if two wires terminating in water, and connected with the pile, were discharging one oxygen and the other hydrogen, when they were removed from it, they would still continue to discharge the gases, but the operation would be reversed. These wires, in this state, may be considered as charged, and if a greater number of similar wires be placed between the ends of the pile, they will all become charged. The nature of the experiment will not be affected, if, instead of wires terminating in water, plates of metal be substituted, with wet cards interposed. An instrument will thus be formed, which of itself cannot produce any signs of electricity, but which may be rendered electrical, by being placed in contact with the primary pile. When the two piles are connected, the action of the ends of each are reversed to each other, and, as when they are separated, the ends of the secondary pile are again reversed, consequently the ends of both the piles will now act in the same manner. It is necessary for the pile of Ritter to remain for some time in contact with the pile of Volta, in order that it may be sufficiently charged. It is stated that the chemical effect of Ritter's pile, that is, its effect in decomposing water, does not bear a regular ratio to its physiological effect, that is, its effect in giving shocks. The author observes, with respect to the voltaic pile, that its tension is the greatest, and it produces the strongest effects on the sensations immediately after it is constructed, but that its chemical effects are the most powerful after it has been acting for some hours. See *Journ. de Phys.* lvii. 345.

…scribed.

…fects.

…rther ex…periments …f Ritter, …the vol…taic pile.

Shortly after the publication of the account of the secondary pile, Ritter made a number of experiments with the pile of Volta, which are original and curious. He observed that when a communication was formed between the positive end of the voltaic pile and the earth, the whole instrument became negatively electrified, and when the communication was made with the negative end, the instrument became positive. These changes do not, however, destroy the chemical action of the pile, which goes on in the same manner as before the communication was formed. He supposes that the decomposition of water is effected in consequence of the positive end disengaging oxygen, and the negative end hydrogen, and that the two ends have also a tendency to dispose metals to unite with oxygen and hydrogen respectively. He says, if the positive end be armed with gold leaf, and the negative with charcoal, and these substances be then brought into contact, the gold will be burned; but if the position of the substances be reversed, the charcoal will be burned. When the extremities of a pile do not communicate, it is said that the action exercised between the different plates is very unequal; the zinc, which is nearest the positive end, is the most oxidated. It is also asserted, that if a pile be broken into separate parts, by a number of wires inserted between every fifth pair of plates, those wires nearest the positive end will be the most oxidated; while, on the contrary, those wires near the negative end will be less oxidated than if they had been simply plunged in water. Hence he infers, that at the negative end an action has taken place, or a state has been induced, the reverse of oxidation. He goes so far as to say, that different sensations are excited by the two ends of the pile, the one expanding, and the other contracting, the muscular fibre; the positive end strengthens the pulse, and produces heat, the negative weakens it, and produces cold. See *Journ. de Phys.* lvii. 401.

History.

Different effects in different parts of the pile.

Remarks on Ritter's experiments.

So far as we have been able to learn, few, if any, of the experiments of Ritter have been repeated, either in England or in France; a circumstance which is not a little remarkable, when we consider that many of them are quite original, and would lead to important theoretical deductions. His language and manner of writing are, however, unfortunately obscure; and he abounds so much in hypothesis, that he has not obtained that degree of attention to which he would seem to be entitled, from his industry and ingenuity. It is scarcely to be supposed that he could have been mistaken respecting the effect of the secondary pile, or that he would have invented a series of facts, the fallacy of which might be so easily detected. With respect to the experiments on the voltaic pile, their authority is more doubtful; they seem to have been performed with a manifest view to a particular hypothesis; some of them are of an indeterminate nature, and we may imagine that many are exaggerated, or even inaccurately stated.

Biot's opinions respecting the nature of the galvanic action.

The attention of the different experimentalists was now much occupied with the comparative merits of the two hypotheses, the electrical and chemical; generally speaking, the English seemed to incline to the latter, and the continental writers to the former. Biot drew up a candid and judicious memoir, in which he compares the merits of the two opinions, and endeavours to shew how far either of them is supported by acknowledged facts. Electricity, he observes, is certainly excited, but it is not certain whether we ought to regard it as cause or effect. He proceeds to inquire, whether the action of the instrument depends entirely upon the oxidation of the water, entirely upon the influence of the metals, or whether it is not produced by the two in conjunction. This he decides to be the case; and yet, at the same time that he makes this decision, he appears to have a leaning towards the chemical hypothesis. See *Ann. de Chim.* xlvii. 1.

Hisinger and Berzelius on the transfer of substances. 1804.

In the year 1804, a very valuable memoir was written by Hisinger and Berzelius, which must be regarded as containing the fundamental principle of those doctrines, which have since been so extensively developed by Sir Humphry Davy. By passing the galvanic influence through solutions of the different neutral

History.

salts, they found that there was a transfer of the acid and alkali to different parts of the apparatus. They formed the general conclusion, that whenever electricity is sent across a fluid, it disposes its constituents to separate and pass to the two sides respectively; combustible substances, alkalies, and earths, are attracted to the negative; acids, oxides, &c. to the positive extremity of the pile. The force of the decomposition they suppose is in the ratio of the quantity of electricity, and that the electricity is in proportion to the surface of metal which is in contact with a moist conductor. The decomposition is also influenced by the affinity of the components of the substance, its power of conducting electricity, and other circumstances. See *Ann. de Chim.* li. 167.

Supposed production of muriatic acid. 1805.

Mr Cruickshanks, among his earliest discoveries, had observed, that an acid and an alkali were generated at the two ends of the wires in the interrupted circuit, and this fact had been confirmed by other experimentalists. The substances produced were supposed to be nitric acid and ammonia; the first originating from the union of oxygen with the azote of air dissolved in the water, the latter from hydrogen combining with the same element. But it was now announced that muriatic acid and soda were generated by passing the electric current through pure water, and where this salt could not be suspected to be present in any part of the apparatus, or in any of the materials employed. In the spring of 1805, the following letter was published, purporting to be written by Mr Peel of Cambridge: "I took about a pint of distilled water, and decomposed about one half of it by means of galvanism, the other half I evaporated, and found to remain at the bottom of the glass a small quantity of salt, which, upon examination, proved to be muriate of soda. The salt could not have been contained in the water before I made the experiment, because I used every precaution to have it free from impurities. I even took the trouble to repeat the experiment, though a tedious one, and I again obtained the same result. A friend of mine has just informed me that he has tried my experiment, and has succeeded in procuring the salt." See Tilloch's *Mag.* xxi. 279.

Peel's experiments.

Pacchioni's experiments.

Almost at the same time that this notice was published in London, Pacchioni, professor at Pisa, gave an account of some experiments upon the action of galvanism on water, in which he obtained results analogous to those stated above. He informs us, that when water had been for a long time subjected to the galvanic influence, and had been parting with its oxygen from the extremity of a gold wire, the fluid was found to contain a quantity of oxymuriatic acid. From this experiment he drew the following conclusions: Oxymuriatic acid is an oxide of hydrogen; it consists of water deprived of part of its oxygen; muriatic acid is water in a still lower degree of oxidation; and, of course, oxygen and hydrogen are susceptible of different degrees of oxidation. See *Edinburgh Med. Journ.* i. 393.

Not confirmed.

A great degree of attention was excited by these experiments, to which the more credit was attached, because they proceeded from sources entirely independent of each other. They were repeated by different experimentalists in this country, and in some cases with apparent success. Mr Sylvester in particular, obtained traces both of muriatic acid and soda, where proper precautions were supposed to have been taken, to exclude the muriate of soda from every part of the apparatus. But from facts which have been subsequently discovered, we may conclude, that the substances obtained in these cases were not derived from the decomposition of the water. Pacchioni's experiments are now universally admitted to have been incorrect; and it appears that no such individual as Mr Peel could be found in Cambridge, so that the letter bearing his name is a complete fabrication. It was not, however, entirely without its use; for the minute examination of the effects of galvanic electricity upon water, to which it gave rise, may probably be regarded, in some measure, as the immediate cause of Sir H. Davy's most important discoveries.

Erman's experiments. 1806.

An elaborate memoir was, about this time, written by Erman, on the conducting power of different bodies, which obtained the prize from the French Institute. His object was to remove some anomalies, which appeared to exist in the relation of the galvanic electricity to the different conducting substances.

Five species of bodies.

He divides all bodies into five classes: 1st, Perfect non-conductors; 2d, Perfect conductors; 3d, Imperfect conductors; 4th, Positive conductors; and 5th, Negative conductors. The nature of the three first classes requires no explanation; the fourth and fifth class of bodies act as perfect conductors, when applied to either of the two poles separately, but when placed between them, insulate either the positive or negative pole respectively, and do not form a communication between them. The flame of a spirit lamp is described as a positive conductor; if it be applied to each polo separately, it conducts the electricity; but if it be placed between the two poles, it will not form a communication between them, in consequence of its insulating the negative electricity. Although flame is a conductor of galvanism, it does not conduct it so perfectly as metals. No effect is produced, when flame is interposed between the extremities of the pile. Flame is, however, a very different substance according to the body from which it is procured: the above observation refers to the flame of a hydro-carbonous body. The flame of sulphur insulates both the poles; and that of phosphorus insulates the positive, and conducts the negative influence. Phosphorus must therefore be placed in the fifth class of bodies; and perfectly dry soap is also a negative conductor.

Flame a positive conductor.

Soap a negative conductor.

The author gives an account of a number of experiments that he performed on this latter substance, many of which are curious and original. Hard soap, when perfectly dry, if applied to either end of the galvanic pile, conducts all the electricity from that extremity into the ground, and there appears to be no perceptible difference in its action upon the two extremities. If wires be connected with each end, and be made to terminate in a prism of hard dry soap, which is kept insulated, the circuit will not be completed; but if this soap be uninsulated, by establishing a communication with the ground, an electrometer connected with the positive pole, manifests a great degree of divergence, while one on the negative pole loses all signs of it. "Consequently," M. Erman observes, "the soap which insulates the positive effect, is a perfect conductor for the negative." As a proof and illustration of this property, the author informs us, that "if one finger be applied to the wire of the positive pole, and another finger wetted to the soap, no shock is felt, and the electrometers do not show the least change in their respective divergencies. But if the experiment be repeated, by establishing a communication between the positive pole and the soap with both fingers wetted, a very perceptible shock will be felt, and the two electrometers will arrive at an equal, and a very weak degree of intensity." He proposes the

History.

Erman's nomenclature.

following nomenclature for these five classes of bodies: 1st, Insulators; 2d, Perfect conductors; 3d, Bipolar imperfect conductors; 4th, Positive unipolar; and 5th, Negative unipolar: (*Jour. Phys.* lxiv. 121.) Although, as we shall afterwards find, Mr Brande explains the facts upon rather a different principle, yet they are highly important, and M. Erman is entitled to much commendation for the skill with which he conducted his experiments.

Guyton's observations on metallic oxides.

Guyton suggested an idea, which appears sufficiently plausible, that the action of galvanism may affect the formation of metallic oxides, and even cause them to assume the particular forms which they occasionally exhibit: (*Ann. de Chim.* lxiii. 113.) Bucholtz detailed a series of experiments which he performed, where a metallic oxide, held in solution by an acid, was precipitated in the metallic state by the metal itself. The metallic solution was placed in the bottom of a cylindrical jar, and a stratum of water was carefully spread over it. A slip of the same kind of metal that formed the solution was then placed perpendicularly in both the fluids. The upper part of the metal which was in the water was oxidated, while the lower part in the metallic solution had particles of the reduced metal deposited upon it. The reduction of the oxide was always expedited by whatever promoted the oxidation of the upper part of the metal. Experiments of an analogous nature were performed by Grotthus, on what he calls the *arborization* of metals, which, like the circle of actions described by Bucholtz, he attributes to a galvanic operation. In these processes, however, there are two metals concerned; and he shews that the tree is formed by successive portions of the dissolved oxide being reduced and attached to the solid metal, which, in its turn, becomes oxidated: (*Ann. de Chim.* lxiii. 5.) We have a little anticipated the chronological order in the relation of these two last sets of experiments, in order that we might not be interrupted in narrating the account of the decomposition of the alkalies and earths, which composes the third period of the history of galvanism.

Sect. III. *Decomposition of the Alkalies and Earths.*

Davy's electro-chemical researches. 1806.

About the conclusion of the year 1806, Sir H. Davy read to the Royal Society of London the first of his series of papers, on what has been styled the electro-chemical action of bodies, which have been so justly celebrated, no less for the brilliant discoveries of which they give an account, than for the acuteness and sagacity which the author displays in his researches into the most hidden operations of nature. He commences by some remarks on the action of galvanic electricity upon water. He notices the experiments in which acids and alkalies appear to have been formed in water subjected to the galvanic current; and he states, that when he employed separate portions of water, connected together by slips of bladder, and united by gold wires to the voltaic battery, he obtained nitro-muriatic acid at the positive, and soda at the negative wire. It was, however, conjectured, that the animal matter placed between the two portions of water might contain muriate of soda, and thus afford the substances procured in the experiment; he therefore, at the suggestion of Dr Wollaston, substituted asbestos for the slips of bladder. It was also conceived, that when glass vessels were used, the alkali might proceed from a partial decomposition of the glass; and after trying various other substances, at length conical vessels of gold were employed. With these precautions, and when the water was very carefully prepared, no acid or alkali were obtained; and consequently the author concludes, that in all those experiments which were attended with contrary results, the acid and alkali must have proceeded from some extraneous source, not having been generated, but evolved, either from something held in solution by the water, or from some of the materials employed in the apparatus. Perfectly pure water, when subjected to the action of electricity, affords nothing except oxygen and hydrogen.

Action of galvanic electricity upon water.

Plate CCLXIII. Fig. 9.

No acid and alkali generated.

The very powerful action of the galvanic electricity, in the decomposition of various earthy and saline compounds, as experienced by Sir H. Davy in the researches above mentioned, offered an extensive field for farther investigation. Hisinger and Berzelius, in the valuable memoir to which we have already referred, noticed the tendency which different bodies possess, to attach themselves to one of the wires exclusively; acids and analogous bodies being attracted to the positive, while alkalies, metals, and all inflammables, were attracted to the negative wire. Our author had observed similar phenomena in his own experiments, and was induced to make them the more immediate subject of his examination. Acids and alkalies were found uniformly to observe this order; and it was perceived, that when substances, not supposed to be soluble in water, formed part of the circuit, they were also decomposed, and their components carried to the positive and negative wires respectively. In this way was effected the decomposition of sulphate of lime, sulphate of strontites, fluate of lime, and sulphate of barytes. It was also perceived, that where small portions of acid and alkaline bodies entered into the composition of solid earths, they might be detected by the galvanic influence, and would be transmitted to their respective wires. In this way, lime and soda were obtained from basalt and from zeolite, potash from lepidolite, &c. In proportion to the solubility of a salt, its decomposition was the more readily accomplished; and when neutral salts were employed, the separation of the component parts seems to have been quite complete.

Decomposition of earthy and neutral salts.

The tendency which different substances possess to attach themselves to their appropriate wires, causes them to be transferred across a medium which may be interposed. Thus, if muriate of lime be at the positive wire, the lime will pass, for a considerable space, to gain the negative wire, and may be conveyed from one vessel to another along the conducting fibres of the asbestos. In the same manner, when nitrate of silver was on the positive side, and distilled water on the negative, the silver passed along the transmitting amianthus, so as to cover it with a thin metallic film. When a neutral salt was placed in a vessel, between two other vessels of water connected by asbestos, the alkali passed to the negative, and the acid to the positive side: the decomposition in this case is complete, and the substances produced quite pure. A small vessel of the infusion of litmus was interposed between pure water and the solution of sulphate of potash, and the latter was negatively electrified. The acid passed across to the positive wire, and reddened the litmus, but the change of colour did not extend beyond the centre; so that the negative side, although it was transmitting the acid, was not affected by it. An experiment of precisely an opposite kind was performed with the infusion of turmeric, with a similar result; and afterwards the two operations were combined in the same experiment, so that soda passed through turmeric, and muri-

Transfer of the constituents of compounds.

Plate CCLXIII. Figs. 10, 11.

History.

atic acid through litmus, each without changing their colour.

Passage of acids and alkalies through different media.

As it appeared that acids and alkalies could be conveyed through water, without affecting colouring substances dissolved in it, Sir H. Davy next tried whether this power might not extend to other bodies. He accordingly found, that acids could be transmitted through alkalies, and alkalies through acids, to their respective wires, without neutralizing each other; and, in short, that the electrical state which was induced upon a substance, by the contact of the galvanic apparatus, had the power of counteracting, or even changing, the effects of chemical affinity. The general principle was thus completely established, that hydrogen, alkalies, and metals, are attracted by the negative, and repelled by the positive end of the pile, while acids and oxygen are attracted by the positive, and repelled by the negative. For the production of this effect, it is necessary that there be a conducting chain of particles through the transmitting fluids; the transfer cannot take place where insoluble compounds are formed, because in this case the new compound is carried out of the sphere of action.

General principle.

Effect of electricity in producing chemical changes.

The establishment of the general principle mentioned above, suggested some views of the nature of the change produced by electricity, which led to a new train of experiments. Sir H. Davy observes, that many bodies, after being brought into contact, exhibit opposite states when they are separated. When a galvanic combination is formed from an acid, an alkali, and a metal, the alkali appears to acquire, and the acid to part with, a quantity of electricity; the alkali is therefore rendered positive, and the acid negative, and they will of course have an attraction for each other. He found, that when such acids as were capable of being employed in the dry state were touched by metals, and then separated, the acids were rendered negative, and the metals positive; but when the metals were touched by the alkaline earths, the metals became negative. Hence it may be concluded, that acids and alkalies not only exhibit opposite electricities, when they have been in contact with metals, but also when they have been in contact with each other. The attraction of oxygen and acid for the positive, and of hydrogen and alkalies for the negative electricity, is so powerful, as to counteract their usual chemical affinities.

Relation between the electricity and affinity of bodies.

These considerations induced the author to enter into some farther speculations respecting the relation between the electricity of bodies and their chemical affinities. We have seen that chemical affinity is destroyed by giving a body an electricity different from its natural one, and is, on the contrary, increased by giving it a greater share of its natural electricity. It would farther appear, that all those bodies which possess a chemical affinity for each other are naturally in opposite states of electricity, and hence we conclude, that by inducing a state of electricity upon any body, contrary to its natural one, its chemical relations may be changed, and that thus we have in our possession an agent of indefinite power for affecting the decomposition of substances which had hitherto withstood all our attempts.

Action of the voltaic pile.

With respect to the action of the voltaic pile, Sir H. Davy conceives, that the first step in the process is the destruction of the electrical equilibrium, and that the chemical changes tend to restore it to its original state. The saline solution, which is interposed between each pair of plates, is decomposed, the acid is transferred to the zinc, and the alkali to the copper surface. This tends to restore the equilibrium, which is destroyed by the contact of the metallic elements of the pile; but the solution of the zinc, which then takes place, again alters the electrical condition of the bodies, and maintains the energy of the apparatus. Upon the whole, although it may be supposed that the chemical changes are an essential part of the process, they are considered by the author as only of secondary importance; the first step in the process, and that which immediately gives rise to all the rest, being an electrical effect arising from the action of bodies placed in contact.

Primary effects electrical.

Importance of this paper.

The uncommon merit of this paper has induced us to give a copious abstract of its contents. It may be regarded, not only as giving rise to some of the most important experiments and discoveries that have occurred in the history of modern science; but as leading to the establishment of a new train of reasoning, and to a new theory, respecting the action of bodies upon each other, and the connexion which subsists between the different branches of natural philosophy. The general principle being clearly established, the consequences were comparatively obvious, and the skill and ingenuity, which Sir H. Davy afterwards manifested, in the contrivance and execution of the experiments, which are next to be related, although attended by such brilliant results, are really less meritorious, than that profound insight into the operations of nature, by which they were suggested. Highly, however, as we appreciate the merit of Sir H. Davy, we think it proper to remark, that the views suggested by Hisinger and Berzelius must be regarded as leading to the theory that was so amply detailed and so firmly established by our illustrious countryman. See *Phil. Trans.* for 1807, 1.

Decomposition of the fixed alkalies. 1807.

About a year after the reading of the above paper, Sir H. Davy presented a second to the Royal Society, in which he most happily applied his hypothesis to practice, and succeeded in solving the problem, which had so long remained involved in obscurity, respecting the composition of the fixed alkalies. After encountering some difficulties in the arrangements of the operation, the grand object was at length accomplished in the following manner. "A small piece of pure potash, which had been exposed for a few seconds to the atmosphere, so as to give conducting power to the surface, was placed upon an insulated disc of platina, connected with the negative side of the battery, of the power of 250 of 6 and 4, in a state of intense activity; and a platina wire, communicating with the positive side, was brought into contact with the upper surface of the alkali. The whole apparatus was in the open atmosphere. Under these circumstances, a vivid action was soon observed to take place. The potash began to fuse at both its points of electrization. There was a violent effervescence at the upper surface; at the lower, or negative surface, there was no liberation of elastic fluid; but small globules, having a high metallic lustre, and being precisely similar in visible characters to quicksilver, appeared, some of which burst with explosion and bright flame, as soon as they were formed, and others remained, and were merely tarnished, and finally covered by a white film, which formed on their surfaces."

Relation of the experiment.

Base of potash and soda.

These globules proved to be the substance of which the author was in search, and were found to be a peculiar inflammable body, possessed of very singular properties, which constituted the base of potash. By employing a similar kind of process, a substance was procured from soda, which exhibited properties of an analogous nature, and which was the basis of the mineral, as the former was that of the vegetable alkali.

Proved to be metals.

The author then proceeded to examine the properties

History.

of these bodies, and by a masterly train of experiments, simple yet conclusive, he demonstrated that they are metals; that they have every quality which is deemed essential to characterise this class of substances, and that the alkalies are oxides of these metals. The theory of the decomposition of the alkalies, by means of the galvanic apparatus, is sufficiently obvious, and follows as the direct consequence of the facts that had been previously established. In all the decompositions that had been effected by the electrical influence, combustible substances were developed at the negative wire, while oxygen was produced or evolved at the positive termination. That this was the case with the alkalies, was not only rendered probable by the result of the process, but was afterwards proved by subsequent experiments. "When solid potash or soda, in its conducting state, was included in glass tubes, furnished with electrified platina wires, the new substances were generated at the negative surfaces; the gas given out at the other surface, proved by the most delicate examination, to be pure oxygen; and unless an excess of water was present, no gas was evolved from the negative surface."

Theory of the process.

Recomposition of the alkalies.

The experiments by synthesis confirmed the results of those by analysis. The new metallic bodies were converted into potash, by exposure to the air, and it was found that this depended upon the oxygenous part of it. When the globules were placed in contact with oxygen, they combined with it, and were covered with an alkaline crust. Sir H. Davy observes very justly, "that in these facts there is the same evidence for the decomposition of potash and soda into oxygen and two peculiar substances, as there is for the decomposition of sulphuric and phosphoric acids and the metallic oxides, into oxygen and their respective combustible bases." The two components of the alkalies obey the general law which was laid down in the former paper; the metallic or combustible base is attracted by the negative extremity of the apparatus, and perhaps repelled by the positive; while the oxygen, which reduces it to the state of an oxide, follows the contrary order. In the recomposition of the alkalies, the substances exert their natural affinities; according to circumstances, either simple oxidation is produced, or a more rapid combination, attended with the extrication of heat and light.

Properties of new metals.

Sir H. Davy next proceeded, in an elaborate train of experiments, to ascertain the physical properties of these metals, to which he gave the names of potassium and sodium, and their chemical relations to other bodies. He examined their fusibility, the power which they possess of conducting electricity and caloric, and their specific gravity. He afterwards observed their action on water, the acids, sulphur, phosphorus, the metals, oils, and metallic oxides. It is scarcely necessary to remark, that the examination was conducted with the address and dexterity which characterizes all the operations of this distinguished experimentalist. A minute detail of the particulars would be foreign to the object of this article, and strictly belongs to the science of chemistry; galvanism being no farther connected with these bodies, than as the instrument by which they are produced. On this account it will not fall under our province to notice the discussions which ensued respecting the nature of these new metals; for although it was generally admitted that the substances were the bases of the fixed alkalies, and were metallic, yet there were some circumstances in the mode of their formation, which led to the supposition, that they were a compound of a metal and hydrogen; but this opinion is now abandoned.

History.

Attempts to decompose ammonia.

The analogy which exists between the properties of the fixed and the volatile alkalies, led Sir H. Davy to apply his powerful means of decomposition to ammonia. The analogy of properties, however, which causes them to be placed in the same class of bodies, seemed to be counteracted by the experiments of Berthollet, who, as is well known, had resolved this latter substance entirely into hydrogen and azote. Accordingly the metallic nature of ammonia has not yet been proved, and although Sir H. Davy, in his earlier experiments, conceived that he had procured oxygen from it, and Berzelius obtained a species of amalgam, by exposing it in contact with mercury to the galvanic influence, yet subsequent experiments by Henry, and Gay-Lussac and Thenard, appear to explain these appearances on other principles, and to restore the original conclusion, that ammonia is a compound of azote and hydrogen alone. See *Phil. Trans. for* 1808, p. 1.

Decomposition of the earths.

Sir H. Davy next turned his attention to the earths. He found them more difficult to decompose than the alkalies, and many arrangements were employed without success. The object was, however, at length, to a certain degree, accomplished by mixing the earth with a metallic oxide, and placing this in contact with a globule of mercury negatively electrified, when an amalgam was formed, consisting of the mercury and the metal of the earth employed. In this way it appeared, that a metallic basis had certainly been obtained from the four alkaline earths, to which the names of barium, calcium, strontium, and magnium, were respectively applied. The remaining earths, silex, alumine, zircon, and glucine, were still more refractory, probably in consequence of their more powerful affinity for oxygen. No decomposition could be effected by the same means which had been found successful with the alkaline earths; but it was at length partially accomplished, by keeping the earth in fusion with potash, inducing upon it positive electricity, and touching it with a negative wire. In this case an amalgam was produced, which probably consisted of the metal of the earth employed and potassium. See *Phil. Trans. for* 1808, p. 333.

Confirmation of Davy's experiments.

The brilliant discoveries of Sir H. Davy, and still more the new and powerful agent which he had introduced into chemistry, could not fail to engage the attention of all those who were interested in the progress of the science. Among these, Gay-Lussac and Thenard in France, and Berzelius in Sweden, immediately commenced their operations in the application of galvanic electricity to the decomposition of bodies, made many important experiments, and brought to light many new facts. The general result was, to afford an ample confirmation of the statements of our illustrious countryman in their most important parts, although in some particulars they regarded the subject in a different point of view, both as to the mode of accounting for the effects, and the consequences which they deduced from them. These discussions, as well as the many new and interesting experiments connected with them, which have completely changed the aspect of many branches of chemistry, and have enlarged our knowledge of the nature of bodies far beyond its former limits, it does not belong to our department to detail. It will be proper, however, to lay before our readers some of the observations that were made by Gay-Lussac and Thenard, on what strictly belongs to galvan-

History.

ism, reserving the consideration of the hypothetical opinions to the second division of the article.

Gay-Lussac and Thenard's researches. 1811.

These sagacious experimentalists remark, that, next to the construction of the pile itself, the most important discovery was made by Hisinger and Berzelius, who found that when the electric current decomposed a neutral salt or an oxide, the oxygen and acid were carried to the positive end, and the base to the negative. The application of this principle enabled Sir H. Davy to effect the decomposition of the alkalies. The authors point out the distinction between the electrical and the chemical energy of the pile; actions which are essentially dissimilar, and which do not exist in the same ratio. They state, that a comparatively few plates, with acid interposed between them, will decompose the alkalies; while a greater number, with water instead of acid, will not produce this effect, and will yet exhibit a higher electrical tension. The power of the apparatus was found to be nearly in proportion to the strength of the acid employed; and some comparative experiments were instituted, for the purpose of comparing the effects of acids, alkalies, and neutral salts. The test which they employed to judge of the quantity of effect produced by the pile, was the amount of gas evolved from a fluid, subjected to the action of the wires connected with its two extremities: this they conceived was a more exact measure of its energy than the different lengths of wire which it was capable of consuming.

Difference between the electrical and chemical action.

Shock produced by a large battery.

When they employed a very powerful battery, it was observed that considerable shocks were given by it to an individual; but that in a chain of four or five persons, it was not felt in the centre; and in the extremities of the chain, that part of the body received the greatest impression which was nearest to the apparatus. This fact is supposed to prove, that the electric fluid cannot circulate through the whole circuit, according to the Franklinean hypothesis. When the battery is put into strong action, its chemical effect, *i. e.* its power of decomposing water, soon declines, or altogether ceases, while its electrical tension remains for some time longer unimpaired.

An interesting train of experiments is next detailed, in which mercury was interposed between the wires, and formed an amalgam with the substance which was intended to be decomposed: an arrangement which we have already pointed out as having been employed by Sir H. Davy in his decomposition of the proper earths. They repeated the experiments of this philosopher on ammonia, and they formed the amalgam with mercury, which he conceived was composed of this substance with the metallic basis of ammonia; but they differ from him in their idea of its constitution, and suppose that there is no evidence of the existence of the metal of the volatile alkali, although the analogy of the fixed alkalies offers so powerful an argument in its favour.

De Luc's analysis of the pile. 1810.

While Sir H. Davy was pursuing, with so much success, his interesting researches into the electro-chemical action of bodies upon each other, M. De Luc undertook to investigate the nature of the galvanic pile, and to examine the mode of its operation. After some animadversions upon the hypothesis of the inherent electric energies of bodies, which constitute the origin of the train of phenomena that are connected with the pile, he proceeds to dissect this instrument into three parts. He divides it into three separate groups, corresponding to what he regards as the three elements of the pile. These elements are the two metals and a fluid. They were first placed with the fluid between the two metals; then with the fluid in contact with one, and afterwards in contact with the other metal, the different groups being kept distinct from each other by small wire stands, so as to confine the action to that part alone. When the piles were fitted up in these three different ways, a delicate electrometer was attached to each extremity, and they were also connected by the interrupted wire passing through water. His first set of experiments were made upon the pile in which the groups were arranged with the fluid between the two metals. By means of the electrometer, he observed which ends of the apparatus were in the positive and negative states respectively; and he likewise made some new observations on the direction which the electric current takes in its passage across the water—in the interrupted circuit—and in the body of the pile itself. His observations agreed with those originally made by Nicholson, that the extremity of the pile which is connected with the wire emitting oxygen, is positive, and that the current is directed from this to the wire which emits the hydrogen. He informs us, however, that although electrometers placed at the extremities, when they are affected, indicate the electricity to be in the state mentioned above; yet they are not always both of them affected, sometimes only the positive electricity is visible, sometimes only the negative, while at other times both of them are perceptible. He conceives that, from various causes, the electric fluid passes through the apparatus with different velocity at different times, or through its different parts at the same time, so as to produce a partial accumulation or deficiency: It seems to be always retarded when it passes from the point of the wire into water. He observes, that the expressions positive and negative, as applied to the ends of the pile, or to the wires in the interrupted circuit, can only be regarded as comparative terms, because the chemical action of the pile goes on as usual in the decomposition of water, although the whole instrument be rendered positive or negative, by attaching it to the prime conductor, or to the rubber of the electrical machine. This experiment is adduced to prove, that the action of the pile is not necessarily connected with the electric energy of the substances that enter into its composition. The pile, when dissected in the first way, with the fluid interposed between the two metals, acts in the same manner as if the parts were continuous, except that the effect is rather less powerful.

Dissection of the pile.

History

Plate CCLXII Figs. 14–18.

Fig. 19.

First dissection of the pile.

Observations on the direction of the current, and on the positive and negative states.

Second dissection.

M. De Luc then examined the action of the pile, when dissected according to the second arrangement, where the metals were placed together, and the wet cloth in contact with the zinc, or the most oxidable of the metals; the ternary groups being separated from each other by the wire frames. The extremities of the pile indicated to the electrometer the same states of positive and negative, as in the former instance, but no shock was experienced; when the wires of the interrupted circuit were placed in water, although it appeared that there was a communication established through the fluid, yet no decomposition took place, nor did there appear to be the retardation of the electric current upon its entering the fluid, as in the former case. Hence the author concludes, that the electrical and chemical effects originate from different causes, because in this state of the instrument the electrical effects continue, although the chemical effects are suspended. The third dissection of the pile was now made, *i. e.* it was divided into ternary groups, consisting of the metals contiguous to each other, and the wet cloths in contact

Third dissection.

History.

with the silver; the groups being separated as before, by wire supports. Here there was no effect perceptible, either electrical or chemical.

Muriate of soda employed between the plates.

In the above experiments, the cloths which were employed to retain the fluid were moistened with water: A second set of experiments was now performed, in which a strong solution of muriate of soda was employed. The pile, whether moistened with water or the saline solution, had the same effect upon the electrometers, both as to quality and quantity; but when the salt was used, there was a more powerful effect upon the sensations. He observed, that a new shock was experienced every time either of the hands was brought into contact with the apparatus, or removed from it; but that no effect took place as long as they remained in contact. When the interrupted circuit was applied between the extremities of the pile, the shock might be felt, but it was rendered less violent; and the chemical effects were diminished, but not suspended, while the contact of the body was preserved: hence it may be inferred, that the body is about an equally good conductor with water. The retardation of the current appeared to be rather greater in this case, than where the apparatus was supplied with pure water.

The pile was now dissected in the same three ways as before, muriate of soda in solution being employed instead of water. In the first dissection, *i. e.* with the moistened cloths between the plates, the same electric effects were exhibited by the electrometers, the same shock was felt, and the same chemical effects were produced, only in rather a less degree than in the continuous pile, with muriate of soda. The second and third dissections of the pile produced exactly the same effect, as when the same dissections were employed with pure water.

Hypothesis of the different cause of the electrical and chemical effects.

The author afterwards enters upon a number of speculations respecting the manner in which the electric fluid circulates through the apparatus, and upon the immediate cause of the electrical and chemical phenomena. He conceives, that when no cause of retardation exists, the electric fluid circulates so rapidly through the pile, as not to exhibit any of its effects, or indeed not to indicate its presence; and that when these are manifested, it always depends upon some retarding cause. The electrical and chemical effects are supposed to originate from different parts of the pile, or from different groups, considered in their relation to the parts contiguous to them. The electrical effects consist simply in the combination of the two metals, each pair being separated by a non-metallic conductor; while for the chemical effects, ternary groups are necessary, the two metals with a fluid between them. This distinction between the two sets of properties, or the two modes of action, is supposed to be proved by the different effects which are produced by the pile in its three states of dissection. In the pile dissected in the first manner, which indeed may be regarded as equivalent to the instrument in the continuous state, both the electrical and chemical action takes place: for here are the two metals, either in contact, or connected by the wire frames, for the electrical effects; and for the chemical effects, there are the two metals with the wet cloth interposed. In the pile as dissected in the second manner, there are the binary groups, *i. e.* the metals in contact, and accordingly they produce the electrical effects; but we have no chemical effects, because they have no fluid between them. In the third dissection, no effects are produced; we have not the chemical effects, because the metals have not the wet cloth between them, and we have no electrical effects, because the zinc has the copper plate on one side, and the wire frame on the other, which have the same electrical relation to the zinc, and therefore counteract each other.

Pile of silver and pewter.

The different effects which seemed to ensue, between the pile when furnished with pure water, and with the solution of a neutral salt, induced M. De Luc to examine what connexion existed between the oxidation of the zinc, and the chemical action of the instrument. For this purpose he formed a pile of silver and pewter, the pewter being selected for the experiment, because it has an electrical relation with silver, and is oxidable by muriatic acid, at the same time that it is not much affected by pure water. In the first instance, water was interposed between the plates; the extremities of the pile, as indicated by the electrometer, became electric, the pewter side negative, and the silver positive; but there was no shock, nor any decomposition of the water in the interrupted circuit. A pile was then formed of such a number of zinc and silver plates, that its electrical energy might be the same with the pewter pile; but here there was both the shock produced, and the decomposition of water. The pile of pewter and silver was then fitted up with muriatic acid; and in this case, when the pewter plates became oxidated, the shock and the decomposition of water were both produced. From these experiments, the author deduces the following conclusions. When the metal is not oxidated, no chemical effect is produced on the water in the interrupted circuit. When the oxidation is produced by means of pure water, there is no shock, although the chemical effects take place; and lastly, when either of these effects are produced, the current of electricity is retarded in its passage across the water in the interrupted circuit.

General conclusions.

Discovery of the electric column.

It was in the prosecution of these experiments, while he was examining the effect of different conducting substances placed between the plates, that M. De Luc was led to the discovery of the curious instrument, called the Electric column; a pile consisting of a number of discs of zinc and gilt paper, placed alternately upon each other, and included in a glass tube. This has already been described under the article ELECTRICITY, p. 469, and as it must be regarded as a stricly *electrical* apparatus, we shall not enter into any details respecting its effects or its mode of action. See Nicholson's *Journal*, xxvi. 39.

Children's large battery. 1809.

While Sir H. Davy and M. De Luc were thus enlarging our knowledge of the powers of galvanism as a chemical agent, and of the means by which its wonderful effects are accomplished, Mr Children was advantageously employing himself in improving the apparatus. He formed a battery, constructed upon a principle, originally suggested by Volta, according to which the plates are not cemented together, but are connected only at the top by a metallic conductor, and are then immersed in the cells of a trough. He employed 20 pair of plates, of four feet by two, making in all a surface of 92,160 square inches. The fluid that he used was a diluted mixture of nitric and sulphuric acids, the whole quantity being no less than 120 gallons. The effect of these large plates was to fuse entirely, in about 20 seconds, 18 inches of platina wire, of one-thirtieth of an inch in diameter, and to render three feet of the same wire red hot. Charcoal was burned with intense brilliancy. It seemed not a little remarkable, considering the powerful effect on platina wires, that the action of this battery on iron wires was comparatively trifling. Of iron wire, 1-70th of an inch in diameter, it barely fused ten inches, and had not power

PLATE CCLXIII. Fig. 5.

History.

to ignite three feet. It had not the power of decomposing barytes and other similar substances; it did not affect Bennet's electrometer; and it seemed scarcely able to produce a perceptible shock.

Comparative effects of smaller plates.

Mr Children next formed a battery of 200 pairs of plates of two inches square, affording a surface of 3200 inches. With this the alkalies and alkaline earths were readily decomposed, and a considerable divergence was produced in the gold leaves of the electrometer. From this comparison of the effects of the two batteries, we are led to the conclusion which has been already referred to, that the *intensity* of the electricity is increased with the number. and the *quantity* of it with the extent of the metallic plates. Upon this principle, we may explain why the platina wire was acted upon more readily than the iron wire, the more perfect conducting quality of the former presenting no obstacle to the passage of the electricity through it; while the tendency of the iron to oxidation required a greater intensity of the fluid to effect its transmission through the wire. In this paper, the author states, that he has removed one of the objections that have been urged against the identity of the galvanic and the common electricity, that the former has no striking distance; by employing a proper apparatus, he ascertained that the galvanic spark was capable of passing through a certain space between the extremities of two platina wires.

Striking distance of galvanic electricity.

General conclusion.

Mr Children's general conclusion is, that "the absolute effect of a voltaic apparatus is in the compound ratio of the number and size of the plates; the intensity of the electricity being as the former, the quantity given out as the latter; consequently, regard must be had in its construction, to the purposes for which it is designed. For experiments on perfect conductors, very large plates are to be preferred, a small number of which will probably be sufficient; but where the resistence of imperfect conductors is to be overcome, the combination must be great, but the size of the plates must be small. But if quantity and intensity be both required, then a great number of large plates will be necessary. For general purposes, four inches square will be found to be the most convenient size." See *Phil. Trans.* for 1809, p. 32.

More powerful battery. 1813.

Mr Children has since constructed a still larger and more powerful battery, consisting of 20 pairs of copper and zinc plates, each plate being six feet by two feet eight inches. It ignited six feet of thick platina wire, and melted platina with great facility; it also melted iridium and osmium. At the suggestion of Dr Wollaston, a singular fact was ascertained, that a greater length of thick platina wire was ignited, than of platina wire of a much smaller size. See Thomson's *Annals*, ii. 147.

Brande's remarks on Erman. 1814.

We have given some account of a paper of Erman's, in which he endeavours to show, that certain bodies are what he calls Unipolar, that is, that they are conductors of one kind of electricity only. Mr Brande conceived, that the facts brought forward by Erman, might admit of a better explanation upon a different principle, viz. that some chemical bodies, being naturally positive, and others naturally negative, they would be attracted to the surface of the pile in a contrary state to their own, the positive to the negative, and the negative to the positive surface.

Experiments.

In order to submit his opinion to the test of experiment, Mr Brande procured two insulated metallic balls, one connected with the prime conductor, and the other with the rubber of an electrical machine; and placing between them the different substances under examination, he observed to which of the balls they were attracted. He found that the flame of a candle, which principally consists of carbon and hydrogen, was attracted to the negative ball; while the flame of phosphorus, which would contain a quantity of phosphoric acid, was attracted to the positive side. Here the bodies seemed to follow the known laws of electro-chemical attraction, according to the idea of their inherent electrical states; and the other experiments which he performed of a similar nature generally tended to the same conclusion. The facts stated in this paper are conceived to be favourable to the hypothesis of Sir H. Davy, respecting the natural electricities of bodies, and also, when viewed in connexion with Erman's observations, to afford an additional proof of the identity of electricity and galvanism. See *Phil. Trans.* for 1814.

Wollaston's elementary battery. 1815.

Dr Wollaston has constructed an apparatus, which he calls an elementary galvanic battery, the object of which is to exhibit the most minute arrangement of electrical substances, by which visible ignition can be produced. The smallest that he has constructed consists of a thimble, without its top, flattened until its sides were about one-fifth of an inch asunder; a small plate of zinc was then contrived to be fixed within the thimble, but without touching it, and a proper appendage of platina wires was added. The zinc plate was less than three-fourths of an inch square, and even when a very diluted acid was employed, a platina wire of $\frac{1}{3000}$ of an inch in diameter was readily fused. See Thomson's *Annals*, vi. 309.

These experiments of Dr Wollaston's are the latest that have been made on the subject of galvanism, and will bring down the history of the science to the present period.

PART II. THEORY OF GALVANISM.

Theory. General remarks.

According to the plan which was laid down, we must now proceed to give an account of the theories and hypotheses that have been formed to explain the phenomena of galvanism. We have had occasion to allude to many of these in the course of our historical sketch; and the reader will, in some degree, have anticipated our opinion respecting them. The subject divides itself into several branches, partly corresponding with the progress of our knowledge of the facts that were gradually developed, and partly depending upon the supposed relation of galvanism to the other departments of natural philosophy.

Galvani's hypothesis.

In this concise view of the science, we shall not think it necessary to enter into the merits of the earlier speculations, that have been superseded by later discoveries. Of this nature is the original hypothesis of Galvani himself, that the convulsions which he observed in the muscles of frogs, were produced by a new and peculiar agent, residing in the body, to which he gave the name of Animal Electricity. Although there are some few cases which seem to militate against the supposition, it must, upon the whole, be regarded as being decisively proved, that all the phenomena which we stile galvanic, depend merely upon the action of electricity, modified by the manner in which it is produced or excited.

What is galvanism?

Hence arises an interesting question, and one which lies at the very foundation of all our future inquiries, heory.

Remarks on the defini-

How does galvanism differ from common electricity? This question may refer both to the nature of the phenomena themselves, and to the means employed for their production. We may define galvanism, either by enumerating the specific characteristics of those events which we class together under this title; or we may show how they have all a reference to each other, from the similarity of the processes that are employed for their developement. The definition that we have given at the commencement of the article, may be regarded as sufficiently correct and comprehensive, without exceeding the limits to which a definition ought to be restricted. It appears to include every action of bodies upon each other, which is usually considered as belonging to this particular branch of natural philosophy; while it excludes those that are, by common consent, referred to a different department. It is, however, in some cases, difficult to draw the exact line of distinction between electricity and galvanism, and indeed we may doubt, whether any precise distinction actually exists. For as it is conceived, that they both depend upon the same agent, having merely experienced some modification in its nature, or mode of action, we must conclude, that there may be some intermediate or indeterminate state, which might be referred to one or the other with almost equal propriety.

finition.

To recur then to the former definition: "Galvanism is a series of electrical phenomena, in which the electricity is developed without the aid of friction, and where we perceive a chemical action to take place between some of the bodies employed." This definition may perhaps be thought to limit the science too much, and to remove from it many facts, which have always been regarded as galvanic. For example, a great number of the original experiments of Galvani himself, and his immediate contemporaries, where contractions were excited in the muscles of animals, by the application of the two metals, many of those of Fowler, and the first set of Volta's experiments, would, according to this definition, be reduced to the effects of common electricity. To this objection we may reply, that wherever moisture comes in contact with the zinc, or more oxidable metal, it is not improbable that some chemical action is produced, but that it is very slight, and has therefore not been noticed. If, however, upon a strict examination, it is found not to be the case, and that there is actually no change in the chemical condition of any part of the apparatus, it must be admitted, that, according to our present ideas, the phenomena are not to be referred to galvanism. The first unequivocal experiments where the chemical effects were observed, and were connected with the electrical condition of the substances, are those of Fabroni's; and it was not until Volta's discovery of the pile, that we were put in possession of a method by which we were enabled to examine, with any degree of accuracy, the relation between these two actions. Even if we find it necessary to conclude that Galvani, although he had the good fortune to have his name associated with a new department of science, did not witness any of the facts to which we now apply the term, the contradiction will be more apparent than real; and we must not permit the mere circumstance of *names* to influence our opinion respecting the essential nature of *things*. The present state of our knowledge seems, however, to warrant the conjecture, that the action of the two metals on the parts of animals, is strictly galvanic, *i. e.* accompanied by a chemical action on the metals and the fluids, so as to reduce it within the limits of the proposed definition.

i: proper ga nic experiments.

Theory.

Difference between electricity and galvanism.

Waving, however, the farther discussion of this point, which indeed can only be decided by experiment, we must recur to the question already stated, respecting the essential difference between galvanism and common electricity; and, conceiving it to be ascertained, that in the production of the former, a chemical action takes place, which is not necessary in the latter, we must next inquire, in what way this chemical change of the substances imparts to the electricity that particular state or modification which we style galvanic. With respect to the nature of this chemical change, experimentalists are generally agreed: as to the metals, it consists in the oxidation of that metal which possesses the strongest attraction for oxygen; and with respect to the fluid interposed between the metals, it consists in its decomposition, the oxygenous part being attracted to the most oxidable metal, and the alkaline to that which is the least oxidable. Although, as we have already had occasion to remark, there are various galvanic combinations, into which only one metal enters, or even some entirely without metals, yet, as the most powerful and complete circle is that which consists of two metals with a fluid interposed, we shall confine our illustrations to this form of the apparatus.

What is the chemical change?

Galvanic electricity of low intensity.

We may consider it as proved by a number of experiments, which have been stated in the first part of this article, that the electricity, as it is evolved by the different galvanic combinations, always exists in what has been styled a state of low intensity; and that, to whatever extent we increase the apparatus, and however powerfully it acts, still the intensity is but little augmented. Unfortunately it is still a doubtful point of theory, upon what the intensity of electricity depends, or in what it precisely consists. Some writers have ascribed it to a greater or less concentration of the fluid; some to a difference in the velocity of its motion, or in the strength of its affinity for the surrounding bodies; and others to its containing a greater or less portion of caloric. For the present, we must rest satisfied with admitting the fact of the low intensity, as manifested by the phenomena, without being able to explain its cause; and we may next proceed to inquire, whether there be any circumstances in the different methods of exciting or producing electricity, by the machine or the pile respectively, which should cause the first to develope the fluid in a higher, and the latter in a lower state of intensity.

Remarks on electrical intensity.

Electricity as excited by the machine.

And here, it must be confessed, we have little to direct our inquiries but conjecture and uncertain analogy. Of these, however, as being our only guides, we must make the best use that lies in our power. It is generally agreed, that all bodies possess a certain quantity of electricity, which is said to be natural to them, and which, while it remains undisturbed, manifests no indications of its existence. There are many processes which alter the state of this natural electricity, by which it is extricated from one body, and may be transferred to others in the neighbourhood. But this additional portion, being more than their natural share, seems to be retained by them with difficulty, and is ready to fly off in all directions, in order to restore the equilibrium. This may be considered as descriptive of what occurs in the operation of the common electrical machine, where, by the friction of the rubber against the cylinder, a portion of the electric fluid is carried off from one or both of them, and is transferred to the conductor. From the conductor it may be communicated to a variety of other bodies that are placed within the sphere of its influence; but, in all

Theory.

these cases, it is retained by them for a certain space of time only, and is continually passing off, more or less rapidly, to all the surrounding bodies.

Electricity of the pile.

But besides this temporary transfer from one body to another, without their undergoing any farther alteration, they occasionally experience a more permanent change in their electrical state, when, in consequence of their acquiring different physical and chemical properties, their capacity for electricity is entirely altered. When their capacity is diminished, a more gradual, but more continued discharge of the electric fluid takes place; and in this appears to consist the essential action of the pile, as contrasted with that of the machine. In the action of the machine, by which the electric fluid is set at liberty, and transferred from one body to another, no change appears to take place in the substances employed, except the alteration in their respective quantities of electricity. Their attraction for it is neither increased nor diminished; and, consequently, they have a tendency, the one to lose, and the other to acquire, the electricity which has been thus, as it were, forced into the one, and out of the other. According to the nature of the action by which the electricity is evolved, whether the substances experience any permanent change in their capacity, or whether their equilibrium is merely disturbed in a temporary manner, the state of the fluid appears to be affected, so as to cause a difference in its intensity.

The two electricities compared.

When we employ the machine, the electricity that we procure appears to be in a highly elastic state, its particles strongly repulsive of each other, and at the same time not disposed to enter into a permanent union with other bodies. The galvanic electricity which we procure from the pile, is more readily united to other bodies, and has a tendency to form new combinations with them, which is so powerful as to counteract some of the strongest chemical affinities. At the same time, it exhibits less of what may be called mechanical action: its particles are less repulsive of each other; its motions appear less rapid; it causes less commotion in its passage from one body to another; and although its ultimate effects are more powerful, it seems to act with less violence. The one may be compared to a small quantity of an agent highly concentrated; the other to a larger quantity, but in a state of greater dilution. The phenomena of electricity, as excited by the common machine, depend upon the attraction and repulsion of the electric fluid, and its passage from one body to another; while the most important actions of galvanic electricity result from the chemical changes that it produces in the composition of bodies. The excitation of common electricity is not necessarily attended with any permanent alteration in the state of the substances that are employed in producing it. It is usually developed by the mechanical aid of friction, and the same apparatus may continue to be employed for an indefinite length of time. Friction, on the contrary, has no effect in the production of galvanic electricity; it requires a chemical change in some part of the apparatus; and the individual parts which have been employed in generating it acquire new properties, and are incapable of any farther galvanic action.

Action of the pile.

After these general observations, which, scanty and inconclusive as they are, appear to be all that our present knowledge upon the subject will warrant, we must proceed to examine more minutely into the nature of the action that is exercised by the galvanic apparatus. From the remarks that have been already made, it will be obvious, that in the operation of the pile, there are both electrical and chemical phenomena produced; and it has been a point very warmly contended, which of these is the most essential, or rather which of them is the primary effect, and, consequently, is to be considered as the cause of the other, and of the whole train of actions. Volta, and most of the continental philosophers, support the electrical hypothesis; while there are several distinguished experimentalists in this country who maintain, that the chemical action is the one which gives rise to all the changes that are produced, and therefore constitutes the primary action of the instrument.

Volta s[upports the] electric [hy]pothesis.

In all the experiments that were performed with the two metals, previous to the discovery of the pile, with the exception of those of Fabroni, which seem to have been but little attended to, the only point in discussion was, whether the effects were to be referred to the electric fluid, or to a new agent inherent in the animal body. Volta strenuously adopted the opinion, that they depended simply upon common electricity, and accounted for them by supposing, that the contact of the two metals had the power of altering the quantity of electricity which was natural to them, adding a portion of it to the one, and subtracting it from the other respectively. To this power he gave the title of *electro-motion;* and he spoke of it as a new property, which had not been before noticed, and distinctly claimed to himself the merit of its discovery.

Forms pile.

He conceived that he might increase the power of the instrument, or rather concentrate the effect of a number of separate pairs of metal, by interposing between each pair a conducting substance, which, without altering the electric state of the metals, might increase the effect, by transmitting it through a number of successive stages. Whatever we may think of the hypothesis, the experiment to which it gave rise was most fortunate; for it led to the construction of the pile; an apparatus by means of which the most curious and important discoveries have been made in the different departments of natural philosophy.

Did n[ot no]tice its [che]mical [ef]fects.

Although Volta completed the discovery of the pile, and fully ascertained its action on the animal body, yet it is not a little remarkable, that he limited his inquiries to this object, and seems to have been totally ignorant of the farther powers of the instrument of which he was possessed. This circumstance must appear the more remarkable, when we recollect that upon the very first employment of it by Messrs Nicholson and Carlisle, they perceived its chemical action, and became aware of its importance as an agent in the decomposition of bodies. Cruickshanks, Davy, Wollaston, Henry, and the other English philosophers, farther developed its powers in this respect, which had so completely escaped the notice of Volta, and they were consequently led to form a different idea of the mode of its operation. Dr Wollaston seems to have been the first who decidedly adopted the opinion, that the chemical action of the pile is the primary origin of all the changes which it experiences, and is the cause of the electrical effects; and the same idea was embraced by Sir H. Davy, although he has since abandoned it for the hypothesis of electric energies.

An ac[count] of the [elec]tric h[ypo]thesis [of] the pi[le].

We must now proceed to examine the two leading theories of the galvanic action, as exhibited in the pile, with more minuteness; and we shall begin with that of Volta's, or the one which supposes a change in the electrical condition of the metals to be the primary cause of its operation. This philosopher has given a statement of his opinions on the subject, in several letters which he wrote to his friends, and which have been

Theory.

published in different scientific journals. His first communication was in a letter to Cavallo; the second to Gren, (*Phil. Trans.* 1793; *Ann. de Chim.* xxiii. 276.): both written before his discovery of the pile. His original account of this apparatus is contained in a letter to Sir Joseph Banks, in which he explains his ideas respecting its action; and he afterwards farther developed them in letters to Delametherie and to Van Marum, (*Phil. Trans.* 1800; Nicholson's *Journal*, 8vo, i. 135; *Ann. de Chim.* xl. 225.) In some of these papers, Volta details his hypothesis at considerable length; yet, after an attentive examination of them, it appears to us that they are not altogether consistent with each other; and that, without any intimation of the circumstance, he has, in fact, given to the world two distinct hypotheses.

The letter written to Cavallo, of which we have already given some account, is Volta's first essay on the subject of galvanism, and contains an account of Galvani's original discovery, and of the additional experiments which he had himself performed by the combination of the two metals. He accounts for all the facts on the principle, that when metals are placed in certain circumstances with respect to each other, there is "a destruction of the equilibrium" of the electricity. This action is stated to consist essentially in two metals, when placed in contact, giving the one to the other a portion of its natural electricity, so that the one becomes positive and the other negative. Some combinations of metals possess this electro-motive faculty much more powerfully than others; those that Galvani and Volta originally employed were zinc and silver; and in this case the zinc acquired the electricity and became positive, while the silver lost electricity or became negative. In this paper no other principle is referred to, and the action is not spoken of as belonging to any class of bodies except the metals. Volta speaks of the principle as a new law of electricity, which had not been before noticed, and decidedly claims to himself the discovery of it.

In the letter to Delametherie, written after the discovery of the pile, Volta still farther developes his hypothesis, but without altering the ground on which it rests. He describes each pair of metals as the efficient part of the apparatus, and speaks of the fluid that is interposed between them, as merely carrying the electricity from one pair to another, without producing any change in it. In his letter to Van Marum, he relates the following fundamental experiment, as it is called: A plate of copper and a plate of zinc are placed in contact with each other, but so that a part of each plate projects beyond the other; and he finds, that of the parts which thus project, one becomes positive and the other negative. So far all these opinions appear to be consistent with each other; but in the letter written to Gren, an idea is brought forward, which is not noticed in the other essays, and which seems to be essentially different from them. All conductors of electricity are divided into two classes, the dry and the moist; and electricity is supposed to be always excited, when two conductors of either of these classes are placed in contact with one conductor of the other class. In this way one metal only would appear to be sufficient for a galvanic combination, provided there be two moist conductors in contact with it. How the fluids act in this case, or what relation they bear to each other and to the metal, we are not exactly informed; but we may conclude, that it is not from any chemical operation, because in the letter to Delametherie, written four years after that to Gren, it is expressly said, that the fluids have no effect but in transferring the electricity from one metal to another.

General view of the electric hypothesis.

Upon the whole we may conclude, that Volta conceives the electricity to be excited by the metals producing a degree of electro-motion, or by destroying the natural equilibrium of the electricity; one metal thus becoming positive and the other negative, they each of them exhibit signs of electricity to an electrometer or other similar instrument. The only use of the fluid is to transfer the electricity which is excited by one pair of metals to the next pair; and although a chemical action may take place between the fluid and the metal, this action is merely incidental, and is not essential to the production of the galvanic effects.

Objections to it.

The objections to Volta's hypothesis are very forcible; in the first place, it does not appear that the chemical effects of the pile are, as he supposes, merely incidental. They seem, indeed, absolutely essential to its action, for when perfectly pure water is interposed between the metals, or when the apparatus is placed in any situation, where it is excluded from obtaining a supply of oxygen, it ceases to act. The same thing happens when the acid, or other oxidating fluid, is all expended; and in short it may be stated, that whatever promotes the action of the fluid upon one of the metals increases the energy of the instrument, and whatever tends to prevent or destroy this action suspends the energy. It has been urged as an objection to Volta's hypothesis, that it does not provide for any absolute increase of the electric power. The two metals, by their contact, become one positive and the other negative, and this is equally the case with each pair; but the fluid that is interposed between the metals is conceived to restore the equilibrium of the electricity, which has been disturbed by the metals. This is the whole effect of the apparatus, and we are not informed how any electricity can be actually produced or generated, as it would appear that the nature of the instrument is to cause an electric action in one part, which must be immediately counteracted by another part. Whatever deficiency of electricity there was in any copper-plate would be instantly supplied by the water communicating the superabundant electricity of the opposite zinc plate, so that the effect of the whole would be reduced simply to the difference between the two extreme plates of copper and zinc. A third, and perhaps a still stronger argument against the electric hypothesis, is, that the fundamental position on which it rests, is itself objectionable. Volta supposes that two metals, as for example, a plate of zinc and one of copper, when placed in extensive contact with each other, may become respectively positive and negative. This he endeavours to prove by direct experiment; but it will be found that in none of the cases is the experiment precisely in point. He adduces some facts, where metals were found respectively positive and negative, that *had been* in contact, but were afterwards separated: in one of his experiments the metals never actually touched, but were connected by a moist conductor; and in the experiment which we have related above, it was only the projecting parts of the plates that could be made to exhibit the opposite electric states. And here we may be allowed to entertain some doubt respecting the accuracy of the fact; it is evidently an experiment of a most delicate nature, and Mr Cuthbertson, who attempted to repeat it, obtained results contrary to those

Theory.

stated by Volta: (Nicholson's *Journ.* 8vo. ii. 281.) In the experiments of Bennet and Cavallo, where electricity was induced upon metallic bodies by contact, it is to be observed, that they were no longer in contact when they manifested signs of electricity, and it appears not easy to conceive how two metals can be in extensive contact, without communicating their electricity to each other, so as to acquire precisely the same state. The experiments of De Luc, on the dissection of the pile, seem to be strongly adverse to the electric hypothesis. In the second distribution of the ternary groups, the two metals are in contact, and therefore any electrical effect might be produced, which would arise from this circumstance; there was also the fluid between them, which would serve as a conductor of electricity, yet because the apparatus was so arranged that this fluid could not act upon the zinc and oxidate it, no proper galvanic effect ensued.

Chemical hypothesis.

As we have already remarked, Dr Wollaston was the first who decidedly pronounced the chemical action of the pile to be the primary cause of its effects; but in establishing this point, he did not proceed to explain the nature of the operation, or show what was the train of events which contributed to the final result. This was attempted by Mr Cuthbertson, who, in the essay to which we referred above, after pointing out the inaccuracy of the experiments that were brought forward by Volta in favour of the electric hypothesis, offers some observations in support of the contrary opinion. He conceives that the chemical action of the interposed fluid upon the zinc, alters the electric properties of the metal, and disposes it to part with electricity; that this evolved electricity cannot enter into the remainder of the zinc which has not been acted upon, because it retains its former electric state, but that it is "propelled forwards from the zinc, through the menstruum, to the next adjoining copper in the pile or trough. This effect, however, can only happen in a progressive manner, because the fluid is but an imperfect conductor; and to this he ascribes many of the peculiar phenomena of the apparatus. Dr Henry, in a judicious essay "*On the Theorics of the Excitement of Galvanic Electricity,*" (*Manchester Mem.* ii. 293, 2d Series), observes, that "the explanation of Mr Cuthbertson is unequivocally a valuable supplement to the theory of Volta, inasmuch as it takes into account the efficiency of chemical menstrua." But, as he farther remarks, it is defective, because it does not explain why "the action of the menstruum is chiefly, if not entirely, exerted in oxidizing and dissolving the zinc plates, and why the evolution of hydrogen gas, or of nitrous gas, occurs chiefly at the copper surface." This deficiency was attempted to be supplied by Dr Bostock, who, about the same time, published an essay on the action of the galvanic pile, which he has since considerably extended and modified in such a manner, as to accord with the recent discoveries. (Nich. *Journ.* iii. 8vo. 9. and 69. Thomson's *Annals*, iii. 32.)—He proceeds upon the principle which was laid down by Dr Wollaston, that electricity is evolved by the oxidation of metals; and generalizes it so far as to conclude, that the electric fluid is always liberated when an oxidable substance is united to oxygen. In addition to this principle, he proposes to admit the two following postulates, that the electric fluid has a strong attraction for hydrogen, and that when in passing through a chain of conductors, it leaves the oxidable substance to be conveyed through water, it combines with the hydrogen, and is again disengaged from it, whenever it again enters into an oxidable substance.

Cuthbertson's opinion.

Bostock's hypothesis.

We shall quote the account which Dr Henry gives of this hypothesis, as it appears to afford a correct, and at the same time a concise view of it.

Henry's account of it. PLATE CCLXIII Fig. 21.

"To the efficiency of the pile, two circumstances are essential; that the electric fluid should be disengaged, and that it be confined and carried forward in one direction, so as to be concentrated at the end of the apparatus. The first object is fulfilled by the oxidizement of the zinc; the second, as Dr Bostock supposes, is effected by the union of the evolved electricity with nascent hydrogen, and by the attraction of the next copperplate for electricity. At the surface of this plate, the hydrogen and electricity are supposed to separate; the hydrogen to be disengaged in the state of gas, and the electricity to be conveyed onwards to the next zinc plate. Here, being in some degree accumulated, it is extricated in larger quantity, and in a more concentrated form, than before. By a repetition of the same train of operations, the electric fluid continues to accumulate in each successive pair; until, by a sufficient extension of the arrangement, it may be made to exist at the zinc end of the pile, in any assignable degree of force." For a farther account of this hypothesis, we must refer our readers to the original essay, and more especially to that part of it where the author explains the action of the interrupted circuit in the decomposition of water, and the evolution of the gases at the extremities of the two wires: (Thomson's *Ann.* iii. 88.) It must be admitted that it satisfactorily explains the phenomena, and that it accords with all the facts that have hitherto been discovered, but it labours under the great objection of being founded upon a gratuitous supposition, of which there is no proof, except the facility with which it explains the appearances.

The pile both an electrical and galvanic instrument.

We think that part of the difficulty which has occurred in forming a theory of the pile, has arisen from our not clearly discriminating between its effects in exciting common electricity, and that modification of it which is called galvanism. We have endeavoured to point out in what respect these two actions differ from each other; and, imperfect as our knowledge is concerning the cause, we conceive that there is an obvious difference in the effect. Now, it appears to us, that the pile, as it is usually constructed, is both an electrical and a galvanic instrument; and that when we attempt to form a theory of its action, we have two distinct sets of phenomena to explain. The power of producing muscular contraction is an electrical effect, that of decomposing chemical bodies a galvanic effect; while that of burning metallic leaves, or igniting wires, probably partakes of both these actions. That the electric and galvanic effects of the pile bear no proportion to each other, that one may exist in a great degree while the other is scarcely apparent, is rendered evident from the experiments of Mr Singer. In examining the power of different kinds of fluids interposed between the plates, he observed, that although some of the effects were rendered more powerful by employing a solution of salt, yet the electrometer was not more effected than with simple water. He even asserts, that in many trials on a very extensive scale, for example, with 1000 pairs of metals, he has "found the electrical effects greatest when the chemical effects have been least." He relates other facts of a similar kind, which appear to place this matter beyond all doubt, and to establish a decisive difference between these two operations of the instrument. See Singer's *Elem.* p. 330.

Singer's experiments.

De Luc's experiments.

M. De Luc's experiments confirm and illustrate this view of the subject; for they not only show this want

Theory.

of proportion between the two effects, but they enable us to separate them from each other. In his second dissection of the pile, we have a powerful electrical instrument, but one which does not produce galvanic effects; and the same may be said of his electric column, which exhibits none of the phenomena that we exclusively refer to galvanism. On the contrary, some of those combinations which have been made by Mr Children, and other experimentalists, where a few large plates were employed, and where a diluted acid was interposed between them, may be considered as precisely the reverse of De Luc's column. Here very slight marks of common electricity were manifested, while the most powerful galvanic effects were produced.

Proper electrical action of the pile.

Our general conclusion on the subject is, that part of the effects, usually proceeding from the pile, are purely electrical, and do not, in any degree, depend upon a chemical change in the state of the metals. We conceive it to be a doubtful point in what way this electrical action is induced, because, for the reasons which we have already given, we do not think that the experiments of Volta, and the others that have been supposed to coincide with them, are applicable to the state of things as they exist in the pile; nor do we think that if we were to admit them, they would account for the continued evolution of fresh portions of electricity; or that they would explain, why the disturbance of the electric fluid, or the electro-motion, as it is stiled, is not counteracted by the conductors that are connected with the metals. As to the proper galvanic effects of the pile, we consider them to be always immediately caused by the chemical action of the fluid upon the metals; and that, in proportion to the extent of this action, as depending upon the quantity of surface exposed, or the nature of the fluid employed, we obtain the evolution of electricity in greater or less quantity, and in a more or less intense state. Our readers will perceive, from these observations, that we are, upon the whole, advocates for the chemical hypothesis; but at the same time that we attach ourselves to this doctrine, we do it with the restriction already referred to. If we conceive that the proper galvanic phenomena depend upon the chemical changes, we also admit, that there are electrical effects produced by the pile, independent of the others, and unconnected with them.

Galvanic effects.

Davy's hypothesis.

The great discoveries that have been made by Sir H. Davy, in his application of galvanism to chemical decomposition, and the importance which must attach to all his opinions upon the subject, induce us to inquire, what view he takes of the question that we have now been discussing. We have already related the experiments which he performed on the chemical action of the pile; and it appears that he formerly considered it as the primary cause of the phenomena. This opinion, however, he afterwards retracted, and adopted an hypothesis which he conceived might reconcile the doctrine of Volta with the experiments of the English chemists. He supposes, that both electrical and chemical actions are necessarily concerned in the production of the effect; that the former are the first in order of time, and that their tendency is to disturb the electric equilibrium of the different parts of the apparatus, while the chemical changes operate in restoring this equilibrium. In the farther detail of the hypothesis we shall employ the author's own words. "In the voltaic pile of zinc, copper, and solution of muriate of soda, in what has been called its condition of electrical tension, the communicating plates of copper and zinc are in opposite electrical states. And with regard to electricities of such very low intensity, water is an insulating body; every copper plate, consequently, produces by induction an increase of positive electricity upon the opposite zinc plate, and every zinc plate an increase of negative electricity on the opposite copper plate; and the intensity increases with the number, and the quantity with the extent of the series."

"When a communication is made between the two extreme points, the opposite electricities tend to annihilate each other; and if the fluid medium could be a substance incapable of decomposition, the equilibrium, there is every reason to believe, would be restored, and the motion of the electricity cease. But solution of muriate of soda being composed of two series of elements, possessing opposite electrical energies, the oxygen and acid are attracted by the zinc, and the hydrogen and alkali by the copper. The balance of power is momentary only; for solution of zinc is formed, and the hydrogen is disengaged. The negative energy of the copper, and the positive energy of the zinc, are consequently again exerted, enfeebled only by the opposing energy of the soda in contact with the copper; and the process of electro-motion continues, as long as the chemical changes are capable of being carried on." See *Phil. Trans. for* 1807, vol. xlv.

This hypothesis agrees with that of Volta, in ascribing the train of actions to the electric condition of the metals, yet it differs from it in many essential points. It supposes the chemical decomposition of the interposed fluid to be a necessary, although not the first step in the process. The conducting power of the fluid is, in both cases, taken into account, yet it is regarded in an opposite point of view. According to Volta, the better is the conducting fluid, the more energetic is the action of the pile; while the hypothesis of Sir H. Davy seems to require the fluid to possess almost a non-conducting property.

Electric energies.

Some of the late speculations of this illustrious chemist have led him to deviate still farther from the ordinary hypothesis, not only as it respects galvanism, but electricity in general. Those effects, which were formerly attributed to a material agent, capable of being added to, or subtracted from a body at pleasure, are now conceived, like gravitation, to be inherent qualities of matter. To these, which are called electric energies, all chemical decompositions are to be ultimately referred; for it is supposed, that chemical attraction, in all cases, results from the circumstance of two bodies possessing opposite electric energies, and consequently having a strong tendency to unite. By means of the galvanic combinations, we have it in our power to excite the electric state of a body to an indefinite degree, and to induce an electricity contrary to that which is natural to it. But the farther consideration of the merits of this theory, belong rather to electricity than to galvanism strictly so called. To whatever cause we ascribe the electric state of bodies, whether to a material agent distributed through them in different quantities, or to some affection of their primary qualities, the states of positive and negative electricity actually exist, and our present business is merely to inquire, what relation they bear to the phenomena of the galvanic pile.

De Luc's objections.

M. De Luc advances an argument, which he conceives to be quite decisive, against the hypothesis of the natural electric energies of bodies producing the phenomena of the pile, that the whole instrument may be rendered either positive or negative, by connecting

Theory.

it with the conductor or rubber of the electrical machine; and yet its operation is not in any degree affected. He also contrived an apparatus, in which there were three wires placed between the extremities of the pile, two of them connected with the ends of the pile, and the third in the centre; the wires having water interposed between them, and electrometers so situated, as to ascertain the electric condition of the wires. In the ordinary state of the apparatus, the terminating wires were one positive and the other negative, corresponding to the ends of the pile to which they were attached, while the central wire was neutral; yet the ends of this neutral wire produced opposite electrical effects, one separating oxygen, and the other hydrogen. By altering the apparatus, the electrical state of the wires were altered; the central wire was rendered at one time positive, and afterwards negative, and the state of the terminating wires was reversed; yet no change took place in the chemical action of the wires, each of them continuing to evolve oxygen and hydrogen as at first, and the two ends of the central wire separating oxygen and hydrogen respectively at its extremities, in the same manner, whether the wire itself was positive, negative, or neutral. See Nicholson's *Journ.* xxvi.

Singer's objections. PLATE CCLXIII. Fig. 22.

Mr Singer has proposed an objection to Sir H. Davy's hypothesis, very similar to this of M. De Luc's. If a number of metallic wires are placed in a line, with their extremities immersed in a fluid, and the whole connected with the pile, each wire will evolve oxygen at one end, and hydrogen at the other. Now, he conceives it impossible that every wire can have an opposite electricity at its two extremities, when it is surrounded by a conducting fluid; for no metallic body can be made polar, *i. e.* one end positive and the other negative, but by the temporary disturbance of the equilibrium of its natural electricity; an event which can only happen when they are separated by a non-conducting substance. But he observes, "No one can maintain, that water, or any saline fluid or acid mixture, is a non-conductor, either of the chemical or electrical effects of the voltaic apparatus; yet the usual chemical changes produced by voltaic electricity occur at every interruption of the metallic circuit in such fluids." See Singer's *Elem.* p. 376.

There appears to us to be considerable weight in these objections; and we confess, that the ideas of Sir H. Davy produce a shock to our usual associations on the subject of electricity, which it is not easy to overcome. However, as we have already remarked, it would be foreign to the object of this article to pursue the discussion any farther; nor do we conceive, that we are at present in possession of sufficient facts to warrant us in coming to any definite conclusion respecting it.

Concluding remarks.

We shall here conclude our account of the theory of galvanism. Our readers will perceive, that much discordance of opinion still exists upon the subject, and that some strong objections attach to every hypothesis which has yet been proposed. The most important points to ascertain are, the difference between electricity, as excited by the friction of the common machine, and that modification of it which is strictly called galvanism. For this purpose, the nature of electric intensity should be farther investigated; for it would appear that if we were able to attach a more precise idea to this term, a considerable insight would be gained into the cause of this difference. Experiments somewhat similar to those of M. De Luc should be prosecuted, in which the electrical and chemical effects of the pile are separated from each other, and a more accurate measure of the proper galvanic power should, if possible, be obtained, than any of which we are now possessed. The conducting power of the fluids concerned in the galvanic apparatus should be carefully examined, and the relation of their chemical action to their conducting power should be ascertained. But it is unnecessary for us to enlarge upon these topics: the rapid succession of discoveries which have been made in this department of science, and the very general attention which it has obtained from the first philosophers of the age, afford every reason to expect, that the farther investigation of it will be followed by no less success, than that which has hitherto attended its progress.

Description of the Figures in Plate CCLXIII.

PLATE CCLXIII. Fig. 1.

Fig. 1. The galvanic pile, as originally constructed by Volta, where the letters C, Z, and F denote the plates of copper and zinc, and the pieces of cloth or pasteboard soaked in fluid. The pile has four rods placed round it, to keep it in the perpendicular direction. The lower end was called the *copper*, and the upper the *zinc end.*

Fig. 2. When the number of plates is very considerable, Volta divides it into two or more parts, each being connected by slips of metal. In this case, it is essential that the same order of parts be observed from one end to the other, up the first pile, down the second, up the third, and, lastly, down the fourth.

Fig. 3. This was a modification of the galvanic apparatus that was formed by Volta, which he called *couronne des tasses,* where the zinc plates Z and copper plates C are not in contact, but are connected by metallic rods, and then immersed in a fluid.

Fig. 4. represents the trough apparatus invented by Mr Cruickshanks; the plates of zinc and copper are soldered together, and are then cemented into a wooden frame, leaving intervals between the double plates, to receive the fluid which is intended to act upon the zinc. It is provided with wires at each end, which are in opposite states of electricity, and may be applied to any substance which it is proposed to subject to its influence.

Fig. 5. represents the battery of Mr Children, which is a combination of the *couronne des tasses* of Volta and the trough of Cruickshanks. The plates are not in contact, but each pair is connected by slips of metal, and the whole is attached to a beam, so as to be lifted out of the cells at pleasure. The trough and partitions may be formed of either wood or earthen ware, and contain the fluid that is to act on the zinc plates.

Fig. 6. is the apparatus for receiving in separate vessels the gases which are evolved by the action of galvanism upon water. The two small jars have metallic wires inserted at their upper end, one of which is connected with the positive, and the other with the negative extremity of the pile. They are filled with water and inverted in the same fluid; and the ends of the wires are so situated, that the gas disengaged from them rises to the top of the jar.

Fig. 7. represents the apparatus in which the gases disengaged from water may be reconverted into water by the electric spark.

Fig. 8. are the agate cups, connected by amianthus,

Description of the Figures.

employed by Sir H. Davy in the decomposition of water; and Fig. 9. are the gold cones employed in the same set of experiments.

Plate CCLXIII. Figs. 9, 10, 11.

Fig. 10. represents the apparatus which Sir H. Davy employed for the decomposition of salts, and the transfer of their constituents. In Fig. 11. we have the combination of three vessels, in which the transfer is exhibited in a more striking manner.

Fig. 12. Fig. 12. represents the apparatus for taking the galvanic spark in gases: it consists of a graduated glass tube, into which two wires are introduced, the one which enters at the side being moveable, and capable of being approached to the other; according to circumstances, they may be tipped with pieces of charcoal, or the wire may be bare.

Fig. 13. Fig. 13. is a variation in the form, which may be employed over mercury. These instruments were invented by Sir H. Davy.

Figs. 15, 16, 17, 18. Figs. 15, 16, 17, 18. The dissected pile employed by De Luc, to illustrate the mode of its action. The shaded part represents the moistened cloths, and the letters C and Z the copper and zinc plates respectively. In Fig. 15. the pile is continuous, in its usual form; Fig. 16. is the first dissection, Fig. 17. the second, and Fig. 18. the third. Fig. 14. is one of the wire stands that are interposed between the plates.

Fig. 19. Fig. 19. represents the apparatus of M. De Luc: it consists of two piles connected by a metallic rod at the bottom; between the upper ends is interposed the interrupted wires terminating in water, and to each extremity one of Bennet's electrometers is applied.

Fig. 20. Fig. 20. represents the lower limbs of a frog, lying on a plate of metal, while another kind of metal is placed in contact with the spinal marrow; these two metals are then connected by a conducting body, and the muscles of the legs are thrown into convulsions.

Fig. 21. is Dr Bostock's numerical illustration of the effect of the pile; the letters point out the nature of the substances, and the figures indicate the increase of power which the electricity acquires by passing along the instrument. See Thomson's *Annals*, iii. 86. Description of the Figures. Plate CCLXIII. Fig. 21.

Fig. 22. is an experiment of Mr Singer's, which is supposed to disprove the hypothesis of electric energies. In this apparatus, each wire will have its ends in the opposite states of electricity, one positive and the other negative. Fig. 22.

Besides the references that we have made in the course of the article, the following works and papers deserve to be noticed, either as presenting an interesting view of the gradual progress of the science, or as containing an abstract of the hypotheses that have prevailed at different times.

Galway.

GALWAY, a maritime county of Ireland, in the province of Connaught. It is bounded on the north by Mayo and Roscommon; on the east by Tipperary and King's County; on the south by Clare; and on the west by the Atlantic ocean. Its aspect is various, some parts of it being almost in a state of nature, and other parts of it fertile and cultivated. The western district is rocky and mountainous; the eastern district is flat with the exception of some low mountains on the borders of Clare. The soil here is warm and fertile, and capable of considerable improvement. The substratum being limestone, the verdure is almost every where exceedingly luxuriant. The best land in the county is situated between Mount Talbot and Portumna, and along by Ballyroan and Kilconneltenagh. That which stands next in quality, extends from Athenry to the town of Galway. It is not arable on account of its rocky nature, but produces excellent pasturage for sheep. The third division in point of quality, lies in the neighbourhood of Monaltee, affording very coarse grass, mixed with heath. The fourth comprehends Conamara and Joyce's land, and is quite destitute of cultivation.

Agriculture is in a very backward state. Indeed, almost the whole country is appropriated to grass. In some places, however, they raise wheat, barley, oats, and flax. Potatoes, of course, they have in abundance. There are scarcely any ditches or hedges; their fences consisting mostly of dry stone walls. They have an excellent breed of long horned cattle, and the finest flocks of sheep that are any where to be seen. To this last branch of rural economy they pay great attention; those who engage in it have both enterprise and capital; and accordingly it is in a very flourishing condition. The principal market for stock is that of Ballinasloe, situated on the east border of the county. Labour is generally paid by rent or price of corn acres, meadow or grass of a cow. In 1811, the average price of various articles were calculated as follows: A man the year round, £11, 10s. 9d.; a woman ditto £6, 10s.; carpenter per day 2s. 2d.; mason ditto 2s. 5½d.; slater ditto 2s. 3¼d.; quarryman 1s. 1d.; thrasher 9d.; saddle-horse ditto 4s. 4d.; plough ditto 5s. 5d.; grazing a cow per week 2s. 3d.; oak per foot 4s.; ash ditto 3s. 3d.; bricks per 1000 £1.; a car mounted £4, 11s.; potatoes per stone 3½d.; salt butter per cwt. £3, 14s. 8d.; fresh ditto per lib. 1s. 2¼d.; hay per ton £2, 17s. 6d.; whiskey per gallon 9s.; ale per quart 3d.; porter per gallon 1s. 6d.; beef per lib. 5½d.; mutton ditto 6d.; veal ditto 8d.; pork ditto 3½d.; lambs per score £19, 10s.; cheese per lib. 1s. 4d.; shoeing a horse 4s. 4d.; shoes per pair 9s. 9d.; salt per stone 1s. 1d.; Swedish iron per cwt. £1, 8s. 6d.; undressed flax per cwt. £3, 14s. 8d.; wool per stone £1.; fowls per couple 1s. 8d.; wheat per barrel £1, 18s. 5¼d.; barley ditto 15s. 6d.; oats ditto 10s. 1d.; malt ditto £1, 15s. 6d.; flour, 1st, per cwt. £1, 9s. 4d.; ditto, 2d, ditto £1, 4s.; ditto, 3d, ditto 17s.; oatmeal per cwt 14s.; labour in hay or corn harvest per day 1s. 1d.; mowing grass per acre 4s. 6½d.; rabbits per couple 1s. 1d.; milk per quart 2d.; herrings per 100, 5s. 3d.; corn acres of oats per acre £5, 6s. 10½d.; ditto meadow

Galway. ditto £6, 13s. 11¼; ditto potatoe land ditto £7, 7s. 6¾d.; flax per rood £1, 18s.

Large as this county is, there is not of property belonging to absentees above £50,000 per annum. Perhaps one-third of the whole land is let in partnership leases; and in some places leases are granted for three lives, or thirty-one years, to an indefinite number of tenants, who are not only joint in occupying the ground, but have the benefit of survivorship. The average rent is £1, 10s. per green acre. A man of large property is here termed a *statesman*, but he who has only a few acres is called a *patchman*. The Earl of Clanricarde, Lord Clancarty, Mr Eyre, and Mr Ross Mahon, have each estates in this county of about £10,000 per annum, Christoper D. Baleu, Esq. has £6000, John Burke, Esq. £7000, Lord French £3500, Malachy Doneyland £5000. Mr Martin has about 70 miles along the coast, and is reckoned the most extensive landed proprietor in the three kingdoms.

There is a good deal of fishing on the coast of Galway; but the fishermen are destitute of sufficient enterprise. The fish-market of Galway town is excellent, being supplied with turbot, salmon, &c. at a cheap rate. Trade is at a low ebb. Galway, though enjoying many local advantages in this respect, has declined very much of late years. Besides Galway, there are the well sheltered havens of Killkerran, Birturby, Roundstone, and Ballynakill. The manufactures of the county are not worth mentioning.

Galway abounds in rivers and lakes. The lake of Lough Corrib covers above 31,000 acres. It is twenty miles in length, and eleven acres at the broadest part. It resembles Lough Earne. Lough Reagh and Lough Coutra are said to be beautiful pieces of water. Several of the rivers have the peculiarity of being subterraneous in a part of their course. These are the Black River, the Clare, the Moyne, and the Gustnamakin. Almost every river and brook in the neighbourhood of Gort has a great number of these *swallows*.—The principal town in the county is that of Galway, which, indeed, is the largest in the province of Connaught. It is resorted to as a bathing-place in summer; and a place of residence in the winter for those families that are fond of society. The houses stand with their gables to the street, and a door in the end, like that of a coach-house.

Galway sends three members to parliament—two from the county and one from the town. There is no overbearing territorial influence. The Roman Catholic property is very extensive, and always supports that interest. The number of freeholders amounts to 4000. The freeholders within the borough, along with the members of the corporation, who are chosen at will, elect its representative.—The inhabitants of this county are mostly Catholics, the Catholics being as forty or fifty to one; in landed property they are about one to three; and in personal property as three to one. In the western parts, there are districts of fifty miles in extent, without a single church or a single Protestant. The militia, consisting of 1000 men, were all Catholics except the band and petty officers, amounting to sixty or seventy. The Catholics are increasing. There are ten Catholics called on the grand jury.

This county contains 1546 square miles, 989,950 acres, 16 baronies, 116 parishes, 28,212 houses, 142,000 inhabitants, 35 acres to a house, and 18.24 souls to a square mile. See Beaufort's *Memoir of a Map of Ireland*. Wakefield's *Statistical Account of Ireland*. (T)

Gama. GAMA, Vasco de, the discoverer of the passage to the East Indies by the Cape of Good Hope, was descended of a noble Portuguese family; and in early life distinguished himself as a naval commander in a war with the French. In 1497, he was selected by Emmanuel, King of Portugal, to command the squadron which had been equipped for the voyage to India. His courage, penetration, prudence, and enterprising spirit, rendered him worthy of the important charge, and were signally displayed in the course of the expedition. His squadron consisted only of three vessels and a store-ship, all of them of a burden and force very inadequate for such a service. On the 8th of July, the shore was covered with the inhabitants of Lisbon, and the adventurous band set sail amidst the tears and prayers of their countrymen and friends. It was the 4th day of November before they touched land on the western coast of Africa, where, in an accidental scuffle with the natives, Gama was wounded in his foot by a dart. From this period all his heroism was called forth in contending with the most tempestuous seas, and combating the mutinous opposition of his crew, till the 20th of the same month, when the storm suddenly ceased, and the Cape of Good Hope appeared in view. Having taken in provisions, and destroyed their store-sloop, they proceeded to sea on the 8th of December, and reached the shores of Mozambique about the beginning of March, where they first experienced the hostile dispositions of the Moors, and Gama narrowly escaped their treacherous attempts upon his life. After various adventures, in which his coolness and intrepidity were equally displayed, he came to anchor before the city of Melinda, where he found several merchant vessels from India, commanded by Christians; and, having procured a skilful pilot, arrived at Calicut on the 22d of May 1498. The sovereign of the country, or Zamorim, at first welcomed the strangers with every demonstration of friendship; but was soon influenced by the Moors to depart from his promises of alliance. On this occasion, Gama gave a noble proof of the most determined resolution and heroic self-devotion to the cause in which he had engaged. In order to complete the object of his voyage, an interview with the Zamorim was absolutely necessary; and, while he boldly committed himself into the hands of strangers, with all his experience of their treacherous dispositions, his whole arrangements and commands were directed, not to his own safety, but to the success of the expedition. He left the most peremptory orders with his officers, that if he were detained a prisoner, or any attempt made upon his life, they should take no step to save him; that they should give ear to no message, which might come in his name; that they should enter into no negotiation in his behalf; that they should not risk the loss of a single man, or endanger in any respect the homeward voyage for his sake; but, the moment they perceived his escape to be impracticable, they should set sail for Europe, and carry to the king of Portugal the tidings of the discovery of India. He escaped the snares of the Zamorim, defeated the Indian fleet, and pursued his homeward course. He reached St Jago in safety; but his brother, Paulus de Gama, sinking under the fatigues of the voyage, was unable to proceed. The generous and affectionate Gama, less elated with the triumphs which awaited his return, than afflicted by the sickness of his brother, sent forward his ship under the command of one of his officers, and remained at Tercera, to soothe the death-bed, and to close the eyes of Paulus. Having fulfilled this melancholy office, he landed at Lisbon on

Gamboge.

the 14th of September 1499, after performing the longest and most difficult voyage that had ever been made since the first discovery of navigation. Honoured with the title of nobility, appointed admiral of the Eastern seas, rewarded with a suitable salary, loaded with the compliments of the court, and followed by the shouts of the populace, he remained inconsolable for the loss of his brother, the companion of his toils; and, shutting himself up in a lonely house on the sea-side at Belem, could not be persuaded till after a long interval, to mingle again in public life. He was appointed, in 1503, to the command of a powerful fleet of 20 ships, destined for India, where he had frequent engagements with the fleets of the Zamorim; and, having secured a friendly commerce with the ports of Cochin and Cananore, he returned home with 12 ships, loaded with the riches of the East. The mal-administration of future commanders in India requiring the presence of some distinguished character, he set sail a third time, in the year 1524, in the office of Viceroy, and with the title of Count de Vidigueyra. Having remedied the errors of his predecessors by his exalted and liberal policy, he was interrupted in the prosecution of his enlightened plans, and died at Cochin three months after his arrival. See Robertson's *History of America*; Abbé Raynal's *History of the East and West Indies*; Mickle's *Lusiad*, Introduction; and *Modern Universal History*, vol. ix. (q)

GAMBOGE is the name of the concrete, gummy, and resinous juice of the *Stalagmitis gambogioides*, a tall tree, with spreading branches, which grows in Cambodia or Cambogia, Ceylon, Siam, and Cochinchina. The gamboge from Siam is sent home in small tears, which exude from the leaf-stalks, and young shoots that are broken off the tree. The gamboge of Ceylon is obtained from deep incisions in the bark, the juice being afterwards inspissated by the heat of the sun, and formed into cakes or rolls. The external colour is brownish-yellow, leaving a deep reddish-orange tint within. Its surface is smooth, and its texture equal and uniform. It has no smell, and very little taste; but when it has remained some time in the mouth, it leaves an acrid impression. It melts and blazes when applied to the flame of a candle, emitting sparks and a dense black smoke. Its flame is white when the gamboge is good, and its ashes grey. The larger and dark-coloured cakes are not good.

When dissolved in water, gamboge forms a fine yellow pigment, which is well known. It is also employed in making the gold-coloured lacquer for staining white wood, so as to resemble boxwood; and in giving a beautiful and durable citron-yellow stain to marble.

The following Table shews the quantity imported and sold by the East India Company from 1804 to 1808, inclusive. The permanent duty is £5, 12s. per cwt. and the war duty £1 : 17 : 6, amounting in all to £7 : 9 : 4.

Years.	March Sale.		Sept. Sale.		Total.		Aver. Price per Cwt.

GANGES, a celebrated river of Asia, whose waters are regarded by the Hindoo as an object of peculiar sanctity and veneration.

Its nam[e]

In Eastern mythology, Ganga, the Ganges, is described as the eldest daughter of the great mountain Himavata, and called Ganga on account of flowing through *gang*, the earth. The Hindoo, willing to adopt what the Brahmin tells him as most congenial to his prejudices of the origin of the sacred river, believes that it issues from the root of the Boohjputre tree, through the semblance of a cow's mouth in stone, and flows directly from heaven; nor does he seek to be undeceived of so agreeable an illusion.

Fabulou[s] origin.

True ori[gin]

Until lately, much obscurity existed with regard to the true source of the Ganges; nor indeed to this day has it been traced up to the fountain head. But on this point the field of conjecture and doubt is much narrowed. All the maps, till 1807, assigned a course to the Ganges many hundred miles within the range of Himalaya mountains, the northern boundary of Hindostan. But the late Lieutenant-Colonel Colebrooke, Surveyor-General of Bengal, refused it so remote an origin, on the grounds, that if it pursued such a length of course, it must have swelled to a river of great magnitude long before it reached Gangoutri, from the supply of mountain-snows and rills. This gentleman was directed by the Bengal government to explore the sources of the Ganges; unfortunately, a premature death deprived the world of his services and professional abilities. Lieutenant Webbe, surveyor, was instructed to follow up Colonel Colebrooke's views, but he failed of success, being stopped by the extreme difficulties of the way, when, by all accounts, he was within a few days reach of the ultimate object of his mission. Geographers now agree in deducing the source of the Ganges from no considerable distance beyond Gangoutri, situated in N. Lat. 31° 4′, and E. Long. 78° 9′, among the Himalaya mountains, in the province of Serinagur.

Reasons [as]signed f[or] its sourc[e]

This opinion rests on the following grounds: that all the mountain streams during Lieutenant Webbe's journey were found to be increased during a course of eight or ten miles, from the smallest rivulet, to a considerable and unfordable river, by the supply of springs and tributary rills. The course of the Ganges and Alacananda rivers having been followed, till the former became a shallow and stagnant pool, and the latter a small stream; and both being affected by the dissolution of snows, in addition to springs and rills, it was concluded from analogy, that the sources of these rivers could be at no great distance from the spot where the observations were made. As we have no reason to suppose that the Bhagirathi branch of the Ganges is governed by laws different from other mountain streams, we are warranted in fixing its source on the southern side of the Himalaya range of mountains, and likewise in concluding that all the tributary streams of the Ganges, with the Sarjew or Goggrah, and the Jumna, whose chief fountain is not remote from the Ganges, rise also on the same side of that chain of mountains. Every account agrees that the source of the Ganges extends beyond Gangoutri, which is merely the point whence it issues from Himalaya. It is said to be here fifteen

Ganges.

or twenty yards broad, the current moderate, and waist deep. But the access beyond this place is much obstructed by snows. The pilgrims, and those who reside in the vicinity of Gangontri, and who gain a livelihood by bringing water from the spot, say that the road is only passable for a few miles, when the current is entirely concealed under heaps of snow, which no traveller ever has surmounted, or can surmount. This river assuming the name of the Bhagirathi, continues to flow from the north till it meets the waters of the Alacananda from the east. Their united streams at the town of Devaprayaga, in North Lat. 30° 8′ 6″, form the Ganges. Thus it appears that the Alacananda, which rises at a place called Bhadinath, in North Lat. 30° 42′ 28″, and East Long. 80° 18′ 22″, divides with the Bhagirathi the honour of forming the sacred river.

Formation of the Ganges.

Contrast of the Bhagirathi and Alacananda.

The contrast of these two rivers is remarkable. The Bhagirathi rushes down a steep declivity, foaming over large stones and fragments in its bed, while the placid Alacananda flows with a smooth and unruffled wave, till it unites its murmurs with the boisterous torrent of its sister stream. The breadth of the former is 112 feet, and it is said to rise 40 feet in the rains. It is crossed by a bridge of ropes, elevated 52 feet above the level of the water.

Fair and pilgrimage of Hairu ca Pairi.

The spot where the Ganges enters the plains, after forcing its way through an extensive tract of mountainous country, is called Hairu ca Pairi, situated at the extremity of the town of Hurdwar, and is regarded with peculiar veneration by the Hindoos. Hither an annual pilgrimage is made by people from all parts of Hindostan and the Deccan, for the purpose of ablution in the sacred stream. The bathing commences on the 10th of April. Every twelfth year is celebrated with greater rejoicings, and is called Cumbla Meba, from the planet Jupiter being then in the sign Aquarius. A fair is held here, and numbers repair to it merely from commercial motives. Merchants from the Penjab, Cabul, Cashmere, and other places, furnish merchandize, and from this mart the principal cities in the Duab, Delhi, and Lucknow, are supplied. At this season, sometimes two millions of people are collected. The temple containing the idol rises from the bed of the river. It is a plain building, surmounted by two cupolas. No particular ceremony is observed at the bathing, which consists of simple immersion. Those who are rigidly devout, or who have any apprehension about going into the water, are assisted by a couple of Brahmins, who having dipped the penitent in the holy stream, reconduct him ashore. Few, however, require this assistance; and as the water is not above four feet deep, the women plunge in without hesitation, and both sexes mix indiscriminately. After ablution is performed, the men whose fathers are dead, and widows, undergo tonsure, and the hair is generally strewed in some frequented path, with the superstitious idea, that good or bad fortune is indicated by the person or animal that first chances to tread on it. An elephant is considered peculiarly fortunate.

The five Pruyags.

Although the water of the Ganges, from Gangoutri to Sagor, is esteemed sacred, yet there are certain places, the resort of pilgrims from a distance, more eminently so than the rest. These are chiefly the five Pruyags, or sacred junctions of rivers, of which the principal is Allahabad, called simply Pruyag by way of distinction. The others are situated in the province of Sirinagur, at the confluence of the Alacananda with small rivers, and are named Devaprayaga, Budraprayaga, Carnaprayaga, and Nandaprayaga. Besides its sanctity, the Ganges is much esteemed for its medicinal properties, and drank on this account by Mahomedans.

Inland navigation.

The Ganges and Brahmapootra rivers, with their numerous branches and tributaries, intersect the country of Bengal in such a variety of directions, as to form the most complete and easy inland navigation imaginable. So equally and admirably diffused are those natural canals, over a country approaching to a perfect plain, that 4-5ths of Bengal may be safely said to be so well watered, as to command some navigable stream, even in the dry season, within a distance of 25 miles. This inland navigation employs upwards of 30,000 boatmen. And when it is considered that all the salt, and most of the food consumed by so large a population, is transported by water within Bengal and its dependencies, and at the same time that the commercial exports and imports, the interchange of manufactures and products throughout the country, the fisheries, and travelling, are all carried on by this means, it becomes less a matter of surprize that the inland navigation should employ such a number of hands.

The Ganges, on escaping from the mountains, flows with a smooth navigable stream, through delightful plains, during its course to the sea, diffusing plenty over the adjacent lands, and affording every facility for the transport of the productions of its borders. Nor is it unimportant in a military point of view; opening a communication between the different posts, it serves as a military way through the country, and renders unnecessary the formation of magazines.

Conflux with the Jumna.

After the Ganges issues from the mountains near Hurdwar, to the conflux with the Jumna at Allahabad, (the first large river that it meets), its bed varies from a mile to one mile and a quarter in breadth. From thence its course becomes more circuitous, and its channel wider, till having received successively the Goggrah, the Soane, and the Gunduck, besides many smaller streams, its channel attains its full width; and though afterwards in some places it narrows to half a mile, yet where no islands intervene, it extends to a breadth of three miles.

Its breadth and depth.

When at its lowest, the principal channel varies from 400 yards to $1\frac{1}{4}$th mile wide, and commonly is about $\frac{3}{4}$ths of a mile in breadth. The Ganges is fordable at some places above its conflux with the Jumna, but the navigation is never interrupted. At 500 miles from the sea, the channel is 30 feet deep when the river is lowest; and this depth continues to the sea, where the sudden expansion of the stream deprives it of force sufficient to sweep away the bars of sand and mud thrown across it by the strong southerly winds, so that the principal branch of the Ganges cannot be entered by large vessels.

Influx of rivers into the Ganges.

In its course through the plains, the Ganges receives 11 rivers, some of which are equal in size to the Rhine, and none smaller than the Thames, besides as many more of lesser note. To this vast influx of water, it is owing that the Ganges exceeds the Nile so much in point of magnitude, while the latter exceeds it by one third in length of course.

Its descent and motion.

The general descent of the Ganges does not exceed four inches per mile; and the mean rate of motion, in the dry season, is less than three miles an hour. In the wet season, whilst the waters are running off from the inundated lands, the current flows from five to six miles an hour, and in particular circumstances and situations,

Ganges.

seven or eight miles. An instance is mentioned by Rennell, in which a boat was carried, against a strong wind, 56 miles in eight hours. Considering that the velocity of the stream is three miles in one season, and five or more in the other, or the same descent of four inches per mile, and that the motion of the inundation is only ½ mile per hour, on a much greater descent; no further proof is required, how small the proportion of velocity is, which is communicated by the descent. It is then to the impetus originating at the spring head, or at the place where adventitious waters are poured in, and successively communicated to every part of the stream, that we are to attribute the velocity, which is governed by the greater or less accession of water.

Annual overflowing.

The annual swelling and overflowing of the Ganges, is attributable as much to the rain water that falls in the mountains contiguous to its source, and to the sources of the great northern rivers that fall into it, as to that which falls in the plains. The dissolution of mountain snow adds but little to its increase; for it rises but 15½ feet out of 32 (the sum total of its rise) by the latter end of June, and it is well known that the rainy season does not commence in most of the low countries till about that time.

In the mountains, the rains begin early in April, and by the latter end of that month, when the rain water has reached Bengal, the river begins to rise, but by very slow degrees, the increase being only about an inch a day for the first fortnight. It then gradually augments to two or three inches, before any quantity of rain falls in the low countries. On the rain becoming general, the increase on a medium is five inches per day.

Increase and decrease.

The following Table shews the gradual increase of the Ganges, and its branches, according to observations made at Jellinghy and Dacca.

At Jellinghy.	Ft.	In.	At Dacca. Ft.	In.
In May it rose	6	0	2	4
June	9	6	4	6
July	12	6	5	6
In the first half of August	4	0	1	11
	32	0	14	3

Its daily increase is nearly in the following proportion. During the latter half of August, and all September, from three to four inches; from September to the end of November, it diminishes gradually from three inches to 1½ inch; and at a medium ½ inch per day, from November to the latter end of April. These proportions relate to such parts of the river as are not affected by the tides. By the latter end of July, all the lower parts of Bengal are overflowed contiguous to the Ganges and Brahmapootra, forming an inundation of more than 100 miles in width, nothing appearing but villages and trees, and here and there the site of an abandoned village, resembling an island. Owing to the quantity of rain that falls in Bengal, the lands are generally overflowed to a considerable height long before the bed of the river is filled, the ground adjacent to the bank, to the extent of some miles, being more elevated than the rest of the country. Dikes, kept up at an enormous expence, guard particular tracks from inundation, yet these are liable to be damaged, owing to the want of tenacity in the soil of which they are composed. It is calculated that the length of these dikes, collectively, exceeds 1000 miles. The inundation is nearly at a stand in Bengal, for some days preceding the 15th of August, when it begins to run off, though great quantities of rain still continue to fall during August and September; but by this time a decrease of rain having taken place in the mountains, a consequent deficiency of supply to keep up the inundation ensues. Of the increase of the Ganges, Rennell remarks that there is a difference in the quantity of this increase at places more or less remote from the sea, the height of the periodical increase diminishing gradually from where the tide reaches to the sea, until it totally disappears at the point of confluence. The ocean preserving the same level at all seasons, (under similar circumstances of tide) necessarily influences the level of all waters that communicate with it, unless precipitated in the form of a cataract. At Luckipoor, there is a difference of about six feet in the height at different seasons; at Dacca, and places adjacent, 14; and at Custee of 31 feet. The last place is about 240 miles from the sea, by the course of the river; and the surface of the river there is, in the dry season, 80 feet above the level of the sea at high water.

Quantity of water discharged.

The quantity of water discharged by the Ganges, in one second of time, in the dry season, is 80,000 cubic feet; but the river, when full, having twice the volume of water in it, and its motion being accelerated in the proportion of 5 to 3, the quantity then discharged is 405,000 cubic feet. Taking the medium of the whole year, it will be nearly 180,000 cubic feet per second of time.

Deviation and depredation of its stream.

Europeans view with wonder the remarkable alterations in the course of the Ganges, and the other rivers of Bengal, although the natives of the country, who have long witnessed the encroachments and deviations of their streams, behold these changes without surprise. The greatest injury is sustained during the periodical floods, and while the waters are draining off; and when it is considered that at this season, at the distance of 200 miles from the sea, there is an increase of more than 25 feet in the perpendicular height of the water, some idea may be formed of the velocity with which it will run off, and of the havoc which it will make on the banks. Accordingly it is not unusual to find, when the rainy season is over, large portions of the banks precipitated into the channel, and the devastation extended over fields and plantations; even trees which, with the maturity of a century, have acquired strength to resist the most violent storms, have been suddenly undermined, and swept away by the stream. But the encroachments are as often carried on gradually, and in the dry season; in this case the natives have time to remove their effects, and change their places of abode, if too near the banks. Whole villages are thus seen deserted, whose inhabitants had retired to safer situations. Along the banks of the Ganges, where the depredations of the flood are most to be apprehended, the people are so accustomed to removal, that they make use of light materials only in huts, and such as, on an emergency, can be easily transported. These effects are attributable, in a great measure, to the looseness of the soil; but this destructive operation of nature is in some degree compensated by the formation of new lands, either by alluvions on the opposite shore, or by islands which emerge in the middle of the stream, and ultimately become connected with the main land, by the closing up of one of the channels. The Ganges gives birth to numerous islands, which are of an extent proportional to the bulk of its waters. The rapidity with which these islands have been thrown up, and the size to which they have swoln, appear objects of astonishment to those who have opportunity of observation. When the

Islands formed by its waters.

4

Ganges.

inundation has subsided, and the river found its ordinary level in the dry season, considerable sand banks are seen in places where, the preceding year, the channel had been navigable. The collection of sand becomes sometimes so great, as to divert the main stream into a new and generally more direct course; for it is only by encroachments on the banks that inflexions in the stream are produced, while the sudden alluvions, and frequent depositions of sand, have a tendency to fill up the channel, into which it had been diverted, and to restore the straightness of its course. Such of the islands as are found on their appearance to have any soil, are immediately cultivated; and water melons, cucumbers, and sursoo or mustard, are the produce of the first year. Even rice is seen growing on those parts, where a quantity of mud has been deposited near the water's edge. Some of these islands, before they have acquired sufficient stability to resist the force of the current, are swept away; but when, by repeated additions of soil, they appear to be firm and consolidated, the natives no longer hesitate to take possession of them, and the new acquisitions become immediately a subject of altercation. The settlers transport their families, cattle, and effects. The highest spots are selected for the villages, and dwellings are raised with as much confidence as on the main land; and though the foundation be sandy, the stratum of soil which is uppermost being interwoven with the roots of grass and other plants, becomes hardened by the sun, and at length sufficiently firm to resist the attacks of the stream. Thus these islands are liable to destruction only by the same process of undermining and encroachment to which the banks of the river are subject. When an island is found too extensive for cultivating the whole of it, it is soon overrun with reeds and long grass, forming impenetrable thickets, and affording shelter to tigers, buffaloes, deer, and other wild animals. The rest of the lands produce good pasturage, and feed thousands of cattle. The subsequent inundations fertilizing the soil, to which the burning of the grass greatly contributes, the inhabitants are induced to extend the limits of their cultivation, and settle permanently. The islands of the Ganges are distinguishable from the mainland, by their having few or no trees, even after a communication has been formed, by the closing up of one of the channels, which generally happens in a few years. Dera Khowaspour, one of the largest, has continued longer in an insulated state than any other, owing to its peculiar situation, immediately below the confluence of the Ganges and Coosa rivers. It is 9½ miles in length, and at the greatest breadth 2½ broad, containing about 20 square miles of land, mostly cultivated, with several villages. In the highest floods the inhabitants are obliged to erect temporary huts on pillars of wood, or stages; but they are seldom reduced to this necessity.

[Pic]ture of [the] islands.

If we present to the imagination a wide extended plain, with pens for cattle, and a few humble huts, whose tops are crowned with gourds, the intervening space highly cultivated with wheat, barley, and pulse of all sorts, whose flowers entertain the eye with a variety of rich tints; if we farther imagine the scene animated with numerous herds of cattle, and a few villages scattered over the distance, the horizon bounding the view with no other remote objects than a long line of grass jungle, and a few trees hardly discernible, from the great distance on the mainland, we shall then have a tolerable picture of an island of the Ganges. Finally, if we imagine the air cool, the sky serene and unclouded, we shall have an idea of the state of these islands during at least six months of the year.

State of its banks.

In the higher parts of Hindostan, where a conker soil, or a hard reddish calcareous earth prevails, the banks are not so liable to be undermined, and are even firm enough to resist the utmost efforts of the stream; but in Bengal, there are few places where a town built on its banks can long retain the advantage of its situation, being either liable to be destroyed by the river, or else to be deserted by it. In its course through Bengal, the Ganges may be said to have under its dominion a large portion of the flat country; for not only the channel which contains the main body of its waters, but also the land embraced by its collateral branches, is subject to inundation, or destruction by encroachment of the stream, and may therefore be considered belonging to the river. Nor can the bed of the Ganges through Bengal be said to be permanent. However, from local causes, at some places the main channel and deepest water will always be found, as at Monghir, Sultangunge, Sicrigully, and Rajemahl; at these places rocky points project into the stream, and some parts of the bed are stony, or the banks consist of conker.

Windings of its course.

The following Table will convey an idea of the windings of the Ganges, and its branches:

	Miles.
Within 100 miles the Ganges increases the distance to	125
The Goggrah, or Dewah, to	112
The Hoogly, from Calcutta to Nuddea, increases from 60 to	76
The Goompty from 100 to	175
The Issamutty and Jaboona from 100 to	217

Delta of the Ganges.

About 200 miles from the sea (but 300 reckoning the winding of the river) commences the Delta of the Ganges. The two westermost branches, called the Cossimbazar and Jellinghy rivers, unite and form what is called the Hoogly river, which makes the port of Calcutta, and the only branch of the Ganges commonly navigated by ships. The city of Calcutta stands about 100 miles from the sea, on the east side of the western branch of the Ganges, named by Europeans the Hoogly, and by the natives the Bhagirathi, or true Ganges, and considered by them peculiarly sacred. The river is here, at high water, fully a mile broad; but during the ebb, the side opposite to Calcutta exposes a long range of sand banks. On approaching Calcutta from the sea, a stranger is much struck with its appearance; the elegant villas on each side of the river, the company's botanic gardens, the spires of the churches, temples, and minarets, and the fine citadel of Fort-William, present a magnificent spectacle. Calcutta possesses the advantage of an excellent inland navigation, foreign imports being transported with great facility on the Ganges, and its subsidiary streams, to the northern nations of Hindostan, while the productions of the interior are received by the same channels. Where the Hoogly is joined by the Roopnarain, a very large sheet of water is formed, but it has many shoals; facing directly the approach from the sea, (while the Hoogly turns to the right,) it occasions the loss of many vessels, which are carried up the Roopnarain by the tide. Here is formed a dangerous sand, named the James and Mary, around which the channel is never the same for a week, and requires frequent sur-

Dangerous sand.

Ganges. The Bore.

veys. The Bore commences at Hoogly Point: So quick is its motion, that it hardly takes four hours to run a distance of 70 miles. It does not flow on the Calcutta side, but along the opposite bank; from whence, crossing at Chitpoor, about four miles above Fort-William, it proceeds with great violence past Barnag-ore and Duckinsore. On its approach, boats must immediately quit the shore, and go for safety into the middle of the river. At Calcutta it sometimes occasions an instantaneous rise of five feet.

Sunderbunds.

The part of the Delta bordering on the sea is composed of a labyrinth of rivers and creeks, named the Sunderbunds, which, including the rivers that bound it, give an expansion of 200 miles to the branches of the Ganges at its junction with the sea. A complete inland navigation is formed from the disposition of these natural canals. In tracing the sea-coast of this Delta, there are eight openings found, each of which appears to be the principal mouth of the Ganges. The course of the river fluctuates from one side of the Delta to the other; nothing appearing in its numerous creeks and rivers but regular strata of sand and black mould: The clay is found deposited below.

Their intricate navigation.

The navigation through the Sunderbunds is chiefly by means of the tides, there being two distinct passages; the one the Southern or Sunderbund passage, the other the Balliaghaut. The first is the longest, leading through the widest and deepest rivers, and opening into the Hoogly or Calcutta river, about 65 miles below the town. The Balliaghaut passage opens into a lake on the east side of Calcutta. The navigation of these passages extends above 200 miles through a thick forest, broken into numberless islands by a variety of channels, differing so much in width, that a vessel is at one time entangled among the trees, and at another sails on a broad expanse of water, beautifully skirted with wood. The water is every where salt; and the forest is abandoned to wild beasts, with the exception here and there of the solitary habitation of a fakeer. During the dry season, the salt-makers who visit these rivers exercise their trade at the imminent hazard of their lives; enormous tigers not only making their appearance on their borders, but swimming off to the boats that lie at anchor. In addition to these, the rivers swarm with alligators. These passages are open throughout the year, and during the season when the stream of the Ganges is low, all the trade of Bengal (the western districts excepted) passes either by Channel Creek or by Balliaghaut, but chiefly by the former.

It is neither practicable nor desirable to reclaim these salt marshy lands, generally overflowed by the tide. This forest has always been considered of importance in a political view, presenting a strong natural barrier along the southern frontier of Bengal. Excellent salt in abundance is here manufactured; the woods also furnish an inexhaustible supply of timber for fuel, boat-building, and other purposes.

Remarkable course of the Brahmapootra.

The British nation, with their allies and tributaries, occupy the whole navigable course of the Ganges, from its entry on the plains to the sea; which, by its windings, is about 1500 British miles. The following circumstance attending the Ganges and Brahmapootra rivers is remarkable. Though the sources of the latter have never been explored, they are in all probability only separated from those of the former by a narrow range of snow-clad mountains, about the 32° of North Latitude, and the 82° of East Longitude. From thence directing their courses to opposite quarters, they are more than 1200 miles apart; but afterwards meet, and roll their mighty streams in conjunction to the sea.

Ganges ‖ Ganjam.

Dolphinus Gangeticus.

There is a species of dolphin peculiar to the Ganges, which is particularly described by Dr Roxburgh in the seventh volume of the *Asiatic Researches*. We shall give merely a general outline of this animal. The body is long and slender, thickest about the forepart, and from thence tapering to the tail. The skin is soft, smooth, and of a shining pearl-grey, or lead colour when dry; diversified with lighter coloured spots, or clouds, particularly when old; but when the animal is alive, and as it appears in the water when rising to breathe, it looks much darker. The length of the one described (a young half grown male) was 6½ feet, and 3 feet in circumference where thickest, rather behind the pectoral fins. It weighed 120 pounds. The head is remarkable, being about one-sixth part of the length of the whole animal, and the jaws are furnished with no less than 120 teeth. When in pursuit of fish, it moves with great velocity. Between the skin and flesh is a coat of yellowish-coloured fat, more or less thick according to the state of the animal. This the Hindoos set a high value on, as an application for removing pains of various kinds. The flesh is like the lean of beef in colour, of no disagreeable smell, yet, so far as was learnt, not eaten by the natives. See Colebrooke, *Asiatic Researches*; Rennel's *Phil. Memoir*; Webbe's *Survey*, *Asiatic Researches*; and Hamilton's *East India Gazetteer*. (W. T.)

GANGLION. See SURGERY.

GANGRENE. See SURGERY.

GANJAM is a town of Hindostan, in the circar of Cicacole, near the Bay of Bengal. It is situated on a small eminence along the river, at the distance of about a quarter of a league from its embouchure. The principal public buildings are a large pagoda, and the house of the governor, built of brick. All the other houses are built of a greasy earth, and covered within and without with lime. They are roofed with straw or bulrushes, which are renewed every two years. The town is of a moderate size; the streets are narrow, and ill arranged; but the inhabitants are numerous. In 1711, when the town was rich and populous, it was situated very near the shore, but a violent storm of wind, which rose in the evening, drove out the sea, and inundated the town, so that only a few of the inhabitants escaped. The harbour of Ganjam is commodious; it has five or six feet of water at neap tides, and nine or ten in spring tides. Vessels are built here at a cheap rate, and in great numbers. The finest muslins that are made on the coast are manufactured at Ganjam. Provisions are cheap, and there is plenty of corn and rice. The town is much frequented by the merchants of Bengal, and by the Armenians.

Ganjam is at present one of the five districts into which the northern Circars are divided, and is the residence of a collector and judge. The fort, which stands on the southern side of the river, is a small pentagon, on plain ground, and is capable of making a considerable resistance when well garrisoned. Sugar and jagary are cultivated in the neighbourhood; but the country north of the town is very low, and is inundated in the rainy season.

Between the 1st of May 1811, and the 30th of April 1812, the total value of imports at Ganjam, chiefly from Calcutta, was 106,250 rupees, of which only 6414 rupees was from places beyond the territories of the Madras government. The total value of exports within the same period, was 471,503 rupees, of which only 8553 rupees was to places beyond the Madras territories, viz. 3157 to Calcutta, and 5396 Arcot rupees to Botany Bay. Distance from Calcutta 372 miles; from Madras 650. East Long. 85° 18′ 15″, North Lat. 19° 22′ 30″, according to astronomical observations. See Hamilton's *East India Gazetteer*; Milburn's *Oriental Commerce*; and Peuchet's *Dictionary*.

GARD, the name of one of the departments of France, in the province of Languedoc, formed out of the dioceses of Alais, Uzes, and Nimes. It is bounded on the north by the department of Ardeche, on the west by those of Lozere, Aveyron, and Herault; on the south by the sea; and on the east by those of the Bouches du Rhone, and Vaucluse.

The territory of this department, though mountainous, is very fertile. It contains many rich meadows, and produces grain of all kinds, wines, olives, silk, brandy, and coal. The wines of St Gilles have the greatest reputation. It has also mines of copper, iron, and other minerals. It is bounded by the Rhone on one side, and is watered by the Gardon, which passes below the Pont du Gard, a splendid specimen of Roman architecture. It is an aqueduct bridge of 49 arches, which crosses a valley not less than 160 feet deep. The forests occupy from 47 to 48 thousand hectares, or about 93,000 acres. More than a third of them belong to individuals, the greater part of the remainder to the communes, and the rest to the nation. The contributions in the year 1803, were 2,866,398 francs. The principal towns are

	Population.
Nimes	39,300
Alais	8,947
Uzes	6,191
Le Vigan	3,848

The population of the department is 309,052. See France, p. 676.

GARDENING is a very general term, being employed to signify both the *laying-out* of pleasure grounds, and the *cultivating* of fruit-trees, culinary herbs, and flowers. To the former branch belong the consideration of the general aspect of the ground, and the capabilities of the entire place, the improver often availing himself of hills, rivers, or forests, beyond the boundaries of the domain immediately under his power; the situation and extent of woods, groves, and clumps; the general grouping of trees, and the characteristics of the different kinds; likewise the management of ornamental water, either in the form of rivers or brooks, with waterfalls and bridges; or as lakes, with islands and fountains; also of rocks and ruins; and, lastly, the mansion-house and offices, it being evident that the house and the grounds must agree in character, or be mutually adapted to each other. To the latter belong the formation and culture of the *garden*, properly so called, including the cultivation of fruit-trees, as standards, espaliers, or wall-trees, of kitchen vegetables, and of ornamental plants, with a number of subordinate operations, such as the management of forcing-houses, hotbed frames, hot-houses, conservatories, and greenhouses. The former branch is properly denominated Landscape-Gardening, and the latter Horticulture; and under these titles we purpose to treat of them. The raising of forest-trees in nurseries, and the general ordering of woods and copses, are subjects connected with gardening, which shall receive due attention in a subsequent part of our work. An account of the mode of establishing orchards, and of managing them, with descriptions of the best orchard fruits, may be expected under the word Orchard.

GARMOUTH, or Garmach, is a seaport town of Scotland, in the county of Moray, situated at the mouth of the river Spey. The houses are principally built of clay, but the streets are regular, and the appearance of the place is respectable. From the great rapidity of the Spey, the tide does not run above half a mile up the river, and hence the harbour is often choked up by the gravel which is brought down by the rapidity of the Spey. At neap tides, the ordinary depth of water is from 8 to 9½ feet. Ships of 400 tons can enter and leave the harbour without any inconvenience. The principal trade of Garmouth consists of wood and salmon. The wood, which is cut on the property of the Duke of Gordon, Sir James Grant, and Mr Grant of Rothiemurchus, are floated down the Spey in rafts to a great extent, and is shipped at Garmouth, partly for Hull, and partly for Deptford and Woolwich. The wood, which is of the very best quality, is often cut into planks where it grows. There are two sawmills at Garmouth: One of these, driven by wind, works about 40 saws; and the other, which is impelled by water, works from 30 to 36 saws. Vessels from 50 to 500 tons have been built here, entirely of homegrown wood. Several sloops are employed in conveying salmon to London during the fishing season. There is a fall of 60 feet in the Spey, from Gordon Castle to Garmouth. Inhabited houses 304. Population 1200. West Long. 3°, North Lat. 57° 39′.

GARNET. See Mineralogy.

GARONNE, Higher, the name of a department of France, in Languedoc, formed out of the dioceses of Toulouse, Rieux, and Comminges. It is bounded on the north by the department of the Lot, on the west by those of Gers and the Higher Pyrenees, on the south by the Pyrenees, and on the east by the departments of Arriege, Aude, and Tarn.

The soil of this department is fertile in vines, grains, and pasturage; and it contains large forests, with quarries of marble and mineral springs. The river Garonne passes through the very middle of the department. The forests occupy 48,940 hectares, or about 95 or 96 thousand acres. Half of them belong to the communes, and the rest to the nation. The contributions in 1803 were 4,554,341 francs. The principal towns are

	Population.
Toulouse	50,171
Castel Sarazin	7,000
St Gaudens	4,155
Muret	3,141
Villefranche	2,035

The population of the whole department is 432,263. See France, p. 676; and Toulouse.

GARRICK, David, the celebrated English comedian, was born in the city of Hereford, and baptized on the 20th of February 1716. His grandfather was a French merchant, who, on the revocation of the edict of Nantz, fled to England with other Protestants, and settled in London. His father, Peter Garrick, obtained a captain's commission in the army, and married a daughter of the Rev. Mr Clough, one of the vicars in Litchfield cathedral. Soon after that time, it appears that Captain Garrick sold his commission, and retired

Garrick.

to Litchfield on half-pay. At the age of ten, his son David was sent to the grammar-school, under the tuition of Mr Hunter; but he does not seem to have displayed any early disposition for study. He very soon, however, discovered a turn for mimickry; and imbibed a relish for theatrical performances from the strolling players who occasionally visited Litchfield. Having engaged a set of his school-fellows to undertake their several parts in a comedy, he exhibited the *Recruiting Officer* before a select audience, in the year 1727. Garrick was then eleven years old; he performed the character of *Serjeant Kite*, and is said to have acquitted himself with great humour.

In the year 1729 or 1730, Garrick was sent out to his uncle, a thriving wine-merchant at Lisbon; but being found too volatile for a counting-house, he returned home in the following year. He was once more placed under the care of Mr Hunter; but his vivacity was still superior to serious application. In 1735, the celebrated Samuel Johnson, a native of Litchfield, formed the design of opening an academy for classical education, in which he was encouraged by Mr Gilbert Walmsley, register of the ecclesiastical court, a gentleman of most respectable character and attainments, and a generous patron of genius. Garrick, at that time turned of eighteen, was, with several other young men, consigned to the care of Johnson, and began to apply, with some diligence, to the study of the classics. At the end of twelve months, however, the master grew tired of his undertaking, and resolved to abandon it altogether. Soon afterwards, Johnson and Garrick, having become weary of the contracted sphere of a country town, and desirous of trying their fortune in a more extensive field, determined on an expedition to the metropolis.

These two friends, who were destined to attain a high degree of celebrity in their separate walks, accordingly set out from Litchfield on the 2d of March 1737, provided with letters of recommendation from Mr Walmsley to Mr Colson, a celebrated mathematician, at that time master of the school at Rochester. It was intended that Garrick should place himself under the tuition of Mr Colson; but he seems to have relinquished that intention upon his arrival in London. On the 9th of March 1737, he was entered a student of Lincoln's Inn; but the state of his finances did not enable him to pursue this profession. About the end of that year, his uncle arrived from Lisbon, with the intention of settling in London; but his design was frustrated by a fit of illness, which in a short time put an end to his life. He left his nephew David £1000; and upon this event, Garrick repaired to Rochester, and remained several months under the tuition of Mr Colson. During his stay at Rochester, his father died of a lingering illness; and his mother did not survive her husband above a year. Garrick now took his leave of Mr Colson, and returned to the metropolis. His eldest brother, Peter, had commenced business as a wine-merchant, and in 1738 David was induced to enter into partnership with him. This gave occasion to the saying of the facetious Samuel Foote, "that he remembered Garrick living in Durham-yard, with three quarts of vinegar in the cellar, calling himself a wine-merchant." It is certain, however, that his business was upon a scale rather more extensive; and his situation, in the neighbourhood of the two play-houses, gave him an opportunity of becoming acquainted with the actors of the time, and confirmed his previous inclination for the theatrical profession.

To that career Garrick now determined to devote himself; and the low state of the stage, at this period, seemed to present ample scope for the exercise of his genius. Quin and Macklin were the only male performers of distinguished reputation, and even their excellence was confined within the limits of a few particular characters. Mrs Pritchard, Mrs Woffington, and Mrs Clive shone in comedy. But with these few exceptions, truth and nature seemed to be banished from scenic representation. Comedy was reduced to mere farce and buffoonery; while in tragedy, violent rant and whining declamation were deemed the only just expression of passion and sentiment. Garrick perceived these defects in the style of theatrical exhibition; but he flattered himself that he should be able to revive a better taste, and to succeed by the truth of imitation. In the beginning of the year 1740, he dissolved partnership with his brother, and passed the remainder of the year in preparation for his great design; studying, with all his attention, the best characters of Shakespeare, and of our most esteemed comic writers. Having consulted his friend Mr Giffard, who was manager of the theatre in Goodman's Fields, he determined, by his advice, to make an experiment of himself at a country theatre. Accordingly, they both set out for Ipswich, where, in the summer of 1741, there was a regular company of comedians. Garrick's diffidence was still so great, that he assumed the name of Lyddal; and to prevent every chance of discovery, he chose, for his first appearance, the character of *Aboan* in the tragedy of *Oroonoko*. His reception, however, was such, that, in a few days, he ventured to throw off his black complexion, and shew himself in the part of *Chamont* in the *Orphan*. He afterwards displayed his powers in comedy, and with the same success. Not only the inhabitants of the town, but the gentlemen all round the country, went in crowds to see the new performer; and thus Ipswich had the honour of having first discovered and patronised the genius of a young actor, who soon afterwards became the brilliant ornament of the English stage, and the first comedian of the age in which he lived.

Garrick returned to town before the end of the summer, and resolved, in the course of the following winter, to present himself before a London audience. With this view he offered his services, first to Fleetwood, and afterwards to Rich, the managers of Drury Lane and Covent Garden; but was rejected by both. He then applied to his friend Giffard, and agreed to act under his management, at a salary of five pounds a week. The part he chose for his first appearance in the metropolis was that of *Richard III.* which he performed at Goodman's Fields, on the 19th of October 1741, in a style so new, so natural, and so impressive, as secured for him a most abundant harvest of applause. His fame quickly spread over the metropolis; and the public rushed in crowds to see a young performer, who burst forth at once a complete master of his art. The most elegant company flocked to Goodman's Fields; the celebrated Mr Pope was drawn from his retreat at Twickenham; and Lord Orrery is reported to have been so much struck with the performance, that he said, "I am afraid the young man will be spoiled, for he will have no competitor." In the course of the season, Garrick appeared in a variety of characters; in *Lothario*, *Chamont*, *Sharp* in his own farce of the Lying Valet, *Lord Foppington*, *Captain Plume*, and *Bayes* in the Rehearsal. In this last character, he seized the opportunity of making keen and powerful strictures on the prevail-

Garrick.

ing taste in dramatic composition; and availed himself of his wonderful powers of mimickry in taking off the most eminent performers of the time.

The unparalleled success which had hitherto attended all his efforts, induced Garrick to attempt a nobler flight, and to aspire to the first character in tragedy, by representing the difficult part of *King Lear*. Never was his genius more conspicuously displayed, than in his portraiture of the madness of that unfortunate monarch; it was, perhaps, the most accurate and impressive imitation of nature that was ever exhibited to the view of a theatrical audience. With that wonderful versatility of powers, for which he was so eminently distinguished, he descended from that first character in tragedy, to the farcical part of *Abel Drugger*, and represented the tobacco-boy in the truest style of comic humour. Hogarth, the famous painter, saw him in *Richard III.*, and on the following night in *Abel Drugger*; he was so struck with the various powers of the performer, that he said to Garrick, "You are in your element, when you are begrimed with dirt, or up to your elbows in blood."

Meanwhile the theatres of Drury-Lane and Covent-Garden were almost deserted; and the actors beheld with jealousy the rapid and unprecedented success of the new performer. Quin said, in his sarcastic manner, "This is the wonder of a day; Garrick is a new religion; the people follow him as another Whitfield, but they will soon return to church again." The joke was relished, and soon spread through the town. Garrick thought it required an answer, and replied in the following epigram.—

Pope Quin, who damns all churches but his own,
Complains that heresy infests the town;
That Whitfield Garrick has misled the age,
And taints the sound religion of the stage;
He says, that schism has turn'd the nation's brain,
But eyes will open, and to church again.
Thou Grand Infallible! forbear to roar,
Thy bulls and errors are revered no more.
When doctrines meet with general approbation,
It is not Heresy, but Reformation.

About this time, Garrick produced the farce of *Lethe*, in which he acted three different characters; and in the month of May 1741, he closed the season at Goodman's Fields, after a career of the most brilliant success. In the beginning of June he repaired to Ireland, in consequence of proposals on the part of the managers of the Dublin theatre, inviting him to perform with them during the summer months. He there performed his various comic and tragic characters to astonished and delighted audiences, and received the same applause that had been bestowed upon him in London. Towards the beginning of August he returned to England.

Garrick's reputation, as an actor of first rate excellence, was now completely established; in so much that Fleetwood, the manager of Drury Lane, now solicited those services which he had formerly rejected with disdain. He accordingly opened a negociation with Garrick; and the treaty was soon concluded on a salary of £500, which was more than had ever been given before. Garrick continued to perform at Drury Lane during three successive seasons, gradually augmenting his list of characters, by reviving the masterpieces of our great dramatic poet Shakespeare. *Hamlet*, *Macbeth*, *King John*, and *Othello*, were successively brought forward, and exhibited in a style of varied excellence, which no actor before his time had been able to attain.

Among the numerous merits of Garrick, it ought not to be reckoned the least, that by the correctness of his taste, and the charms of his acting, he contributed to restore our old standard plays to their just rank on the stage, and excited a relish in the public for the works of that great author, whose sublime conceptions of character; and profound knowledge of the most minute springs of human action, have elevated him to the highest seat among ancient and modern poets.

Towards the end of the year 1745, Garrick went over to Ireland, having received an invitation from Sheridan to be joint manager of the Dublin theatre for the season. On his return to England, in May 1746, he was offered advantageous terms by Rich, the manager of Covent Garden, who proposed, as a further inducement, to open his play-house, which was then shut, for six nights, upon an equal share of the profits. Garrick accepted, and played his capital parts with great success. He was also engaged for the ensuing season at the same theatre. Early in January 1747, he produced his farce of *Miss in her Teens*, which was extremely well received, and when, in the course of this season, Dr Hoadley's excellent comedy of the *Suspicious Husband* was brought forward, Garrick provided the prologue and epilogue.

The following season, Garrick attained the great object of his wishes, by becoming joint-patentee with Mr Lacy of the Drury-Lane theatre. At the opening of the theatre, on the 20th September 1747, he spoke an occasional prologue, written by his friend Dr Johnson, in a style superior to every thing of the kind in the English language, if we except, perhaps, Pope's prologue to the tragedy of Cato. During several years, Garrick continued to devote himself, with unremitting zeal and assiduity, to the concerns of the theatre, bringing forward new productions of merit, reviving the neglected plays of Shakespeare, Otway, and our best dramatic writers, occasionally diversifying the mode of entertainment by the exhibition of pantomimes, and continually delighting the public by the display of his own great powers. In the month of July 1749, Garrick entered on a new scene of life, by marrying the fair Violetti, a native of Vienna, who had chosen to adopt an Italian name. She had an elegant figure, and was much admired as a dancer. She was patronized by Lord and Lady Burlington, who, it was generally understood, gave her a fortune of six thousand pounds. In the summer of 1763, he formed a design to visit the continent, having been told by his physicians that he stood in need of air and exercise, and that Mrs Garrick's health would receive benefit from the waters of Barrege. Accordingly, he set out for Dover on the 15th September, leaving his brother George, as his substitute, to act for him in concert with Mr Lacy. During his absence, the affairs of the theatre continued to be managed with considerable profit; but the public longed for the return of their favourite performer. Garrick and his lady arrived in London about the end of April 1765. The news was announced in the papers, and was received with joy by the town. He did not act, however, during the remainder of the season, which ended, as usual, in the month of June. On the 14th of November 1765, his majesty, after opening the session of parliament, commanded, for his evening entertainment, the comedy of *Much ado about Nothing*. This called forth Garrick from his retreat. He came prepared with an address to the audience, and was received with loud acclamations of joy and approbation. From this period he continued to appear occasionally in his best

Garrick. characters, and to conduct the affairs of the theatre with the same spirit and success as he had formerly done.

In the month of March 1773, Garrick lost an able coadjutor by the death of Mr Lacy, the joint-patentee of Drury-Lane. The whole burden of management now fell upon him, at a time when his infirmities rendered him unequal to the task. He therefore appeared as seldom as possible in the laborious parts of tragedy; but still continued to perform his favourite comic characters. In the beginning of the year 1776, he formed the resolution of retiring from the stage, and this intention was first intimated to the public in the prologue which he wrote to Mr Colman's farce, called *the Spleen, or Islington Spaw.* After describing a tradesman, who quits his business to enjoy the air of Islington, he adds,

> The master of this shop too seeks repose,
> Sells off his stock in trade, his verse and prose,
> His daggers, buskins, thunder, lightning, and old clothes.

On the 10th of June, he made his last public appearance. For some time he proposed to finish his theatrical career with the part in which he at first set out; but he thought that after the fatigue of so laborious a character as that of *Richard III.* it would be out of his power to utter a farewell address to the audience, and he therefore chose the part of *Don Felix* in the comedy of *the Wonder.* The profits of the night were assigned to the fund for the relief of those who should be obliged by their infirmities to retire from the stage. After the play he came forward and addressed the audience in a few words, which he uttered in a manner that sufficiently indicated the feelings which agitated his mind. He then bowed respectfully to all parts of the house, and in a slow pace, and with much hesitation, withdrew forever from the scene of his well-earned fame, amidst the regret of all those who knew how to appreciate his unrivalled genius.

Garrick now retired to his villa at Hampton, resolved to pass the evening of his life in peace and rural tranquillity. Here he enjoyed the occasional society of a numerous circle of friends. He lived in an elegant style, and to the luxuries of the table added the charms of his conversation, and the polished manners of one who had enjoyed the best company. During the year 1778, his former complaints returned with increased violence. But his courage had not deserted him; and he endeavoured to conceal his sufferings by assuming an air of gaiety. He was invited to pass the Christmas of that year at Altrop Park, the seat of Earl Spencer, in Northamptonshire; but his enjoyment of that party was soon interrupted by a violent attack of his inveterate disorder. He arrived at his house in the Adelphi on the 15th of January 1779. Medical aid was found to be in vain. During the last four or five days he suffered excruciating pain with great fortitude, and on the 20th of January, at eight in the morning, he expired without a groan. On the 1st of February his remains were conveyed from the Adelphi to Westminster Abbey, and deposited in Poets' Corner, near the monument of Shakespeare. The funeral was magnificent; it was attended by many noblemen and gentlemen of rank and fashion, and by almost all the admirers of polite literature. The train of carriages reached from Charing-Cross to the Abbey. A prodigious concourse of people lined the way, and by their mournful silence gave the most evident demonstration of their sorrow. A handsome monument was erected to the memory of Garrick by the late Mr Albany Wallis, at his own expence.

Garrick's stature did not rise above the middle size; his frame was delicate; his limbs well proportioned; his countenance animated; his voice clear, flexible, and melodious; and his eyes were remarkably keen and penetrating. In private life he was greatly esteemed for his amiable dispositions, as well as on account of his various accomplishments and agreeable manners. He had a fine flow of animal spirits, and a great share of wit and humour; he delighted in polite and liberal conversation, but generally avoided the discussion of political topics. In the outset of life, when his means were slender, he was a strict observer of economy, and his enemies gave it the name of avarice; but as soon as his circumstances would afford it, he was distinguished by hospitality and munificence. He loved his friends, and his purse was often at their service. To merit in distress his benevolence was sure to be extended. Dr Johnson has been often heard to say, that when he saw a worthy family in distress, it was his custom to collect charity among such of his friends as he knew to be in a state of affluence; and, on those occasions, he received from Garrick more than from any other person, and always more than he expected. He was tremblingly alive to his professional reputation, and his anxiety upon this subject sometimes betrayed him into strange revolutions of temper. However, he had a quick discernment of merit in others, and was ever ready to acknowledge and reward it.

As an actor, Garrick burst forth at once in a style of unrivalled excellence, and continued, during the whole course of his career, to stand at the very summit of his profession. It is impossible for us to convey a just notion of the striking effects of his performance, or to do justice to his various merit. Those traits of excellence, by which an actor draws forth the admiration of his contemporaries, are unsubstantial and evanescent; and leave nothing behind from which an adequate judgement can be formed by posterity. As Mr Sheridan has said, in the language alike of truth and of poetry,—

> "The grace of action, the adapted mien,
> Faithful as nature to the varied scene;
> Th' expressive glance, whose subtle comment draws
> Entranc'd attention, and a mute applause;
> Gesture that marks, with force and feeling fraught,
> A sense in silence, and a will in thought;
> Harmonious speech, whose pure and liquid tone
> Gives verse a music, scarce confess'd its own;
> As light from gems assumes a brighter ray,
> And, deck'd with orient hues, transcends the day!
> Passions wild break, and frown that awes the sense,
> And ev'ry charm of gentler eloquence,
> All perishable!—like the electric fire,
> But strike the frame, and, as they strike, expire;
> Incense too pure a bodied flame to bear,
> Its fragrance charms the sense, and blends with air."
>
> *Monody to the Memory of Garrick.*

We are therefore left to form a faint idea of his talents, from the testimony of those who were eye-witnesses of his performance. To a quick and just conception of the peculiarities of every character, he added a wonderful power of adapting his looks and gestures to the circumstances and situation of the person represented. If we may be allowed the expression, his very silence spoke; his countenance was itself a language. Before he uttered a single word, the varying passions visibly began to work, and wrought such rapid changes in his features, in his action, his attitudes, and the expression of his eye, that he was almost every moment a new man. His talents were versatile as they were powerful; and he was equally sure of attaining his ob-

Garstang || Garth.

ject, whether his aim was to excite terror or pity, or to raise laughter. It was one great excellence of his acting, that he constantly held in remembrance the character he played, throughout all its various stages. No situation of it whatever was neglected; nor was he ever, for a moment, inattentive to the business before him. By his extreme earnestness to appear always what he ought to be, he obtained complete possession of his audience, and roused them to a correspondent approbation of his action.

As an author, Garrick has displayed no contemptible powers. He was not, indeed, an author by profession; the duties of his situation engrossed too much of his time to permit him to apply regularly to literary composition. But the comedy of *The Clandestine Marriage*, his farces, and poetical pieces, sufficiently shew that he wanted leisure, rather than wit or genius, to have enabled him to produce works of greater value. See Davies' *Memoirs of the Life of Garrick;* and *The Life of Garrick*, by Murphy. (z)

GARSTANG, is a market and corporate town of England in Lancashire, situated in the hundred of Amounderness, on the great west road from Edinburgh to London. It stands on the western bank of the river Wyer, which runs parallel to the east side of the principal street, supplying the town with excellent water and fish of different kinds.

The town, which is irregularly built, contains a few good houses. The church is a large Gothic structure, which stands about a mile to the south of the town. It possesses no manufactory; but there are several in the neighbourhood, viz. a printing cotton and calico manufactory at Catteral, and spinning manufactories at Seaton, Dolphinholm, and Catston. Number of houses 62. Population 731. See *Beauties of England and Wales*, vol. ix. p. 113.

GARTER, Order of the, is a military order, which was instituted in 1344 by King Edward III. under the title of "Sovereign and Knight's Companions of the most noble order of the Garter." See Heraldry.

GARTH, Sir Samuel, an English poet and physician, was descended of a good family in Yorkshire, and received his academical education at Peterhouse College, Cambridge, where he took his degree of Doctor of Medicine on the 7th July 1691.

On the 26th June 1692, he was admitted a fellow of the College of Physicians; and in 1694, he published his *Dispensary*, a mock heroic poem, in which he ridiculed the company of apothecaries, and some of the members of the College of Physicians, who had opposed the establishment of a dispensary, for supplying the poor with medicines and gratuitous advice. The "Dispensary," which is an obvious imitation of Boileau's Lutrin, went through three editions, and after receiving successive improvements from the hands of the author, it has enrolled his name in the second class of British poets. In 1697, Garth pronounced the Harveian oration before the College of Physicians. It was immediately published, and was regarded as a good specimen of oratory. Dr Garth pronounced a Latin eloge over the remains of Dryden. He addressed some complimentary verses to Lord Godolphin, on his dismissal in 1710. He lamented, in a complimentary poem, the exile of the Duke of Marlborough; and in 1711 he displayed his attachment to the family of Hanover, by the dedication of an intended edition of Lucretius to the Elector, afterwards George I. The gratitude of this prince was shewn upon his accession to the throne, by conferring the honour of knighthood upon Garth, which was done by the sword of the Duke of Marlborough. Soon afterwards he was appointed physician in ordinary to the king, and physician-general to the army; but he did not long enjoy these distinguished honours. After a short illness, he died in January 1719, and was interred at Harrow in Middlesex, on the 22d of that month.

Garum, Gas Lights.

GARUM, is a name which has been applied by medical writers to a pickle, in which fish had been preserved. The garum of the ancients was greatly esteemed as a delicacy at their tables.

GAS, is a name which was given by Van Helmont to aëriform or elastic fluids. See Chemistry, p. 99, and Gases.

GAS Lights, is the name given to the artificial light produced by the combustion of inflammable gases, obtained from the destructive distillation of pit-coal, and several other combustible bodies.

The late Mr W. Nicholson has very properly observed, that during the combustion of oil, tallow, wax, &c. in producing light, the same change takes place among their respective elements which would have been produced by subjecting them to destructive distillation, the inflammable gas being the substance furnishing the light which they afford. The only difference, therefore, between the light of candles, lamps, &c. and the gas lights, is, that in the former the decomposition of the substance, and the consequent evolution of the inflammable gas, is effected by its own heat. In the gas lights, the decomposition is effected in a close vessel by a separate fire; and the gas given out, after being washed, is conducted to a reservoir, from whence it is drawn through small apertures, where it is set on fire. In candles and lamps, the inflammable gas, which is the source of the light, is more or less accompanied with smoke, which, if not burnt, produces a cloudy yellow flame. In the Argand lamp, where the supply of oxygen is great, the smoke is burnt, which of itself furnishes some light; but the brilliant light is more to be attributed to the purity of the inflammable gas after the cloudy matter is removed.

All substances, whether animal, vegetable, or mineral, consisting of such proportions of hydrogen and carbon as to furnish the inflammable gases, are capable of furnishing artificial light by decomposition. The gases produced in the operation are carburetted hydrogen, olefiant gas, and in some cases carbonic oxide and pure hydrogen.

We are indebted to Dr Henry for some valuable facts derived from his experiments, upon several bodies affording inflammable gas by destructive distillation. The following is a small Table from his paper, exhibiting the relative value of the gases from different substances in producing light. Bodies which afford the inflammable gases by destructive distillation.

100 Measures of	Requires of oxygen for its consumption	Producing of carbonic acid
Pure hydrogen gas	50	. . .
Gas by heating moist charcoal	60	35
—— from dried peat	68	43
—— from oak wood	54	33
—— from cannel coal	170	100
—— from lamp oil	190	124
—— from wax	220	137
Pure olefiant gas	284	179

It is found, as we should naturally infer, that the quantity of light furnished is as the quantity of oxygen required to consume the gas. The carbonic oxide, which is already half saturated with oxygen, produces the least light, while the olefiant gas, as will be observed in the Table, requires the most. The gas from moist charcoal contains about 78 per cent. by weight of carbonic oxide, the rest being principally hydrogen. On this calculation, the specific gravity of this gas comes out 6, hydrogen being 1. Its specific gravity by experiment, according to Cruickshank, is 5.4. Those from oak-wood and dried peat probably differ but little from the latter. This, however, might be ascertained nearly, if we knew their specific gravities. The gas from cannel coal, when purified in the manner hereafter to be directed, consists almost wholly of carburetted hydrogen. Its specific gravity, derived by calculation from Dr Henry's table, is 6.5. Carburetted hydrogen, on the authority of Mr Dalton, is 7.5, hydrogen being 1. If Dr Henry's experiment be correct, and 7.5 be the true specific gravity of carburetted hydrogen, then the cannel coal gas must contain free hydrogen, from its specific gravity being less than that of carburetted hydrogen. The carbonic oxide, sulphuretted hydrogen, and sulphurous acid, which the coal gas will contain, if not purified, would contribute to increase the specific gravity.

Olefiant gas produces the most brilliant light of any other gas, which is to be attributed to its consisting entirely of hydrogen and carbon, and its great specific gravity. The gases, from the distillation of lamp oil and wax, in the way the coal is distilled, will be seen in the table to exceed the coal gas; and that from wax nearly approaches the olefiant gas in the consumption of oxygen, and in the property of producing light. The substances, however, affording olefiant gas are too expensive to be applied to the production of light by the process used for obtaining coal gas.

When the Lavoiserian theory was first advanced, it was generally thought that the light and heat were furnished by the oxygen: hence, whatever might be the combustible body, the greatest light and heat would be produced, the greater the quantity of oxygen which entered into combination in a given time; and the intensity inversely as the space in which the combustion took place. It has since been held, and with good reason, that the inflammable body also contributes light and heat.

There does not appear to be any just theory of the production of light and heat by combustion, but that founded on the change of specific heat between the materials of combustion and the body resulting from the combustion. We cannot, however, expect to derive much practical benefit from such a theory, till we are in possession of a correct table of the specific heat of bodies.

Since chemists are sufficiently acquainted with four inflammable gases to obtain them in a state of purity, namely, hydrogen, carburetted hydrogen, carbonic oxide, and olefiant gas, we might, by a few experiments, get some idea of the relative quantities of light afforded by carbon and hydrogen. If we suppose these gases to consist of pure hydrogen, and still retaining their respective densities, then the intensity and quantity of light would be directly as their densities. In as much, therefore, as their light differs from the ratios of their densities, may be attributed the relative quantities of light afforded by the bodies of which they are composed.

Two small gazometers will be necessary for these experiments, the one to contain hydrogen gas, and the other the inflammable gas to be compared with it. Let the pressure of each be exactly the same, and let the gas from each pass through exactly the same sized aperture, at the time it is burnt. The flames must now be compared with each other, by making shadows in them fall upon a white surface; then remove the strongest light backward, till the shadows are of the same intensity. The squares of the distances of the flames, from their respective shadows, will express the ratio of the illuminating powers of the two flames. If, for instance, hydrogen were compared with olefiant gas, and if the carbon of the latter gas contributed as much to the illumination as the hydrogen, then the ratio of the squares of the distances of the flames from the shadows when the shadows were of the same intensity, would be as 1 to 11.85. If, however, the flame of the olefiant gas will not require to be shifted so far back, in order to make the shadows equal, then it will show that the carbon of this gas has not afforded the same light as so much hydrogen would have done. If now the comparison be made between hydrogen and carburetted hydrogen, the ratio of the squares of the distances, if the latter gas were all hydrogen, would be as 1 to 7.5. But the distance of the flame of the carburetted hydrogen gas will probably fall short of the $\sqrt{7.5}$, owing to the carbon it contains; but it contains a less proportion of carbon on the whole than olefiant gas, and therefore ought to produce more light, in proportion to its density, than olefiant gas. In these instances we have presumed, and with good ground, that a given weight of hydrogen, in its combination with oxygen, affords more light and heat than any other inflammable body. In these and all other instances of combustion, the absolute quantity of light and heat will be the same, whatever may be the density of the combustible body and the oxygen; but the intensity may be much increased by diminishing the time of burning the same quantity of matter, and the space in which the combustion takes place. Hence we accumulate light and heat by means of bellows, and other means of furnishing oxygen, with great facility. We should also get a proportionate effect by increasing the density of the oxygen. If hydrogen and oxygen were increased in their density by artificial pressure, and presented to each other for combustion, the intensity of the light and heat would be in the complicate ratio of their increased density. If each were compressed into half the space, then the effect of their combustion would be four times the intensity of that in their natural state. In this way much greater intensity of both light and heat may be produced than we have hitherto heard of. The carburetted hydrogen would much exceed olefiant gas in producing light, if its density were equal to the latter gas, because it contains more hydrogen than olefiant gas. And if pure hydrogen were of the density of olefiant gas, the intensity of its light would be nearly twelve times greater than when burnt in its ordinary state, and it would be to olefiant gas as about 7 to 3.

Method of measuring the intensities of the lights from different gases.

Cannel coal, and the most bituminous of the Newcastle coal, and many others in the country, when exposed to distillation at a red heat, furnish several gaseous products, the principal part of which is the carburetted hydrogen, a quantity of tar, and an aqueous fluid charged with carbonate of ammonia. The separation of the carburetted hydrogen, which when pure burns with great brightness, and without smell, is now effected with great success, on the largest scale, and the other products, part of which have only been applied to useful purposes, will in time find beneficial sources of consumption.

We shall decline entering minutely into the history of the discovery and progress of the art of lighting with gas. With respect to the discovery, it would be difficult to fix any period to it, or with justice to give it to any particular person. Dr Hales and others, among their numerous experiments in obtaining gases from different bodies by heat, cannot have failed to witness the perseverance of their inflammability.

layton's xperi- ients.

An account will be found in the *Philosophical Transactions*, vol. xli. of some experiments upon the distillation of coal by Dr Clayton. He collected the gas in bladders, and burnt it. In Lord Dundonald's attempts to extract tar from coal, the gas evolved at the time was fired. It is singular to remark, that coal is now distilled for its gas and coak, the tar being of no value; and that this invaluable substance should have been the only thing which his Lordship sought for. We do not hear of any attempt to apply the coal gas to the economy of producing artificial light, before the experiments of Mr Murdoch, made at Redruth, in Cornwall. He distilled coal and other inflammable bodies from an iron retort, conveyed the gas to a distance through tinned copper pipes, and burned it as it escaped through small apertures. These experiments were made in the year 1792. After leaving Cornwall, he resumed his experiments at Old Cumnock, in Ayrshire, in 1796, where he exhibited the new phenomena to numerous friends. He after this, in 1798, went to the Soho Foundery, where he constructed an apparatus for lighting the building, in which he made some improvements in the means of purifying the gas, to get rid of the smell. In the spring of 1802, on the event of the general peace, he made a grand display of these new lights at the Soho works, which excited much curiosity.

Ir Mur- och first pplies the ght of the as to eco- omical urposes.

Although Mr Murdoch was certainly not the first observer of the inflammability of the coal gas, he may lay just claim to the application of it to economical purposes; and doubtless first pointed out the practical means of bringing it into use. The manufactory of Messrs Lee and Philips of Manchester was lighted with gas, under the direction of Mr Murdoch, as early as 1805, which, in the present state of gas lighting, is considered as very complete. At that period Mr Lee had his house lighted with the gas.

Mr Clegg, late of Manchester, and originally with Boulton and Watt of Soho, has given much attention to the subject of gas lights, and has contributed many useful improvements in the apparatus used for preparing it. He has given a description, with the aid of a drawing of a gas apparatus, to the Society for the encouragement of Arts and Manufactures, which is published in their transactions for 1808. This apparatus, with some few improvements, is at present considered the best. As we shall describe one embracing several improvements upon Mr Clegg's, it will not, in this limited article, be possible to give a copy of his in addition.

The apparatus generally consists of an iron retort of a cylindrical form, its length being from seven to eight times its diameter. It has an opening at one end, which can be closed by a lid with a conical edge, and pushed up to its place by a catch or wedge. The retort is placed horizontally in a furnace, which allows the flame to pass under it in the direction of its length, and over it on its return, after which it enters the chimney.

The fire should be so intense as to be capable of heating the retort to a bright red heat, and of keeping it up at the same time; but should not be capable of heating it very hot, as the retort itself might be melted, or at least much injured, and the gas less perfect.

Description of the gas light apparatus.

At some distance from the mouth of the retort, which projects a little way beyond the brick work in front, a pipe ascends from the upper side, and at right angles to the length of the retort. Through this the gas escapes, ascending first, and then the pipe turning, it descends into a wide pipe, placed in a horizontal position. This last is called the condenser. From the end of this pipe, an inclining pipe proceeds which conveys the gas, and also the tar, after it has accumulated in the condenser, till this last admits it to run off. The gas and tar now proceed together, the former occupying the upper half of a longitudinal section of the pipe, and the latter the lower half. The tar is at length deposited in a vessel, from whence it can be drawn at pleasure. The gas first ascends from the pipe in which it was accompanied by the tar, and then descends into a vessel containing a mixture of lime and water, by which it is purified. It then passes into an apparatus called a Gazometer. This consists of an outer vessel filled with water. A second vessel, less in diameter, is inverted and immersed into the first. If the common air be allowed to escape from the inner vessel, it will freely descend, and water will occupy the place of the air. If now the source for the escape of air be stopped, and the inner vessel counterpoised by a weight, the inflammable gas, purified as above, may be admitted under the inner vessel, which will ascend to make room for the gas. The suspended vessel is a little heavier than the weight, so that if the force of the entering gas were withdrawn, and an opening made to permit the air to escape, the vessel would descend. This apparatus is not only a reservoir for the gas while its production is going on, but it serves to force out the gas to be burnt, with a gradual and uniform pressure, which gives steadiness to the flame. The gas is set on fire when it is escaping through one or more small apertures, about one-thirtieth of an inch in diameter. These are sometimes disposed in a circle, about the size of the circular wick of the Argand lamp, and hence have been called Argand burners. A glass is placed over them, similar to the Argand lamp. The gas tube sometimes terminates in a spherical head, perforated with different numbers of holes.

Before we proceed to enter into any particulars relative to the practice of gas lights, we shall give a more minute description of the apparatus, in reference to the Plate. Fig. 1. Plate CCLXIV. is a plan and section of the furnace containing the retort. The latter is seen to more advantage in the perspective view. In Fig. A, *e e e* are projecting pieces marked similarly in Fig. 1, for the retort to rest in a horizontal position: *p* is the place where the two parts of the retort are screwed together. The front part contains two ears *t t*. Fig. B is the lid or cover, having a conical edge, which fits the mouth of the retort, and is forced into its place by a wedge Fig. C, which passes through two holes in the ears *t t*; *s* is a pipe, with a plunge to receive the pipe *n*, (Fig. 2.) being cast with the front part of the retort. The fire-place is shewn at *m* (Fig. 2.), *d* is the door, *g* the grate, A the ash-pit, and *f* the flue. The flame first passes along the flue under the retort, where it reaches *r*, and rises to the upper side of the retort, and passes, in the direction of the returning darts, into the chimney C. The separation of the lower half of the flue from the upper is seen in Fig. 3. at *f f*; *b b* are long fire-bricks, which separate the fire place from the

Plate CCLXIV. Fig. 1. Fig. A, B, C. Fig. 2. Fig. 3.

bottom of the retort; this prevents the immediate action of the flame upon the retort, which would soon destroy it. The retort, notwithstanding this apparent power, ultimately receives the whole of the heat without being liable to oxidation. When the retort is charged, and the lid secured, the gas and the other volatile products rise through the pipes *s* and *n*, and enter the larg[illegible]e *c*, which is called the condenser; see Fig. 7. A portion of the tar, &c. condenses in this vessel; till it rises to the level of the pipe *i*, along which the gas and tar descend through a succession of pipes, passing round the inside of the vessel AB, which is filled with cold water. This vessel is square, so that the pipes passing along its sides are of equal length. They are so inclined to the horizon, as to come to the point *v* when they have passed quite round the vessel. The pipe *v x* now brings it out at the point *x*. This pipe continues its direction into the vessel, Fig. 6. which cannot be seen in the profile, Fig. 7. The gaseous products rise up the pipe *h*, Fig. 7, and then descending, terminates in the vessel L; the plan of which is Fig. 5. The tar and ammoniacal liquor condense in the vessel, Fig. 6. which is called the tar vessel. It is made perfectly air tight, and its contents are drawn off at an aperture on a level with the bottom, so that no air can escape till the whole of the liquid is discharged. We now return to the gaseous products, which enter the vessel L; and in order the better to see how they are disposed of, it will first be necessary to describe its office. The vessel in Fig. 7. is a reservoir to contain a mixture of lime and water, for the purpose of supplying the vessel L. The vessel *m* is of a limited depth, in order just to supply the vessel L to a certain height. The transfer from *m* to L is made by means of the pipe *p*, by drawing out the plug *s*. As soon as the vessel L has received its proper quantity, the plug is replaced. The gas enters at *o*. The lime water, which now stands at the level of the top of the vessel *m*, is pressed down to the point *d*. The same quantity, rising along the passage *d e f g*, reaches to the point *g*. The gas now enters at *d*, and passes to *e*, then returning, ascends to *f*, from whence it rises up to *g*, where it enters the pipe *b c*, and the larger pipe *l*, which surrounds *b c*. The pipe *l* is closed at the top, but below the height *l* it is perforated with a number of holes. The vessel AB is filled with water up to the lower extremity of the vessel D. When the gas has passed out at the top of *b c*, it displaces the water in *l*, which is on a level with that in AB, till it sinks to *l*. It now escapes at the holes above mentioned, and bubbles through the water. In this state it is preserved in the gazometer, and is fit for burning. The gazometer we shall now explain more particularly. It may be first proper to return to the lime vessel L. The cavity *d e f g* is formed by six plates of iron, lead, or wood, of the width of the vessel L, arranged in pairs parallel to each other, forming cells, which contain a stratum of fluid three inches thick, fifteen inches wide, and of a length equal to *d e* added to *e f* added to *f g*. This cavity, and the space L, constitute the whole of the capacity of this vessel, which is employed for the liquid, the rest being shut out by the partition 3 *d*, and the plates forming the zig-zag cavity. The gazometer, which receives the gas after it has been purified by the lime water, consists of an outer vessel AB filled with water. It is made of cast iron plates screwed together by flanges. D is a vessel made of plate iron, the plates being united by rivets. This vessel, in an inverted position, falls and rises in the outer vessel as more or less gas is contained in it. For this purpose it is suspended by chains, which pass over the pullies 1, 2. The ends of both these chains are fastened in separate grooves in the edge of the pulley M, which is of such a diameter that the vessel D rises to its full height before the pulley makes one revolution. In another groove in the edge of the pulley M, is fastened the end of a second chain, to which the weight W is suspended. This weight is nearly equal to the weight of the vessel D, and assists it in rising as the gas comes under it. It will be evident, that when the whole of the vessel D is immersed in the water, it will become as much lighter as is equal to its own bulk of water. The vessel will therefore require a greater counterpoise as it rises higher, and will be the heaviest when it is at the top. This is compensated by forming the groove in the pulley M, which contains the weight chain so as to make the radii of the wheel change reciprocally with the relative weight of the vessel D, by which the pressure of this vessel, which is always a little heavier than the weight, will be uniform in every part of its ascent and descent. Before the gas can be admitted, the vessel D is allowed to descend to the bottom of the vessel AB, which is effected by opening the stop cock *y* in the pipe *z q y*, which opens into the gazometer above the water. The common air is expelled, and its place occupied by water. The cock *y* is now shut, and the gazometer is ready to receive the gas.

We have already traced the progress of the gas to the lime vessel, where it is purified. It now rises through the pipe *b c*, as has been already described. When the cock *y* is opened, the preponderating weight of the vessel D forces the gas along the pipe *z q y*, from which it is conveyed by other branches into situations where the light is required. The pipes T and *t* are firmly inserted into the top of the vessel D, and in their motion up and down constantly envelope the tubes *b c* and *q z*. They are for no other purpose than keeping the vessel steady D in its ascent and descent. That part of each projecting above the vessel, forms a recess for the reception of the ends of the pipes *b c* and *z q*, in order that the mouths of the latter may be above the water, when the roof of the vessel D comes to the surface. Without this contrivance, the whole of the common air at the commencement could not be expelled. It will be easy to see, that, from improper management, the gas may, under some circumstances, come over so rapidly as to raise the vessel D quite to the top, and, still accumulating, would bubble out at the lower edge of the vessel. Such gas mixing with the common air of the room, would be liable to explode by the light of a candle; indeed, several serious accidents have already happened from this cause. There are several ways of avoiding the danger attendant on this circumstance, but the most effectual we have yet seen, we shall explain by Fig. 8. AB is a section of the outer vessel of the gazometer, D the inner vessel, *p* a pipe inserted in the top of the latter open at both ends; the lower end being above the surface of the water, while the vessel D remains a little immersed. The part *b c* is a portion of a larger tube, with a bottom which is perforated to receive the pipe *p*, to which it is soldered, so as to form a recess capable of holding water, and hence has been called a water-lute. When another pipe, such as *f*, has been placed in the recess filled with water, a gaseous fluid passing up *p*, would be induced to pass through *f*, if not resisted by a force less than the column of water at the recess *b c*. It will now be evident, that if the tube *f* be fixed in the roof

Plate CCLXIV. Fig. 7. Fig. 6. Fig. 7. Fig. 8.

of the building, and open at both ends, when the vessel D rises till the recess bc receives the end of the pipe f, that the lower end of p will be above the water. The gas will therefore rise through p, and pass forward through f into the open air, and thus prevent its escape into the room.

ᴇ KIV. ¹.

In carrying on the process, the water in the vessel AB will frequently require to be changed, as well from being contaminated with the remaining impurities of the gas, as from becoming warm by the pipes from the retort passing through it. Where water is very plentiful, it would be advisable to have a constant current of warm water from the top of the vessel, and a cold current in at the bottom. The lime-water in the lime-vessel L, Fig. 7, will require changing much oftener than in the vessel AB. The sulphureous acid, carbonic acid, and sulphuretted hydrogen, which come with the carburetted hydrogen, are all taken up by the lime, forming sulphate, carbonate, and hydrosulphuret of lime. From this it will be obvious, that the lime will ultimately be all consumed; but it should be removed long before it arrives at complete saturation. The mixture of lime and water in the vessel m should be about the thickness of cream, and hence has been called the *cream of lime.* When the liquid in the vessel L requires to be changed, the plug k is taken out, while the plug s is kept secure. When the vessel L is emptied, the plug k is replaced, and the plug s taken out. The fresh lime and water in m is now transferred to L; the proper quantity being as much as will run in till m remains full. It must be here observed, that the vessel m is rather a measure with which to fill the vessel L to a proper height, than a reservoir. It is hence supposed to be supplied from a large cistern, in which the cream of lime is prepared in considerable quantity.

e con- on of rners.

When the gas has been carried through the pipe zqy, and its different ramifications, to the places where it is to be burnt, the passage terminates in a small apparatus, called a burner, perforated with one or more small holes, about one-thirtieth of an inch in diameter. The most simple of these terminates in a spherical surface, as seen in Fig. 9. There is one hole in the centre, and several others around it. The surrounding holes, if it were not for the upward current of air, would give flames, radiating in straight lines from the centre of the spherical burner; but the upward motion of the heated air causes the flame to curve upwards, like the spur of a game cock, and hence they have been technically called *cockspur burners.* Fig. 10. is a bracket, at the end of which is a burner, terminating in the face of a cylinder, near the outer edge of which is a circular series of holes, from which the flame rises perpendicularly. These are surrounded by a glass like the Argand lamp. In its general appearance it is so like this lamp, as to have acquired the name of the *Argand burner.* Figs. 11. and 12. are a plan and section of this burner upon a larger scale. The holes in the inner circle, Fig. 11. are supplied with gas from the cavity C, Fig. 12: The same holes appear in section at ab, Fig. 12. The holes in the outer circle, Fig. 11. communicate with the cavity cf, Fig. 12. which also communicates with the atmosphere by the openings ik; gh, is an ornamented rim for the reception of the glass. The air from the glass becoming heated by the flame, rises, and a current takes place from ik, through the cavity ef, and between the burner and the glass. This current in the Argand lamp is both within and without the circular flame, and serves to supply the lamp with oxygen for burning the smoke, as well as to keep the flame steady. In the gas lights there is no smoke to burn: the current of air, therefore, is not so essential. It has the good effect, however, of keeping the flame steady, which otherwise would be agitated by the slightest motion of the surrounding air. Fig. 10. shews the manner of bringing the gas to supply a bracket-lamp fixed to the wall: The stop-cock a is connected with the pipe behind the board cd, which also communicates with the pipe b leading to the burner. Fig. 9. is provided with a similar plate to screw to the wall. These brackets are capable of moving in a horizontal direction. The end of the tube b is ground into the little globe s, so that it will turn round without allowing the air to escape. Fig. 9. is similarly constructed. A great variety of these ornamental brackets, chandeliers, candelabras, &c. will be found in Mr Accum's work upon gas-lights.

Gas Lights. PLATE CCLXIV. Fig. 10.

The apparatus above described, is upon a small scale compared with what would be required for lighting a large manufactory, or upon the scale practised for lighting the streets and shops in the metropolis. The gazometer, lime-vessel, and tar vessel, are all made of cast and wrought iron, precisely in the same way that would be recommended upon the largest scale. It would be found impracticable to increase the fire and the retort to the same extent to which the other apparatus may be increased. It would be improper to make a fire to heat a greater length than from six to eight feet. And if the cavity of the retort were more than 12 inches wide, the coal would not be completely decomposed in the centre. It is found, therefore, more advantageous when a greater supply of gas is wanted, than would be afforded by a vessel of the above dimensions, to use additional retorts and fires, all communicating with the same gazometer, lime-vessel, &c. In Fig. 7. there is but one furnace, but it may easily be supposed that a series of furnaces may join this on the left hand. Each retort having a tube n, they may all be connected with one common pipe c, which is the condenser: to show this, the pipe c in this figure is broken off on the left hand.

When the vessel D is made very large, it requires to be first formed in a skeleton of wrought or cast iron, and afterwards covered with iron plate.

It is strongly advised, where it is practicable, that the retorts should be kept in constant action night and day for the season, or at least never allowed to go below a red heat. The first portion of oxide which forms upon the surface, when allowed to cool, cracks and falls off, leaving a new surface to be acted upon the next time it is heated. By thus being every day heated and cooled, a retort will be destroyed in a few months. When they are kept continually red hot, they frequently last three winters. The writer of this article is indebted to Mr Lee of Manchester for this fact.

In discharging the retort at a red heat, the coak may drop through an opening into a cellar below, the hole being afterwards closed; without this contrivance, the operation would be much annoyed. In applying the gas lights to the streets and shops, pipes of cast iron are employed running along each side of the street, of different sizes, from two to four inches in diameter, according to the supply. The main streets have larger pipes, called *mains*, from which smaller pipes proceed to light the cross streets, alleys, and courts. The pipes are perforated opposite to the shop to be lighted, and an iron pipe ground air tight into the hole. With this, other iron pipes are connected to convey

Gas Lights.

the gas to the place where it communicates with the burner. The pipes in the streets are laid so near the surface, as not to be disturbed by the carriages, or interfere with the paving. They are joined together by slipping one end of one into a widened part in the end of another. The cavity between the inside of one, and the outside of the other, which is nearly one inch, is filled with melted lead, which when set, is afterwards hammered in by the end of a punch.

Having generally described the apparatus used in lighting by gas, we shall give some statements respecting its economy compared with other means of lighting.

Mr Murdoch, of whom we have before spoken, has published a statement of the expence of gas lighting, compared with candles, in the *Philosophical Transactions of London*, for the year 1808. He begins by ascertaining that a tallow candle, of six in the pound, is consumed at the rate of 175 grains, or 1.4 of an ounce in one hour; and that half a cubic foot of carburetted hydrogen, such as comes from cannel coal, burnt the same time, producing a light of the same intensity.

In the calculation of the expence of lighting by gas, he takes his estimate from the manufactory of Messrs Lee and Philips of Manchester, the apparatus being put up by himself. He employed 271 Argand burners, each being equal to four candles of the size above-mentioned, and 633 cockspur burners, each being equal to $2\frac{1}{4}$ candles, the whole amount being equal to 2500 candles of the same size. From what has been stated, it will appear, that to keep so many lights up, will require an hourly consumption of 1200 cubic feet of gas.

He states the average time of working by the gas light throughout the year at two hours per day, this will require a daily consumption of gas equal to 2500 cubic feet; and allowing 313 working days, the yearly consumption will be 782,500 cubic feet.

He found, that to produce this gas, there was required 110 tons of cannel coal at 22s. 6d. per ton,	£124	0	0
Consumption of common coal for distilling the gas, 40 tons, at 10s.	20	0	0
Interest of the capital, and wear and tear of the apparatus,	550	0	0
Total expence	£694	0	0
Deduct the value of 70 tons of coak,	£93	0	0
Nett expence	£601	0	0
The price of 2,347,500 candles, equal to 391,250 lb. at 1s. per lb.	£2000	0	0
Then deducting	600	0	0
Leaves the clear annual saving	£1400	0	0
If the working time per day were three hours, the annual saving would then be	£2350	0	0

The veracity of this author would alone be sufficient to give great weight to these facts; but they have gained greater strength by their strict agreement with subsequent experience.

It is now found that the best form for the retorts is a cylinder, and that they should not much exceed 10 inches in diameter, nor be much more than six feet in length. If they were much wider, the heat would not penetrate the loose coal within sufficiently; and as regards the length, the fire would not act to much advantage, nor the heat be uniform, if the length were much beyond the above statement. This should be the limit for one furnace. If more gas is wanted, more furnaces must be made, as has been shewn in the Plate.

In an apparatus on the scale of these in London for lighting the streets, from 24 to 36 such retorts and furnaces would be required. These retorts contain, independent of the mouth-pieces, about 5655 cubic inches, and will hold conveniently 100 lb. of cannel coal. When the fire is applied to good advantage, each retort gives out all its gas in about four hours. There is no good policy in pushing the distillation very far, as the gas which comes the last, is the least combustible. The retort should not be heated beyond a brightish red, as the gas is not only injured, but the retort would soon be destroyed,

In order to condense as much as possible the most useful facts, we have given a Table founded upon the statements already made. We are indebted to Mr Murdoch for the comparative light given by gas and candles, the gas and coak afforded from a given quantity of coal, and the consumption of common coal to produce the necessary heat for the distillation. The proportion of tar and ammoniacal liquor we have quoted from Mr Accum's work on gas lights.

Explanation of the Table.

The first column gives the number of retorts, each being 10 inches in diameter, and 6 feet long. The second column gives the capacity of the gazometer. The third column, the weight of coal used to furnish the gas. The fourth and fifth columns give the same by measure. The sixth, the coal used to distil off the gas. The seventh, the cubic feet of purified gas. The eighth, the weight of coak left in the retorts. The ninth, the weight of tar. The tenth, the ammoniacal liquor; and the eleventh, the number of candles to produce the same light with the gas; the candles being six to the pound each, when fairly burnt, consuming 175 grains of tallow in one hour.

This Table is formed by doubling the first numbers of each column for the second number, then adding the first number to the second for the third, the third to the first for the fourth, and so on, so that it may be easily extended to any greater number of retorts.

Gas Lights.

TABLE

Shewing the relative proportions of Gas, Tar, and Coak, produced by the Distillation of Coal, and the illuminating power of the Gas compared with Candles.

Number of retorts, 10 inches diameter by six feet long, exclusive of the mouth-piece.	Capacity of the Gazometer.	Coal for producing the Gas in Pounds.	By Measure in Bushels and Pecks.		Coal consumed to distil off the Gas.	Cubic feet of Gas purified.	Coak in ditto.	Tar. *	Ammoniacal Liquor.	No. of Candles, 6 in the lb. to give an equal light with the Gas.
			Bushels.	Pecks.

If it were required to find the number of candles of any other size, or a different number in the pound, multiply the number of candles in the Table by the given number in the pound, and divide the product by 6, the number in the pound of those in the Table; the quotient will be the number required. For example, the number of candles equal to the gas from 800 lb. of coal, which is 2560 cubic feet, is 768, what will be the number of candles of 5 to the pound? $5 \times 768 = 3840$; then, $3840 \div 6 = 640$, the number of candles required.

From this Table it may be seen how much coal is equal to a given weight of tallow. If the number of candles in the last column be divided by 6, the quotient will give the weight of tallow in pounds to the coal in the third column. For instance, the candles equal to 800lb. of coal are 768; the last divided by 6 gives 128lb. of tallow, equal to 800lb. of coal, which is 1lb. of tallow to 6.25 of coal.

Gas light may be compared with candles in another point of view. That is, what number of candles of a given size give a light equal to that produced by the gas when its rate of burning is given; that is, when a given quantity in cubic feet is burned in a given time. We have seen, by the data already given, that half a cubic foot of gas will be consumed in the same time, giving the same light as 175 grains of tallow from a candle 6 to the pound. We therefore should say, that when a cubic foot of air is burnt in two hours, its light will be equal to that of a mould-candle of 6 to the pound; but if the same gas were burned in one hour, either from doubling its velocity or its aperture, then it would require two such candles to produce an equal light in all respects. If the candles to give an equal light with the gas when burnt in one hour be divided by the time, it will give the candles for that time. To find the quantity of candles of any other size, use the rule above given.

Practical rules for the management of the apparatus.

Before we conclude this article, we think it right to give a few useful rules to those who may have the management of the gas light apparatus. These are the substance of the rules drawn up by Mr Clegg for the use of the workmen.

1st, Before closing the retort, take common clay, dried, pulverised, and sifted, to which add as much

* This fluid on distillation affords about one-fourth its weight of a thin light inflammable fluid resembling naphtha, leaving a residuum like pitch or asphaltum.

Gas Lights. water as will give it the consistence of treacle; make both the surfaces where the lid fits the retort very clean, spread the luting thinly over the turned part, then secure the lid in its place by the wedge, Fig. C Plate CCLXIV. If this is not strictly attended to, the retort will lose the gas, and the smell will be very offensive, and injure the health of the operator.

2d, The bridge of bricks, *b b*, Fig. 2. which separates the fire place from the retort, must never exceed a bright red heat. If they are raised to a white heat, the gas will be injured, and the retort be soon destroyed. This may be regulated by a damper in the chimney, or by the register door to the ash pit. See Fig. 7.

3d, The gazometer should be examined at least once a week, which is done as follows: shut the stop cock *y*, Fig. 7. and likewise the retort from the gazometer, no operation going on. Mark the suspended vessel at the surface of the water when it is nearly full of gas. If the mark sinks below the surface, there is some opening where gas escapes. To find out this place, walk slowly round the vessel, and if the leak is not very small the gas may be smelled. Apply a candle to the place, and the issuing gas will be inflamed. Mark the place, and blow it out. In the same way search the vessel all round. There, however, may be a small leak, and yet it will not inflame. About the suspected part apply with a brush a little white lead paint. The place where the gas escapes will become yellow, and ultimately black, from the sulphur in the gas. The place being discovered, take a small piece of linen, dip it in a little melted pitch and bees wax, and apply it to the part while hot, and keep pressing it on till it is cold.

4th, Keep the water in the outer vessel of the gazometer at its proper height, in order that the gas may have to rise through the same column of water.

5th, In the place where the lights are, appoint one person only to superintend their management. Be careful to shut the cocks when the lights are not wanted, and do not suffer them to be opened till they are to be lighted, and then hold a lighted paper over the aperture while the cock is turned. Do not use a candle for this purpose, lest it drop on the burner. (C. S.)

GASES, Sounds produced by. In our article Acoustics, vol. i. p. 119, we have mentioned the experiments by Dr Chladni, on the sounds of different degrees of acuteness produced by the same organ-pipe, when blown with different gases, in appropriate receivers; and in page 118 we stated that the number of vibrations which the same column of gases of different specific gravities should make in a given time, are inversely proportional to the square roots of their specific gravities.

We propose, in the present article, to exhibit, in a tabular form, the results of the principal experiments that are recorded on this subject, for comparison with calculations on the above principles, and with other calculations from the velocities with which sound is propagated though different gases, considering the pitches of the sounds to be inversely proportional to the velocities of propagation.

In the first column of our Table are mentioned the names of fifteen kinds of gases, on which Messrs F. Kirby and Arnold Merrick made repeated experiments, which are fully detailed, and their apparatus described in Nicholson's *Philosophical Journal*, vol. xxxiii. p. 171; and in the second and third columns are set down the mean results of these several experiments, as they have been calculated by Mr John Farey, in the *Philosophical Magazine*, vol. xlv. p. 28. The intervals in column 2. being stated in his notation, (as usual in other parts of our work,) reckoned upwards and downwards from note C, to which the experiment pipe in atmospheric air is supposed to be accurately adjusted. Column 3. shews the nearest notes on the Rev. Henry Liston's Euharmonic *Organ*, (see that article,) followed by the differences, whether more acute +, or grave —, expressed in Schismas; small and capital Italic letters marking the octaves, above and below C *c*.

In column 4, the specific gravities of the gases have been taken from the mean of those mentioned in our article Chemistry; and column 5, (like col. 2.) shews the calculated intervals above and below C; wherein it will be observed, that ether vapour, and sulphuretted hydrogen, appear to be graver notes than C, and olefiant gas more acute than it, contrary to the results of experiments thereon, in col. 2.

In column 7. are contained the velocities with which sound is propagated, extracted from Acoustics, Vol. I. p. 122; in col. 8. are the intervals; and in columns 6. and 9. the several notes and differences, as already described.

By subtracting the intervals in columns 2, 5, or 8, (with due attention to the signs,) the relation or interval of any two gases may be found, and the name of such interval may often be obtained from our 30th Plate, in Vol. II. Thus, in the experiments in col. 2, *hydrogen* appears to yield a sound higher than *azote* by 610 Σ + 12 f + 53 m, or only 1.49 Σ less than an octave. Again, the interval of *azote* and *oxygen*, in col. 5. is 55.29 Σ + f + 5 m, or S — 1.71 Σ; and between the sounds of *oxygen* and *olefiant* gases, is 55.70 Σ + f + 5 m, or S — 1.3 Σ, &c.

The Table here presented will at least serve to shew, that much remains to be done, to reconcile the facts and the principles that have been advanced by different writers on the subject. Careful and numerous repetitions of these experiments, with gases carefully prepared, and in well contrived apparatus, conducted as Mr Farey has recommended, with reference by means of *the beats*, to *fixed notes*, carefully tuned on Liston's organ; not trusting to *unisons* for the comparisons of the sounds in any case, but resorting to the thirds and fifths by way of checks: Experiments so conducted, might, perhaps, so adjust these several intervals, that they may prove of use, in giving greater precision and consistency to the *specific gravities*, *velocities of propagated sounds*, and perhaps to the *weights of atoms* also, of the several gases; if it be true, as has been conjectured (and, as seems nearly true of most of the gases in our Table, and perhaps of others,) that, with the exception of *oxygen* and *olefiant* gases, the weights of atoms, nearly as stated by Dr Thomson in his *Annals of Philosophy*, are exactly double (or octave) of the specific gravities, respectively, (to oxygen, 1.); but *nitrous* gas seems here to form a remarkable exception, as Dr Chladni found it to present, on another point, in his experiments, as mentioned in our first volume, p. 119. It may not be amiss to add, that the specific gravity of nitrous gas being 1.094, its note will be C'♭—3.63 Σ=39.63 Σ + f + 3 m, below C, according to the principle of calculation used in our Table; whereas in Messrs Kirby and Merrick's first set of experiments (see *Phil. Mag.* vol. xxxvii. p. 4.), this gas was observed to sound 52.95 Σ + f + 5 m above C. It must however be observed, that the results of the first and second sets of experiments by these gentlemen, are most of them so greatly different, as to shew strongly the necessity of the repetitions thereof that we have recommended above.

(e)

A very interesting memoir on the sounds produced by hydrogen gas, was published in the *Journal de Physique*, vol. lv. p. 165, by Dr Delarive of Geneva. Dr Higgins and Brugnatelli were the first who published an account of the sounds produced by hydrogen gas passing through a small tube. Professor Pictet made a series of experiments on these sounds, and describes the various musical phenomena which are produced. He explained the influence on the sounds occasioned by the length or width of the tubes, and the situation where the hydrogen is burned; but it was left to Dr Delarive to assign a very ingenious and plausible cause for the phenomena: He supposes, that a brisk vibratory motion is caused by the continual production and condensation of aqueous vapour; and that, in order to produce a sound, this vibratory motion must be able to harmonise with the dimensions of the tube, and is then regulated and equalised by the regular reflexions from the tube, so as to constitute together a clear musical sound. For this purpose there must be a great difference of temperature in the air, and the tube near the flame. For farther information on this subject, see Nicholson's *Journal*, vol. i. p. 129, and vol. iv. p. 23; and Dr Thomas Young's *Natural Philosophy*, vol. ii. p. 267.

GASSENDI, Peter, an eminent French philosopher, was born at Chantersier in Provence, in 1592. After giving very premature indications of his talents, which he did before he had reached his fifth year, he was sent to school at Digne, where he made rapid progress in the Latin language, and acquired a decided pre-eminence among his school-fellows. He was next sent to study philosophy at Aix, and when he had continued there two years, he returned to his father's house, with the view of prosecuting his studies in retirement. A vacancy, however, having taken place at Digne, he was invited, at the early age of sixteen years, to teach rhetoric in that city; and he had scarcely filled this situation for three years, when he was appointed to the vacant chair of philosophy in the university of Aix. The authority of Aristotle was still acknowledged in almost all the public schools of France, and it required no ordinary boldness to call in question his philosophical system. Gassendi, however, did not scruple to expose the errors of that great master, in the indirect form of paradoxical problems, which he published under the title of *Exercitationes Paradoxicæ adversus Aristotelem.* This work obtained for Gassendi the particular friendship of Nicholas Peiresc, president of the university of Aix, who succeeded, by the assistance of Joseph Walter, prior of Vallette, in procuring for him a canonry in the cathedral church of Digne, where he was admitted to the degree of doctor in divinity, and appointed rector of the church. This new situation, which enabled him to resign his chair at Aix, allowed Gassendi the uncontrolled management of his time. He composed a second book of his *Exercitationes Paradoxicæ,* for the purpose of pointing out the absurdity of the Aristotelian logic, and intended to pursue the subject to a much greater extent, but he was violently assailed by the powerful adherents of the ancient sage, and he considered it prudent to abstain from any farther attacks upon the Aristotelian system.

In the year 1628, Gassendi travelled into Holland, in order to make himself acquainted with the philosophers of that country; and during his visit, he composed an apology for his friend the learned Mersennus, in answer to the attack of Robert Fludd on the subject of the Mosaic philosophy. Upon his return to Digne, he resumed with great diligence his astronomical studies. He had the good fortune of being the first that observed a transit of Mercury over the sun's disc. This happened on the 7th of November 1631, the transit having been calculated by Kepler. In the year 1641, Gassendi was called by a lawsuit to Paris, and gained the acquaintance and esteem of the distinguished characters of that metropolis, and particularly of the Cardinal Richelieu, and his brother the Cardinal of Lyons. He had long preserved an intimacy with the great Descartes; but a circumstance now occurred, which for a long time interrupted their friendship. In the year 1629, the singular phenomenon of two parhelia had been seen at Rome, and Gassendi published a dissertation on the subject. Descartes, in his *Treatise on Meteors*, described the same phenomenon, but forgot to make any reference to the dissertation of his friend. Gassendi chagrined at this neglect, and probably not uninfluenced by a secret jealousy of Descartes' fame, attacked the philosophical system of his friend, in a work entitled, *Disquisitio Metaphysica seu Dubitationes*, &c. which was put into Descartes' hands by their mutual friend Mersennus. Descartes replied to the objections of Gassendi, which he has published with his own answers under the head of the *Sixth objection* in his *Meditations.* In 1643, Gassendi composed his *Instantiæ*, as a reply to the answer of Descartes, and circulated it in MS. in Paris, before it was sent to M. Sorbiere to be printed at Amsterdam. This circumstance widened the breach between the two philosophers, which was still farther increased by their respective friends. In 1645, Descartes wrote a reply to Gassendi's *Instantiæ*; but the differences between these philosophers were now on the eve of being adjusted. The Abbé D'Estrees, afterwards Archbishop of Laon and a Cardinal, lamented the dissensions which had so long separated these distinguished philosophers, and resolved to use all his influence in reconciling them. He invited a large party of their friends, among whom were Mersennus, Roberval, and the Abbé Marolles, to meet the two philosophers at a public dinner. Gassendi was prevented by an illness from attending; but so anxious was the Abbé to effect his purpose, that he took the company to Gassendi's apartments, where he and Descartes made mutual apologies for their conduct, and declared that their friendship should not again be interrupted by any difference of sentiment. By the interest of the Cardinal of Lyons, Gassendi was, in 1645, appointed regius professor of mathematics at Paris. He read lectures on astronomy to crowded audiences, and added greatly to the reputation which he had formerly acquired. His constitution had now suffered from the severity of his studies, and having caught a cold, which occasioned an inflammation in his lungs, he was compelled in 1647 to return to Digne for the recovery of his health. His native air produced a considerable amelioration in his strength, and he was able to return to Paris in 1653. He now published his lives of Peiresc, Copernicus, Tycho Brahe, Purbachius, and Regiomontanus; and forgetting the weakness of his constitution, his astronomical studies brought back his former disorder, of which he died in 1655, in the 63d year of his age. A short time before he breathed his last, he is said to have laid his hand on his heart, and feeling the langour of its pulsation, he said, "See how frail is the life of man!" Gassendi was intimately acquainted with the most distinguished characters of his age. His library and philosophical apparatus were purchased by the Emperor Ferdinand III. and deposited in the imperial library at Vienna. His works and MSS. were collected and published after his death in 6 volumes folio by Sorbiere in 1658. They contain the philosophy and life of Epicurus; the philosophy of Gassendi; his astronomical works; the lives of Peiresc, Copernicus, &c.; a refutation of the meditations of Descartes' epistles; a tract on the theory of music; and other treatises. See Bougerelle's *Vie de Gassendi*, Paris, 1737; and Baillet's *Vie de Descartes*, passim.

GAUGING, is the art of measuring the contents or capacities of vessels of any form. See the article MENSURATION, where this subject will be fully treated.

GAUL. See FRANCE, p. 543 and 673.

GAUTS. See GHAUTS.

GAY, JOHN, a celebrated English poet, was born in 1688, at or near Barnstaple, and descended of an ancient family, long possessed of the manor of Goldworthy in Devonshire. He was educated by Mr Luck, the schoolmaster of Barnstaple, a teacher of good reputation, who cultivated a taste for poetry, and published a volume of Latin and English verses.

Inheriting no fortune, and without the prospect of any, Gay was sent to London when young, and placed apprentice to a silk mercer. It is not known how long he continued behind the counter. Feeling, however, the irksomeness of the restraint or servility of his occupation, he procured his discharge from his employer.

In 1712, the Duchess of Monmouth took Gay into her service as secretary. Availing himself of his leisure, he published his first poem, *On Rural Sports*, and inscribed it to Mr Pope, then fast rising into reputation. Pope was much pleased with the compliment, and attracted by the manner and conversation of Gay, he admitted him to the fullest confidence, and a friendship was formed between them which lasted unabated till death. Though Gay was caressed by the association of wits, he appears to have been regarded rather as a play-fellow than a partner, and treated more with fondness than with deference.

Like most poets, he was anxious to place his muse under the fostering wing of a patron, and paid his court accordingly to princes and their favourites; yet his assiduity was not rewarded in proportion to his expectations. When the Earl of Clarendon was appointed envoy extraordinary to Hanover in the room of Lord Paget, Gay was made secretary, for which situation he considers himself obliged to Swift, as he declares in a letter to the Dean. How far Gay would have succeeded in establishing himself as an expert diplomatist, cannot well be ascertained from his short continuance in office, for the death of the Queen deprived him of an opportunity of distinguishing himself; and his dedication of the *Shepherd's Week* to Lord Bolingbroke, is supposed to have excluded him from the patronage of the house of Hanover. Gay, however, still enrolled himself as an expectant of Court favour, and hailed the arrival of the Princess of Wales with a poem. This compliment procured him but little solid advantage. She and the Prince went to see his mock tragedy of the "*What d'ye call it.*" This mark of regard flattered Gay's hopes of farther countenance; but meeting with disappointment, he sunk into despondency, from which his friends conspired to raise him. Lord Burlington dispatched him into Devonshire for amusement; next year he accompanied Mr Pulteney to Aix, and the year following Lord Harcourt invited him to his seat.

Gay having attained celebrity, in 1720 he published his poems by subscription, by which he raised £1000. He seems to have been at a loss how to dispose of his money, and called a consultation of his friends. Lord Oxford's steward, Lewis, advised him to invest it in the funds, and live on the interest; Arbuthnot bid him live on the principal, and trust to providence for a fresh supply. Pope recommended him to purchase an annuity, in which advice he was seconded by Swift. In the calamitous year of the South Sea scheme, Gay having got a present of some stock from young Craggs, he began to dream of nothing but dignity and splendour, and resisted all the importunities of his friends to sell his share. He was even deaf to entreaties to secure himself from want, in case of failure, by selling as much as would give him a hundred a year for life, and enable him, at least as Fenton told him, to command a clean shirt and a shoulder of mutton. Gay risked and lost every thing, and was so completely overwhelmed by the blow, that it required all the tenderness of his friends to restore his health. On this occasion, the attention of Pope was conspicuous. Gay at length having recovered his health and spirits, resumed his studies, and produced his tragedy of the *Captive,* which he was invited to read before the Princess of Wales. On his introduction into the room, Gay found the Princess and her ladies waiting in state to receive him; being completely engrossed by the importance of the occasion, he stumbled over a stool, and in his fall threw down a Japan screen. The Princess was alarmed the ladies screamed, and Gay, after all this flutter and trepidation, had still to read his play.

On the advancement of the Prince and Princess to the throne, Gay expected that something would be done for him; but on the settlement of the household, finding himself appointed gentleman usher to the Princess Louisa, he thought himself insulted, and declined the place. Still, however, he was assiduous in paying court to favourites, and flattered Mrs Howard, afterwards Countess of Suffolk, who was in high favour with the King and Queen. The lady listened to his verses, and did nothing. But the unrivalled success of his *Beggar's Opera* may be supposed to have been some compensation for the neglect and ingratitude of the court. When shewn to Cibber at Drury Lane, it was rejected; it was then carried to Rich; and, as was ludicrously remarked, had the effect of making "Gay rich, and Rich gay."

At length Gay secured himself an asylum for life in the house of the Duke and Duchess of Queensberry. The Duke is said to have undertaken the management of his money, in consideration of his want of economy, and to have allowed him only enough for his necessities. But even the affectionate attentions of the Duke and Duchess failed to soothe the mind of Gay into a state of complacency; his disappointments at court preying on his spirits, he fell into his old distemper, an habitual cholic, in which state he languished with many intervals of ease and health, till a violent fit hurried him to the grave with unusual precipitancy. He died on the 4th December 1732, and was buried in Westminster Abbey. Pope sums up his character as follows: "Gay was a natural man, without design, who spoke what he thought, and just as he thought it; and was of a timid temper, and fearful of giving offence to the great."

Gay dying without a will, his two maiden sisters inherited what he left; amounting to £2000, besides the profits of his opera of Achilles.

Although the genius of Gay was not of the highest order, or deeply inspired, yet it was not destitute of originality; and he must be allowed to be the inventor of the ballad opera, a new species of composition, which has long kept possession of the stage. We have the following account of the origin of the Beggar's Opera, in the words of Pope: "Dr Swift had been observing once to Mr Gay, what an odd pretty sort of a thing a Newgate pastoral might make; Gay was inclined to try at such a thing for some time; but afterwards thought it would be better to write a comedy on the same plan. This was what gave rise to the Beggar's Opera. He began on it; and when first he mentioned it to Swift, the Doctor did not much like the project. As he carried it on, he shewed what he wrote to both of us, and we now and then gave a correction, or a word or two of advice; but it was wholly of his own writing. When it was done, neither of us thought it would succeed. We shewed it to Congreve, who, after reading it over, said, it would either take greatly, or be d——d confoundedly. We were all, at the first night of it, in great uncertainty of the event, till we were very much encouraged by overhearing the Duke of Argyle, who sat in the next box to us, say, 'It will do, it must do, I see it in the eyes of them.' This was a good while before the first act was over, and so gave us ease soon; for that Duke, (besides his own good taste), has a particular knack, as any one now living, in discovering the taste of the public. He was quite right in this, as usual; the good nature of the audience appeared stronger and stronger every act, and ended in a clamour of applause."

It is generally known that the run of this piece was unusually great in London, and all over England. The ladies carried about its songs in fans, and houses were furnished with it in screens; besides, it expelled from England for that season the Italian opera, which had carried all before it during ten years. Of the merit of this performance when it was published, there were a variety of opinions. By some it was commended for the excellence of its morality, placing vice in the strongest and most odious light; while it was censured by others as giving countenance to crimes, by making a highwayman the hero, and dismissing him unpunished. Swift was of the former opinion, and Dr Herring, Archbishop of Canterbury, was of the latter. After the representation of the *Beggar's Opera,* the number of robbers is said to have greatly increased. But perhaps this play, written merely for amusement, was not intended by its author for any moral purpose; yet, in our opinion, such a representation is more calculated to inflame than amend the bad passions of our nature. The picture of a criminal who converts the horror of a prison into a scene of merriment and debauchery, and consumes those hours that are given him for repentance among his cups and prostitutes, can have no good effect upon an audience. And though perhaps, as Dr Johnson observes, highwaymen and housebreakers seldom frequent the playhouse, yet the latent seeds of robbery and pillage may spring up the more readily from viewing highwaymen dignified as heroes, and hearing their speeches made the theme of popular applause. Some such objection as this, (either moral or political,) prevailed with the Lord Chamberlain, who prohibited a second part which Gay produced under the name of *Polly;* he was, however, no loser by this repulse, as he gained thrice as much by a subscription, on publishing the latter, as he did by the publication of the former.

From the variety of his performances, Gay may be reckoned a writer of versatile talents, though perhaps not equally well qualified to shine on every subject he attempted. His *Fables* appear to have been with him a favourite work; he published one volume, and left behind him another. They are told with liveliness; their versification is smooth, and the diction happy. The origin of the *Shepherd's Week* is somewhat singular. Steele having praised Philips' pastorals, as yielding only to those of Theocritus, Virgil, and Spenser, Pope, who was a competitor for fame in this way, piqued at the comparison, incited Gay to write his *Shepherd's Week,* in order to prove that if nature be scrupulously followed, rural manners must be delineated as gross and ignorant. But Gay mixed so much truth and nature with the coarseness and humour of his compositions, that his pastorals became generally popular as just representations of country manners. (W. T.)

GAZETTE, or NEWSPAPER, is a term derived from *Gazetta,* a species of coin formerly current at Venice, which was the ordinary price of the first newspaper printed in that city. The first Gazette is said to have been published at Paris in 1631. The first English Gazette appeared at Oxford on November 7, 1665, in a folio half sheet. When the court removed to London, it was called the London Gazette.

GAZOMETER. See Chemistry, p. 155; and Gas Lights.

GELATINE. See Chemistry, p. 130.

GEMS. This appellation is employed in two different senses: first, in denoting jewels or precious stones, which, from rarity and beauty, have always been highly prized by mankind; secondly, in characterizing stones, which, though not of the former description, are sculptured or engraved with various subjects, and more especially if executed by the ancients. But the name of gems is likewise applied, in a less appropriate signification, to artificial compositions designed to imitate the finer precious stones, either when polished in the natural state, or when they have passed through the hands of the engraver. In our article Mineralogy, we shall have occasion to consider the subject of precious stones at some length, and we shall at present confine our attention to the subject of Engraved Gems.

Engraved gems.

It is probable that no stone of sufficient hardness was excluded from receiving the engravings of the ancients; but it has been doubted whether they were acquainted with the means of cutting the diamond, or sculpturing the emerald and topaz. Much difference is experienced in working hard stones: the emerald is only to be conquered by uncommon patience, and a long time is requisite to produce a good engraving. The Eastern nations are unacquainted with the proper method of cutting and polishing the diamond; and it is said that little more than a century has elapsed since the means of disposing its lustre to the greatest advantage in brilliants was discovered. The ancient Jews, in the days of Aaron, according to Scripture, could engrave on diamonds; and if the same art was unknown to the Greeks or Romans, they were sufficiently acquainted with the use of this stone in cutting other jewels. But if we consider the ingenuity of the Greeks and Romans, it is not unreasonable to conclude, that they frequently engraved on precious stones. There are indeed few instances of the fact: thousands of their works must have perished many centuries ago, and many are still to be brought to light. Yet it is affirmed, that the art of polishing the diamond, as it now appears, is not of anterior date to the year 1456, and that engravings upon it belong exclusively to the moderns, having been attempted only about the succeeding century. In the year 1500, Ambrose Caradosso, an Italian, engraved the portrait of a father of the church on a diamond, which he sold to Pope Julius II. a great patron of the arts, for £5500, an immense sum at that period. His example was followed by subsequent artists, and diamond dust was used in reducing this gem itself.

Substances chosen.

The substances most frequently sculptured by engravers, both ancient and modern, are rock crystal of different colours, jasper, calcedony, cornelian, onyx, blood stone. Rock crystal, which is well known, is not considered of sufficient hardness, and the same has been observed of malachite, which is also sometimes used. Jasper is found in great variety, as well in appearance as quality, and in pieces of large dimensions; none but the finest and most compact is employed; and this occurs both in the colder and warmer climates. Cornelian and calcedony are so nearly allied, that their names are mutually interchanged according to the tinge which either exhibits; but the latter, which is also called white cornelian by lapidaries, is to be distinguished by a greyish-white colour, bearing marks which resemble the scoopings of a knife on wood, and occasionally exhibiting a sky-blue colour. The ancients are supposed to have obtained the best species by the route of Carthage, from the mountains of the Nasomenes in Africa, and also from Thebes. One of their most favourite stones was the cornelian, on which all the ingenuity of their art has been anxiously bestowed: its colour, hardness, and texture, are the most favourable for delicate engravings, and it seems to have been diffused in much greater abundance than any other. This stone is seen of different shades, from cherry red to flesh colour, and sometimes of a yellowish tinge, or brownish colour; but exposed to moderate heat it becomes white. The ancients divided it into two species, male and female, the latter being pale yellow; and they obtained both from India, Arabia, and other parts of Asia, as well as the Mediterranean islands. At present the finest cornelians come from the east, particularly the Indian peninsula, where they are found from the size of a nut to several inches in diameter, and constitute a considerable article of traffic: the Dutch also brought a quantity from Japan, during the subsistence of their trade with that island. A large proportion of ancient and modern engravings are executed on beautiful cornelian, the colour of which may be deepened and improved by the proper application of heat. The onyx has been esteemed valuable since the earliest periods of Jewish history, from the singular combination of its colours; and it was equally prized by the Greeks and Romans, who applied it to their most valuable works of art. This stone is considered a calcedony, the colours of which are disposed in alternate zones or strata. Generally they do not exceed two or three; five or six are extremely rare. The proper gems of onyx consist of parallel zones, as these only can be worked to advantage; but there are other two varieties with undulated zones, or concentric nuclei, resembling the eye of animals. Where the stripes are of various colours, lapidaries commonly call the stone a sardonyx, a vague and indefinite appellation, and used in another sense by mineralogists. But some apply the name of sardonyx where the ground is coloured, and that of onyx where it is white. It is not known where the latter was obtained by the ancients, but it is now found principally in Germany and Scotland. Artists have ingeniously disposed of the combination, particularly in sculpturing cameos or figures in relief: a white subject appears on a dark ground; or if there be three colours, the third is artfully converted to drapery, or some accessory of the general design. This may be easily understood on reflecting, that the thickness of each zone is worked so as to leave one surface entire, or penetrating still deeper, the artist avails himself of two. M. Mariette speaks of a gem of this kind, consisting of four equidistant zones of different colours, describing four ellipses within each other in as great perfection as if drawn mathematically; and in the centre was engraved a small figure of a Bacchante adapting his footsteps to the sound of his lyre, as if it had been a picture fitted into a frame. The largest onyx said to exist, is an oval of eleven inches by nine, on which is sculptured the apotheosis of Augustus in four zones, two of which are brown and the others white. Several stones of the same species have attracted the particular notice of antiquarians: such is the Brunswick vase six inches in height, representing Ceres in quest of Proserpine; Venus on a marine animal surrounded by Cupids, engraved upon an onyx of two zones;

Gems.

Marcus Aurelius and Faustina in one of four zones, two white, and two of lilac. Many are wont to consider the finest works of art as insipid when not diversified by colour; but this objection is removed by the onyx, and it has hence been in great request both among the ancients and ourselves. Scipio Africanus, according to Pliny, first brought it into notice. Engraved gems of two colours, as the onyx, are called cameos, a word of uncertain etymology. It is more usually applied to such subjects as are in relief or elevated, while all hollow engravings are called intaglios, a name adopted from the Italian, or in French *en creux*. Some artists are inclined to distinguish an onyx with a red ground as the cornelian onyx. The ancients seem to have been well acquainted with blood stone, called *heliotrope* by them, and on the continent at present, *speckled agate*. There are two species in use with engravers, one of which has the ground of deep green irregularly sprinkled with red specks, and not opaque. It is found in Siberia, Sicily, Germany, and likewise in Scotland, in considerable pieces, but of very unequal quality; and the red which is thought to be iron, sometimes separates from the substance of the stone. Engravers have here, as in the former instance, availed themselves of colour; and M. Brard acquaints us, that there is a gem, though not antique, in the national library at Paris, representing the head of Christ under flagellation, where the crimson specks imitate the drops of blood. In the other species, the specks are so numerous, that at a little distance the whole stone appears of a reddish cast. Besides these, the art of engraving has been exercised on many other stones, even on some which, from softness and the intermixture of colours, were ill adapted for it.

Ancient nations which engraved on gems.

Before alluding to the subjects represented by engraving on stones, a few words may be said of the nations among which it was anciently practised; and here it is natural to expect the utmost diversity according to the progress of the arts. The Egyptians had gems both in intaglio and relief, but more commonly the former; and those preserved are for the most part called *scarabei*, from the figure resembling a beetle, consisting of green jasper, cornelian, and calcedony. The Jews perhaps learned engraving from the Egyptians among whom they dwelt, and some notices respecting it are preserved in sacred writ, while describing the decorations of the high priest. Of the jewels which were in the ephod, Moses was directed to take two onyx stones and grave on them the names of the children of Israel, six of their names on one stone, and the other six names of the rest on the other stone, according to their birth. "With the work of an engraver on stone, like the engravings of a signet, shalt thou engrave the two stones with the names of the children of Israel." The Greeks, before the decline of their own country, and afterwards when their artists were under the patronage of the Romans, have been much more eminent for their gems than all the other nations of antiquity. The most refined taste for the arts prevailed among them: they excelled alike in architecture, sculpture, and painting; and almost every succeeding artist has formed his works after their model. They practised seal-engraving at a remote period, though it does not appear to have been upon stones; for we are told, that a law of Solon prohibited engravers from keeping or making copies of seal-rings; and Mnesarchus, the father of Pythagoras, was a seal engraver. The names of many celebrated artists are preserved on their works, which M. Millin, a learned antiquarian, has endeavoured to arrange in chronological order; an undertaking of much difficulty, and one that can never be free of doubt. But the catalogue given by him of the Greeks and later engravers being long, we can only make a brief excerpt from it. Those who flourished anterior to the era of Alexander, he supposes, were Theodore of Samos, who engraved a lyre on a famous emerald belonging to the king Polycrates, 750 years before Christ, which the owner, to mortify himself, threw into the sea; Mnesarchus, none of whose works are extant; Heius, Phrygillus, Thamytos. Pyrgoteles was cotemporary with Alexander, who is reported to have issued an edict prohibiting all other artists from engraving his effigy. Between the era of this sovereign and the Augustan age, are enumerated Admone, Apollonides, Polycletes, who was also a statuary, Tryphon, whose period is well ascertained, and others. They become still more numerous on descending later; Aulus, Chronius, and especially Dioscorides, to whom some of the most beautiful works are ascribed, and who engraved the Roman emperor Augustus. Alphæus Ehvodus, Antiochus, Æpolian, flourished in the age of his more immediate successors; but the exact era of the greater number cannot be ascertained. Some of the most celebrated of these are Aetian, Agathemeros, Allion, Apollodotus, said to be the first engraver who added his profession to his name; Pamphilus, whom some have supposed a pupil of Praxiteles, and who engraved upon an amethyst Achilles playing on a lyre; Teucer, Carpus, and others, whose names would protract the catalogue to a great length. Among the Roman artists, M. Millin includes all those whose names do not appear of Greek origin, or are written in Latin; such as Aquilus, Felix, Quintillus, Rufus, and a few, but not many more. The Greeks still preserved their taste for engraving on fine stones during the earlier part of the darker ages; nor was it obliterated entirely from among the Romans. But the doctrines of Christianity, which gradually spread over the eastern and western empire, were adverse to the art, from discountenancing images; and those again being supplanted in the seventh century by the Mahometan religion, it may be said to have entirely disappeared. Here the history of ancient gems concludes; because the empire of the ancients was overrun by barbarians, the arts sunk into insignificance, and those that had shone with the greatest lustre were obscured in the gloom of ignorance.

Greek artists.

In retracing the qualities of the gems anterior to the first centuries of Christianity, we find the Egyptians did not produce any works of excellence; their engravings were principally symbolical, or representing rude figures of their divinities in partial human shape, or the animals that they worshipped. The Jews are said only to have written names. The Etruscans present few if any works of skill, or of much interest. But what remains of Grecian workmanship, or that of the Romans in their zenith of refinement, exhibits beauty and perfection belonging to no other people. Wherever the arts are patronised they flourish; for mankind, always guided by self-interest, will soon discover the way to celebrity. Many circumstances conspired to encourage engraving in Greece: The opportunity of receiving the best materials from foreign nations; the historical events of their own advancement to power; the variety, complication, and allurements of their religion, all contributed to afford an infinite variety of interesting subjects. The taste for gems may be called original with the Greeks: Among other nations, it is rather to be deemed imitative, and to have been introduced along with a taste for the various arts. The Greeks chose many interesting subjects; the heads of emi-

Gems.

nent men; their divinities, with their adventures either in heaven or on earth; historical events, which were transmitted to posterity; and the like. They were particularly successful in the beautiful representation of the human body naked; and they always preferred pictures undisguised by drapery. They were masters in engraving animals either in a passive state, or when animated with rage and ferocity. Dioscorides engraved naked figures at Rome; but the Romans, whose works do not bespeak the same character as those of the Greeks, generally concealed them in drapery. These nations produced works in relief and intaglio; and there are rare examples of gems being engraved on both sides. The artist just alluded to, worked in very slight relief, which is reputed to be of extremely difficult execution; but many figures rise highly prominent on the gem. It has been supposed by the learned, that the Greeks had better models than have fallen to the lot of the more modern nations. "To judge by the heads alone which we see on engraved stones, and particularly by those which unquestionably are portraits, their models abounded in beauties rarely found among ourselves. The set of the eyes, the figure of the nose, the smiling lips, the majestic countenance, in short, those undefinable graces, which are the offspring of internal sensation, never were the fruit of the artist's imagination only. The work declares, that he must have beheld them in his model, and that nothing belonged to him but to make a faithful representation. The Greeks besides had another advantage in being able to study the proportions and attitudes of the human body. Far from being disgraceful to appear naked in public, the most distinguished characters contended for the prizes bestowed for wrestling, running, and similar exercises. Many opportunities were thus presented for artists to examine the natural motions of the person, far preferable to the constrained or languishing postures of our mercenary models. Their draperies too were so simple, that we might affirm they were devised to betray the human figure itself; and of this we are so well aware, as invariably to adopt them when dignity or expression are required."

Amidst all the variety of subjects represented on gems, it is not wonderful that antiquarians should be led into errors and controversies; of which, a notable instance appears in Michael Angelo's seal, now preserved at Paris. By one, this subject is supposed to be Alexander the Great represented as Bacchus; by another, it is thought a religious procession of the Athenians; and there are others, who suppose it simply a vintage, or sacrifical rites relative to the conquest of India. But it is said to be proved, that instead of being an antique, this gem was engraved by an intimate friend of Michael Angelo himself; which is sufficient evidence of the uncertainty relative to ancient engravings. The seal is a cornelian; it was bought by the keeper of the cabinet of Henry IV. of France for 800 crowns; and Louis XIV. having afterwards acquired it, frequently wore it as a ring. Specimens of Greek workmanship are always more anxiously sought by those who appreciate the arts of antiquity.

Modern engraved gems.

We can scarcely recognise the appearance of gems, before the revival of the art of engraving among the Italians in the fifteenth century. It experienced several fluctuations during those which succeeded, but was at length completely re-established, and several masters have produced works which almost rival those of the ancients. The names of Dominico de Camei, Maria de Pescia, Caradosso, Tagliacarne, Valerio de Vincenti, and more recently Sirleti, who died in the year 1737. This artist claimed his descent from a cardinal of the same name, who had distinguished himself in ecclesiastical affairs; he was a goldsmith, as well as an engraver on fine stones, and the style of his performances bears a close analogy to that of the Greeks. Amidst a multitude of subjects, he engraved the Apollo Belvidere, the Farnese Hercules, and the rest of the finest statues preserved at Rome; but his *chef d'œuvre* is esteemed the groupe of Laocoon on an amethyst. The art has been successfully cultivated in that country, in the most recent times, by Santarelli, Capperoni, Rega, and by a female artist, Signora Talani, of great celebrity in Rome. France has produced some good engravers, though the ability which they have displayed has been less permanent than in Italy; but the best was probably M. Guay, a native of Marseilles, who flourished in the middle of the preceding century, and is extolled by Gori as *opificum gemmarum decus et ornamentum.* He studied first at Paris, next at Florence, and afterwards at Rome, where he prosecuted his profession in imitating the chosen productions of the ancients. After returning to his native country, he was appointed engraver of fine stones to the king; and with his decease the art is considered to have expired in France, until restored under the patronage of the National Institute, in awarding a preminm to M. Jeuffroy in 1810. There are very few, if any, of the arts in which the Germans have not excelled; indeed, they seem to stand pre-eminent among the moderns for mechanical ingenuity. Yet their first engraver on gems, Henry Enghelhart, was only a cotemporary of Albert Durer. One of the best was Laurence Natter, a native of Biberach in Suabia, who followed the profession of a jeweller both there and in Switzerland; then travelling through Italy, he established himself at Venice, devoting his attention exclusively to engraving gems. After visiting England, he repaired to Denmark and St Petersburg. In Denmark he engraved several of the royal family, especially the Princess Royal, whom he represented on an oval black and white onyx, three inches long, and in relief so prominent, that the head projected about half an inch from the stone. He next engraved an elephant, for one of the royal orders, also in relief, on an oriental jasper, which being of different colours, enabled him to make the elephant and a man mounted on it white, the tower reddish on its back, and the feet of the animal darker, while the ground of the whole was a fine deep green. Natter was treated with particular regard by the King, Christian VI. who assigned him an apartment in his palace, and bestowed upon him valuable presents when he departed for England, where he died in the year 1763. Natter was the author of a treatise on gems, wherein he draws a comparison between the works of the ancients and the moderns, and lays down the principles of the practical part of the art. It has been erroneously maintained, that he is the only author who does so; but in a treatise by M. Mariette, a few years anterior, it is discussed still more at large: Both these works are extremely useful to the artist and antiquarian.

Counterfeit gems.

Modern gems, by common consent, are judged inferior to those of antiquity, and hence many attempts have been made to substitute fictitious gems for those which are real. This is accomplished by two or three different methods: the improvement of a stone, which is really precious,—the imposition of an absolute counterfeit of it, —or the insertion of the name of an ancient engraver on a production of modern origin. This last expedient is by no means uncommon; and some of the most reputable engravers are accused of lending their assistance to the fraud, which may be detected, at least in some instances, in the inferiority of the spurious work compared with that of the master. The beauty of the gem should always correspond with his celebrity; and, if a number should be offered under the same name, strong suspicions may be entertained whether they be genuine, because engraving on hard stones is a tedious and difficult art. The principal engravers, for the most part, employed themselves only on the finer stones; and therefore the names of these annexed to stones of inferior quality render them doubtful, especially if ascribed to the Greeks, or if they are of indifferent execution. Greek engravers inscribed their names in their own characters, which are borrowed by the Romans for the same purpose; and even modern engravers have not hesitated to use Greek characters on the works from which they themselves expected to gain celebrity. The most common deception is the insertion of a celebrated name on a gem, ancient or modern, where it is entirely wanting; and the artists most successful here were Natter, Pichler also a German, and Sirleti. The first of these rather appears to defend the practice; for he observes, "Scarcely had I arrived at Rome when the Chevalier Odam engaged me to copy the Venus of M. Vettori, and convert it to a Danae, adding the name of Aulus. I afterwards sold this production, though a trifle, to M. Shwanav, who was then governor of a young prince, and he seemed to prize it highly, knowing it to be in my style. I have no hesitation in avowing, that I still continue to make similar copies whenever they are commissioned; but I defy all the world to convict me of having sold any one of them as an antique." A gem with a counterfeit name was sold in 1749 for 450 Roman crowns, to a Polish nobleman, who presented it as genuine to the Marchioness of Luneville. Precious stones are of unequal value, from their faintness or intensity of colour, which has led to different methods of improving them. This is generally done by heat, which, if applied in a proper degree, and sufficiently regulated, has sometimes an admirable effect. From the uniform beauty of the ancient cornelians, and the great inequality of the modern, it has been suspected there was some method of purifying them, as is alluded to by Pliny. The Japanese are said to possess the secret; and it is common elsewhere to raise the pale yellow of a species bearing little value, to a fine glowing red. Gems being transparent, their colour is affected by that of the substance whereon they rest; and hence the variety of foils employed in setting them, which may deceive an uskilful person. But a more ingenious kind of deception is practised, in interposing the thinnest possible layer of any colour between two pieces of fine rock crystal, which counterfeits the real gem. Many rules are given for the detection of frauds; but they are of difficult acquisition, and can be learned only by practice.

Independent of these expedients in counterfeiting ancient gems, or in improving the appearance of hard stones, the imitation of the latter has been carried to a very great extent, as forming a branch of experimental chemistry. Seneca acquaints us, that Democritus had discovered the art of making artificial emeralds; but, in the opinion of Professor Beckmann, this was nothing more than giving a green colour by cementation to rock crystal. Pliny mentions several artificial stones; and Trebellius Pollio relates, that Gallienus, enraged at a deception in selling "certain glass gems to his wife for real jewels," punished the cheat with castration; and when the byestanders expressed their surprise, he ordered the crier to proclaim, *imposturam fecit et passus est.* The difficulty of obtaining glass in extreme purity, was in itself a sufficient guide to colour it in imitation; and this art was undoubtedly known from an early age. At Alexandria, the glass manufacture was in high repute, which is corroborated by an Egyptian priest presenting several glass cups, sparkling with every colour, to the Emperor Adrian, who valued them so highly, that he allowed them to be used only at festivals. The coloured glass of this city was ascribed by Strabo to a kind of earth found in the neighbourhood. Many of the antique fictitious gems, or pastes as we more commonly denominate them, are preserved; and the art seems to have been one of the few which was not lost during the darker ages. Heraclius, an author of the ninth century, gives directions, in uncouth Latin verses, how to imitate precious stones after this manner, in a treatise *de Artibus Romanorum.* We do not know what perfection was then attained; but the imitations were so successful, or the people so unskilful, that coloured glass passed current for the precious original, and donations were unsuspectingly made by crowned heads of this as of the most valuable substance. A celebrated vase belonging to the cathedral of Genoa was believed to be a real emerald during centuries, and, on a certain emergency, was pledged for a sum equivalent to £30,000 sterling. Natter, one of the most skilful modern artists, was long deceived by a composition in imitation of onyx. The surface was blue, with a black ground, and the whole so intimately resembled a natural production, that it was not before some accidental circumstance induced him to put it to the test, that the truth was ascertained. An antique green paste belonged to the same artist with a white zone in the middle exactly like an onyx, and which did not undergo any alteration from heat. The ancients were, besides, acquainted with the art of compounding such party coloured pastes of large size, which they are supposed to have accomplished by dipping a black, blue, or brown lump of glass in a mass of milk-white enamel glass, and blowing it into its proper form; then the outside being cut away, the figures required were represented in relief. Mr Raspe says, that something of the same kind is at present practised in the glasshouses of Bohemia. The art of making fictitious gems was revived and carried to an uncommon degree of excellence by ingenious chemists of the seventeenth and eighteenth century, whereby the most accurate imitation of precious stones, combined with antique engraving, has been effected. Neri, Kunkel, and particularly Orschall, who all flourished in the former period, made important improvements; but the two latter seem to have attended more to the imitation of a ruby colour, which was considered most difficult to obtain, and was then the subject of animated controversies. They were succeeded by Homberg, an eminent chemist, who was patronised by the Duke of Orleans, regent of France, and who has left a tract on the subject in the Memoirs of the Royal Academy for 1712; Lippert of Dresden, originally a glazier; Riffenstein at Rome; Dr Quin of Dublin; James Tassie of Glasgow; and a female artist, M. Feloix, who of late years carried on the fabrication of artificial gems with great success in Paris. To these names must be added that of M. Fontanieu, who, by a numerous series of experiments, has explained an improved method of making pastes for every different species of stone. Tassie perhaps extended the art farther than any of the rest; for, availing himself of the skill and industry of others, he collected no less than 15,000 subjects, originals, counterfeits, and impressions, the whole of which he seems to have imitated. This artist

Gems.

was born in Scotland, and practised modelling and sculpture in Dublin during three years preceding 1766. He then repaired to London, where, amidst the study of various branches of the fine arts, he confined himself principally to the composition of coloured pastes and artificial gems. The former were first brought into repute by the London jewellers, employing them for ornamental purposes; the latter consisted of a beautiful hard white enamel, which struck fire with steel, and was not affected by heat. Tassie carried on an extensive traffic in these fictitious gems, which he sold from eighteen pence to two guineas, according to the quality; and the late empress of Russia, a liberal patron of the arts, commissioned a complete set of his whole collection. This he executed in a masterly manner, imitating original gems where circumstances admitted of it, where otherwise the pastes were chiefly transparent; and cabinets containing them are now in the imperial palace of Czarsko Celo. As public fashions are fluctuating, pastes began to lose their value, and fictitious engraved gems are at present in little repute in Britain, though imitations of precious stones are still worn as personal ornaments.

Practical art of making fictitious gems.

The practical part of the art of making fictitious gems, in so far as relates to colour and consistence, is amply explained by M. Fontanieu, from whose work we shall quote a few observations, as his principles have received general approbation. M. Fontanieu's primary object was the discovery of a colourless base, constituting the elements of all gems, which, by the addition of metallic oxides, would imitate their respective tinge; and he found it might be obtained from different siliceous substances, pure sand, flint, pebbles, or rock crystal. Any of these, such as crystal or pebbles, being pounded, are put into a crucible and heated red hot; the contents are emptied into a wooden bowl filled with clean cold water, and being shaken from time to time, the lighter particles of extraneous matter escape and rise to the surface, while the rest, together with any metallic particles, remain below. The water is then decanted, and the mass being dried and pounded, is sifted through a sieve of the finest silk, after which the powder is digested four or five hours in the muriatic acid, shaking the mixture frequently. Having poured off the acid, a pure vitrifiable earth remains, which, being frequently washed, is again dried and sifted when it becomes fit for use. From the earth now obtained, M. Fontanieu formed six different bases, of which the fifth seems to be that which, in respect of quality, is preferred by himself; and his proportions are all calculated in parts of eight ounces each. The first base is formed by 20 ounces of lead in scales, 12 ounces of prepared rock crystal or flint, 4 ounces of nitre, 4 ounces of borax, and 2 ounces of arsenic, which being well pulverized and mixed, are melted in a Hessian crucible, and poured into cold water. The mass is melted again a second and a third time, always in a new crucible, and after each melting poured into cold water as at first, taking care to separate the lead that may be revived. This forms the first base. The second is obtained from a mixture of 20 ounces of white ceruse, 8 ounces of prepared flint, 4 ounces of salt of tartar, and 2 ounces of calcined borax, all melted in a Hessian crucible, and poured into cold water. The melting must be repeated, and the mass washed a second and third time with the same precautions as before. A compound of 16 ounces of minium, 8 ounces of crystal, 4 ounces of nitre, and 4 ounces of salt of tartar, constitutes the third base, being treated as in the preceding examples. The fourth is formed by 8 ounces of rock crystal, 24 ounces of calcined borax, 8 ounces salt of tartar mixed and melted together, and poured into warm water. The mass being dried, an equal quantity of minium is to be added, and the whole repeatedly melted and washed as before. Fifthly, a base judged by the author as one of the finest crystalline compositions, and called by him the *Mayence* base, is procured in the following manner: Eight ounces of rock crystal, or flint pulverised, is baked along with 24 ounces of salt of tartar, and the mixture left to cool. It is afterwards poured into a crucible of hot water to dissolve the frit, and the solution is received into a stone ware pan, and the nitrous acid added until it no longer effervesces. The water being decanted, the frit must be washed in warm water until it ceases to have any taste; and the frit being then dried and mixed with 12 ounces of fine ceruse, or white lead in scales, the mixture is to be well levigated with a little distilled water. An ounce of calcined borax is now to be added to twelve ounces of this powder when dried, the whole well mixed in a marble mortar, then melted and poured into cold water, in the same manner as in the rest of the bases already described. After repeating these fusions and lotions, and the mixture being dried and pulverised, five drachms of nitre are to be added, and the whole being melted for the last time, a mass of crystal will be found in the crucible with a beautiful lustre. Lastly, a very fine white crystal may be obtained from eight ounces of ceruse, two ounces of borax finely powdered, half a grain of manganese, and three ounces of rock crystal treated as above.

The colour of artificial gems is obtained from metallic oxides, a fact that must have been almost coeval with the discovery of vitrification; but the opinion of chemists has differed as to their proportions and combinations. The diamond being colourless, is imitated simply by the Mayence base; and M. Fontanieu gives receipts for making all other fictitious gems, of which the following are examples. The oriental topaz is prepared by adding five drachms of antimony to colour 24 ounces of the first and third base: the amethyst, by taking 24 ounces of the Mayence base, to which are added for colour, four drachms of manganese, prepared by being exposed to a red heat, and quenched in distilled vinegar; then dried and powdered, and passed through a silk sieve, and also four grains of precipitate of cassias. The hyacinth is obtained from a base of prepared rock crystal, and two drachms 48 grains added for colour. To imitate the beryl, 96 grains of antimony, and four grains of the calx of cobalt, are added to 24 ounces of the third base. Precautions, however, are necessary in preparing the oxides; and these the author has detailed at length in his original work, of which there is an abstract in the *Journal de Physique*, 1778. A fictitious turquoise, from a composition by M. Sauviac, has lately appeared in France, which is a perfect imitation of the original, and the colours penetrate the substance of the mass. It is now ascertained that the genuine turquoise is not what may be called an original product of nature, but the petrified bone of an animal. The same artist, M. Sauviac, has likewise made fictitious malachite.

The quality of artificial gems consists in their absolute uniformity of texture, compactness, hardness, and lustre; and it is surprising to what perfection repeated practice has brought the art. Fictitious gems may be detected from their softness, which always yields to the file, and from their small specific gravity.

The artist having chosen his natural gem, it is put into the hands of the lapidary to give it surface and

Practice of Engraving Gems.

figure. Next he models the subject in wax, as delicately as possible, which he means to represent, in order that he may constantly avail himself of the resemblance, or he has some other subject which he is to imitate before him. His tools are few and simple, consisting of a lathe nearly on the same principle as the turning lathe, into the end of the spindle of which he can insert points, knobs, or circles. These project a certain distance, and receive a rapid motion from a wheel below. The gem is fixed with mastic to the end of a small piece of wood as a handle, and the artist sketches the subject upon it with a copper point or a diamond. It is then applied to the end of one of the tools in motion, which, being wet with diamond dust and olive oil, quickly grinds off the surface; and, by long perseverance, or frequent repetition, produces the outline of the figure, and then the hollow or relief. Frequent impressions must be taken in the course of the work, to shew where there is any excess or defect; for the slightest error in one part, may occasion the alteration of the whole. Such impressions, however, are necessary only in intaglios,* not in cameos, because both the prominences and depressions are there obvious to the eye; and experienced artists consider it more easy to work on a convex surface, from the distance interposed between the tool and the hand. Although the most elegant curves may be produced with skill and attention, much difficulty is experienced in cutting angles; for the tool being the segment of a circle, can never be closely applied; and hence all the letters on the ancient gems, even of the first masters, are imperfect.

The tools employed are either of soft iron or copper; and in defect of diamond powder, that of the ruby, or other hard stones, may be substituted. In cutting the amethyst, the Bohemian emerald, or crystal, water is used to wet the diamond dust instead of oil. Tools of still softer metal, along with tripoli, or rotten stone, and lastly brushes, are used in giving gems their final polish; but it has been observed, that, in this respect, the moderns have never been able to equal the ancients. We describe this process in few words, but it is a slow and tedious operation, and requires a penetrating eye, and a delicate hand. The artist must be master of drawing and modelling, and he must be a sufficient naturalist to be intimately acquainted with the properties and imperfections of the various finer stones.

Various ... [margin note partially cut off]

Although the art of engraving gems might have been preserved during the darker ages, it is doubtful whether the method of giving impressions to paste, without engraving, was not entirely lost. It was revived, however, by M. Homberg, who, in the year 1712, explained it in such a manner, that all later artists have been enabled to follow his precepts. A quantity of soft, smooth, red tripoli is pounded in an iron mortar, sifted through a fine silk sieve, and set aside for use. Another species, called yellow, or Venetian tripoli, which has a natural kind of unctuosity, is then scraped with a knife, and bruised in a glass mortar, with a glass pestle, until reduced to a very fine powder; the finer it is the more favourable for the impression. The red tripoli is now to be mixed to the like consistence of paste with water, and when moulded between the fingers, it is put into a small flattish crucible, scarcely exceeding half an inch in depth, and little more in breadth at the surface than the size of the gem, whose impression is to be taken. The crucible is then to be filled with the paste, slightly pressed down into it, and the dry yellow tripoli strewed over its surface. Here the stone which is to give the impression must be laid, and pressed down so much on the paste, as to give it a strong, clean, and perfect impression; and the tripoli is to be collected and applied nicely to the edges, with the fingers or an ivory knife. After the stone has lain a few seconds to allow the humidity of the paste to moisten the dry powder of the yellow tripoli scattered over it, the operator must raise it carefully by a needle fixed in a wooden handle, and the crucible being inverted, it will fall out, while the impression remains on the tripoli still adhering to the crucible. The stone must now be examined, to ascertain that none of the paste has come off along with it, otherwise there will be a corresponding defect in the impression, and the operation must be repeated. Having allowed the crucible and paste to dry, the artist selects a fictitious gem of the suitable size to be laid over the mould, but in such a manner as not to touch the impression, which would thus be obliterated or injured; and the crucible being gradually brought nearer the furnace, is to be heated until it can no longer be touched by the hand, when it must be placed in the furnace under a muffle, surrounded with charcoal. When the gem begins to appear bright, it is the sign of being ready to receive the impression. The crucible must now be taken from the fire, and the hot gem pressed down with an iron implement, to make it receive the impression from the mould below it; after which the crucible is to be set by the side of the furnace, to cool gradually without breaking. When cold, the gem may be removed, and its edges nipped or grated round with pincers, to prevent it from cracking, which sometimes happens. Red tripoli is used for the paste only from economy, as it is the yellow species alone which is adapted for the purpose. Casts of plaster of Paris may be substituted for both, made into small cakes half an inch thick, and being put into a furnace without a crucible, the gem is to be pressed down upon it to take the impression.

Many discussions have arisen among the learned concerning the use of those ancient gems, now preserved with so much care in our cabinets. The beauty and rarity of natural jewels constitute their principal recommendation, and they have always been employed as personal ornaments, some being more prized than others, according to fashion or ideal properties. It has been supposed that engraved gems were applied in the same manner, and purposely sculptured for ornaments.

During some time, there was an ordonnance of the Roman emperors, prohibiting the use of rings bearing their portraits, the infringement of which was little less than a capital crime; and we are told of the prætor Paulus being exposed to imminent danger, from having a cameo representing the Emperor Tiberius. Vespasian wisely removed this restriction. But the use of those elegant subjects of mythology and history, which appear in relief, is less evident, unless it had some relation to the religious principles of the owner, or was like a picture, designed to perpetuate historical events. It is said that the Romans long abstained from engraving any image of their gods on gems; but adopting the religious fashions of other nations, they became enslaved by superstitions. Augustus sealed with the head of Alexander, and then substituted his own, engraved by Dioscorides. Before resorting to either, he had sealed with a sphynx. Nero is said to have had a seal engraved with the subject of Apollo flaying Marsyas; that of Pompey represented a lion holding a sword; and the Emperor Galba retained the seal of his ancestors, representing a dog on the prow of a vessel. Sylla, proud of the capture of Jugurtha, caused a representation of the King Bocchus, deliver-

* An intaglio may be raised into a cameo optically, and *vice versa*, by viewing it with a microscope which inverts objects. Ed.

Gems || Genera.

ing up the Prince, to be engraved on a ring which he wore on his finger, and always sealed with it; and Scipio Africanus did the same to commemorate one of his conquests.

The ancients entertained a great partiality for rings; they wore many of the most valuable kinds at a time, loading their fingers, in the words of Pliny, with extravagant wealth, *censu opimo digitos onerabant;* and these rings, as we have seen, contained either natural jewels or engraved gems. Most probably, numerous cameos were worn in the same way, merely for ornament, and cutting them might simply be a display of art in miniature, as sculpturing a statue, or painting a picture. But they had special collections of gems; as a taste for works of nature and art was not inferior at certain periods of ancient empires to what now prevails. Cæsar had a splendid cabinet, which he had collected at an immense expence, and of which the pearls of Great Britain constituted a valuable portion. This he consecrated to the temple of Venus Genetrix; and Pompey deposited the gems and rings found among the spoils of Mithridates in the capitol at Rome.

With the irruptions of barbarians, the arts were overthrown; and the most ingenious works of antiquity were consigned to oblivion. Among those which escaped, some became votive offerings in the hands of the earlier Christians to the shrines of their saints, and have thus been preserved through ages; but by far the greater part were lost or destroyed.

GEMMI, is the name of a lofty mountain of Switzerland, situated between the Upper Vallais and the canton of Berne. Its name is derived from *Gemini*, indicating the two summits of the mountain. The height of Gemmi above the level of the sea is 6985 feet. On the southern side of the mountain, which is extremely precipitous, a road has been cut in the rock, which is accessible to mules and beasts of burden, and is reckoned the greatest wonder in Switzerland. It was constructed by the Tyrolese, between the years 1736 and 1741, at the joint expence of the Vallais and the canton of Berne. It is about nine feet broad, and the traveller is separated from the precipice only by a small parapet. The descent of this mountain is particularly alarming to those who are subject to giddiness. The invalids from the north of Switzerland, who frequent the baths of Leuk, are carried upon a barrow by eight men, who relieve one another by turns. When they arrive at the frightful passage, the invalid is turned with his back to the precipice; his eyes are tied up, and the undaunted guides endeavour to dispel his fears by singing. From the baths of Leuk to the Chalets of Gemmi is a distance of 10,110 feet, and the vertical height of the wall of Gemmi above the baths is 1600 feet. From the highest part of the road, there is a magnificent view of the Southern Alps, which separate Piedmont from the Vallais. See Alps, p. 578.

GENDER. See Grammar.

GENERA, in Music: with Euclid and others of the ancient Greek writers, implied or included the various modes of dividing and disposing of the divisions of the Tetrachord, or minor *Fourth*, which Interval seems to have been considered as the constant boundary of sounds with the ancients, as the Octave is now with us. The three genera were called Chromaticum, Diatonicum, and Enharmonicum. The two first of these genera have been already treated of under their respective articles, and the other remains to be described.

Gen

According to Euclid, in the *Enharmonic* genus, the Tetrachord was so divided, that the first degree was a diesis or quarter of a major tone, the second degree the same, and the third degree such a ditone as would make up the true fourth: that is, in our notation, Plate XXX. Vol. II.

$$\begin{aligned} & 202\,\Sigma + 4\ f + 17\tfrac{1}{2}\,m \\ \tfrac{1}{4}T = {} & 26\,\Sigma + \tfrac{1}{2}f. + 2\tfrac{1}{4}\,m \\ \tfrac{1}{4}T = {} & 26\,\Sigma + \tfrac{1}{2}f + 2\tfrac{1}{4}\,m \\ \hline 4th = {} & 254\,\Sigma + 5\ f + 22\ m \end{aligned}$$

According to Aristoxenus, in this genus, the tetrachord was divided into 30 equal parts, which were thus distributed, viz. $3+3+24=30$; or

$$\begin{aligned} \tfrac{24}{30}\text{ths, or } \tfrac{4}{5} \times 4th = {} & 203.19686\,\Sigma + 4\,f + 18\,m \\ \tfrac{1}{30}\text{ths, or } \tfrac{1}{10} \times 4th = {} & 25.32674\,\Sigma + f + 2\,m \\ \tfrac{3}{30}\text{ths, or } \tfrac{1}{10} \times 4th = {} & 25.32674\,\Sigma + f + 2\,m \\ \hline 4th = {} & \begin{cases} 253.85034\,\Sigma + 6\,f + 22\,m \\ 254.00000\,\Sigma + 5\,f + 22\,m \end{cases} \end{aligned}$$

Dr Pepusch, Mr Overend, and Dr Boyce, were of opinion, that this genus was thus constituted, viz.

$$\begin{aligned} T + t \text{ (or III)} = {} & 197\,\Sigma + 4\,f + 17\,m \\ \mathcal{E} = {} & 21\,\Sigma + 2\,m \\ \vartheta = {} & 36\,\Sigma + f + 3\,m \\ \hline 4th = {} & 254\,\Sigma + 5\,f + 22\,m \end{aligned}$$

According to Ptolemy, this genus is said, by Dr Wallis, to have been $\frac{45}{46} \times \frac{23}{24} \times \frac{4}{5} = \frac{3}{4}$; or

$$\begin{aligned} \tfrac{4}{5} = {} & 197.00000\,\Sigma + 4\,f + 17\,m \\ \tfrac{23}{24} = {} & 37.53974\,\Sigma + f + 3\,m \\ \tfrac{45}{46} = {} & 19.46026\,\Sigma + 2\,m \\ \hline 4th = {} & 254.00000\,\Sigma + 5\,f + 22\,m \end{aligned}$$

(ς)

GENERATION. See Physiology.

GENEVA, is a city in Switzerland, and capital of an ancient and independent republic of the same name. It is situated on the confines of Savoy and France, at the southern extremity of the Lake of Geneva, where the Rhone issues from it in two rapid transparent streams of a beautiful blue colour, which unite after passing the city. These two branches of the Rhone are crossed by two wooden bridges destitute of beauty, and divide the town into two unequal parts. The principal part of Geneva is situated on the left bank of the Rhone upon a rising ground, about 80 or 90 feet above the level of the Lake.

Geneva is surrounded, except towards the Lake, with high walls and fortifications, which were begun at the commencement of the seventeenth century under the direction of Agrippa D'Aubigné. The building of the bastion of Hesse, which is well worthy of being visited by strangers, cost no less than 10,000 crowns, which Philip, landgrave of Hesse, had given to the republic for this purpose. The southern gate of the city is remarkably beautiful. The double ditches round this gate are filled with water. Fortifications.

The town of Geneva is irregularly built. Some of the streets are extremely steep. The houses are lofty, consisting frequently of four or five stories; and in the commercial part of the town, particularly in the Rue Basse, they have gloomy arcades of wood supported by huge wooden pillars, which rise to the very top of the eneva.

house, and thus protect the foot passengers from the effects of the sun and the rain. In this street, there are two rows of low wooden shops in front of the houses, separating the street from the foot pavements.

The upper part of the town forms a striking contrast with the lower part, not only from the splendid views which it commands, but also from the admirable houses that it contains. The Rue Nouveau de Beauregarde, commanding a splendid view of the Lake and the Western Alps, contains many elegant houses; and the Terrace, which looks to the mountains of Sion, consists of the houses of M. M. Tronchin, Boissier, Sellon, Saussure, &c. which are large quadrangular buildings.

lic dings.

The principal public edifices and establishments, are the cathedral of St Peter's; the Hotel de Ville; the arsenal; the college; the public library; the hospital; the theatre; and the places of worship.

Cnedral.

The cathedral, situated in the upper part of the town, is a large modern church of Gothic architecture in the interior, with a fine organ, and windows of painted glass. The portal is in imitation of that of the Rotondo at Rome. It is built of rough marble, and consists of a fine peristyle of six Corinthian columns supporting a pediment which is surrounded by an ugly substitute for a dome covered with tin. In the time of the Allobroges and the Romans, a temple, consecrated to the sun, occupied the spot on which the cathedral now stands. It contains the tombs of the Duke de Rohan, the head of the Protestant party in France, who was banished by the Cardinal Richelieu, and who died of the wounds which he received at the battle of Rhinfeld. His wife, the daughter of the great Sully, erected this monument to his memory. Another tomb is erected to his son Tancred; and another to the celebrated Agrippa D'Aubigné, who died in 1630. The view from the top of the cathedral is very extensive and magnificent. The other churches of Geneva have nothing remarkable in their appearance. That of St Madelaine is very plain without, but neat within; and the church of Fustiere, in the square of the same name, is more like a large house than a religious edifice. The Hotel de Ville is situated in the upper part of the town. It is an ancient and uninteresting building, with large Gothic halls, and has a singular paved staircase without any steps, like an inclined plane. Between the two principal gates, is an inscription in commemoration of the abolition of the Catholic religion. The arsenal, like all other buildings of the kind, contains specimens of ancient armour, and arms for 12,000 men.

C ege.

The college is a quadrangular building. Each class has a separate and commodious school-room on the ground floor, so as to occupy the two sides of the quadrangle, and the upper part of the building contains apartments for the use of the principal or general inspector, and for the public library of the city. The public library was founded by Bounivard, prior of St Victor, who lived in the time of the Reformation, and who was twice imprisoned, for having asserted the independence of Geneva against the Dukes of Savoy. He bequeathed to it his manuscripts, relative chiefly to the history of Geneva, and his books, and left his fortune

iary.

for the support of the college. It now contains about 50,000 printed volumes, and 200 MSS. of which an account was published in 1779, by M. Senebier the librarian, entitled, *Catalogue raisonnée des Manuscrits conservés dans la Bibliotheque de Geneve.* Among these, are 24 volumes of Calvin's sermons, and a large collection of the letters of that celebrated reformer. There are also MS. letters of Beza and Bullinger, the homilies of St Augustine, written upon the papyrus in the sixth century, and a book of the expences of Philip le Bel for 1314. This curious journal consists of six tablets of wood covered with a kind of wax, in which the letters are engraved. One of the chambers of the library contains a collection of optical and mathematical instruments, anatomical preparations, and antiquities. Among these is a round buckler of silver 34 oz. in weight, with the following inscription: *Largitar D. N. Valentiniani Augusti.* It was found in the bed of the Arve in 1721, and it is the only one of the kind in existence, excepting that which is preserved in the royal library of Paris. The library is also adorned with paintings of several eminent men; and at one end of it is a fine bust of Charles Bonnet, the celebrated naturalist. One of the halls of the college contains several models in gypsum of ancient statues, groups, busts, and bas-reliefs, and also some fine paintings of St Ours and De la Rive.

Hospitals.

The public hospital is a large and elegant quadrangular building, and along with other four charitable establishments, it has an annual expence of 80,000 crowns. In these establishments about 4000 persons are annually relieved, and their benefits are extended even to indigent foreigners.

Theatre.

The theatre is a neat edifice, situated at the south gate. The front of the theatre consists of six Ionic columns, fluted two-thirds of their length from the capital downwards. Geneva is supplied with water by a hydraulic machine, which raises it to the height of 100 feet, and furnishes 500 pints of water in a minute to the public fountains. The principal piece of antiquity at Geneva is the Tour Maitresse, a remnant of the ancient wall, built in 1366 by William de Marcossai.

Collections of natural history.

Among the collections of natural history in Geneva, one of the most celebrated is that of the able chemist Theodore de Saussure, the son of the celebrated Saussure. It contains a fine collection of minerals, petrifactions, volcanic productions, insects and birds, and a collection of philosophical instruments and chemical apparatus. The collection of Dr Jurine, besides a cabinet of ornithology and entomology, contains a collection of all the fossils of St Gothard. There are also collections of minerals in the possession of M. M. Pictet, Tollot, Tingry, De Boissy, and De Luc.

Baths and mineral springs.

Geneva is well supplied with excellent baths both warm and cold. The baths of Lullin are erected in the very middle of the Rhone, where it issues from the lake. The warm baths in the quarter called *Le Derriere du Rhone*, are much frequented, on account of the fine view which some of the apartments enjoy. A warm mineral spring was some years ago discovered at St Gervais, in Savoy, at a little distance from Sallenche. Buildings have been erected on the spot, and have been in use since 1809. The temperature of the water is 33° of Reaumur. Fifty pounds of it contain,

	Oz.	Dr.	Gr.
Sulphate of lime mixed with one-seventh of carbonate of lime	1	0	2
Sulphate of soda	1	6	0
Carbonate of soda	0	7	2
Carbonate of magnesia	0	2	20
Petroleum	0	0	2
Concrete carbonic acid	0	1	8

It is supposed to have the same medicinal qualities as the baths of Leuk in the Vallais.

Views and promenades.

There is perhaps no town in the world, which can boast of such an immense variety of splendid and interesting views as Geneva. Within the city, the houses which form the lofty terrace already mentioned, those in the street of Beauregard, and those which are near the cathedral, enjoy, from their elevated situation, very interesting views of the lake of Geneva, the Eastern Alps, the Saleve Mountains, &c. The principal promenades within the city, are the *Treille*, the Bastions, and the Place de St Antoine, from which there is a fine

Geneva.

view of the lake, with the various villas on the side of Cologny as far as Yvoire, where the Lake begins rapidly to expand itself. It commands also a view of the opposite side of the lake, including Copet, the seat of Madame de Stael, Nyon, and Morges, which is not far from Lausanne. The Little Languedoc is also a favourite promenade, when the wind blows from the north.

View of Mont Blanc and the Alps.

The country around Geneva is so extremely grand and beautiful, that it is impossible to walk in any direction without being gratified with the views and objects which are constantly presented to the eye. The right, or western bank of the lake, is more interesting than the Savoy side. Mont Blanc, in clear weather, is a principal feature in every landscape. About a quarter of a league from the town, on the road to Fernay, the Mole, a hill about 4516 feet above the level of the lake, first presents itself among the Eastern Alps. To the right of this rises the Great and the Little Saleve, 3022 feet high, remarkable for the whiteness of their rocks. On the left, the round mountain of the Voiron (3112 feet high) stretches its enormous and well wooded flanks far to the east, and between it and Saleve, rises the round and beautifully shaped hill of Montoux, 625 feet high. Between the Mole and the Voiron is seen the Aiguille des Argentieres, and at a little greater distance the rounded summit of Mont Buet. The mountains of Brezon and Vergi (4000 or 5000 feet high) appear between the Mole and the Saleve; and above them Mont Blanc rises in all its majesty to the height of 13,428 feet. In looking to the north-east, we can observe from the village called Little Sacconez, all the mountains which stretch beyond Montreux and Chillon, (at the eastern extremity of the lake,) as far as Molesson, which is 5047 feet high, and is situated above the Gruyeres, in the canton of Fribourg, about seventeen leagues in a straight line from Geneva. To the west and the north, the grand ridge of Jura stretches its uninterrupted length. Its three highest summits are, the Reculet de Thoiry, 4062 feet high; the Dole, 3948 feet; and the Montendre, 4036 feet high, and to the north of Reculet.

The splendid view which we have now described, becomes more distinctly seen as we advance along the road to Fernay, and is developed in all its majesty from the beech tree promenade, in the garden of Voltaire. The writer of this article had the good fortune to see this magnificent prospect under the most favourable circumstances; but he was much more overpowered with the majesty of Mont Blanc when he saw it from the heights of Fourriere, or from the Quai de la Guillotierre, at Lyons, a distance of about 160 miles.

System of education.

The system of education which prevails at Geneva, is perhaps not surpassed by that of any other city in Europe. It is not associated, indeed, with those splendid establishments, nor supported by those rich endowments, which are to be found in the other cities of Europe; but it is kept alive and regulated by a love of science, and an enlightened and patriotic zeal among the learned men of Geneva, which we believe has no other example. The system of public education which prevails in this city, relates to the studies of childhood, those of adolescence, and those of the learned professions of divinity, law, and physic.

The first of these departments resembles that of our Eton or Westminster schools. It is conducted by eleven masters, called *regens*, under the superintendance of a rector, a principal, and the academy of professors. Children from the age of five to sixteen are successively taught reading, writing, orthography, arithmetic, and the elements of Greek, Latin, and mathematics. The college is divided into nine classes, each having a separate and commodious class room. The scholars generally continue a year in each class, and no one is permitted to leave his form, till he is fit for being promoted to a higher one. An account of the degrees of good and bad conduct of every boy is regularly and faithfully kept, which is summed up at the end of the week. Twice every year prizes are distributed for good conduct, and for progress in study; and once in the year, generally in the beginning of June, exercises are proposed to each class, and prizes are adjudged to the best. These prizes are distributed on the day called the Day of Promotion, the day before that on which the properly qualified students are promoted to a higher class. A grand solemnity is on this occasion celebrated in the cathedral church, and is attended by all the public bodies in their robes, and by crowds of citizens of every class. On the celebration of this fete on the 20th June 1814, 88 silver medals were distributed.

The second department of the system of education at Geneva, is entrusted to the professors, who occupy the highest station in the academy. It is subdivided into different classes, called *auditoires*. All the courses of lectures begin on the first Tuesday of August, and continue summer and winter, with several vacations, which amount to between four and five months in the year. Four years attendance is necessary to complete the studies of this department: the two first are devoted to the Belles Lettres, and the two last to the different branches of philosophy. The pupils are examined daily on the subject of the preceding lecture.

When the student has completed this course, which he generally does at the age of 18, he may then attend to the study of divinity, law, or physic. The following is a list of the subjects on which lectures are delivered:

Natural philosophy	M. A. Pictet.
Mathematics	M. M. D'Huillier and Schaub.
Rational or moral philosophy .	M. Prevost.
Pharmaceutical chemistry . . .	Dr De la Rive.
Botany	M. M. Vaucher, and Necker, sen.
Mineralogy	M. Theodore Saussure.
Geology	M. Necker, jun.
Chemistry applied to the arts	M. M. Tingry, Boissy.
Zoology	M. Jurine.
Anatomy	M. Maunoir.
Theory and practice of medicine	Dr Odier.
Rhetoric	M. Weber.
Belles Lettres	M. Sismondi.
History and statistics	M. Picot, jun.
Latin and Greek literature . .	Duvillard.
French literature	M. Weber.
Roman law	M. M. Fort and Girod Jolivet.
Sacred eloquence	Rev. M. Picot, sen.
Sacred Oriental languages . . .	Rev. M. De Roches.
Dogmatic theology	Rev. M. Duby.
Ecclesiastical history	Rev. M. Vaucher.
Evangelical morals	Rev. M. Peschier.

Our readers will no doubt be surprised to learn that the preceding establishment, in which more than 1000 pupils are educated, is supported exclusively by a population of 30,000. The annual salary of the professors is not more than 60 guineas, and scarcely half of the professors are entitled to this sum, the rest being merely honorary teachers, who give their labour to the community without any remuneration. The honour of teaching is here considered as a sufficient compensation for its labour; and such is the esteem in which even the masters of the schools are held, that one of the

Geneva.

regents, was made a member of the provisional government at the restoration of the republic.

As it is very probable that many of our countrymen will send their sons to Geneva for the sake of acquiring the French language, and other advantages which cannot be easily obtained at home, we have dwelt more minutely on the subject of education than we would otherwise have been entitled to do. There is certainly no place in the world to which a father may send his children with fewer anxieties than to Geneva. The vices which prevail in many of the principal towns of Europe, are here in a great measure unknown. The young men are regularly instructed in the duties and principles of Christianity, and all the decent proprieties of religion are observed here, as in our own country. An Englishman, and a Scotchman still more, finds himself at home in the society and customs of this happy republic. The religion of Geneva has lost much of the austerity which she wore in former times. Cheerful and enlightened, she now appears in her native character; and there is no danger of the religious habits of our youth experiencing any violent change among the virtuous inhabitants of this city. The similarity of our institutions to theirs, the civil liberty and religious toleration which distinguish both countries, have attached the Genevese to the English character; and we have no hesitation in saying, that if an Englishman could for one moment expatriate himself, even in imagination, he would wish to be a citizen of Geneva.

Society of Natural History.

There are several literary societies at Geneva, the principal of which is the Society of Natural History, composed of all the distinguished individuals in the city. It meets, we believe, alternately at the houses of the different members: and the memoirs which are read are in general published in the *Bibliotheque Britannique*, a monthly journal, which is perhaps the best conducted in Europe. It was founded by M. A. Pictet, who is one of the principal editors; and the chief object of the work is to give an account of British publications. Geneva has also a society for the advancement of the arts, founded by M. Fuisar, a clockmaker. There is a small observatory at Geneva, which contains some good instruments; and a botanical garden.

Manufactures.

Geneva cannot be considered as either a commercial or a manufacturing town. It has long been celebrated for its manufactures of watches and jewellery; and towards the end of the 18th century, five or six thousand persons of both sexes were employed in this occupation. London and Geneva were long regarded as the general magazines from which the rest of Europe was supplied with clocks and watches; and it is stated by Peuchet, that 25,000 gold and silver watches are manufactured every year. The rough part of the work is in general done by the inhabitants of the mountainous districts of Switzerland, and they are sent to Geneva to be finished for sale. There are also in this city manufactures of velvet, India stuffs, silk stockings, hats, and leather. A great manufacture of imitation India shawls is carried on by M. Pictet of Rochemont. In order to accommodate the manufacturing class, a kind of bank called *Caisse d'Escompte*, has been established. Manufacturers and tradesmen can here obtain money upon good bills, at a moderate discount.

Climate.

The climate of Geneva is extremely salubrious, though rather cold. The air is always colder than at Paris. In the greatest colds at Geneva, Reaumur's thermometer stands at from 14° to 18°; and in the greatest heats, from 26° to 27°. There is a very singular coincidence in the variations of the barometer at London, Paris, and Geneva. Geneva is situated in North Lat. 46° 12′, and East Long. 6° 9′ 30″. Population 26,140.

Republic of Geneva.

GENEVA, Republic of, is a small territory comprehending the following districts:

	Population.
Town of Geneva	26,140
The suburbs	4,104
The Chatellenie of Peney and its dependencies	2,622
The Chatellenie of Jussy and Vandœuvres	1,301
The two seignories of Tuvretin and Chateauvieux	537
Total population	34,704

These inhabitants, with about 300 strangers, making in all 35,000 nearly, are contained in $3\frac{7}{100}$ square leagues which gives 11,080 to every square league; a density of population which is very remarkable.

The Genevese territory is extremely fertile and beautiful. The villages are large and well built, and the country is adorned with numerous villas.

Geneva formed part of the territory of the Allobroges. Cæsar established here a place of arms against the Helvetians, and built on the left bank of the Rhone a wall 9000 paces long, and 16 paces high, to oppose the passage of the Helvetians across the Roman province. The city was twice destroyed during the Roman emperors. In 1032, under the successors of Charlemagne, it was united to the German empire. After the 13th century, it was a constant source of discord among the bishops, the counts of Geneva, and those of Savoy; and from the middle of the 13th century, till 1536, it had to struggle against the ambition of the Dukes of Savoy; but, in consequence of the alliance which it formed with the towns of Berne and Fribourg, it was enabled to establish its independence. This epoch of the civil liberty of Geneva was also marked by the commencement of its religious freedom. The doctrines of the Reformation were preached in 1533 by William Farel; and in 1535, the reformed doctrines were adopted in full council. Calvin and Beza now adorned this asylum of liberty, and men of principle and character found here a sanctuary from the cruelties of civil and religious tyranny. In 1542 and 1543, the plague committed dreadful ravages in the city. In 1584, a treaty of alliance was formed between Geneva, Zurich, and Berne. The house of Savoy made its last attempt against the liberties of Geneva in 1602; but though this perfidious attack was bravely repelled, the independence of the republic was never solemnly recognized by the house of Savoy till the year 1754.

In the year 1768, 1782, 1789 and 1793, Geneva was agitated with intestine commotions, of which we cannot find room to give any particular account. On the 15th April 1798, it was occupied by French troops. Its independence was destroyed, and it was incorporated with the French empire, forming part of the department of Leman. The restoration of European independence, in 1814, by the overthrow of the colossal power of France, restored Geneva to the possession of its independence and its ancient laws; and we had the good fortune, a few months after this glorious event, of witnessing the happiness of a free people newly emerged from a foreign and oppressive yoke.

In our article Switzerland, our readers may expect an account of the constitution of this republic.

GENEVA, Lake of, in French *Leman*, and in Latin *Lemannus*, is an extensive lake in Switzerland, resembling in its general shape the form of the moon when she is a few days old. The concave side embraces Savoy, the convex side the Pays de Vaud, and a line joining its extremities stretches in the di-

Lake of Geneva.

rection NE. by E. Its length measured along the great arch which forms the coast of Savoy, is $18\frac{3}{4}$ leagues, but when measured in a straight line across Chablais, it is only $14\frac{3}{4}$. Its greatest width, which is between the towns of Rolle and Thonon, is $3\frac{1}{4}$ leagues. Its breadth at Nyon, near Geneva, is $1\frac{1}{4}$ league; and from this place it constantly diminishes to Geneva, where it is only 300 or 400 feet wide. It is about 620 feet deep about a league from Evian; near the castle of Chillon it is only 312 feet, but in an intermediate place in the environs of Meillerie its depth is 950 feet. The lake occupies 26 square leagues; and its height above the level of the sea is 1134 feet according to M. Pictet, and 1154 feet according to Sir G. Shuckburgh. The lake of Geneva is said to have once extended as far as Bex, about 4 leagues up the Rhone. The village of Port Vallais, once on the banks of the lake, is now half a league distant from it. From the year 1626 to 1726, a large tongue of land, half a league long and 120 feet wide, has been formed between Villeneuve and the mouth of the Rhone. No fewer than forty-two rivers empty themselves into this lake. The Rhone, which is the principal of these, enters it by three branches, and issues from it in two; and after forming an island containing part of Geneva, they both unite, and at the distance of one fourth of a league below that city they receive the Aar. In 1711, the Aar was so much swollen that it pushed back the Rhone, and their united waters flowed back into the lake of Geneva, which they discoloured even to the distance of a league from the town.

The lake of Geneva never freezes, excepting a few paces from its margin; and in very severe winters it freezes between Geneva and the bank of sand. Its waters have a beautiful blue colour; and such is the purity of the atmosphere, that a town upon its banks illuminated by the sun, may be easily seen at the distance of about forty miles. In autumn, fogs 1200 feet in perpendicular height often rest upon the lake when it is the finest weather among the mountains. On the 1st of November 1793, during a fall of snow, a singular waterspout was seen at Cuillus by M. Wild. The foaming waters appeared to rise to the height of 100 feet, and the surface of the lake immediately below it appeared to be excavated. The lake is also subject to sudden agitations similar to those which have been seen in Loch Tay. (See the article AGITATION.) The water rises suddenly to the height of four or five feet, and descending, forms a species of ebbing and flowing which lasts for several hours. This phenomenon, which is called *Seiches*, is particularly seen near Geneva. There are no islands in the lake, excepting a small one with a few trees near Villeneuve. The lake of Geneva contains twenty-nine different species of fish.

The most common winds on the lake, are the *Bise* or north wind, and the *Sechard* or north east wind; and the most dangerous are the *Bise* and the *Vaudaise* or south east wind. Sometimes when the *Bise* is very strong, boats can go from Savoy to Geneva, a distance of fifteen leagues, in 4 hours.

The lake of Geneva is undoubtedly the most beautiful lake in Europe, and that of Constance alone has been supposed to equal it. It is impossible to convey any idea of its varied beauties to those who have not travelled along its banks. On the south east, east, and north east, it is encircled with lofty mountains 5000 feet high, while on the south, the south west, and the west, the banks of the Pay de Vaud rise in terraces from 200 to 600 feet high, resting on the flanks of the ridge of Jura, which occupies the whole of the western horizon.

The scenery which is presented to the traveller between Villeneuve and Vevay, and as far as Lausanne, is certainly the finest and the most varied in Switzerland, and we had an opportunity of viewing it in the finest weather, and at that season of the year when nature developes all her beauties. In travelling down the Vallais along the banks of the Rhone, after passing the village of Rennaz, we first obtain a view of the lake and the Pays de Vaud. Over its blue waters appears the town of Vevay, at the bottom of a round hill, and in the distance rises the hill and town of Gourze, finely projected against the dark blue range of Jura. A little farther on, the town of Villeneuve is seen on the very margin of the lake, situated at the mouth of a finely wooded valley, and the lake gradually discloses itself as we approach the town. The road is now almost washed by the blue waves. The dark flanks of the Savoy hills, clothed with gloomy forests, and occasionally enlivened with smiling villages, form a fine transition from the verdant borders of the lake to their peaked and rugged summits. Numbers of vessels open their white sails to the wind, and on the Swiss side, one town appears after another, disclosing a succession of the most sublime and picturesque views. The old castle of Chillon, almost immerged in the lake, and the ivy clad precipices which overhang it, next attract the notice of the traveller; the hills on the right now retire from the lake, and open more extensive prospects. The wooded recess which embraces the hamlet of Vaiteau, is the commencement of this new scenery, and at the village of Montreux, both the distant and near objects are combined in forming the loveliest landscape we have ever seen. The terraced vineyards begin to diminish the picturesque effect of the woods and rocks, and the beauty of the scenery declines as we approach to Vevay. The view of the lake of Geneva from the terrace of the cathedral of Vevay is much admired; but we had the good fortune to be wandering along the promenade on the margin of the lake, when the sun had just begun to descend behind the ridge of Jura. A bright glow of purely yellow light gilded the whole of the western sky. A warm tinge of red appeared at a greater altitude, and the whole expanse of the lake, towards the west, shone with the liveliest purple. As the sun descended, the yellow tints of the sky gradually deepened into orange, and the purple colour of the water declined into a more sober hue. In turning the eye to the south, this lively scene became less brilliant. The mountains of Chablais faintly reflected the red twilight, and the Alps of the Vallais, and the part of the lake which intervened, were involved in almost impenetrable darkness.

GENITIVE. See GRAMMAR.

Lake of Geneva || Genoa.

GENOA, a celebrated city in the north of Italy, is situated in Lat. 44° 25′ N. and Long. 8° 58′ E. on the northern shores of the Mediterranean. It is built in the form of an amphitheatre, on the slope of a mountain, rising gradually from the sea, having for a centre the harbour, which is of very considerable extent, and having sufficient depth of water to admit a ship of 44 guns. The harbour is protected on two sides by piers, which, however, are sometimes found insufficient to shelter the vessels from the south-west wind, which although it does not blow directly into the port, often occasions considerable damage. The entrance also to the harbour, although wide, is not free from danger, and can only be approached with safety from the east side.

Genoa is surrounded by two ramparts, one of which incloses the town, and is about six miles in circuit; and the other, which forms a circumference of thirteen miles, is carried round the hills which command the city. The external appearance is extremely magnificent. In no other city in the world is there to be found such a profusion of marble and other rich materials, both in public and private edifices; while their situation on terraces, ascending one above the other, adds an additional degree of splendour to their appearance. On entering the city, however, the narrowness and darkness of the streets produce a mean effect, but ill corresponding with its magnificent exterior, although lined with palaces of vast and lofty dimensions, some entirely of marble, and all ornamented with marble portals, porticos, and columns. The interior of these mansions is no less magnificent. The staircases are of marble, and the long suites of spacious saloons opening into each other, are adorned with the richest marbles and tapestries, with valuable paintings, and gilded cornices and pannels. Of these, the most remarkable are those of the Doria, Durazzo, Balbi, and Serra families. The first of these (consecrated by the recollection of the restorer of his country's liberties,) is a beautiful specimen of the pure and simple stile of architecture, but in magnitude and splendor is far surpassed by the Durazzo palace, which, both in its materials and furniture, is superior to the abodes of most of the sovereigns of Europe.

The public buildings of Genoa are no less splendid than the abodes of her citizens; but the profusion of party-coloured marbles and gilding, which gives an air of wealth and grandeur to the palaces, is offensive to the eye of taste in churches and temples, where all unnecessary and gaudy ornaments detract from that simplicity which should always characterize such edifices. Of this description are the cathedral of St Laurence, the churches of the Annunciation, St Siro, and St Dominic. That of Santa Maria di Carignano is in a purer stile, and placed in a very commanding situation. It was built about the middle of the 16th century, at the expence of Bendinelli Sauli, a noble citizen of Genoa. The approach to this church is by a lofty bridge of three arches, about 90 feet high, across a deep dell, now a street. Genoa owes this building also to the munificence of the Sauli family. It was begun by the grandson, and finished in the years 1725, by the great-great-grandson of the founder of the church di Carignano.

The great hospital or infirmary is a magnificent building, which was formerly possessed of ample funds, dedicated to the relief of the sick or infirm of the poorer classes; but these and the funds of the Albergo dei Poveri, another charitable institution on the same grand scale, have been swallowed up by the exactions of the French armies, and the edifices remain as monuments of the munificence of former times, and serving only, like the city itself, to recal to the recollection of the traveller the days of the commercial greatness, the military glory, and the freedom of the republic.

The population of Genoa in the year 1766, amounted to 100,000, and in 1800 to 80,000. The suburbs of Bisagno and Polcevera were supposed to contain 20,000, and the total population of the Ligurian territory, 480,596. The ordinary military force of the state was about 3000; in the Spanish succession war, however, the contingent of the republic amounted to 10,000.

Commerce was always the favourite pursuit of the Genoese; and as it was considered by no means disgraceful for the nobles to become merchants, the bulk of the capital of the nation was invested in commercial speculations.

The exports from the Genoese territory consist chiefly of silks, fruits, oils, &c. There are also marble quarries of considerable value. The manufacture of velvet is at present the most extensive branch of Genoese trade. Velvets of every sort are made in the neighbourhood of Genoa, but principally black velvets; and it was computed that at one time 6000 workmen were employed in the manufacture. There is also a considerable manufacture of a coarse sort of paper, the most of which is exported to the Indies. It is to be presumed, that while under the dominion of France, the trade of Genoa, like the rest of the empire, must have suffered much during the late war; and the comparative poverty to which its late wealthy nobles have been reduced, together with the decay of public credit, and the failure of the bank of St George, render it improbable that it will ever regain its former state of prosperity.

From the barren nature of its territory, the articles imported into Genoa are very numerous. From France she is supplied with wine; from Italy, with corn, cattle, fuel, &c.; from Germany and Switzerland, linen; from England, woollen cloths; from Holland, spiceries; from Sweden with wood, iron, and copper; from Russia with furs and hides; and from Spain and Portugal with dressed leather, bullion, and American produce.

The earliest mention in history of Genoa, is in the year 241 B. C. when it is described as one of the principal cities of the Ligurians, at that time defending themselves against the encroachments of the Romans, a struggle which they maintained for more than 80 years. It was then erected by the Romans into a municipal city; and continuing faithful to that republic during the Punic wars, was destroyed by Mago, the Carthagenian general, in the year 205 B. C. It was, however, soon rebuilt, and, from the advantages of its situation, and the enterprizing spirit of its inhabitants, appears to have early acquired such a degree of importance, as to be stiled by Strabo, *Emporium totius Liguriæ*.

After the ruin of the Roman empire, Genoa, separated by its mountains from the rest of the world, long maintained its connection with the Grecian emperors; and although for a short period successively under the power of the Lombards, Franks, and Saracens, soon expelled its invaders, and before the end of the 10th century, had established a free constitution resembling in its form the Roman republic. The government, however, as in the other Italian cities, was far from being fixed or stable; and for a long series of ages, the history of Genoa presents little else at home but a continuation of struggles between the nobility and the people. Frequently too, the latter, worn out by the vexatious oppressions of the nobles, threw themselves under the protection of some foreign prince, choosing rather the impartial dominion of a distant sovereign, than the name of liberty and real subjection to a haughty and tyrannical oligarchy. For a more particular account of these revolutions, see the article Italy. But tedious and uninteresting as the relation of the struggles of the Genoese factions may be, the history of its external transactions gives us a high idea of the enterprizing greatness of the republic. In the year 1050, the Genoese forces, united with those of Pisa, achieved the conquest of the island of Sardinia, at that time under the possession of the Moors.

In 1100, in conjunction with Venice and Pisa, they sent to the assistance of the crusaders a fleet of 28 galleys, and six vessels, and a body of troops commanded by one of their consuls, who, after a short siege, took by assault the city of Cesarea. The republics of Pisa and Genoa were soon after engaged, by a mutual jealousy, in a bloody war, which lasted, with various success, for many years, till put an end to in the year 1162, by the interposition of the Emperor Frederick Barbarossa. But this peace was of no long duration; and in two years the war was again renewed from a quarrel between the vassals of the two republics in Sardinia. In 1190, however, we find them both arming a fleet to assist the Emperor Henry VI. in an unsuccessful enterprise to recover the crown of Sicily.

In the succeeding century, a much wider field was opened for the restless and enterprizing spirit of the Genoese. The Venetians having, with the other crusaders, dethroned the Greciam Emperor, received, as their share of the spoil, one fourth and a half of the empire, in which were included all the maritime parts of Greece, with the island of Crete or Candia, and most of the islands of the Archipelago. Unable, however, to colonize their conquests, many of them were left unoccupied, a circumstance which the Genoese did not fail to take advantage of. Their first attempts to obtain settlements in Candia, the Morea and Corfu, were conducted by a private individual, and the Venetians soon succeeded in expelling them.

About this period also, having warmly engaged on the side of the Pope, their fleet sustained a signal defeat from the united forces of the Pisans and Neapolitans, of 27 galleys, three being sunk, and 19 taken. Undismayed by this reverse, they still continued in the papal interest, until 1261, when, having engaged in a long and bloody war with Venice about their possessions in Palestine, they entered into a strict alliance with Michael Paleologus, and bound themselves to assist him against the Venetians, French, and the other crusaders. In this war they were successful; and on Michael's regaining the throne of Constantinople, obtained from him the grant of many commercial privileges, with the isle of Chios in the Archipelago.

Shortly afterwards, a fresh war broke out with Pisa, on account of their Corsican possessions; and large fleets being armed on both sides, continued for some time inactive, until the year 1284, when the Genoese, under the command of Oberto Doria, completely destroyed the Pisan fleet, of above 100 sail, commanded by Alberto Morosini, at Meloria. In this battle, the Pisans lost 5000 men, besides 11,000 prisoners, whom the Genoese retained for 16 years in captivity.

In 1298, commanded by another Doria, they obtained a signal victory over the Venetians at Corzola, which for a time put an end to the war. Their mutual jealousy, however, still continued; and, in 1306, the Venetians having embraced the interests of Charles of Valois, and the Genoese that of the Grecian Emperor Andronicus, the war broke out with fresh vigour. It was also about this time that civil dissensions arose at Genoa between the nobles and the people, which terminated in 1339 in the elevation of Simon Boccanigra, to the dignity of Doge, under whose vigorous administration the republic at length enjoyed a season of tranquillity.

The Genoese had now obtained many valuable settlements in the Grecian empire, and had extended their commercial relation with the Russians and the north of Europe: they possessed the colonies of Kaffa and Tana in the Crimea, and of Pera and Galata near Constantinople, which served as a depot for the merchandize brought by them from India, Armenia, Egypt, and Arabia.

Their riches and power now began to excite the envy and avidity of Cantacusenus, the Emperor of Constantinople, whom they soon overcame, but to whom they granted peace on moderate terms. With the Venetians they were not so successful, and the war continued with great obstinacy and various success for many years. At one time the Genoese, discouraged by the signal defeat of their Admiral Grimaldi, threw themselves under the protection of John Visconti, Archbishop of Milan. Some time after his death, however, in the year 1356, they threw off the yoke of his cruel and tyrannical nephews, and reasserted their liberty.

On the other hand, in the year 1379, the Genoese reduced the Venetians to the last extremity; took the fort of Chiozza, and nearly made themselves masters of Venice.

At length, in 1381, the peace of Turin put an end to the war. In it the Venetians lost their continental possessions, and the greater part of their wealth. Nor was it less fatal to the victorious Genoese. Deprived of their best fleet and the flower of their sailors, and the finances of the republic exhausted by the length of the war, they were again forced to throw themselves under the power of a foreign master, and submit to the authority of Charles VI. king of France, and afterwards of the Dukes of Milan; a slavery under which they continued for more than a century, notwithstanding many ineffectual attempts to recover their liberty. At last, in 1528, Andrew Doria having expelled the French, restored the ancient form of government and freedom to his country;—a rare instance of disinterested patriotism, as, supported by his fleet and the powerful assistance of the Emperor Charles V. he might easily have retained possession of the sovereign power, and have even been aided by the people, to whom his liberality and military virtues had justly endeared him. See Doria.

After this period, the republic, although deprived of its former conquests, for a long time enjoyed, with liberty, peace and prosperity.

In 1624, it was engaged for a short time in a war with France and Savoy; and in 1636, the city was unsuccessfully attempted to be surprised by the Spaniards; but these wars were of no long duration.

In 1684, having incurred the displeasure of Louis XIV. the republic was attacked by that monarch, and obliged to give up the island of Corsica, and to submit to other terms peculiarly mortifying and degrading; the Doge and four of his counsellors being forced to appear in person at Versailles to sue for peace, and the state bound to disarm all their gallies except six, with a promise not to fit out more without the consent of the king.

During the remainder of the 17th and the early part of the 18th century, the republic continued to observe a strict neutrality; but in the war which broke out in 1743, having joined the French and Spaniards against the Austrians, Savona and other Genoese ports were bombarded by the English fleet, and the city, in 1746, obliged to capitulate to the Austrian army. The people, however, soon expelled their invaders, even without the concurrence of the senate; and in 1748, the peace of Aix-la-Chapelle again restored to the state tranquillity.

In 1798, by the ascendancy of the French, the ancient form of government was abolished, and one resembling the French constitution adopted, under the name of the Ligurian Republic. The following year, General Massena's lines in the neighbourhood of Genoa being forced by the Austrians, he was obliged to throw himself into the city, which was besieged for some time, and suffered considerably. By the treaty of Campo Formio in 1801, between the Austrians and French, the Ligurian republic's independence was acknowledged; but it continued under the power of France, and might actually be considered as a part of that empire. The British having made themselves masters of Savona, blockaded Genoa, which in 1814 surrendered to Lord William Bentinck, who issued a proclamation, holding out some hopes to the Genoese that their liberties should be restored. It was however determined, at the congress of Vienna, that the territory of Genoa should be united to Savoy and Piedmont. It was accordingly, in 1815, given up by the British to the troops of the King of Sardinia, and may now be considered as an integral part of that monarchy. GEOGRAPHY.

Geography. Definition.

The term Geography, is derived from two Greek words, *γη the earth*, and *γραφω I write*, and in its original acceptation signifies *a description of the earth*. In the progress of science, however, its meaning has become gradually more extended, and it is now taken to denote, not merely an account of the divisions, produce, inhabitants, &c. of the earth taken as one whole, but also the explanation of various phenomena arising from its relation to other bodies of the solar system. It was indeed from discoveries respecting the heavenly bodies, that men first derived correct notions with regard to the figure and magnitude of their own planet; and it is only by the application of astronomical principles, that the apparently simplest of all geographical problems can yet be solved,—that of accurately measuring, or distinctly expressing, the distance between two points on the surface of the earth. Astronomy and geography have thus become intimately connected, not as two sciences which have merely a certain affinity to each other, and which philosophers, from a wish to generalize and simplify the subjects of their investigation, have thought proper to combine, but because the latter separated from the former ceases to be a science. It is not merely for the language of geography that we are indebted to astronomy. It is from the same source, that we derive the method of constructing a correct representation of the globe, determining the relative position of different places on its surface, and exhibiting a familiar view of the various changes that are continually taking place in its position and outward circumstances.

General division of Geography. Mathematical.

In a system of geography, therefore, it is necessary, in the first place, to consider the earth as a part of the solar system; to illustrate, from astronomical principles, its figure, magnitude, and motion; to explain the construction of the globes, with their application to the solution of problems; and describe the various methods of projecting maps and charts. This constitutes what is properly called *Mathematical Geography*. The geographer may then proceed to consider the globe as one whole, and examine its internal structure; the natural divisions and inequalities of its surface; the phenomena of tides and currents; the modifications of its atmosphere with regard to weight, temperature, humidity, and motion, with other natural appearances usually included under *Physical Geography*.

Physical.

And, in the last place, he may view it as the habitation of animated and rational beings, divided into different kingdoms and states, and exhibiting various monuments of human industry and skill. This forms what may be called *Political Geography*.

Political. Object of the present article.

In the following article, we shall confine ourselves to the first of these, leaving physical geography to be discussed under Physical *Geography*, Meteorology, Mineralogy, &c.; and political geography under the names of the respective countries, and other articles, where they will be treated more fully, and with greater propriety, than they could possibly be in the present article. Before entering on the subject, however, it may be proper to take a short view of the origin and progress of geographical discoveries.

History of geographical discoveries.

In a rude state of society, it seems to have been the universal opinion, that the earth was a large circular plane or disc, every nation supposing itself to be placed in the centre. Of the unexplored parts of this plane, various fanciful and absurd opinions were entertained.

History. Geography of the early Greeks fanciful and absurd.

The early Greeks, for example, imagined, that in the immense expanse of the ocean numerous islands were scattered up and down, inhabited by giants, pigmies, and a vast variety of other beings, which never existed but in the extravagant dreams of a fertile and untutored imagination; while the extreme verge of the disc terminated in a chaotic gulf of unknown extent, and impenetrable darkness. The difficulties and dangers which travellers and navigators at first encountered, in attempting to pass the limits of their own country, and which they were on all occasions disposed to magnify, served rather to confirm than refute these erroneous notions. This remark is strikingly exemplified in the case of the Phœnicians, who, as early as a thousand years before the birth of Christ, had navigated the whole of the Mediterranean from the eastern extremity to the Atlantic Ocean, and had founded the colonies of Utica, Carthage, and Gades. That bold and enterprising people, anxious to reap the whole advantages of their discoveries, were careful in concealing the success of their adventures, but took all possible pains to magnify the dangers and difficulties which they had encountered. Accordingly we find, that long after this period the Greeks still regarded the islands in the western part of the Mediterranean, and even Sicily, as the habitations of monsters, and the scenes of enchantment. Nor did the discovery of their error in one instance, lead them to suspect the accuracy of their opinions in general. So firmly indeed were they persuaded of the truth of that system, which the writings of their poets, and particularly of Homer, had rendered in some measure sacred, that they no sooner became acquainted with a new region, than they immediately transported to more distant islands those fanciful beings, which they had at first erroneously supposed to be inhabitants of places less remote.

Drawn from the writings of Homer.

Common to all rude nations.

Even in later times, when the true figure of the earth was understood, the notions of the ancient Greeks, which were perhaps common to all nations in similar circumstances, continued to pervade the writings of travellers, navigators, and historians, and thus prejudice tended to suppress that spirit of curiosity and adventure, which the discoveries of science might otherwise have inspired. No motive perhaps less powerful than avarice, could induce men to engage in an expedition in defiance of difficulties and dangers, against which they were taught to believe, that human strength and human prudence were equally unavailing; and when such expeditions were undertaken, it would generally be by men little qualified, and still less disposed to communicate correct and interesting information to their less adventurous brethren. In such circumstances, it does not appear at all surprising, that so many ages should have elapsed, before any very extensive or regular intercourse was established between different countries.

Geography of the Hebrews. B. C. 1700.

The first authentic account that we have of any considerable portion of the earth's surface, is derived from the writings of Moses. The object of that writer, indeed, was not to teach men a system of geography; and therefore the information which he affords, regards the earth considered rather as the habitation of moral beings, than as the subject of physical research. We

History.

learn, however, from his writings, that, 1700 years before Christ, a commercial intercourse subsisted between the Midianites, who inhabited the country on the northern extremity of the Persian Gulf, and Egypt, by way of Palestine. From that period, till within 500 years of the Christian era, the Hebrew writings make frequent allusions to the commerce of eastern countries, and it is probable that the Phœnicians were at this time acquainted with many countries, particularly to the west, of which history makes no mention. The geography of the Hebrews themselves, however, does not appear to have extended, at this period, beyond Mount Caucasus to the north, the entrance of the Red Sea to the south, and the Archipelago to the west, including the countries of Asia Minor, Armenia, Assyria, and Arabia in Asia, with Egypt, and a little of Abyssinia in Africa.

Limits of the geography of the Hebrews. B. C. 500.

The Greeks, about the same period, reckoning Delphi the centre of the habitable world, were acquainted with little more than the country included under the name Greece, together with the islands in the Archipelago, the western part of Asia Minor, the sea-coast of Egypt and Lybia in Africa, and a little of the south of Italy. Beyond this circle all was involved in darkness and conjecture.

Geography of the Greeks. B. C. 500.

With regard to the Egyptians, with whom it has been supposed that the science of geography originated, there are no authenticated facts to show, that they had ever been distinguished for enterprise or adventure, previous to the period of which we are speaking, still less that they had ever led the way in geographical discoveries. From the peculiar circumstances of their situation, they must have been obliged, at an early period, to apply themselves to topography, as they did to geometry; but there is every reason to believe that, for their knowledge of foreign countries, they were indebted to the Phœnicians and others, who visited them for the purpose of commerce.

Claims of the Egyptians to the origin of geography

Such was the condition of the most enlightened nations of the world with regard to geographical knowledge, at the commencement of the fifth century, before the birth of Christ. In the course of the next seventy years, however, many interesting and important discoveries were made by the Greeks. Colonies of that people, either driven from their native country by intestine commotion, or induced by the prospect of wealth to go in quest of new settlements, successively established themselves in Sicily, Sardinia, Corsica, and even some of the southern provinces of Spain. For their success in these enterprises, they are said to have been greatly indebted to the geographical and nautical charts which they contrived to obtain from the Phœnicians, and which, with the sphere alleged to have been constructed by Anaximander the Milesian, and disciple of Thales, were the first attempts of which we have any authentic information, towards delineating the whole, or any considerable portion of the earth's surface. But whatever might have been the merits of Anaximander's globe, or of the Phœnician maps, it is certain that the Greeks had not borrowed from either, any correct notions with regard to the figure of the earth. It was reserved for Herodotus to contradict, from his own personal observations, the idea of the habitable world being a circular plane, surrounded by the *river Ocean*. This distinguished writer, who has been styled the father of history, and who, as an attentive and intelligent traveller, has never been surpassed, perhaps seldom equalled by any, either in ancient or modern times, was a native of Halicarnassus, in lesser Asia. Imbibing, in all probability, that spirit of commercial enterprise for which his countrymen were distinguished, and possessing confidence in himself sufficient to raise him above vulgar prejudices, and opinions not founded in facts, he pushed his researches into many countries, which till that time had never been explored. He visited the Greek colonies on the Black Sea, and measured the extent of the latter from the Bosphorus and the mouth of the Phasis at the eastern extremity. He traversed the country between the Borysthenes and Hypanis, now a part of southern Russia, explored the coasts of the Palus Mœotis, (sea of Azof) and obtained correct information with regard to the situation and extent of the Caspian Sea. He visited Babylon and Suza, and was well acquainted with the greater part of the Persian monarchy. He travelled through the whole of Egypt, where he obtained a great deal of interesting information respecting the caravans from the interior of Africa, and also visited the Grecian colonies of Cyrene. From his description of the straits of Thermopylæ, it is obvious that he had been in Greece, and he traced the course of the Ister (Danube,) from its mouth almost to its source. He terminated this career of discovery and adventure, as useful to others as honourable to himself, in the southern part of Italy, where it is also supposed that he finished his much admired history.

History.

In estimating the extent of the geographical information furnished by Herodotus, we are by no means to limit it to the circle which he described, and which we have just traced out. Possessing in an eminent degree those qualifications which distinguish the intelligent traveller from the mere tourist, he was enabled to collect much valuable information respecting countries which he had no opportunity of visiting; and the accounts which he gives of these countries have been confirmed by the most unquestionable of all evidence, the striking similarity in the characteristic features of their ancient and modern inhabitants. Viewing it in this light, the geography of Herodotus extended to the greater part of Poland and European Russia, western Tartary, the country on the Indus from its source to the confines of the Cashmere, Arabia, and the northern parts of Africa. He sometimes mentions Carthage, and gives an account of a traffic carried on without the intervention of language, between the Carthaginians and a nation beyond the Pillars of Hercules, which has been considered as applicable to that of Senegambia. There is nothing explicit, however, in the text of Herodotus, with regard either to the name or the situation of the country.

Limits of the geogr phy of H rodotus.

Before concluding this short review of the travels of our author, it may not be improper to notice the information which he gives, or is supposed to give, on three subjects, which still continue to agitate the scientific world, we mean the Niger, the Nile, and the pretended circumnavigation of Africa by the Phœnicians. With regard to the Niger, the only passage in Herodotus that can possibly allude to this river, is the account which he gives on the authority of Etearchus, king of the Ammonians, of a journey into the interior of Africa, undertaken by five young Nasamons, a people situated at the extremity of the Gulf of Sydra. These travellers having, in the first part of their journey, passed through an inhabited country, came to an immense sandy desert, through which they continued their route westward, till they reached an extensive plain covered with vegetation. While they were enjoying the shade, and eating the fruit of the trees which they found there, they were fallen upon by men of a very diminutive size, who conducted them across a swampy country, till they came to a town inhabited by black people,

His accou of the Ni ger.

History.

and situated on the bank of a large river, running from west to east. Though the vague and indefinite nature of the account itself, the authority on which it rests, and the circumstance of its being obviously introduced for the purpose of proving that the Nile runs from the west, tend to throw considerable doubts on the truth, or at least the accuracy of this relation, yet some eminent geographers are of opinion, that the town mentioned above is no other than Tombuctoo on the banks of the Niger.

Of the Nile.

Of the Nile, Herodotus speaks with more precision; and, as his information on the subject appears to have been derived from personal observation, it is on this account entitled to more credit. After detailing at some length the manner of ascending the river, and describing minutely the nature and inhabitants of the countries through which it passes before entering Egypt, he concludes by affirming that it certainly runs from the west, though he acknowledges that beyond the country of the Automoles it had never been explored. The Automoles, otherwise called Asmach, were originally descended from a colony of Egyptian fugitives, but, at the time of Herodotus, inhabited a province subject to the king of Ethiopia, and lying as far to the south of his capital Meroe, as Meroe was from the great cataract. According to Eratosthenes, and other ancient geographers, this town was situated on an island formed by the junction of the Atbar or Tacazze with the Nile; and this account is farther confirmed by the testimony of Mr Bruce, who discovered magnificent ruins to the north of Chandi, opposite the island of Kurgos. If this opinion be correct, it fixes the situation of Meroe in 17 degrees of north latitude, about 6 degrees south of the cataract, and 6 north of the Automoles. Herodotus, therefore, must have been acquainted with the course of the *western* branch of the Nile, as far as the *eleventh* parallel; and of its course beyond this, no subsequent traveller has yet given any satisfactory information.

Of the circumnavigation of Africa by the Phœnicians. B. C. 604.

With regard to the circumnavigation of Africa by the Phœnicians, Herodotus relates the story apparently as he received it, without determining any thing as to its being true or false. When Neco king of Egypt had completed his famous canal between the Nile and the Arabian gulf, he dispatched vessels manned with Phœnician sailors, who, after navigating the ocean to the south of the Red Sea, were to return to Egypt by the pillars of Hercules and the Mediterranean. This they are said to have accomplished in less than three years, including their stay on the coast of Africa, while they sowed and reaped a crop of corn. On their return, they related among other wonders, that in sailing round Lybia, the sun appeared to be on their right. "This," says Herodotus, "appears to me altogether incredible, but it may not perhaps appear so to others." On this passage it has been remarked by those, who are disposed to admit the truth of the circumnavigation in question, that the very circumstance which the historian rejects as incredible, is one of the strongest arguments possible in favour of the tradition. The truth of this remark is too obvious to be disputed, and we are ready to admit the full force of the argument which it affords. At the same time we cannot by any means consider it as decisive. The Phœnicians we think might have sailed far enough to the south in the Indian Ocean to have observed the phenomenon of the sun to the north of the zenith, though they had never attempted, far less executed the circumnavigation of Africa; and we cannot avoid observing in passing, that they who are disposed on all occasions to magnify the discoveries, and exalt the merits of the ancients, would do well to be on their guard, lest they pull down with one hand what they have taken pains to erect with the other. May not the incredulity expressed by Herodotus with regard to the position of the sun, be brought forward with some plausibility, as presumptive evidence against the commonly received opinion with regard to the extent of his own travels up the Nile? It is difficult to conceive how he could possibly have advanced so far as to the eleventh parallel of latitude without having heard at least of the sun being observed towards the north. To say that such a journey as this would never be undertaken while the sun was advancing towards the tropic of Cancer, on account of the overflowing of the Nile, is hardly a satisfactory solution of the difficulty.

Discoveries of the Carthaginians.

It has already been observed, that before the time of Herodotus, the Carthaginians had established a commercial intercourse with some of the nations on the western coast of Africa, though it is not exactly known when this intercourse began, or how far it extended. There is reason, however, to believe, that the voyage of Hanno, which some say reached to the mouth of the Senegal, was not earlier than the end of the fifth, or beginning of the fourth century before Christ, and that it was about the same time that the Carthaginians first became acquainted with the Canaries, the northern provinces of Spain, and the British islands. The latter, indeed, had in all probability been visited at a much earlier period by the Phœnicians, who carried on a lucrative trade in *tin* with the inhabitants of Cornwall.

Hanno. B. C. 430.

During this same period, the Greeks continued to cultivate geography with ardour and success. Hippocrates, the celebrated physician of Cos, retracing the footsteps of Herodotus, and sometimes penetrating beyond his predecessor, collected many valuable observations on the temperature and humidity of different climates as affecting the human constitution, and may perhaps be justly styled the father of physical geography. The subject in all its bearings wanted only to be reduced to a regular and systematic form, to be placed on a footing with the other sciences, and fortunately the execution of this task fell to one who of all men perhaps was the best qualified to do it justice. Aristotle directing towards it the energies of his powerful mind, stamped a value on the discoveries and observations of others, which till his time they had never possessed. He collected and combined the whole of these facts into one system of geographical knowledge, deduced from them the spherical figure of the earth, (the fundamental principle of all geography), and in this simple form put the science, along with others, into the hand of his royal pupil, to smooth the march of conquest, and make some reparation for the violated liberties of mankind.

Hippocrates. B. C. 420.

Aristotle. B. C. 340.

Discoveries of Alexander and his followers. B. C. 333.

The expedition of Alexander constitutes an era in the history of ancient geography. As eager to be thought the patron of science as the conqueror of the world, he was careful on all occasions to blend the two characters, and judiciously left to posterity an accurate geographical account of his expeditions, as the most durable monument of his military glory. His successors indeed, however anxious they were to imitate him in other respects, did not shew the same predilection for literary fame. But from the school which he established in Alexandria, the light of science continued to emanate with increasing splendour; and even to one of his generals, Seleucus Nicanor, who carried his victo-

History.

Seleucus explores India. B. C. 312 to 291.

rious arms from the Indus, where Alexander's expedition terminated, to the mouth of the Ganges, geography was not a little indebted. His ambassadors Megasthenes and Daimachus, who were sent to Palibothra, the capital of a large kingdom on the Ganges, and thought to be the Allahabad, or according to others, Baliputra of modern India, collected a great deal of important information with regard to the natural history of the country, as well as the manners of the inhabitants. The spirit of commercial enterprise, which prevailed particularly in Greece during the century after Alexander's death, served not only to keep up a constant intercourse with the countries thus discovered, but also to extend the boundaries of geography to others before unknown. The Grecian kings of Egypt carried on a regular trade with India and Taprobane (Ceylon), while the Carthaginians extended their commerce along the western coast, as well as into the interior of Africa.

Expeditions of the Romans. B. C. 264 to 146.

The Romans also, having obtained possession of all Italy, began to aspire after foreign conquest. Their expeditions against Carthage made them acquainted with Africa, and what was of still greater consequence, taught them the construction and management of ships. In the Macedonian war they acquired a knowledge of Greece, and rendered themselves formidable in Asia Minor by the defeat of Antiochus. Their subsequent conquests were still more important in a geographical point of view. Julius Cæsar gave the earliest and the most accurate account of the interior of Gaul and the south of Britain, Germanicus penetrated as far as the Elbe, and Elius Gallus traversed the interior of Arabia.

Julius Cæsar. B. C. 50.

Thus by the commencement of the Christian æra, geography had received a vast accession, not merely in extent, but in point of accuracy. Countries that had only been heard of from the casual visit of a solitary traveller, or misrepresented by the selfish policy of the avaricious trader, were now familiarly known, from the march of victorious armies, whose leaders were as anxious to describe as to conquer, and by a happy combination of events, a Strabo arose to transmit an account of all these discoveries to posterity.

Strabo. B. C. 30.

Limits of his geography.

Of the elegant and learned work of this celebrated writer, we cannot pretend to give any thing like an analysis, ; and indeed no analysis could do it justice. We have only to observe, that the portion of the globe which he describes is bounded on the north by the Baltic, towards the east by the Ganges, and on the south nearly by the line joining the mouth of that river with the mouth of the Senegal. Of course his description of all the countries contained within these limits cannot be equally minute, nor is he always accurate in his delineation of those that were more perfectly known. He is frequently mistaken with regard to the situation of particular places, the course of rivers, and the direction of chains of mountains. These, however, are errors which will readily be overlooked, when we consider the period at which the work was composed, a period when the traveller had to struggle with difficulties in all inland expeditions, and the geographer laboured under disadvantages from the want or the imperfection of instruments, of which moderns can hardly form an idea.

Thule of the ancients according to Pytheas.

The only other subject which we would notice as connected with this period of ancient geography, is the situation of the much disputed Thule. Pytheas, a navigator of Marseilles, who lived a short time before Alexander the Great, after having explored the east, or as he thought the north east coast of Britain, continued his voyage, as he says, to the north, that is to the north-east, and after six days fell in with land which he calls Thule or Thyle, and which he states to be 46,300 stadia from the equator. The situation of this place has long been a disputed point both with ancient and modern writers, and the difficulty arises from not knowing, in the first place, which of the ancient stadia is here meant, and secondly, what was the precise length of the stadium. The different kinds of stadia in use among the ancients, are generally reduced, by modern geographers, to four, but the respective lengths of these have by no means been accurately determined. Without, however, entering into a detail of the various opinions which have been entertained on the subject, we shall merely state that of an eminent writer, which is perhaps as accurate as any other. This author (M. Gosselin) supposes, that of the longest stadia $666\frac{2}{3}$ were equal to one degree of the equator, of the second kind 700, of the third $833\frac{1}{3}$, and of the fourth or Egyptian $1111\frac{1}{9}$. Applying these different measures successively to Pytheas's account, we shall have for the latitude of Thule 69° 27′; 66° 8′; 55° 34′, and 41° 40′. Of these results the third appears to be the most probable, as it determines Thule to be on the west coast of Jutland, and as it is to Jutland only that Pytheas' description can at all apply. He says, for example, that there the sea, the earth, and the air, seem to be confounded in one element; a description strikingly applicable to the downs of Jutland, where the sand is frequently driven about with violent winds, and being scattered over the surface of the marshes, conceals from the unwary traveller the gulf beneath. His account of the produce of the country is equally applicable; and the whole is rendered more probable, from there being in Jutland, about a degree farther north than the situation of Thule, as now determined, a part of the coast still denominated Thy or Thyland, and in the ancient language of Scandinavia, Thiuland. Other arguments might be urged in favour of this opinion, notwithstanding the scepticism of Strabo, and other ancient geographers; but more, perhaps, has already been said on the subject than is consistent with the nature of our plan. See Foulah.

Supposed to be Jutland.

Circumstances that retarded the progress of geographical discovery after the commencement of the Christian æra.

For some time after the commencement of the Christian era, the progress of geographical discovery was neither rapid nor very extensive. The Romans had by this time, indeed, subdued the greater part of the known world, and had consequently a great deal in their power with regard to the advancement of science. But their attention was directed more to what they already knew, than what they might still have to discover. They soon began to perceive that conquests were more easily made than retained, and that, by attempting to gain more, they might eventually lose what they already possessed. They had therefore no longer any inducement to extend their researches into foreign countries for the purpose of conquest, scarcely even for military renown; and thus geography was deprived of the aid which it had formerly derived from a spirit of military adventure, and to which, more than any other circumstance, perhaps, it was indebted for its success. Nor had the Romans the same temptation as formerly to explore unknown regions, for the purpose of commerce. Asia continued long to supply them in abundance with every luxury which they could desire, through the ordinary channel; and while that supply kept pace with the demand, it was not to be expected that they would give themselves much trouble either about discovering new countries, or exploring new channels of communication with such as were already known to them. Add to all this, that geographical discovery was approaching that point when its farther extension could only be looked for in the event of some new and important improvement in the art of navigation, or some discovery in those sciences on which it chiefly depends. But though these circumstances were sufficient to prevent the Romans from extending in any great degree the sphere of geographical knowledge, they were by no means inattentive to the cultivation of the science in general. The civil and military establishments which they were obliged to maintain in all the conquered provinces, and the security which trade enjoyed under a regular and efficient government, gave rise to a closer and more regular intercourse among all the countries which composed the empire, than had ever been known at any former period. Were we indeed to point out the limits of Roman geography, we should probably not include a much greater extent than has been already assigned to that of Strabo. But in point of accuracy and minute detail, the difference is considerably in favour of the former. They were well acquainted with all the countries on the Danube and the Vistula, nor was the Rha or Wolga unknown to them, though sometimes confounded with the Tanais or Don. Of the intermediate space containing Scythia, Sarmatia, and Dacia, we have accounts from various Roman writers, though it is obvious that in many things they follow Herodotus. Their knowledge of the countries on the southern coasts of the Baltic, as well as Jutland, then called Cimbria Chersonesus, was tolerably accurate with regard to situation and extent; but the origin and names of the different nations were by no means well ascertained, and notwithstanding the labours of modern geographers and critics, they are still involved in darkness and confusion. The Romans little thought, in the meridian of their glory, that they were ultimately to fall a sacrifice to the ravages of nations so barbarous as to be without the limits of the civilized world, and so rude as to be incapable of communicating to others any account of their own origin or early history. Of the countries to the north of the Baltic, the Romans knew comparatively little. The southern part of Sweden was denominated Scandia, and was considered as an island of unknown extent. It seems, indeed, to have been the general opinion, that the Baltic was part of the northern ocean, containing an archipelago of large islands, and it may perhaps be inferred from this opinion, that their geographical knowledge, in this direction, did not extend beyond the large lakes in the south of Sweden, and the entrance of the gulf of Bothnia. Proceeding westward, the next country we meet with in the geography of the Romans is Britain, of which we have a very minute account, comprehending not only the mainland of England and Scotland, but also Ireland, the Isle of Man, the Western Islands, and the Orknies. Ptolemy speaks of Thule as situated to the north-east of Britain, by which he has been understood as meaning one of the Shetland islands. It cannot, however, be inferred from this, that the Romans were really acquainted with these islands. Of Gaul and the other western countries of Europe, it is hardly necessary to take any notice, the Roman accounts of these being familiar to every body.

From the west of Europe we naturally pass to Africa, and we find that the Romans were acquainted with about one-third of that continent. Pliny, from a statement by Agrippa, estimates the breadth from north to south, through Cyrenaïca and the country of the Garamantes, that is from Barca towards Bournu, at 910 Roman miles, a distance from the Mediterranean which falls considerably short of the Niger. It appears, however, that they were not altogether ignorant of that river in another direction. Pliny, on the authority of Juba, king of Mauritania, mentions that the Nile rises from a lake in the interior of that country, and that, after running under ground through a desert of twenty days journey in extent, it makes its appearance again on the confines of Ethiopia, where its source is called Nigris. From this modern geographers have concluded, that the desert here mentioned is the great desert of Sahara, that what Pliny calls the Nile is only a small river running along the south side of Mount Atlas, and that its pretended reappearance is no other than the source of the Niger or Joliba. In this our readers will recognise the opinion of Herodotus, expressed in a more detailed form, that the Niger and the Nile are the same river, and they will also observe, that the Roman geographers, in the time of Pliny, were not better acquainted with the western part of Africa, than their rivals the Carthaginians had been. Ptolemy, indeed, distinctly mentions the Niger, and enumerates some of the towns situated on its banks, as Tucabath, Nigira, Ta-Gana and Panagra, in which later geographers have discovered the modern towns of Tombuctoo, Cashnah, Ganah, and Wangara; but even his account of the interior is very partial and indistinct. Of the Canaries, the Romans undoubtedly knew more than the Carthaginians, though these islands were still regarded too much as the region of fiction. They were called in general the *Fortunate Isles,* a name famous with the poets, and perhaps too frequently employed in the more sober details of the historian. Among the particular names, we find Canaria and Nivaria, the former obviously the same with modern Canary, the latter, perhaps, denoting Teneriffe with its snowy summit. On the eastern side of Africa, the geography of the Romans was neither very distinct nor very extensive. They seem to have been acquainted with the Nile, as far as the Automales of Herodotus, but not to have penetrated farther. On the shores of the Indian ocean, their navigation terminated at the promontory of Prasum, a point which Ptolemy represents as lying to the south of the equator, but which, from a careful investigation of the measures employed by him, is found to correspond with Cape Brava, two degrees to the north of the line.

When we turn to Asia, we find the geographical improvements of the Romans much more interesting in a scientific point of view, as well as more important in regard to commerce. These improvements may be almost wholly ascribed to the discovery of the monsoons, by which the communication with India was completely altered, and the trade of that rich and luxurious country prodigiously extended. Embarking at the Egyptian ports on the Red Sea, and passing the straits of Babel-mandel, the merchant was carried by the south-west monsoon, or Hippalus, so called from its discoverer, directly to the peninsula of Hindostan, and back again by the Vulturnus, or north-east monsoon, in the course of the same year. This navigation was first undertaken during the reign of Augustus, till which time the route to India was either across the desert from Syria to the Euphrates, down the Persian gulf and along the northern coast of the Arabian sea to the mouth of the Indus; or farther to the north by the Caspian sea, and the Oxus or Jihon. Some ancient writers represent the latter as much more easily accomplished than it could possibly have been, by supposing that the Oxus fell into the Caspian Sea, or rather that Lake Aral was a gulf of that sea. But even if this had been the case, the conveyance of merchandise by such

Discovery of the monsoons in the reign of Augustus.

History.

a route, must have been exceedingly slow, expensive, and precarious, compared with the direct course across the Arabian Sea. By the latter, also, the western coast of the peninsula of India became better known, and opened the way for other discoveries in the interior as well as on the Bay of Bengal. The whole extent of country south of the line joining the mouth of the Indus and the mouth of the Ganges, was soon explored, and is described with considerable minuteness by Pliny and Ptolemy. Of the north of India, the accounts of these writers are extremely vague; but it appears that Thibet was pretty well known under the name of Serica. On this subject, indeed, there has been much learned disquisition among critics and geographers, some supposing, as we have now stated, that Serica included Thibet, with part of the north of India, while others consider it as denoting China. This last opinion is chiefly founded on the calculations of Ptolemy, by which Serica appears to be situated in the middle of the Pacific Ocean; but these calculations are obviously in direct contradiction, not only to Pliny, but to Ptolemy himself. According to the former, Asia terminated a little to the east of the Ganges and the north of the Caspian Sea; and he distinctly says that the Seres inhabit the middle of the eastern regions, of which the Scythians and Indians occupy the two extremes. The latter also describes Serica as bounded on the east by unexplored countries, and on the south by the mountains of Emondus, (the modern Emod, Hema, or Himmala), which separate it from India. It is unnecessary to observe, that neither of these accounts can possibly apply to China, while both are accurate if understood of Thibet. "Here, then," to use the words of a modern geographer, "among the Alps of Asia, and on the borders of the great desert of Shamo, expired the last ray of the geographical knowledge of the ancients."

Geography of Pliny and Ptolemy. A. D. 100 to 140.

A. D. 140 to 650.

To pursue the history of geography through the period on which we are now about to enter, would be to trace the decay of every thing dignified and ennobling, and to mark the progress of ignorance and barbarism, triumphing over science and civilization. We should find, in the course of a few centuries, the inhabitants of the whole civilized world completely extirpated, and succeeded by a race of men who knew nothing of themselves farther back than their recollection carried them, and nothing of the rest of mankind but what they learned during their career of victory and bloodshed. We should perceive the termination of all friendly intercourse among different countries, and wars carried on no longer with a view to conquer and civilize, but to extirpate and destroy. It is not consistent, however, either with the nature or the limits of the present article, to enter into a minute detail of the circumstances that conspired to accelerate the destruction of the Roman empire, or enumerate the various tribes that took possession of the different countries of Europe, and the revolutions that took place in their manners and form of government. We shall only observe, therefore, that during the latter period of the Roman history, literature and the fine arts had in a great measure banished the cultivation of science, and the ardour of curiosity, so necessary in all laborious researches, but particularly for geographical discovery, had degenerated into a love of indolence and ease. A great deal still remained to be done by active and enterprizing adventurers, before the science of geography could be successfully prosecuted in the retirement of an academy; but enterprize and adventure were no longer to be found among a people enervated by every species of luxury and dissipation. We find, accordingly, that from the time of Ptolemy, till the overthrow of the Roman empire, there is scarcely a single fact on record that deserves a place in the history of geographical discoveries. From that period, the progress of all knowledge was retrograde. The monuments of learning that had been reared by the persevering labours of many ages, were successively overthrown; till Alexandria itself, the last refuge of persecuted science, fell a sacrifice to the merciless fury of a barbarous fanatic. The work of devastation was now complete. The last faint glimmerings of intellectual light were extinguished, and the gross perversion of religious principle in Europe, with the establishment of a false system in Asia, threatened to perpetuate that darkness which had enveloped the civilized world.

Such was the state, and such the prospect, of literature and science about the middle of the seventh century. There was still one country, however, which had not yet felt the shock of revolution, and from which the light of science was again destined to emanate. Arabia, from time immemorial, had preserved its independence; and while the rest of the civilized world was hurrying into decay, it continued to enjoy its ancient laws and privileges, and made considerable progress in many of the useful arts. Even the establishment of Mahometanism, at first so fatal in its operation, and which, like every other false system of religion, might have been supposed inimical to the progress of science, eventually contributed to the advancement of geographical knowledge. The Arabians, possessing a great extent of sea-coast, had from a very early period carried on an extensive trade, which was considerably increased by the conquests of Mahomet and his immediate successors. In their eagerness to propagate the doctrines of Islamism, the Arabian caliphs extended their arms to the pillars of Hercules in the west, and the banks of the Ganges in the east, and thus geographical discovery was once more associated with its most powerful ally, a spirit of military and commercial adventure. By the middle of the ninth century, the Arabians had formed settlements in different parts of China, and established an intercourse with Madagascar, the Maldives, Ceylon, Sumatra, Java, and other oriental islands. Nor was it to geography, considered in a commercial point of view, that their attention was exclusively directed. Their generals had orders to procure geographical accounts of all the countries which they subdued; and we find the Caliph Al Mamon, as early as 833, obtaining the measurement of a degree of latitude in the desert of Sandgiar, for the purpose of ascertaining the magnitude of the earth.

While the followers of Mahomet were thus extending the boundaries of geography in Asia, a spirit of enterprise seemed for a time to break out in the north of Europe. The earliest account of Denmark, Norway, and Sweden, on which any reliance can be placed, is that given by Alfred king of England, towards the end of the 9th century. This account is chiefly founded on the information of certain Norman adventurers, who finding the southern parts of Europe already in possession of their own countrymen, were forced to betake themselves to maritime expeditions in quest of new settlements. These adventurers gradually extending their researches into the Northern Ocean, discovered Greenland and the Shetland isles, on both of which they planted colonies, about the end of the 10th century. In the year 1001, Biorn, a Norman navigator, while steering round the coast of Greenland in search of his father, was driven by a storm a considerable way to the south-west, where he fell in with land, afterwards called Vinland, and supposed to be part of North America. Subsequent voyages to the same place tend to confirm this opinion, particularly that of the Zeni, two noble Venetian brothers, who, in the account of their adventure in 1390, describe a country called by them Estotiland, corresponding in every respect with Vinland, and agreeing in many points also with Newfoundland in North America. From this circumstance it has been inferred, that Columbus, in his anticipations of a western continent, was guided by something more decisive than bare conjecture. But whatever truth there may be in this supposition, it seems to be generally admitted, that the Normans had at a very early period landed on the coast of America. The consequences of the discovery however, were neither interesting nor important. Europe still continued ignorant and inactive, or engaged in pursuits suited only to an age of ignorance and barbarism. Even when her energies were awakened by the crusading mania towards the end of the 11th century, they promised to be productive of little benefit to the cause of literature and science. The professed object of the crusades was in itself chimerical, and it is difficult to say what advantage would have resulted from them, had they been completely successful. But though the immediate effects of these fanatical expeditions are still somewhat problematical, there can be no doubt that they were ultimately beneficial in a commercial point of view. It was in order to supply the crusaders with stores and ammunition, that the Genoese were first tempted to cultivate the art of ship-building, which for many centuries had been almost totally neglected, and to extend their short coasting expeditions to the most distant extremity of the Mediterranean. The same enterprising people having afterwards succeeded in re-establishing the Greeks on the throne of Constantinople, were rewarded with certain exclusive privileges in the way of commerce. By this event, their rivals the Venetians, who had shared with them the advantages of a trade with India nearly by the same route as was formerly known to the Romans, were excluded from the navigation of the Black Sea. The monopoly, however, was in this case beneficial to the cause of commerce. The Venetians, by concluding a treaty with the Sultan of Egypt, opened a communication with India by the Red Sea; and Alexandria soon became the grand depot of commerce, as it had formerly been the retreat of literature and science.

While the consequences of the crusades were thus apparent in exciting a spirit of enterprise in the commercial world, there were not wanting men who, actuated by motives very different from those of avarice or even curiosity, contributed from time to time to extend the boundaries of geography in the East. These consisted of ecclesiastics, who, animated by a sincere though mistaken zeal for promoting the doctrines of a corrupted church, undertook long and painful journies into countries which European commerce had not yet reached, and endeavoured, by the more captivating method of persuasion, to propagate opinions, which the sword had in vain attempted to impose. From the accounts of these missionaries, scanty and unsatisfactory as they frequently were, a great deal of information was obtained respecting the interior of Asia, particularly the north of India and Tartary. Among those who chiefly distinguished themselves in these expeditions, the first place is due to Marc-Paul, a noble Venetian of the 13th century. This celebrated traveller set out with his father Nicolas Paul, who had already acquired considerable reputation as a missionary to the East, and some Dominican monks in 1271, and after 26 years spent in unremitted labour, during which time he not only traversed those countries that were already known, and explored many new regions on the continent of Asia, but also visited Borneo, Java, Sumatra, the Nicobar islands, Ceylon, Madagascar, and other islands in the Pacific and Indian Ocean, till then unknown to Europeans, returned to Italy, where he was soon after made prisoner in a war with the Genoese. It was during his captivity in Genoa, that he wrote the account of his travels; a work which, though composed in a very irregular and confused manner, continued long to be the guide of Europeans in all matters relating to oriental countries. Of himself and his writings it has been justly observed, that he was the father of the modern geography of Asia, the Humboldt of the 13th century, though the misfortunes of the latter part of his life, by preventing him from publishing a more accurate and systematic account of his travels, have thrown a shade over the glory of his own name, and robbed science of the advantages which she might otherwise have derived from his labours.

History. Travels of Marc-Paul. A. D. 1271 to 1297.

Passing over the other events of the 13th and 14th centuries, as presenting nothing very striking or important, we hasten forward to a period of all others the most brilliant and interesting in the history of geographical discovery. About the beginning of the 15th century, the Portuguese began to attract the notice of the other European states, by the glory of their military exploits, and the fame of their naval discoveries. Having succeeded in driving out their inveterate enemies and oppressors the Moors, they carried their arms into Africa, where their achievements were such as might have been expected from a combination of every motive that could lead to acts of fearless bravery. Religious zeal inflamed them with the desire of extirpating the enemies of the Christian faith; avarice inspired them with the hope of sharing the treasures of a rich and powerful people; and a spirit of chivalrous and romantic gallantry threw a charm over military enterprise, more powerful perhaps than either of the other principles. The youthful adventurer of every country ranged himself under the standard of Portugal, and courted the approbation of his mistress by deeds of valour on the shores of Africa. Success in such circumstances could be neither slow nor uncertain, and every new victory led the way to a new expedition. The coast of Africa as far as Cape Nun, had been formerly explored more than once; but all beyond that was still enveloped in impenetrable darkness. The art of navigation, however, from the discovery of the compass, was rapidly improving; and the daring spirit of enterprise that had just been awakened, could no longer be confined within the former limits. In attempting to extend their discoveries towards the south, the Portuguese fell in with, and took possession of Madeira in 1420; and in 1433, Cape Nun was doubled for the first time by Gilianez. It is generally supposed, that in the same year the Azores, or Western Islands, were discovered, though on this point geographers are by no means agreed.

Discoveries of the Portuguese after the beginning of the 15th century.

Madeira. A. D. 1420.

The discoveries of the Portuguese along the coast of Africa, though not very rapid, became after this period progressive. In 1445 they reached the Senegal; and in 1456 discovered the Cape Verd Islands. A short time after this, Pierre de Cintra penetrated as far as Cape Mesurada, where the coast of Africa stretching

Cape Verd islands. A. D. 1456.

towards the east, promised a speedy accomplishment of the great object of all their expeditions, the circumnavigation of Africa. It was just at the dawn of these hopes, that the death of Prince Henry, the author of all the grand projects of the Portuguese, threatened to put an end to exertions equally honourable to his country, and beneficial to the interests of science. The spirit of the prince, however, had by this time been communicated to the nation, and the progress of discovery scarcely suffered any interruption. Prince's Island, St Thomas, and Annobon, were discovered in 1471; in 1484, Diego Cam entered the river Zaire, or Barbela, in the kingdom of Congo; and finally in 1486, fifty-three years after Gilianez had first doubled Cape Nun, Barthelemy Diaz reached the southern point of Africa, which he named the *Stormy Cape*, but which King John II. afterwards more properly denominated the *Cape of Good Hope*.

Cape of Good Hope. A. D. 1486.

Slow progress of the Portuguese not a conclusive argument against the circumnavigation of Africa by the Phœnicians.

While the slow progress of the Portuguese in exploring the west coast of Africa, has generally been accounted for from the imperfect state of navigation at that period, it has also been considered by some geographers, as a conclusive argument against the pretended circumnavigation of Africa by the Phœnicians, it being quite incredible, in their opinion, that the latter should have been able to accomplish in three years, twice as much as the Portuguese, with the assistance of the compass, could effect in half a century. Without at all entering again into the merits of the question, we would observe, that the conclusion drawn from the preceding fact is by no means legitimate. The Portuguese, in all their expeditions, seem to have confined themselves chiefly to the coast, where the compass could be of comparatively little use; and there can be no doubt, we think, that in every thing connected with coasting navigation, the Phœnicians had acquired much greater skill and dexterity than the Portuguese could possibly have at the commencement of their African expeditions. But to proceed with their discoveries.

Portuguese reach India. A. D. 1498.

In 1497, Vasco de Gama was dispatched for the purpose of exploring a passage to India by the Cape of Good Hope, at the same time invested with a commission to conclude a treaty with Prester John, whom the Portuguese supposed to be the prince of Abyssinia, or some other country on the eastern coast of Africa. That celebrated navigator, after touching successively at Port Natal, Mozambique, and Melinda, obtained pilots at the last of these places, and traversing the Arabian sea, in 1498, landed at Calicut, on the Malabar coast, the whole of which he soon after explored. About 1506, succeeding navigators pushed their discoveries along the eastern coast of Africa, as far as the straits of Babelmandel, and thus completed the circumnavigation of that continent. In the same year they discovered Ceylon, and in 1511 established themselves in Malacca. Their discoveries after this period are too numerous to be particularized. It is enough to observe, that by 1520 they had visited the Sunda islands, the Moluccas, Philippines, and indeed almost all the islands to the south-east and east of Asia, as far north as the thirtieth degree of latitude. Their being prohibited from entering China, probably led to the discovery of many islands in the Pacific at a much earlier period than would have happened, had the Portuguese been permitted to open a commercial intercourse with that country.

Ceylon. A. D. 1511.

Discovery of America by Columbus. A. D. 1492.

While geographical discovery was making such rapid progress in the East, the West also had become the scene of very interesting and important events, by the vast and daring projects of Columbus. Hitherto the course of navigators, in all voyages of discovery, had been determined by the direction of the coast, and was probably, for the most part, within sight of land; but Columbus, leaving the guidance of the shore, and trusting to the compass alone, ventured across an ocean of unknown extent, in search of a continent whose existence was extremely doubtful. In order still further to excite our admiration of this extraordinary man, it has been said, that he was strongly impressed with the idea of there being a great western continent, and attempts have even been made to point out the train of reasoning by which a man of genius might be naturally led to form such an opinion. We do not think, however, that the character and merits of Columbus require any adventitious support of this kind. If the circumstances to which we have already alluded respecting the adventure of the Zeni, in 1390, be well founded, it proves, that Columbus was not less distinguished for prudence than for intrepidity; and if it be false, we apprehend that his adventure is to be ascribed to an error common to him with Aristotle and many of the ancients, that the eastern extremity of Asia was not far distant from the shores of Spain. But whatever was the origin or the nature of the opinion formed by Columbus on this subject, it is certain that he undertook his voyage under a strong conviction of his ultimate success; and it is a curious coincidence, that at the very time when Vasco de Gama was taking possession of the peninsula of Hindostan in the name of the King of Portugal, Columbus was adding a new continent to the kingdom of Spain. It is unnecessary here to detail the circumstances connected with the discovery of America, as we have already done so in another part of our work, (See America and Columbus.) We cannot, however, avoid noticing the striking contrast which the history of that period exhibits, between the speculations of a few bold and aspiring individuals, and the childish prejudices which still enslaved the great bulk of mankind. While Columbus supposed that the nearest route to the eastern shores of Asia was by the western ocean, the Pope imagined, that, by a line of demarcation drawn on one side of the globe, he had completely separated the discoveries of the Spaniards and Portuguese!

Though Spain, in exploring a nearer passage to the East Indies, had discovered and taken possession of a new continent, she did not relax her endeavours to effect her first object. Accordingly, in 1520, Magellan was sent out on another voyage of discovery, when he succeeded in passing the extremity of South America by the strait which still bears his name, and, pursuing his voyage westward, reached the islands on the east coast of Asia. After his death, which happened at one of the Philippines, his companions continued their course, and, after touching at the Moluccas, returned by the Cape of Good Hope, having accomplished the first navigation of the globe in 1124 days. The attempts of the Spaniards to discover a passage by the north of America were not so successful. Some indeed have imagined, from their description of the Strait of Anian, that it was Bhering's Straits which they had reached by the north-west; but it is obvious that this strait was no other than Hudson's Strait, about the position of which the navigators of that period had formed some erroneous notions.

The success that had hitherto attended the adventures of the Spaniards and Portuguese, soon stimulated other nations, particularly such as had thrown off the

...story.

...ir ...ncis ...ke. ...D. 1578.

Papal yoke, to undertake similar expeditions. In 1578, Sir Francis Drake discovered the southern extremity of Terra del Fuego, with some parts on the western coast of America, and completed the circumnavigation of the globe in 1051 days. In 1556, some English navigators, in seeking a north-east passage to India, fell in with Nova Zembla, and about the same time the Dutch discovered Spitzbergen. Of the discovery of New Holland, or Australasia, various opinions have been entertained, some ascribing it to Gonneville in 1503, others to Menezes, a Portuguese navigator, in 1527; but the first authentic account of a landing on the coast is by Captain Dirk Hartigh, a Dutchman, in 1616, (See Australasia.) It would be tedious to enumerate the various voyages of discovery, as well as land travels, that have been undertaken by different nations since the commencement of the 17th century, and still more so to give a catalogue of the islands and countries with which their labours have made us acquainted. We cannot conclude this sketch, however, without mentioning the names of Cook, Flinders, and Park, who may all be justly denominated martyrs in the cause of geographical discovery. With Captain Cook's discoveries in the South Sea, Captain Flinders' expedition to the south of Australasia, and Mr Park's interesting travels in Africa, our readers cannot fail to be acquainted. Cook, indeed, has been accused, by some French writers, of having entertained a mean jealousy of other navigators, unbecoming in any man, but particularly unworthy of one who had deserved so well, and enjoyed so much, of the grateful admiration of mankind. But the history of his successor proves, that even those who are loudest in their praises of liberality, and the most strenuous advocates for the maxim *palmam qui meruit ferat*, are not always proof against the pitiful and degrading vanity of attributing to themselves the discoveries made by another. At the very moment that the accusation above alluded to was brought against Cook, the accusers themselves were joining a *national* league to deprive the deeply injured Captain Flinders of his hard earned glory, as they had before done of his freedom and his property. Accident and misfortune threw him into their hands in the isle of France, where he was, in violation of every law, both of hospitality and humanity, detained a prisoner, and treated as a criminal for more than six years, obviously for no other purpose but to afford time to the French navigators who had followed his track under the protection of British passports, to publish the account of discoveries which had been stolen from another. Justice indeed has at length extorted an acknowledgment of the fraud, and the geographers of other countries are erasing from their charts the names, by which the authors of this infamous plot thought to immortalise themselves at the expence of an individual. This much was due to the merits and memory of Captain Flinders, and a triumph more honourable or more complete, the friends and admirers of that lamented navigator can neither desire nor expect. But what expiation will ever wipe away from the character of a great nation, the blot which it has sustained, by permitting itself to be either deluded or wilfully drawn into a participation of such baseness, as to lend its sanction to an imposition, the most abominable in the annals of science? See Strabonis *Rerum Geograph.* libri xvii. &c. Oxon. 1807; Rennel's *Geography of Herodotus*; Malte Brun *Precis de la Geographie Universelle*, tom. i.; Flinders' *Voyage to Terra Australis*, 1801, 1802, 1803: also our articles Africa, Cook, and Park.

Unjust treatment of Captain Flinders by the French. 1803.

MATHEMATICAL GEOGRAPHY.

Mathematical Geography.

CHAP. I.

Of the Sphere.

Sect. I. *Of the Figure of the Earth, and of the Sphere in General.*

...rical ...ge of ...earth.

The fundamental principle of all mathematical geography, and what of course naturally claims our first attention, is the spherical figure of the earth. The proof of this, however, is neither elaborate nor abstruse, the various phenomena from which it is inferred being so obvious and so conclusive, as to require only to be mentioned. The first, and perhaps the most simple of these which we shall notice, is the appearance of a ship at sea, either approaching to, or receding from, an observer on the shore. In the former case the vessel seems to rise out of the water, and in the latter to sink beneath it, a phenomenon that can only be accounted for from the convexity of the earth's surface; and as the same appearance is observed at all times and in all situations, this convexity must also hold in every direction, that is, the earth must be spherical. The same conclusion may also be drawn from other phenomena; as the change which takes place in the visible part of the earth's surface, as well as of the heavens, to an observer who changes his situation—from the circular form of the earth's shadow, as observed in eclipses of the moon—and, finally, from the actual circumnavigation of the globe. Our readers will find these appearances illustrated at greater length under the article Astronomy, at p. 658 of the second volume of our work. Without, therefore, attempting any farther proof of the fact, we shall proceed on the supposition that the earth is a perfect sphere. This, indeed, is not exactly the case, the globe being flattened or compressed at two opposite points, forming what mathematicians call an oblate spheroid, and at the same time having its surface diversified with numerous elevations and depressions. But to the geographer, these inequalities are of no importance, as they are too inconsiderable to affect any of the problems that he may have occasion to solve. The longest diameter of the earth is to the shortest nearly as 1 to .9968, or as 301 to 300, and the highest mountain on the earth, if represented on a sphere of six feet nine inches diameter, would not project from its surface farther than $\frac{1}{11}$th of an inch. In a system of geography, therefore, we may safely omit the consideration of such minute irregularities, and regard the globe as really a perfect sphere.

...red ...f vari... ...appear...

Not affected by the inequalities of its surface.

General properties of the sphere.

As our chief object in the present article is to render the principles of geography intelligible to our readers in general, we shall endeavour, as much as possible, to exhibit a popular view of the subject, referring the scientific reader to those articles of our work, where the propositions that we may assume, and the phenomena that we shall have occasion to explain, are examined and illustrated on the most rigid principles. Agreeably to this plan, we shall here throw into the form of definitions, some of the properties of the sphere in ge-

Mathematical Geography.

neral, referring for a demonstration of these properties to the article Trigonometry.

Definition of a sphere. *A sphere* is an uniformly round body, every point of whose surface, is equally distant from a point within the body, called the centre. Hence,

If a circle is made to revolve about its diameter, which remains fixed, its circumference will describe or trace out the surface of a sphere. The circle thus revolving is called the *generating circle.*

Diameter. *The diameter* of a sphere is a straight line passing through the centre, and terminated both ways by the surface.

Axis. *The axis* of a sphere is that diameter about which the generating circle, or sphere itself, is supposed to revolve.

Circle of the sphere. If an indefinitely thin plane or flat surface cut or pass through a sphere, the part of the plane that lies within the sphere will be a circle, whose circumference appears on the surface, and is called a *circle of the sphere.*

Pole of a circle. *The pole* of a circle of the sphere, is a point on the surface, from which every point in the circle is equally distant. Hence

Every circle of the sphere has two poles, diametrically opposite to one another.

Great circle. *A great circle* of the sphere, is that whose plane passes through the centre, and consequently divides the sphere into two equal parts or hemispheres.

Small circle. *A small circle* of the sphere is that whose plane does not pass through the centre, but divides the sphere into two unequal parts.

Division of a circle. Every circle is supposed to be divided into 360 equal parts, called *degrees;* each degree into 60 equal parts, called *minutes;* and each minute into 60 equal parts called *seconds.* These different subdivisions are denoted by the signs ° ′ ″, thus 12° 15′ 10″ mean 12 degrees, 15 minutes, and 10 seconds.

Length of an arch. *The length of an arch* is expressed by the number of degrees, minutes, and seconds which it contains; thus the fourth part of a circle, or a quadrant, is said to be equal to 90°.

Distance between two points. *The distance between two points,* on the surface of a sphere, is measured by an arch of a great circle intercepted between them.

Great circles equal. All great circles of a sphere are equal, and intersect one another in two points diametrically opposite.

Measure of an angle formed by two great circles. The angle formed by the intersection of two great circles, is measured by the arch of another great circle, cutting the other two at the distance of 90° from the point of intersection in each.

When two great circles make with one another an angle of 90°, that is, when their planes are at right angles to one another, they pass through each others poles, the poles of a great circle being 90° distant from its circumference.

Sect. II. *Of the Celestial Sphere.*

General view of the celestial sphere. The heavenly bodies as seen from the earth, appear to be placed in the concave surface of a hollow sphere, having the earth in its centre, and seem to describe circles every 24 hours of a greater or less circumference, according as they are farther from, or nearer to a certain point, that appears fixed. Diametrically opposite to this point is another, about which also the heavenly bodies seem to describe circles, thus exhibiting the same appearance, as if the whole celestial sphere revolved about a diameter from east to west. In this motion, which is called the *diurnal revolution* of the sphere, all the heavenly bodies seem to participate, but the sun, with others of them called planets, have also a proper motion of their own in a contrary direction, by which, in a certain time, they perform a complete revolution of the sphere, though this is generally a very long period compared with that of their diurnal revolution. Thus the sun, by his proper motion from west to east, describes a circle of the celestial sphere in 365 days, the moon in 27, and the other planets in different periods between 87 and 30689 days. In order to illustrate these motions, as well as to determine the relative positions of the bodies themselves, certain imaginary points and lines are supposed to be marked or traced out on the surface of the celestial sphere. The most important of these we now proceed to explain.

(Margin note: Diurnal revolution.)

Definition. Poles of the world. *The north and south poles* of the world, are those points in the celestial sphere that appear to be fixed. The poles are also termed *arctic* and *antarctic*; the arctic or north pole being that which is visible in this as well as in every other country of Europe.

Axis. *The axis* of the world is that diameter of the sphere which connects the poles, and about which the whole sphere seems to revolve.

Zenith. *The zenith* of any place on the earth, is that point in the celestial sphere which is directly over the place, or it is the point in which the plumb-line at that place, if produced upwards, would meet the celestial sphere. When the sun or any other heavenly body is in the zenith of a place, it is said to be *vertical* to that place.

Nadir. *The nadir* is a point in the sphere diametrically opposite to the zenith.

Equinoctial. *The equinoctial* is a great circle of the sphere whose poles coincide with the poles of the world.

Horizon. *The horizon* is a great circle whose poles are the zenith and nadir.

Cardinal points of the horizon. *The cardinal points* of the horizon are its north, south, east, and west points, which divide it into four quadrants, the two first being opposite to each other, as also the two last. The point of the horizon nearest the north pole is called the north point.

Meridians. *Meridians,* called also *hour circles* and *circles of right ascension,* are great circles perpendicular to the equinoctial, and consequently passing through the poles of the world.

Meridian of the place. *The meridian of the place,* or the *twelve o'clock hour circle,* is the meridian that cuts the horizon in the north and south points.

Six o'clock hour circle. *The six o'clock hour circle,* is the meridian at right angles to the meridian of the place.

Azimuth. *An azimuth or vertical circle,* is a great circle perpendicular to the horizon, and consequently passing through the zenith and nadir.

Prime vertical. *The prime vertical,* is a vertical circle passing through the east and west points of the horizon, and consequently cutting the meridian of the place at right angles.

Ecliptic. *The ecliptic* is a great circle representing the sun's annual path, and cutting the equinoctial at an angle of about 23° 28′. Hence the poles of the ecliptic are about 23° 28′ distant from the corresponding poles of the world.

Signs. *The signs* are the twelve equal parts into which the ecliptic is divided, each consisting of 30°. They are written and named as follows:

♈ Aries.	♎ Libra.
♉ Taurus.	♏ Scorpio.
♊ Gemini.	♐ Sagittarius.
♋ Cancer.	♑ Capricornus.
♌ Leo.	♒ Aquarius.
♍ Virgo.	♓ Pisces.

Mathematical Geography. Equinoxes.

The cardinal points of the ecliptic are the two *equinoctial* and two *solstitial* points.

The equinoctial points or *equinoxes*, are those points of the ecliptic where it intercepts the equinoctial, viz. the beginning of Aries and the beginning of Libra 180° distant from each other. The sun enters Aries about the middle of spring, and Libra about the middle of autumn; hence the former is called the *vernal*, and the latter the *autumnal equinox*.

Solstices. *The solstitial points* or *solstices*, are those points of the ecliptic that are at the greatest distance from the equinoctial, viz. the beginning of Cancer and the beginning of Capricorn, also 180° distant from each other. The sun enters the former about the middle of summer, and the latter at the middle of winter; hence the one is called the *summer*, and the other the *winter solstice*.

Colures. *The equinoctial colure* is a meridian passing through the equinoctial points.

The solstitial colure is a meridian passing through the solstitial points.

Circles of longitude. *Circles of celestial longitude* are great circles perpendicular to the ecliptic, and consequently passing through its poles.

Parallels of declination. *Parallels of declination* are small circles parallel to the equinoctial.

Every point in the celestial sphere between the equinoctial and the poles appears to describe a parallel of declination in 24 hours. When part of this parallel is above, and part below the horizon, the former is called the *diurnal*, and the latter the *nocturnal arch*.

Diurnal and nocturnal arches. Tropics. *The tropics of Cancer and Capricorn* are parallels of declination passing, the one through the summer solstice 23° 28′ to the north, and the other through the winter solstice 23° 28′ to the south of the equinoctial. They are so called from a Greek word signifying to *turn*, because the sun in his annual course appears to recede from the equinoctial till he reaches the tropics, after which he returns towards it.

Polar circles. *The arctic and antarctic polar circles* are parallels of declination, 23° 28′ from their corresponding poles.

Parallels of latitude. *Parallels of celestial latitude* are small circles parallel to the ecliptic.

Declination. *The declination* of a heavenly body is its distance from the equinoctial measured on a meridian; or it is the arch of a meridian intercepted between the equinoctial, and a parallel of declination passing through the body. It is called north or south according as it is to the north or south of the equinoctial.

The declination of a body cannot exceed 90°.

Right ascension. *The right ascension* of a heavenly body is its distance from the vernal equinox measured on the equinoctial; or it is the arch of the equinoctial intercepted between the vernal equinox and a meridian passing through the body, reckoning in the order of the signs.

Latitude. *The latitude* of a heavenly body is its distance north or south from the ecliptic, measured on a circle of longitude; or it is the arch of a circle of longitude intercepted between the ecliptic and a parallel of latitude passing through the body.

Longitude. *The longitude* of a heavenly body is its distance from the vernal equinox measured on the ecliptic; or it is the arch of the ecliptic intercepted between the vernal equinox, and a circle of longitude passing through the body.

Altitude. *The altitude* of a heavenly body is its height above the horizon measured on a vertical circle; or it is the arch of a vertical circle intercepted between the horizon and the body. The arch of the same circle between the body and the zenith, is called its *zenith distance*. The altitude and zenith distance are together equal to 90°. The former is greatest when the body is on the meridian of the place, which is then called its *meridian altitude*, and at equal distances on either side of the meridian, the altitude is the same.

Zenith distance. Meridian altitude. Azimuth. *The azimuth* of a body is its distance from the meridian of the place measured on the horizon, or it is the arch of the horizon intercepted between the meridian of the place, and the vertical circle passing through the body. It is called *eastern* or *western* azimuth, according as the body is on the east or west side of the meridian.

Rising, &c. of a heavenly body. A body is said to *rise*, *culminate*, and *set* when its centre is in the eastern side of the horizon, the meridian of the place, and the western side of the horizon respectively.

Amplitude. *The eastern* and *western amplitude* of a body is the arch of the horizon intercepted between the point where the body rises or sets, and the east or west point of the horizon.

Zodiac. *The zodiac* is a zone or circular space of the celestial sphere, extending about 9° on each side of the ecliptic.

Illustration of the preceding definitions. PLATE CCLXV. Fig. 1. The preceding definitions will be rendered more intelligible perhaps, by referring to Plate CCLXV. Fig. 1. where HZRN represents the celestial sphere, and *hzrn* the earth, situated in its centre. Then if Z be the zenith of a place *z*, P and S the north and south poles of the world, and C the vernal equinox, HR will be the horizon, ÆQ the equinoctial, EL the ecliptic, and P′ its pole, PS the equinoctial colure, HZRN the solstitial colure, TL the tropic of Cancer, and ED the tropic of Capricorn. Also, since the circle HZRN passes through Z, P and P′ the poles of the horizon, equinoctial and ecliptic, it represents a vertical circle, a meridian, and a circle of celestial longitude. If, therefore, A be a given star, the arch RA will be its altitude, and ZA its zenith distance to an observer at *z*, or rather at the centre of the earth, QA will be its declination, LA its latitude, CQ its right ascension, and CL its longitude. In this case, its azimuth is nothing, the star being on the meridian of the place. It is hardly necessary to observe, that though CL and CQ, as represented in the Figure, appear to be straight lines, they are nevertheless arches of great circles, the point C being the pole of the hemisphere HZRN. The same is true of all the other straight lines passing through the point C.

Heavenly bodies. Having thus explained some of the principal points and lines, which geographers have imagined to be traced out on the celestial sphere, we shall briefly mention the different classes and characters of the heavenly bodies themselves. These are all comprehended under three heads, *Fixed Stars, Planets*, and *Comets*.

Fixed stars. The *fixed stars* are those heavenly bodies, that have always the same situation relatively to one another, having no other motion than what they derive from the apparent diurnal revolution of the celestial sphere from east to west. In order to distinguish them more easily from one another, they are divided into classes, according to their brilliancy and apparent magnitude, the brightest and largest being denominated stars of the first magnitude, the next largest of the second magnitude, and so on to the sixth. Stars less than those of the sixth magnitude, are not in general visible by the naked eye, and are called *telescopic stars*. Besides this classification, the fixed stars are also divided into groups called *Constellations*, each being named after some animal, or other object, to which the stars, in their arrangement, bear a fancied resemblance. There are twelve

Magnitudes. Telescopic stars. Constellations.

Mathematical Geography.

such constellations in the zodiac, and it is from them that the signs of the ecliptic take their names. The stars in each constellation are distinguished by the letters of the Greek alphabet, the first letter denoting the largest star of the constellation, whatever may be its magnitude. Stars not included in any of the constellations, are called *Unformed Stars.*

Unformed stars.

Planets.

The *planets*, as we have already observed, are bodies which, besides their diurnal revolution, have also a motion of their own in a direction contrary to the other. They are *eleven* in number, and are found to revolve about the sun as a centre, in different periods, and at different distances. These eleven are denominated *Primary Planets*, to distinguish them from the *Secondary* or *Satellites*, with which some of them are accompanied, and to which they serve as centres of revolution. The path which a planet describes about its centre is called its *Orbit*. The primary planets are written and expressed as follows:

Primary and secondary orbit of a planet.

☿	♀	⊙	♂	⚵	⚶
Mercury	Venus.	Earth.	Mars.	Juno.	Vesta.

⚳	⚴	♃	♄	♅
Ceres.	Pallas.	Jupiter.	Saturn.	Georgium Sidus, Herschel, or Uranus.

For the distances of the planets from the sun, the periods of their revolutions, magnitudes, &c. see ASTRONOMY *Index.*

Comets.

Comets are luminous bodies, which appear in the heavens only occasionally, and for a limited period, generally consisting of a nucleus surrounded by a luminous vapour, sometimes shooting out into a long train or *tail.* Comets, besides the diurnal revolution common to all the heavenly bodies, have also a motion peculiar to themselves. In some, this motion is in the same direction with that of the planets, and in others it is in the contrary direction. See ASTRONOMY and COMETS.

SECT. III. *Of the Earth, or Terrestrial Sphere.*

Revolution of the earth the cause of the apparent revolution of the sun and celestial sphere.

IF all the inequalities of the earth's surface were removed, it would appear to its inhabitants to be a circular plane, fixed in the centre of the celestial sphere. There are two deceptions, however, in this appearance. The earth is not a plane, neither is it at rest. Its true figure, as we have already shown, is spherical, and it is continually in motion, revolving both daily on its own axis, and annually in an orbit round the sun. It must be obvious, on a moment's reflection, that the apparent diurnal motion of the heavenly bodies may be produced, either by the revolution of the celestial sphere from east to west, or by the rotation of the earth on its axis from west to east. Of the two explanations of the phenomenon, therefore, we are bound to adopt that which is liable to fewest objections, and this will be found to be the rotation of the earth. The revolution of the heavens, indeed, presents difficulties both physical and mechanical, which it is impossible to remove, while the other hypothesis is perfectly simple in itself, and in unison with the other phenomena of the universe. The same observations will apply, with perhaps still more force, to the annual revolution of the earth round the sun, which is the true cause of the sun's apparent motion in the heavens from west to east. The earth, therefore, is to be ranked among the planets, revolving about the sun in a year from west to east, having the ecliptic for its orbit, and accompanied by the moon as a satellite or secondary planet. But though we have thus noticed the real motions of the earth, as the causes of the apparent revolution of the sun and the celestial sphere, we shall not, in the remaining part of the present article, always confine ourselves to this view of the subject. In the solution of geographical problems, it is often much simpler to consider the apparent revolution of the celestial sphere, and the motion of the sun in the ecliptic, as real, than as produced by the combined motions of the earth, while the solution is the same in both cases. We shall not hesitate, therefore, to assume the first of these, whenever by doing so we can render the subject more intelligible or concise.

Circles of the terrestrial sphere. PLATE CCLXV. Fig. 1.

It is obvious from Plate CCLXV. Fig. 1. that the planes of all great circles of the celestial sphere form, by their intersections with the surface of the earth, corresponding great circles on the latter. Thus *hr*, *zn*, *ps*, *æq*, &c. on the earth, correspond to HR, ZN, PS, ÆQ, &c. in the heavens. This transference of the circles from one sphere to the other, may be still more clearly understood, by conceiving the celestial sphere uniformly contracted in its dimensions, without any change in the relative position of its parts, till it be just sufficient to cover the terrestrial sphere. By this method, the small as well as the great circles of the heavens may be transferred to the same positions on the earth; thus TL would coincide with *tl*, and ED with *ed*.

Poles. Equator. Rational horizon. Sensible horizon. Meridians. Parallels of latitude.

The points *p* and *s* on the earth, immediately under the poles of the world, are called the *north* and *south poles of the earth*; *æq* the *equator* or *equinoctial*; *hr* or HR the *rational horizon*, to distinguish it from H′R′, the limit of an observer's vision at *z*, and which is called the *sensible horizon*; *ps* and *hzrn meridians*, or *circles of longitude*; and *tl*, *ec*, *parallels of latitude*. In general, all parallels of declination on the celestial sphere become parallels of latitude on the earth, retaining however their proper or individual names. Thus the tropic of Cancer in the celestial sphere, is a parallel of declination 23° 28″ to the north of the equinoctial, and on the earth it is a parallel of latitude at the same distance from the equator.

Besides the terms already defined in the account of the celestial sphere, there are others peculiar to the earth, which require to be explained.

First meridian.

The first meridian of any country, in modern systems of geography, is the meridian passing through the capital of that country, from which the position of other meridians is determined. The ancients chose for their first meridian that of the Fortunate Isles, which they conceived to be the limit of the habitable world. In later times, the meridian passing through Ferro, one of the Canary Islands, and nearly the same with that of the ancients, was used as the first meridian by geographers of many countries; but now every nation generally reckons from the meridian of its own metropolis.

Terrestrial longitude.

The longitude of any place on the earth is its distance from the first meridian, measured on the equator; or it is the arch of the equator intercepted between the first meridian and the meridian of the place. It is called *east* or *west* longitude, according as the place lies to the east or west of the first meridian. Longitude on the earth corresponds, not to longitude, but to right ascension, on the celestial sphere. As the longitude of places on the earth is reckoned in two directions, it never can exceed 180°, whereas the right ascension of a heavenly body may be any thing between 0 and 360°, being always reckoned in one direction only, viz. in the order of the signs.

Difference of longitude.

The difference of longitude between two places, is the distance between them measured on the equator; or it is the arch of the equator intercepted between the meridians

Mathematical Geography.

of the places. When the places are on different sides of the first meridian, the sum of their longitudes gives their difference of longitude.

Longitude, difference of longitude, expressed in time.

As the sun in his apparent diurnal revolution round the earth moves over 360° in 24 hours, or 15° in one hour, he is on the meridian of any given place, or it is noon at that place one hour sooner than at any other place 15° farther west. Hence longitude, and difference of longitude, may be expressed in time, allowing 15° to one hour, or 1° to four minutes. As the degree and hour are similarly subdivided, any number of degrees, minutes, and seconds, divided by 15, will give the corresponding number of hours, minutes, and seconds; and, on the contrary, hours, minutes, and seconds of time, multiplied by 15, give the corresponding number of degrees, minutes, and seconds.

Terrestrial latitude.

The latitude of a place on the earth is its distance from the equator measured on a meridian, or it is the arch of a meridian intercepted between the equator, and a parallel of latitude passing through the place. It is called *north* or *south* latitude, according as the place lies to the north or south of the equator. The distance of the place from the nearest pole measured on the meridian is called the *co-latitude* of the place, or the complement of the latitude. Latitude on the earth, corresponds to declination on the celestial sphere.

Co-latitude.

Difference of latitude.

The difference of latitude between two places, is the distance between them measured on a meridian; or it is the arch of a meridian intercepted between the parallels of latitude passing through the places. If they lie on opposite sides of the equator, the sum of their latitudes gives their difference of latitude.

A zone.

A zone is any portion of the earth's surface, included between two parallels of latitude. There are, however, usually reckoned five zones; the *Torrid*, the two *Temperate*, and the two *Frigid*.

Earth divided into five zones.

The torrid zone is the space included between the two tropics: the temperate zones extend from the tropics to the polar circles; and the frigid from the polar circles to the poles. To explain this division of the globe mathematically, we may observe, that whatever be the position of the sun, he always illuminates one half of the terrestrial sphere at once, and that the great circle which separates the light from the dark hemisphere, and which is called the *circle of illumination*, has for its pole that point on the surface of the earth, to which the sun is vertical. Now, as the sun appears to be always in some point or other of the ecliptic, moving over EL, (Fig. 1.), between the middle of winter and the middle of summer, and from L to E on the opposite side of the sphere in the next half year, the phenomenon is precisely the same as if he vibrated along the arch DL, viz. from D to L during the first of these periods, and from L to D during the next; the earth, in the mean time, revolving daily on its axis. When the sun is at Q, he is vertical to q; that is, the circle of illumination corresponds with a meridian ps; and every point of the earth's surface is successively 12 hours above and 12 hours below that circle. When the sun advances 1° towards L, he becomes vertical to a point 1° to the north of q, or the circle of illumination falls 1° below p towards p', and rises 1° above s towards r; that is, while the sun's declination is 1° north, the circular space about the north pole to the distance of 1° from it, never sinks below the circle of illumination, and a similar space around the south pole never rises above it. As the sun approaches L, a greater space about P continues to be permanently within the circle of illumination, and a corresponding space about s to be permanently without it. When the sun reaches L, or is vertical to l, the circle of illumination falls 23° 28′ below P, and rises as far above s, and may be represented by $p'g$; that is, on the day of the summer solstice, the whole of the north frigid zone is within the circle of illumination, and the whole of the south frigid zone is without it for 24 hours. From this period the sun again returns towards the south, when the circle of illumination also begins to move backwards, till at the autumnal equinox, three months after the summer solstice, it again occupies the position ps, so that for six months the north pole is above, and the south pole is below the circle of illumination. The sun still continuing his motion southward, reaches D by the middle of winter, when the circle of illumination occupies the position bf, and the circumstances of the frigid zones are just reversed. Hence, to every place within the torrid zone, the sun is vertical twice a year, which it never is to any other part of the earth. In the temperate zones, no place is either above or below the circle of illumination for 24 hours together. And in the frigid zones, a place may be in the dark or light hemisphere for any period, between 24 hours and six months. The zones might also be distinguished from each other physically, by the difference in the intensity of the sun's rays, as indicated in the difference of mean temperature in different latitudes. But for the investigation of this subject, we refer to PHYSICAL *Geography*.

Limits of the zones.

Circle of illumination.

Illustration. PLATE CCLXV. Fig. 1.

A Climate.

A climate is also a portion of the earth's surface, included between two parallels of latitude, and of such a breadth, that the longest day under the parallel nearest the pole, is half an hour longer than under the other. There are twenty-four such climates between the equator and either of the polar circles. Between the polar circle and the pole, there are six climates of such a breadth, that the longest day under the two parallels varies by a month. There are thus thirty climates in all on each side of the equator.

Each hemisphere divided into thirty climates.

Illustration. PLATE CCLXV. Fig. 2.

The principle that has already been employed, in explaining the division of the earth into zones, may serve also to illustrate the nature of climates. When the sun is vertical to Q, (Fig. 2.), the circle of illumination coinciding with the meridian NS, divides the equator ÆQ, and every parallel of latitude into two equal parts, or the day and night are equal all over the globe. When the sun passes to either side of Q, as northward towards L, the equator is still divided into two equal parts by the circle of illumination, as it must always be by a great circle; but the parallels of latitude are divided unequally, the greater arch of the northern parallels being above, and of the southern below, the circle of illumination; that is, the day and night are still equal at the equator, but in northern latitudes the day is longer than the night, and in southern the night is longer than the day. This inequality continues to increase in all latitudes, as the sun approaches L; and of two given parallels, as cd, el at any time, the inequality is greatest at that which is nearest the pole. When the sun reaches L, or at the summer solstice, the day is longest in all northern, and shortest in all southern, latitudes. At the polar circle it is 24 hours, the whole of the parallel ab being above the circle of illumination. At the parallel cd, the day is to the night as twice pd to twice pc, or as pd to pc; at eL it is as qL to qe, &c.; and at the equator they are equal. It is obvious, therefore, that between the equator and the polar circle, the length of the longest day varies from 12 to 24 hours, and that consequently 24 parallels may be found at such distances from each other, that

Mathematical Geography.

the longest day under the one, shall exceed that under the other, by half an hour. With regard to places within the polar circle, it is evident that the parallel which comes to be wholly above the circle of illumination, half a month before the sun reaches the summer solstice L, or two months and a half after he passes Q, will continue to be a month above the circle, viz. half a month before the sun reaches L, and half a month till he returns to the same position. In like manner, the parallel that begins to be wholly illuminated one month before the sun reaches the solstice, or two months after the vernal equinox, will continue to be so for two months, and so of others. As the pole rises above the circle of illumination at the equinox, or three months before the solstice, it continues, as was formerly observed, to be illuminated for six months. Hence, between the polar circles and the poles, six parallels may be found such, that the longest day under the one, shall be a month longer than under the other. The same reasoning will apply to the southern hemisphere during the sun's progress from Q to *h*; and, in general, it is to be observed, that at any time, the length of the day, at a given latitude in one hemisphere, is always equal to the night, at the same latitude in the opposite hemisphere. The climates, as above defined, are contained in the following Table, where the first column shews the number of the climate, the second the length of the day under the highest parallel, or that nearest the pole, the third the latitude of that parallel, and the fourth the breadth of the climate.

Other divisions of the earth.

Besides dividing the earth into different climates, the ancients also employed certain terms to distinguish the inhabitants of particular countries, which it may be useful to notice. Those who live under the same meridian and parallel of latitude, but on opposite sides of the equator, were called relatively to one another *Antœcii*, from αντι, *opposite to*; and οικια, *a habitation*. They have always the same hour of the day, but opposite seasons of the year. Those who live on the same side of the equator, and under the same parallel of latitude, but differ 180° in longitude, were called *Periœcii*, from περι, *about*; and οικια, *a habitation*. They have always the same seasons, but opposite hours of the day. The inhabitants of places under the same parallel of latitude, but on opposite sides of the equator, and differing in longitude 180°, were called the *Antipodes* of each other, from αντι, *opposite to*, and πους, *the foot*. They have always opposite hours of the day, as well as contrary seasons of the year. The inhabitants of the different zones were also distinguished according to the projection of their shadows. Thus the inhabitants of the torrid zone were called *Amphiscii*, from αμφι, *around*; and σκια, *a shadow*; because their shadow is projected sometimes towards the north, and at other times towards the south; or *Ascii*, from α, *without*; and σκια; because they sometimes have no shadow. The inhabitants of the temperate zones were called *Heteroscii*, from ἑτερος, *different*, and σκια; because their shadows are always projected in opposite directions, or towards the poles. And the inhabitants of the frigid zones were named *Periscii*, from περι, *about*, and σκια; because during their longest day, their shadows describe a circle round them.

Different positions of the sphere.

As the celestial sphere, in its apparent revolution, may present itself under three different aspects, according to the situation of the observer, it becomes necessary to distinguish them by particular names. Accordingly, to an observer at the equator, the celestial sphere is said to be *right*, because the equinoctial and parallels of declination, or circles described by the heavenly bodies, are at right angles to the horizon, and divided by it into two equal parts. To an observer between the equator and the pole, the sphere is *oblique*, because the equinoctial and parallels of declination are inclined to the horizon, so that all heavenly bodies not in the equator, are above and below the horizon during unequal periods. And from the pole the sphere appears *parallel*, the equinoctial coinciding with the horizon, and the heavenly bodies revolving in circles parallel to it.

Dimensions of the earth.

In the view that we have hitherto taken of the earth, we have considered it merely as a spherical body, without any regard to its actual magnitude and dimensions. All the phenomena, indeed, which we have yet noticed, depend entirely on the figure and situation of the hemati- Geogra- phy.

earth; and therefore, in the explanation of these phenomena, it is not necessary to take the volume of the globe into the account. In practical geography, however, it is frequently an important question to express the distance between different points on the surface of the earth, in terms of some known measure, as miles, yards, feet, &c.; and as these distances cannot always be subjected to actual measurement, it becomes necessary to determine the dimensions of the globe itself. Various attempts have accordingly been made by astronomers to solve this problem, though it is only from the perfection of modern instruments, that they have been able to accomplish it with any degree of accuracy.

isure- t of the h by tos- es.

If the earth were perfectly spherical, it is obvious that, to determine its circumference, nothing more would be necessary, than to find the length of a degree of the terrestrial meridian, that is, the distance between two places lying under the same meridian, but differing 1° in latitude, and multiply that distance by 360. It was upon this principle that Eratosthenes, computing the difference of latitude between Alexandria and Syene to be 7° 8′ 45″, and estimating the distance between them at 5000 stadia, determined the circumference of the earth to be about 252,000 stadia. This estimate is valuable, as being the result of the first attempt to ascertain the dimensions of the globe en correct principles. In point of accuracy, however, as might be expected, it is very deficient. Independent of the uncertainty with regard to the length of the stadium which Eratosthenes employed, he committed a considerable error in supposing Alexandria and Syene to be under the same meridian, and his calculation was also affected by an irregularity of which he was not perhaps aware. It has been found, from actual measurement, that the degrees of a meridian on the earth increase in length from the equator towards the poles; that is, if two points be taken in a terrestrial meridian, at such a distance from each other that perpendiculars at these points, or lines in the direction of gravity, when produced to the heavens, include between them 1° of a celestial meridian; and if other two points be taken on the same meridian, but nearer the pole, such that perpendiculars from them also include between them 1° of the celestial meridian, then it is found, that the distance between the two first points, measured on the surface of the earth, is less than the distance between the two last. This difference, indeed, is the necessary consequence of the spheroidal figure of the earth, which we formerly mentioned; and though, in geographical problems in general, the irregularity may be safely neglected, yet it is of importance to take it into account, in determining the dimensions of the earth. At the equator, a degree of latitude has been found to measure 60480.247 fathoms; at the parallel of 45°, 60759.473; and in latitude 66° 20′ 10″, 60952.374. Taking the second of these as nearly a mean for all latitudes, and multiplying by 360, we have for the whole circumference of the meridian 21873410.28 fathoms, or 24856.148 English miles. The circumference of the equator is found to be 24896.16 miles, or 40 miles greater than that of the meridian.

rence e de- of la- e.

rn tre- e

de- of tude.

As all the meridians on the globe intersect one another in the poles, the distance between any two of them diminishes as the latitude increases. In many cases, it is of importance to know the law of this diminution, that is to determine the length of a degree of longitude on any parallel of latitude, the degree on the equator being given. In order to solve this problem with the greatest possible accuracy, it is necessary to make allowances for the spheroidal figure of the earth, or the difference in the length of degrees of latitude at different distances from the equator. But as there are irregularities in these differences, that have led to doubt whether the earth be a regular spheroid, and as for ordinary purposes it is not necessary to aim at a degree of accuracy, which is after all perhaps a mere waste of calculation, we shall suppose the earth to be a sphere, and on this principle exhibit in a Table the diminution of the degrees of longitude for every degree of latitude. In such tables, it is usual to express the degree of the equator in terms of English miles; but as the length of this degree is estimated differently by different writers, we shall, in the following Table, assume it equal to unity, and exhibit the corresponding arches of the parallels in decimal fractions.

Mathemati- Geogra- phy.

Table of the Diminution of a Degree of Longitude for every Degree of Latitude, that of the Equator being reckoned Unity.

30	.86603	60	.50000	90	.00000

Construction of the preceding table.

Since the circumferences of circles are to one another as their radii, if the radius of the equator be taken to express a degree of the equator, a degree of any parallel will be expressed by the radius of that parallel. But the radius *e* D (Fig. 2.) of any parallel *e* L, is the sine of *e* N the colatitude, or the cosine of Æ *e*, the latitude of that parallel to the radius ÆC. Hence to construct the above Table, we have only to take the natural cosines of the different parallels to radius 1, or the natural numbers corresponding to the logarithmic cosines, removing the decimal point ten places towards the left hand in each. Thus, let it be required to

Mathematical Geography.

find a degree of longitude on the parallel of 25°. The natural cosine of 25° is 90,631 to radius 100,000, and making radius 1, the cosine becomes .90631, the length of the degree required. Thus also the logarithmic cosine of 25° = 9.957276, and the number corresponding to this logarithm is 9,063,100,000, which is the length of the degree required, that of the equator being 10,000,000,000, or radius of the trigonometrical table. But as it would be inconvenient to operate with these numbers, they may both be divided by 10,000,000,000, or the decimal point may be removed ten places to the left hand in each, which will give 1 for the degree of the equator, and .90631, as in the preceding Table, for that of the parallel of 25°. This number may also be found at once from the logarithmic Tables, by subtracting 10 from the cosine, and finding the natural number corresponding to the remaining logarithm. Thus the cosine of 25° becomes $\bar{1}.957276$, and the number corresponding in the Table of logarithms is .90631.

The application of the above Table for finding the length of a degree of longitude under any parallel, consists in simply multiplying the fraction opposite to the given latitude, by the length of a degree of the equator. Thus, to find the length of a degree on the parallel of 25°, that of the equator being 60 geographic miles, multiply .90,631 by 60, and the product 54.3786, or 54.38 nearly, gives the degree required in geographic miles. If the earth be considered as spherical, a degree of the equator may be assumed equal to the degree of the meridian bisected by the parallel of 45°, or 60759.473 fathoms, which gives for the geographical mile 6075.947 feet.

Method of finding the area of a given zone of the earth.

Before concluding this account of the dimensions of the globe, it may perhaps be of use to some of our readers, to point out a simple and expeditious method, of finding the superficial contents of any given zone of the earth. By geometry, the superficies of a sphere, is equal to the product of the circumference, multiplied by the diameter, and that of a zone to the product of the circumference multiplied by that part of the diameter, intercepted between the planes of the two parallels containing the zone; that is, the area of the zone is to the area of the whole sphere, as the perpendicular distance of the two parallels of the zone is to the diameter. But the distance B D (Fig. 2.) between any two parallels *fg*, *e* L, is the difference of the sines of Æ*e* and Æ*f*, the latitudes of *e* and *f*; therefore the area of the zone *fe* L *g* : area of the globe : : sin. Æ*e* — sin. Æ*f* : diameter : : $\frac{\text{sin. Æ}e - \text{sin. Æ}f}{2}$: radius. If, therefore, the radius of the sphere be taken to express the whole area; half the difference of the natural sines, or of the natural numbers corresponding to the logarithmic sines of any two latitudes, will express the area of the zone included between these latitudes, the radius of the sphere being equal to the radius of the respective Tables. If the radius be reduced to unity, the area of the zone will be a decimal fraction. In the common logarithmic Tables, this is done by removing the decimal point ten places towards the left hand, or the fraction may be found at once, thus: From the trigonometrical tables, take the sines of the latitudes, subtract ten from the index of each, and find the numbers corresponding to the remaining logarithms; half the difference of these numbers will express the area of the zone, that of the sphere itself being unity.

Example. It is required to find the area of the zone contained between the parallels of 56° and 57°, that of the globe being 1.

First, by a Table of natural sines.

sin. 57° = 83867
sin. 56. = 82904

963

and $\frac{963}{2} = 481.5$ is the area required, the radius of the Table being 100,000, and removing the decimal point five places towards the left, the radius becomes 1, and the area of the zone .004815.

Secondly, by a Table of logarithmic sines.

sin. 57° (subtracting 10 from index) = $\bar{1}.923591$
sin. 56. . . . . = $\bar{1}.918574$

The natural numbers corresponding to these logarithms are,

.83867
.82904

Difference .00963

and $\frac{.00963}{2} = .004815$ is the area required.

Table of zones.

Upon this principle, the following Table is constructed, exhibiting the area of every zone of 1° from the equator to the pole, that of the globe being unity.

Latitude.	Area.	Latitude.	Area.	Latitude.	Area.
0° to 1°	.008725	30° to 31°	.007520	60° to 61°	.004295
1 — 2	.008725	31 — 32	.007440	61 — 62	.004165
2 — 3	.008720	32 — 33	.007360	62 — 63	.004030
3 — 4	.008710	33 — 34	.007275	63 — 64	.003890
4 — 5	.008700	34 — 35	.007195	64 — 65	.003760
5 — 6	.008685	35 — 36	.007105	65 — 66	.003620
6 — 7	.008670	36 — 37	007010	66 — 67	.003475
7 — 8	.008650	37 — 38	.006925	67 — 68	.003340
8 — 9	.008630	38 — 39	.006830	68 — 69	.003200

10 — 11	.008580	40 — 41	.006635	70 — 71	.002915
11 — 12	.008550	41 — 42	.006535	71 — 72	.002770
12 — 13	.008520	42 — 43	.006435	72 — 73	.002620
13 — 14	.008485	43 — 44	.006330	73 — 74	.002480
14 — 15	.008450	44 — 45	.006225	74 — 75	.002335
15 — 16	.008410	45 — 46	.006115	75 — 76	.002185
16 — 17	.008365	46 — 47	.006005	76 — 77	.002035
17 — 18	.008325	47 — 48	.005895	77 — 78	.001890
18 — 19	.008275	48 — 49	.005785	78 — 79	.001740
19 — 20	.008225	49 — 50	.005665	79 — 80	.001590
20 — 21	.008175	50 — 51	.005555	80 — 81	.001440
21 — 22	.008120	51 — 52	.005430	81 — 82	.001290
22 — 23	.008060	52 — 53	.005315	82 — 83	.001140
23 — 24	.008005	53 — 54	.005190	83 — 84	.000985
24 — 25	.007940	54 — 55	.005065	84 — 85	.000835
25 — 26	.007875	55 — 56	.004945	85 — 86	.000685
26 — 27	.007810	56 — 57	.004815	86 — 87	.000535
27 — 28	.007740	57 — 58	.004690	87 — 88	.000380
28 — 29	.007670	58 — 59	.004560	88 — 89	.000230
29 — 30	.007595	59 — 60	.004430	89 — 90	.000075

Area of zone than

To find from the preceding Table the area of a zone, less than 1° in breadth, take a proportional part of the zone of 1° of which the other forms a part. Thus to find the area of a zone between 43° and 43° 35′, take from the Table the area of the zone between 43° and 44°, which is .00633 and say 60′ : 35′ : : .00633 ; area athemati- Geogra- phy.

Mathematical Geography.

required nearly $= \frac{35}{60} \times .00633 = .0036925$. The true area, as found from the Table of sines, is .003705.

rea of a gment of zone.

To find the area of a segment of a zone, terminated at both extremities by meridians; multiply the area of the whole zone, by the length of the segment, and divide by 360. Thus, to find the area of a segment of the zone between 43° and 43° 35′, terminated by two meridians 6° 20′ distant from one another, multiply .0036925 by 6° 20′, and divide by 360, that is the area of the segment $= \frac{6°20'}{360°}$ or $\frac{380}{21600} \times .0036925 = .000065$.

ea of any ven coun- y.

To find the area of any particular country or district, divide the country into segments of zones, by parallels of latitude, and find the area of each segment separately; the sum of these areas will be the area required.

In some cases, this operation may be considerably abbreviated without affecting, in any great degree, the accuracy of the result. Let it be required, for example, to find the area of Portugal. Instead of dividing the whole surface into segments of zones of different lengths, according to the difference in the extent of the country from west to east, we may suppose the whole to consist of one segment, of a uniform length and breadth, viz. between 37° and 42° north latitude, and between 7° and 9° west longitude. By this arrangement, indeed, the eastern boundary cuts off a part of Tralos Montes and Beira, and the western a part of Estremadura; but, in lieu of these, the former includes a portion of Andalusia in Spain, and the latter a part of the Atlantic ocean. Supposing, therefore, these exchanges to be nearly equivalent, the area may be found thus:—

Take the sum of the areas of the zones between 37° and 42°, which is .03366, multiply by 2 the length of the segment, and divide by 360, that is,

$$\text{Area} = \frac{2}{360} \times .03366 = \frac{.03366}{180} = .000187.$$

Taking the circumference of the globe at 24856.148 English miles, the radius is 7911.964, or, making the circumference 21600 geographical miles, the radius becomes 6875.499. By the former the area of the globe is 196660948 English square miles, and by the latter 148510778.4 geographical square miles. The area of a zone is found by multiplying these numbers by the fractional value of the zone. Thus the zone included between the parallels of 56° and 57° is equal to 196660948 × .004815 = 946922.46 English square miles, or 148510778.4 × .004815 = 715079.39 geographical square miles. Thus also the area of Portugal is equal to 196660948 × .000187 = 36775.6 English square miles, or 148510778.4 × .000187 = 27771.5 geographical square miles.

deter- ne the ent of visible izon.

There is another problem connected with the figure and dimensions of the earth, which, though properly belonging to trigonometry, may, from its application to the present subject, and the facility with which it can be solved, be properly introduced here, viz. to find the most distant point of the globe visible to the eye at any elevation; or to determine the extent of the visible horizon from any given point.

ATE LXV. . 3.

Let ABG (Fig. 3.) represent the circumference of the globe, and GB a diameter produced to E a given elevation above B, it is required to find the most distant point visible to the eye at E, supposing the eminence BE to be in a level country, or on the sea coast.

Through E draw EF a tangent to ABG in D, then D is the limit of the horizon as seen from E; the arch BD is the measure of the distance required in degrees, minutes, or seconds, and DE the tangent of that arch to the radius CB or CD. But in very small arches, as BD must always be, even though E were the summit of the highest mountain on the globe, the tangent hardly differs from the arch itself; therefore ED may, without any sensible error, be considered as the distance required. Now $ED^2 = GE.BE$ (see GEOMETRY) = (since BE is very small compared to GB) GB.BE nearly, and therefore $ED = \sqrt{GB.BE}$. Hence, if d represent the diameter of the globe in English miles, f the given height of the eye in feet, that is $\frac{f}{5280}$ the height in miles, and d' the distance required in miles, we have $d' = \sqrt{d \times \frac{f}{5280}} = \sqrt{\frac{d}{5280}} \times f$. If the diameter of the globe be assumed = 7912 English miles, the formula becomes

$$d' = \sqrt{\frac{7912}{5280}} \times f = \sqrt{1.49,84,} \times f = 1.224126 \times \sqrt{f}.$$

In every case, therefore, the square root of the height in feet multiplied by 1.224126 will give the radius of the visible horizon in English miles, supposing the ray of light to come from the verge of the horizon to the eye in a straight line, viz. in the direction of the tangent DE. This, however, is not exactly the case, the ray by the refractive power of the atmosphere, being bent downwards, so as to meet BE at a point below E; that is the point D is visible to the eye at an elevation less than BE. From E therefore, the horizon extends to a greater distance than D, and consequently the value of d', as found by the preceding formula, is too little by a quantity corresponding to the refraction, and which is found to vary from $\frac{1}{7}$ to $\frac{1}{14}$ of the whole distance, according to the state of the atmosphere with regard to weight and humidity. In a medium state, the refraction is about $\frac{1}{14}$, or .0714, which may therefore be considered as a near approximation to the truth in all ordinary cases. With this correction the preceding formula becomes $d' = 1.224126 \times 1.0714 \times \sqrt{f} = 1.3115\sqrt{f}$; and reduced to the form of a rule, it may be stated thus: *Multiply the square root of the height of the eye, in feet, by 1.3115, and the quotient will be the radius of the visible horizon in English miles.*

Example 1. Required the distance or radius of the visible horizon to the eye, situated six feet above the surface of the sea.

Here $d' = 1.3115\sqrt{6} = 1.3115 \times 2.449 = 3.2118$ English miles, the distance required.

Example 2. At what distance may a mountain 21440 feet in height be seen, the eye being on the surface of the sea.

In this case $d' = 1.3115\sqrt{21440} = 1.3115 \times 146.42 = 192$ English miles. Hence the summit of Chimborazo, the highest of the Andes, ought to be seen at a distance of 192 miles, if its height be as it is stated, 21,440 feet.

CHAP. II.

OF THE GLOBES.

SECT. I. *Construction of the Globes.*

As soon as geographers had discovered the spherical figure and diurnal revolution of the earth, they would naturally be led to a very simple method, of representing

Mathematical Geography.

Properties of the globe as illustrative of mathematical geography.

its motion and various positions, by means of an artificial sphere. We find, accordingly, that from a very early period, the globe, with certain modifications, has been made use of for this purpose, and notwithstanding all the discoveries and improvements in the astronomical apparatus of modern times, it still continues to afford the simplest, and at the same time a correct illustration, of the principles of mathematical geography. We have already seen in what way, and to what extent, the earth differs in figure from a true sphere, and how imperceptibly small the irregularities of its surface become, when represented on a sphere six or seven feet in diameter. If the sphere be reduced to one-third of this, which is more nearly the size of ordinary globes, these irregularities will totally disappear, and the difference between the polar and equatorial diameters, or between the meridian and equator, be itself inappreciable. The earth therefore, with all its inequalities, can alone be represented by a sphere; and the only remaining question is, how can the instrument be accurately constructed, and most extensively applied?

General description of the terrestrial globe.

In constructing an artificial sphere or globe, the first operation is to prepare a spherical body of wood, metal, ivory, or such other substance as may be found most convenient. The materials commonly employed, and perhaps upon the whole best adapted for this purpose, are paper and plaster, prepared and combined by the following process: On a spherical block or mould of wood, somewhat less than the size of the intended globe, are laid successive coverings of paper or pasteboard, attached to one another by glue or paste, till the whole is about the thickness of $\frac{1}{10}$th or $\frac{2}{10}$ths of an inch. When completely dry, this covering is cut into two hemispheres, by which it is separated from the mould; and the hemispheres being again placed on a wooden axis, previously prepared for the polar diameter of the globe, they are stitched together in the same position, as when attached to the block or mould. In the extremities of the wooden axis, are fixed pins of iron or other metal, which represent the poles, and by which the globe is suspended in a metallic semicircle, whose diameter is exactly equal to that of the intended globe. In this state, a composition of whiting and glue is applied to the surface of the paper, the globe in the mean time being made to revolve, so that the interior edge of the semicircle, which is prepared for the purpose, pares off the superfluous plaster from the projecting parts of the surface. The whole being thus made perfectly smooth and spherical, and at the same time equally balanced on its axis, so as to remain in any position in which it may be placed while suspended by the poles, it is set aside to dry and harden, when it is ready to receive the various circles which geographers have imagined to be described on the surface of the earth, and which we have already explained, viz. the equator, ecliptic, meridians, the tropics, polar circles, and other parallels of latitude. These circles being described by some of the methods afterwards to be explained, the various parts of the surface of the earth are then delineated, according to their actual situation, the position of every place being determined by the intersection of its meridian and parallel of latitude. The iron pins in the extremities of the axis, formerly used for fixing the globe in the metallic semicircle, for the purpose of applying the plaster, are now employed to suspend it in a brass circle, of such a diameter that the globe may revolve easily without coming in contact with any part of its interior edge. This ring is called the *universal meridian*, because by the revolution of the globe, it may be made to represent the meridian of any place. The frame in which the globe is placed is variously constructed, according to the taste and fancy of the workman; but its top or upper part always consists of a broad horizontal circle of wood or metal WNES, (Fig. 4.) of which the interior diameter WE is equal to the interior diameter of the brazen meridian. The latter, with the globe suspended in it, passes through notches at N and S, and rests by its under edge in a groove in which it may be made to slide, so as to elevate or depress the pole at pleasure. In every position, however, one half of the globe is above, and another below the surface of WNES, which is therefore taken to represent the rational horizon. On the surface of this horizontal rim are described several concentric circles, variously divided, according to the purposes which they are intended to serve. The largest, or that towards the outer edge, is named the calendar, being divided into 365 parts, representing the days of the year, classed under their respective months. The next represents the ecliptic divided into signs and degrees, and so arranged that each point of the ecliptic stands opposite to the day on which the sun is at that point. The names or characters of the different signs are placed at the beginning, or opposite the middle of each. The innermost circle represents the horizon divided into quadrants, two of these being reckoned from W the west point, and the other two from E the east point, towards N and S, the north and south points. This circle, or rather another concentric with it, but larger, is divided into 32 equal parts, representing the points or rhumbs of the mariner's compass. The side of the brazen meridian facing the west is divided into degrees, or if the size of the circle will admit into degrees and minutes, reckoning from the equator towards both poles on two quadrants, and from the poles towards the equator on the other two, each quadrant being numbered from 1 to 90. The circle representing the equator is also divided into degrees in two directions, on each side of the first meridian, which, on British globes, is that of Greenwich. The 15th, 30th, 45th, &c. degrees towards the west are marked I. II. III. &c. to facilitate the conversion of longitude, and difference of longitude into time, and the contrary. The ecliptic, which is generally made to intersect the equator and first meridian in the same point, is divided into 12 signs, each sign being again subdivided into 30 degrees, and reckoned from the first meridian eastward. The characters of the signs are placed at the beginning, or opposite the middle of each, as on the horizon.

Plate CCLXV. Fig. 4.

Such is a general view of the artificial sphere usually employed to represent the earth. It is called the *terrestrial globe*, to distinguish it from that used to represent the heavens, and which is denominated the *celestial globe*. The latter, like the terrestrial globe, is suspended by the poles in a brazen or universal meridian, and mounted in the same way in a horizon. On its surface are described the equinoctial, the ecliptic, the tropics, the polar circles, the equinoctial and solstitial colures, circles of celestial longitude, and parallels of celestial latitude. As the celestial sphere revolves from east to west, the graduation of the brazen meridian is towards the east, but, in other respects it is the same as that of the terrestrial globe. The ecliptic is divided in the same way as on the other globe, but opposite each degree is a dot, representing the day on which the sun is at that point. The degrees of the equator are reckoned in one direction only, viz. towards the east, and the equinoctial and solstitial points are determined from

Celestial globe.

Mathematical Geography.

actual observation of the heavens. On the surface of the celestial globe are represented the fixed stars, in their true relative positions, distinguished according to their magnitudes, and arranged in constellations.

Instruments belonging to the globes.

Besides the parts already described, there are other appendages common to both globes, which yet remain to be explained. The principal of these are the *horary* or *hour circle*, the *quadrant of altitude*, and the *compass*.

Horary.

The *horary* is a small brass circle, generally fixed on the north pole of the globe, and divided into 24 equal parts, representing the hours of the day. The divisions are numbered from 1 to 12 along the first semicircle, and again from 1 to 12 along the next, in the contrary direction to that in which the globe naturally revolves. The circle is moveable separately by the hand, so that any given hour may be brought to the brazen meridian; but when left to itself, it turns with the globe, and thus serves to measure the whole, or any part of a revolution.

Quadrant of altitude.

The *quadrant of altitude* is a graduated slip of brass, so thin and flexible, as to be easily applied to the surface of the globe. It is furnished at one extremity with a nut and screw, by which it may be fastened to any part of the meridian. When this extremity is fixed on the zenith of the globe, the zero, or commencement of the graduation, coincides with the horizon, thus forming the fourth part of a vertical circle. The graduation is also continued to the other extremity of the quadrant, which is generally about 18 or 20 degrees. It takes its name from being applied to measure the altitude of heavenly bodies.

Compass.

The *compass* consists of a magnetic needle, suspended over the centre of a circle, on the circumference of which are marked the 32 points or rhumbs of the horizon. It is, in fact, the simplest form of the mariner's compass, fixed in the under part of the frame or mounting, and used for placing the brazen meridian in the meridian of the place.

It would be tedious, even to enumerate the various improvements and alterations, that have been from time to time recommended, in the construction and use of the globes, as well as of their appendages. Such an enumeration, however, is we conceive unnecessary, because any body who understands the general principle of the globes, as we have now explained it, will find no difficulty in using any of the instruments, with which they may be accompanied; and because more information will be acquired, in half an hour, from inspecting the globe itself, than we could communicate in a whole volume of descriptions and drawings. While, therefore, we have endeavoured, in the preceding short sketch, and by help of the representations, Figs. 5 and 6. Plate CCLXV. to convey some idea of the nature of the globes, we would conclude, by recommending to such of our readers as wish to become thoroughly acquainted with the subject, to draw their information from the instrument itself.

Plate CCLXV. Figs. 5, 6.

Method of describing the circles on the globe.

The most natural, as well as the most correct method of tracing out the circles of a globe, may easily be deduced from the preceding description. Suppose, for example, it is required to delineate on the surface of a spherical body, the various lines and figures of the terrestrial globe. From either of the points that represent the poles, with a radius equal to half the distance between them, a circle is described to represent the equator, and divided into degrees. From the 90th degree of the equator with the same radius, another circle is described, passing through the poles, and representing the first meridian. Other meridians are described in a similar manner, by taking for a centre every fifth, tenth, or fifteenth degree of the equator, according to the number required. The first, or any other meridian, being divided into degrees, from the equator towards the poles, the tropics and polar circles may be described from the poles as centres, with radii extending to $23\frac{1}{2}°$ and $66\frac{1}{2}°$ respectively. Other parallels of latitude are described in a similar manner. The ecliptic is described, by taking as a centre the point which is in 90° west longitude, and $66\frac{1}{2}°$ north latitude, and for a radius one-fourth of the circumference of the globe. Having thus described all the circles, it only remains to lay down the different places of the earth, according to their respective longitudes and latitudes, as determined by observation, and described in books of geography.

Method commonly adopted.

But though this method of delineating globes is in itself simple, and capable of being carried to almost any degree of exactness, those whose business it is to construct them for sale, have found it necessary, in order to furnish them at a moderate price, to adopt another method, less accurate perhaps, but much more expeditious. This method consists in delineating, on separate pieces of paper of the form ÆNQS, (Fig. 7.) called *gores*, separate portions of the earth or the heavens, according as they are intended for a terrestrial or celestial globe, and afterwards fixing them in order on the surface of the sphere, when N and S coincide with the poles, NÆS, NMS, and NQS become meridians, and ÆMQ an arch of the equator. Strictly speaking, indeed, no portion of paper can be accurately fitted to a spherical surface; but if ÆQ be very small compared to the whole circumference, the portion of the sphere, covered by the segment ÆNQS, will not sensibly differ from a plane in the direction ÆQ; that is, the arches of the equator ÆM, QM, and of the parallel of latitude *ab*, *cb*, may be considered as straight lines perpendicular to NS. The number of segments necessary to cover the globe, will depend on the length of the arch ÆQ; but when the whole have been once carefully designed and accurately fitted to the sphere, it is only necessary to make correct engravings of the originals, in order to construct, with comparatively little labour, any number of globes of the same dimension. Sometimes the segments are truncated at each extremity AB, CD, so as to leave a small circular space about the poles. These spaces are considered as plane surfaces, and are accordingly covered with one circular piece of paper, on which the portions of the meridians form radii of a circle. The method of delineating the gores will be explained when we come to the projection of maps.

Plate CCLXV. Fig. 7.

Having thus shortly noticed the different methods of constructing globes, we should now proceed to what more properly constitutes the object of this Chapter, the application of these instruments to the solution of problems. Before concluding this Section, however, we would observe, that in perusing the terrestrial globe, the eye of the observer is in its natural position; but in the case of the celestial globe, he must conceive himself situated in the centre, and looking towards the concave surface. This will perhaps be better understood by referring to the *armillary sphere*, as represented Fig. 8. Plate CCLXV. This instrument consists of a number of metallic rings, so connected as to represent the circles of the sphere, and at the same time to exhibit the apparent relative positions of the earth and heavens. As delineated in the figure, N and S represent the poles, and the line NS the axis of the world, with the earth G in the centre; HR the horizon, ÆQ the equinoctial, EL the ecliptic, ÆNQS the solstitial colure, KM the equinoctial co-

Armillary sphere.

Plate CCLXV. Fig. 8.

Mathematical Geography.

ture, TC the tropic of Cancer, T′C′ the tropic of Capricorn, AP the arctic circle, and A′P′ the antarctic circle. The meridian ÆNQS is graduated in the same way, as the brazen meridian of the celestial globe, viz. from Æ towards N and S, and from N and S towards Q; and the horizon is moveable, so that by raising or depressing it at the north and south points, it may be made to intersect the meridian ÆNQS, in any two opposite points. The whole instrument rests on the southern extremity S of the axis, and is generally so constructed that the earth G, with the meridian ÆNQS, and horizon HR, may be made to revolve from west to east, while the other circles remain at rest; or the latter may be made to revolve from east to west, while the former remain fixed. By means of the joint B, the sphere may be placed so as that the north pole N may have any elevation, the angle of that elevation being measured by the graduated arch F, attached to BS, and passing through a slit in BD. In using the celestial globe, then, the eye is supposed to be situated on G, and viewing the circles of the armillary sphere, the latter in all cases being placed in the same situation with the globe.

Sect. II. *Solution of Problems by the Globes.*

I. *By the Celestial Globe.*

To rectify the globe.

Prob. I.—To rectify the globe for any place, that is, to give the globe the same position, as the celestial sphere has, to a spectator at any place on the earth's surface.

Elevate the north or south pole, according as the place is north or south of the equator, till its altitude be equal to the latitude of the place.

To find the sun's place.

Prob. II.—To find the sun's longitude, or place in the ecliptic, for any given day.

Find the day under the ecliptic on the globe, and opposite to it will be the *sign* and *degree* required. The problem may also be solved, by finding the day in the calendar on the wooden horizon, marking the sign and degree opposite to it, and finding the same sign and degree in the ecliptic on the globe. As the sun is always in the ecliptic, he has no latitude.

To find the sun's right ascension, &c.

Prob. III.—To find the sun's right ascension and declination for any given day.

Bring the sun's place in the ecliptic to the graduated edge of the brazen meridian, then the degree of the equator under the meridian will shew his right ascension, and the degree of the meridian over his place will be his declination. When the sun's declination is less than 23° 28′, there are two corresponding places in the ecliptic, which may be found by marking those two points on the ecliptic, which pass successively under the given declination on the meridian.

To exhibit the appearance of the heavens.

Prob. IV.—To dispose the celestial globe, so as to exhibit the actual appearance of the heavens at any given time and place.

Rectify the globe for the latitude of the place, and bring the sun's place in the ecliptic, and the 12th hour of the horary to the brazen meridian. Turn the globe towards the east or west, according as the time is before or after noon, till the given hour on the hour circle comes to the meridian, and the globe will represent the actual appearance of the heavens, at that time and place.

To find the stars that never rise, &c.

Prob. V.—To find those stars that never rise, and those that never set, at a given place not under the equator.

Rectify the globe for the latitude, and make it revolve. The stars that do not sink below the wooden horizon, are those that never set, and the stars that do not appear above it, are those that never rise in that latitude. If the place be under the equator, every star is 12 hours above and 12 hours below the horizon.

To find right ascension, &c. of a star.

Prob. VI.—To find the right ascension and declination of a fixed star.

Bring the star to the brazen meridian, and its right ascension and declination will be found, as in Problem III.

To find star from its right ascension, &c.

Prob. VII.—The right ascension and declination of a star being given, to find the star on the globe.

Bring the degree of the equinoctial denoting the right ascension to the meridian, and the degree of the meridian, denoting the declination, will be over the star.

To find longitude, &c. of a star.

Prob. VIII.—To find the longitude and latitude of a given star.

Place the upper extremity, or 90th degree of the quadrant of altitude, on the north or south pole of the ecliptic, according as the star is north or south of the ecliptic, and let its graduated edge fall upon the star; then the degree of the ecliptic, intersected by the quadrant, will be the longitude of the star, and the degree of the quadrant over the star, its latitude.

To find star from its longitude, &c.

Prob. IX.—The longitude and latitude of a star being given, to find the star upon the globe.

Place the extremity of the quadrant of altitude on the pole of the ecliptic, and make its graduated edge intersect the ecliptic, in the longitude of the star; then the star will be found, under the degree of the quadrant denoting its latitude.

To find what stars are rising, &c.

Prob. X.—To find what stars are rising, setting, or culminating, at any given time and place, and also the altitude and azimuth of any star, at the same time and place.

Dispose the globe as in Prob. IV. then the stars under the eastern side of the horizon are rising, those under the western side are setting, and those under the meridian are culminating.

To find the altitude, &c. of a star.

If the quadrant of altitude be fixed on the zenith, and its graduated edge made to fall on a given star, the degree of the quadrant over the star, will be its altitude, and the degree of the horizon intersected by the quadrant its azimuth.

To find when a star rises, &c.

Prob. XI.—To find when a given star rises, sets, or culminates at any place on any given day.

Dispose the globe and hour circle as in the first part of Prob. IV. then bring the star successively to the eastern side of the horizon, the meridian, and western side of the horizon, and the times of its rising, culminating, and setting on the hour circle, will come to the meridian respectively.

To find angular distance between two stars.

Prob. XII.—To find the apparent angular distance between two stars; that is, the arch of the great circle intercepted between them.

Apply the quadrant of altitude to the globe, so that its graduated edge may fall on both the stars, the zero, or commencement of the graduation, being on one of them; then the degree of the quadrant over the other will be the angular distance required.

To find when a planet rises, &c.

Prob. XIII.—To find when a planet rises, sets, or culminates on any day at a given place.

Find the planet's place on the globe, from its longitude and latitude, or right ascension and declination, as given in the Nautical Almanack, or any other ephemeris, and fix on that place the name or character of the planet; then its rising, setting, or culminating, also its altitude, azimuth, &c. may be found in the same way as if it were a fixed star. In general, all the problems relative to the fixed stars are applicable to the planets,

Mathematical Geography.

the places of the latter being determined from the ephemeris.

To illustrate the harvest moon.

Prob. XIV.—To illustrate, generally, the phenomena of the harvest and hunter's moons.

The moon's orbit forms with the ecliptic an angle of $5\frac{1}{3}°$, and advances about 13° daily from west to east. But to simplify the problem, let it be supposed, in the first instance, that her orbit coincides with the ecliptic, and that her place and hour of rising being given for one day, it is required to find her hour of rising for the next.

Rectify the globe for the latitude, bring the moon's place to the east side of the horizon, and the hour to the brazen meridian, then turn the globe westward till the point of the ecliptic, 13° from the given point, come to the horizon, and the hour required will be under the meridian.

By solving this problem for various points of the ecliptic, assumed as the moon's places, it will appear, that the difference in the time of her rising on any two consecutive days, to a place not under the equator, is always considerably less when the moon is in Pisces and Aries, and greater in the opposite signs, than in any other point of the ecliptic, and that this difference increases with the latitude of the place of observation. Thus if the globe be rectified for the latitude of 56° north, and the above problem solved, supposing the moon's place to be the beginning of Libra, it will be found, that the time of her rising one day, will be upwards of $1\frac{1}{4}$ hour later than on the preceding; but if her place be the beginning of Aries, her time of rising will be little more than one quarter of an hour later, so that she rises for several days nearly at the same time. This phenomenon, though it must obviously happen every month, was long considered as peculiar to the autumnal months, when the sun is in Virgo and Libra, because it is only then that the moon is in Pisces and Aries, at the time of her being full.

Such is a brief illustration of the harvest and hunter's moon, on the supposition that the moon revolves in the ecliptic. As her orbit, however, is inclined to that circle at an angle of $5\frac{1}{3}°$, and as her nodes, or points where her orbit intersects the ecliptic, are constantly shifting, it may easily be shewn by describing several great circles, inclined to the ecliptic at an angle of $5\frac{1}{3}°$, but cutting it at different points, and solving the above problem, that the difference of time in the moon's rising during these months, is sometimes greater, and sometimes less than it would be if she revolved in the ecliptic. See Astronomy, Vol. ii. Page 668.

To find the path of a comet.

Prob. XV.—To trace the apparent path of a comet on the celestial globe.

If the right ascension and declination of the comet be known, at two different periods, find its position at each by Prob. VII. lay the quadrant of altitude through both, and join them with a pencil line, which will represent the intermediate path. If the longitude and latitude of the comet be observed, its places may be determined by Prob. IX. and if its azimuth and altitude be known at any hour, the latitude of the place of observation being also given, its place may be found thus: Dispose the globe as in Prob. IV. fix the quadrant of altitude on the zenith, and make its graduated edge intersect the horizon in the azimuth of the comet; then the degree of the quadrant denoting its altitude will be over the comet's place. If the positions of the comet, as determined in any of these ways, be at a greater distance from each other, than the length of the quadrant of altitude, they may be both brought to coincide with the horizon, and the path traced accordingly.

The preceding examples, though only a few of the problems that may be solved by the celestial globe, will be sufficient to shew the general principle of such solutions, and if that principle be well understood, the reader will find no difficulty in applying it to any particular case. The problems relating to the sun, and which are frequently solved by the celestial globe, we consider as bearing more directly on the subject of this article. We have therefore reserved them for the second class of problems, viz, those solved by the terrestrial globe, to which we now proceed.

II. *By the Terrestrial Globe.*

To find the latitude and longitude of a place on the earth.

Prob. XVI.—To find the latitude and longitude of a given place on the earth's surface.

Set the twelfth hour of the horary circle to the first meridian, bring both to the brazen meridian, and turn the globe till the given place be under the brazen meridian; then the degree of the meridian over the place will be its latitude, the point of the equator intersected by the meridian its longitude in degrees, and the hours of the horary that pass under the meridian the longitude in time.

If the equator be divided into hours as well as degrees, the problem may be solved without any previous adjustment of the hour circle, by simply bringing the place to the brazen meridian.

To find a place from its latitude and longitude.

Prob. XVII.—The latitude and longitude of a place being given, to find the place on the globe.

Find the longitude on the equator, and bring it to the brazen meridian, then the degree of the meridian denoting the latitude will be over the place.

To find the difference of latitude, &c. between places.

Prob. XVIII.—To find the difference of latitude and the difference of longitude between two given places.

Find the latitudes of both places by Prob. XVI. and take the difference or sum of these according as they lie on the same side, or on different sides of the equator. The difference of longitude is found in the same way, by taking the difference or sum of the longitudes according as they lie on the same side, or on opposite sides of the first meridian.

To find the hour at any place.

Prob. XIX.—The hour being given at one place, to find the hour at any other place at the same time.

Bring the given place and hour to the meridian, then turn the globe till the other place comes to the meridian, and the hours that pass under the meridian added to, or subtracted from the first given hour, according as the second place, is to the east or west of the first, will give the hour required.

To find when it is any given hour.

Prob. XX.—The hour being given at any place, to find the places where it is any other given hour at the same time.

Bring the given place, with the hour at that place, to the meridian, then turn the globe towards the east or west, according as the second given hour is earlier or later than the first, till the difference between them pass under the meridian, and the places required will be under the meridian.

To find the distance between two places.

Prob. XXI.—To find the distance between two given places on the earth.

Find the number of degrees, of a great circle, intercepted between them; these degrees multiplied by 60, or by 69.045, will give the distance in geographical and English miles respectively. The number of degrees may be found from the brazen meridian, if the places are under the same meridian; from the equator, if they are both under the equator; and from the quadrant of altitude applied to them, if they are neither under the equator, nor on the same meridian.

Mathematical Geography.

To find the angles of position between two places.

Prob. XXII.—Given two places, it is required to find the angle which a great circle passing through them, makes with the meridian of each.

When the places are under the same meridian, the angles are 0, and when they are under the equator the angles are 90°.

When the places are neither on the same meridian, nor under the equator, place the globe in such a position, that both the places may be in the horizon together, and a line drawn with a pencil along the horizon will be a great circle passing through the places; the globe being then rectified for both places successively, as in Prob. I. and the places themselves brought to the brazen meridian, the arches of the horizon, intercepted between the meridian and the circle passing through the places, will be the measures of the angles required.

Solution of questions in navigation.

This and the preceding problem may be very conveniently applied to the solution of questions in globular sailing. Thus, if the ship be steered on an arch of a great circle, the distance sailed is found by Prob. XXI. and the rhumbs on which the ship must leave the one place and arrive at the other, by Prob. XXII.

Given difference of longitude and latitude, to find the course and distance sailed.

Example 1. A ship leaves A, Lat. 16° south, Long. 5° 50′ west, and sailing on a great circle arrives at B, Lat. 32° 30′ north, Long. 63° 30′ west, required the distance sailed, and the rhumbs on which she left A and arrived at B?

1. Describe on the globe with a pencil a great circle passing through A and B, and find the length of the intersected arch by Prob. XX. which in this case will be about 73° 30′, or 4410 geographical miles.

2. Rectify the globe for the latitude of A, bring it to the meridian, and mark the point where the great circle passing through B intersects the horizon, which will be about 48° from the north point towards the west.

3. Rectify the globe for the latitude of B; bring it to the meridian, and mark the point of the horizon again intersected by the great circle, and which will now be found to be nearly 58° from the north towards the west. It appears, therefore, that a ship sailing from A to B, upon a great circle, must leave A on the rhumb N. 48° W., and gradually changing her course, must arrive at B on the rhumb N. 58° W. having run a distance of about 4410 geographical miles.

Given difference of latitude and course, to find difference of longitude and distance.

Example 2. A ship leaves A, Lat. 16° S. on a course N. 48° W. and sailing on a great circle arrives at B, Lat. 32° 30′ N.; required the difference of longitude and distance between A and B?

Rectify the globe for the latitude of A, and bring it to the meridian. Fix the quadrant of altitude on A, and make its graduated edge intersect the horizon in the given course (N. 48° W.); then the point where the quadrant of altitude intersects the parallel of 32° 30′, is the position of B. The place being thus determined, the difference of longitude may be found by Prob. XVIII. and the distance by Prob. XXI. In this example the former is about 57° 40′, and the latter 4410 geographical miles.

Given difference of longitude and course, to find the difference of latitude and distance.

Example 3. A ship sails from B, Lat. 32° 30′ N. on a course S. 58° E. and when she reaches A, her difference of longitude is 57° 40′; required the difference of latitude, and distanee between A and B, the ship having sailed on a great circle?

Bring B to the meridian, and rectify the globe for its latitude. Place the quadrant of altitude on B, and let its graduated edge intersect the horizon in the given course (S. 58° E.); then the point where the quadrant intersects a meridian, 57° 40′ E. of the meridian of B, will give the position of A, and A being determined, the difference of latitude and distance may be found by Probs. XVIII. and XXI. The former in this example is 48° 30′, and the latter 4410 geographical miles.

Examples of this kind might be multiplied, but the preceding are sufficient to illustrate the general principle. See Navigation.

To find where the sun is vertical for a day.

Prob. XXIII. To find those places in the torrid zone, to which the sun will be vertical, on any given day.

Find the sun's place in the ecliptic by Prob. II. solution 2d, bring that place to the meridian, and mark the degree of the meridian over it; all the places that pass under that degree while the globe revolves, will have the sun vertical that day.

To find where the sun is vertical at an hour.

Prob. XXIV.—The day and hour being given at any place, to find where the sun is then vertical.

Find the sun's declination, or the parallel to which he is vertical that day, and bring the given place and hour to the meridian; then turn the globe, till the 12th hour at noon come to the meridian, and the intersection of the meridian, with the parallel of latitude to which the sun is vertical, will be the place required.

To find when the sun is vertical at a given place.

Prob. XXV.—A place being given in the torrid zone, to find on what days the sun will be vertical there.

Find the latitude of the place, and the points of the ecliptic which have the same latitude; the days in the calendar, opposite to these points, will be the days required.

To find the sun's altitude, &c.

Prob. XXVI.—To find the sun's altitude and azimuth at any given time and place.

Rectify the globe for the given latitude, and bring the sun's place in the ecliptic and the 12th hour of the horary to the brazen meridian. Turn the globe towards the east or west, according as the time is before or after mid-day, till the difference between the given hour and 12 is under the meridian. Fix the quadrant of altitude on the zenith, and make its graduated edge fall on the sun's place in the ecliptic; then the degree of the quadrant over the sun's place will be his altitude, and the point of the horizon intersected by the quadrant his azimuth.

If the sun's meridian altitude be required, it is found by rectifying the globe for the latitude, and bringing the sun's place to the meridian, when the arch of the meridian intercepted between the sun's place and the horizon will be the altitude required. In this case the azimuth is nothing.

To find the circle of illumination.

Prob. XXVII.—To find the circle of illumination for any day, and the places that are above or below it at any hour of that day, reckoning the time at a given place.

Rectify the globe for the latitude to which the sun is vertical, and the horizon will represent the circle of illumination. Bring the given place and hour to the meridian, and turn the globe towards the west or east, according as the hour is before or after mid-day, till 12 of the hour circle be under the meridian; then the horizon will represent the circle of illumination at the given hour. To the places in the western side of the horizon, the sun is rising, to those in the eastern side, he is setting, and to those under the meridian, he is culminating.

To find the hour of the sun rising, &c.

Prob. XXVIII.—To find the hour of the sun's rising or setting, as well as his amplitude, on any day, at any place, whose latitude does not exceed 66° 32′.

Rectify the globe for the latitude of the place, and bring the sun's place in the ecliptic, and the 12th hour of the horary, to the brazen meridian. Then turning the globe eastward till the sun's place be in the horizon, the hour under the meridian subtracted from 12 will be the hour of his rising, and the point of the horizon coinciding with his place will be his eastern amplitude. In like manner, turning the globe westward, till the sun's place be again in the horizon, the hour under the meridian subtracted from 12, will be the hour of his setting, and the point of the horizon, coinciding with his place, will be his western amplitude.

Mathematical Geography.

In solving this problem by the celestial globe, the method now shewn, is the most obvious and natural; because in using the celestial globe, the heavens are supposed to revolve, every point rising above the horizon in the east, and sinking beneath it in the west, while the earth itself remains fixed, and the hour circle is graduated accordingly. But in solving the problem by the terrestrial globe, when the sun is supposed to be stationary at his place in the ecliptic for that day, and the time of his rising or setting to any place, is the time when that place, by the revolution of the earth from west to east, is on the west or east side of the circle of illumination, the following method, when the hours of rising and setting only are wanted, is perhaps more natural.

Find the circle of illumination for the day; bring the given place and the 12th hour of the horary to the meridian; then turning the globe westward till the place is in the horizon, the hour under the meridian will shew the time of the sun's rising, and turning it eastward till the place is again in the horizon, the hour under the meridian will shew the time of his setting. It is an advantage attending this method of solution, that the horary shews the time at once, and by one rectification of the globe, may be found the length of the day, in any latitude between the polar circles, as well as those places within the polar circles where the sun never rises or never sets on that day.

Find the length of the day, &c.

PROB. XXIX.—To find the length of any day or night, at any given place.

Find the hour of sun rising and sun setting by Prob. XXVIII. double the latter will be the length of the day, and double the former the length of the night.

Find how long the sun is present to, or absent from the frigid zone.

PROB. XXX.—To find when, and how long, the sun is present to, or absent from, a given place within the frigid zone.

Rectify the globe for the latitude of the place, and while it revolves on its axis, mark the points of the ecliptic, which coincide with the north or south point of the horizon, according as the place is in the north or south frigid zone. Find the days in the calendar corresponding to these points, and they will be the limits of the time, during which the sun never sets at the given place. If the points of the ecliptic intersected by the opposite point of the horizon be marked, the days corresponding to these points, will be the limits of the time, during which the sun never rises at the place.

The problem may be solved without rectifying the globe thus.

Find the sun's places in the ecliptic when his declination is equal to the co-latitude of the place, and on the same side of the equator; the days, corresponding to these points, will be the limits of the time during which the sun is present to the place. In like manner, find his places when his declination is equal to the co-latitude of the given place, but on the opposite side of the equator; and the days, corresponding to these points, will be the limits of his absence from the place.

Find the latitude where a day is of a given length, &c.

PROB. XXXI.—To find in what latitude any given day, not one of the equinoxes, is of any given length less than 24 hours.

Rectify the globe for the sun's place in the ecliptic, and bring the first, or any other meridian, with 12 of the hour circle, to the brazen meridian; then turning the globe eastward, till the hour denoting half the given length of the day, be under the brazen meridian, the point of the first meridian, intersected by the eastern side of the horizon, will be the latitude required.

The problems, for finding in what latitudes the longest day is of any given length, and for determining the boundaries of the different climates, between the polar circles, are only particular cases of the preceding general problem.

To find the hour of the day, &c.

PROB. XXXII.—To find the hour of the day by exposing the globe to the sun's rays.

Place the globe so that the wooden horizon may be level, and the brazen meridian may coincide with the meridian of the place. Rectify the globe for the latitude, and bring the sun's place in the ecliptic, and 12 of the hour circle, to the brazen meridian. In the sun's place fix a small pin or needle perpendicular to that place, and turn the globe till the pin has no shadow, that is, till it point directly towards the sun; then the hour under the brazen meridian, subtracted from 12, will be the hour of the day.

For various other methods of solving the preceding problem, see Adam's *Astronomical and Geographical Essays.*

To find the beginning, &c. of twilight.

PROB. XXXIII.—To find when the twilight begins in the morning, and ends at night on any day.

Rectify the globe for the latitude of the place: bring the 12th hour of the horary and the sun's place in the ecliptic to the brazen meridian, and fix the quadrant of altitude on the zenith. Turn the globe westward, till the point of the ecliptic diametrically opposite to the sun's place cut the quadrant of altitude 18° above the eastern side of the horizon, and the hour denoting the beginning of twilight in the morning, will be under the brazen meridian. By turning the globe in the opposite direction, till the point opposite the sun's place, be 18° above the western side of the horizon, the hour circle will shew the end of twilight in the evening. In those latitudes where the sun does not sink more than 18° beneath the horizon, the twilight continues all night. See ASTRONOMY, vol. ii. p. 660.

To construct a dial.

PROB. XXXIV.—To construct a horizontal dial by the globe.

Rectify the globe for the latitude of the place, and bring the first meridian to the brazen meridian; the arches of the horizon, intercepted between the first meridian, and the meridians passing through every fifteenth degree of the equator, will be the measures of the angles, which the hour lines must make, with the meridian line.

Example. It is required to construct a horizontal dial for Edinburgh, supposing its latitude to be 56°.

Elevate the north pole 56° above the horizon, and bring the meridian of London to the brazen meridian. While the globe remains fixed in this position, the meridians on each side of the first meridian, and 15° distant from it, will intersect the horizon 77½°, or more accurately 77° 28′ from the east and west points, that is 12° 32′ from the south point, therefore the hour lines for 11 forenoon, and 1 afternoon, must make with the meridian line, each an angle of 12° 32′. The meridians on each side of the first meridian, and 30° distant from it, will intersect the horizon in 64° 25′, that is 25° 35′ from the south point, which is therefore the angle that the hour lines, of 10 and 2, must make with the meridian. In the same manner may be found the angles

Mathematical Geography.

made by the other hour lines, after which the dial is to be constructed according to the directions given under the article DIALLING, § 40. vol. vii. p. 697.

The lines for half hours and quarters may be found in the same way as the hour lines, if meridians be described on the globe, dividing every 15° of the equator, into four equal parts, that is at the distance of 3° 45′ from each other. But as globes have seldom so many meridians, the half hours and quarters may be found thus:

Having disposed the globe as directed above, turn it in either direction, till the brazen meridian intersect the equator in 3° 45′, and the arch of the horizon, intercepted between the brazen meridian, and the first meridian, will be the measure of the angle, which the line of three quarters past 11, or a quarter past 12 must make with the meridian line. Turn the globe in the same direction, till the brazen meridian intersect the equator in 7° 30′, and the arch of the horizon intercepted between the brazen meridian, and the first meridian, will measure the angle which the line of half past 11, or half past 12, must make with the meridian line, and thus every other quarter and half hour line may be found, by bringing successively to the brazen meridian every 3° 45′ of the equator. If the globe is moved only 1° 15′ at once, the successive arches of the horizon, intercepted between the brazen meridian and first meridian, will measure the angles which the lines of every 5 minutes must make with the meridian line, and so of any other subdivision.

To construct a vertical south or north dial, rectify the globe for the co-latitude of the place, and proceed as in the case of a horizontal dial. See DIALLING, § 51, vol. vii. p. 700.—The application of the armillary sphere to the solution of problems, is the same in principle with that of the globes.

CHAP. III.

OF MAPS.

SECT. I. *Of Maps in General.*

General definition.

THOUGH the representation of the terrestrial sphere, by means of a globe, is the simplest as well as the most accurate, it has been found in many respects deficient for the purposes of geography. If the globe be made very large, it becomes expensive and incommodious; if small, the places which it ought to represent are either too much crowded, or altogether omitted. To remedy these defects, geographers have contrived to delineate the earth's surface on a plane, by which means the whole or any portion may be easily represented, on a greater or less scale, according to circumstances. Such representations are in general denominated *maps*, and are also distinguished by particular names, according to their nature or use. Thus a map representing the whole world is called a *planisphere*; if it represent a considerable portion of the globe, it is called a *general map*, and a *particular map* if it contains only a country. When a portion of a country is represented on a large scale, with the direction of roads, the course of small rivulets, and the position of villages and single houses, it is called a *topographical map*. Hence also *mineralogical maps*, intended to illustrate the geological structure of a country; and *nautical maps or charts*, used for the purposes of navigation. With regard to the position of maps, it may be observed, that whatever be

Different kinds of maps.

Planisphere.

Topographical.

Mineralogical.

Nautical.

their nature or use, the north is generally at the top, the east on the right hand, the south at the bottom, and the west on the left hand. The graduation of the equator, or degrees of longitude, are marked at the top and bottom, and the graduations of the meridian, or degrees of latitude, on the right and left sides.

Methods of describing maps.

The various methods adopted by geographers in the construction of maps, may be referred to two principles, PROJECTION and DEVELOPEMENT. By *projection* is meant, a representation of the surface of the sphere on a plane, as it appears to the eye situated at a particular point; and by *developement* is to be understood the unfolding, or spreading out, of a spherical surface on a plane. We are now to explain briefly, the construction of maps according to both of these principles; but as we shall frequently have occasion to employ lines of chords, sines, tangents, secants, &c. we shall here show the method of constructing these lines, and explain so much of their nature and use, as may be necessary for our present purpose.

PLATE CCLX. Fig. 9.

From any point C, (Fig. 9.) draw CA, CD at right angles to one another, and with any convenient radius CA, describe a quadrant ABD. Join AD, and from A as a centre, through every degree of the arch ABD, describe arches intersecting AD, marking these intersections with the corresponding degrees of the quadrant. Then AD will be a *line of chords*. From each degree of the quadrant let fall perpendiculars on AC, and it will be a *line of sines*. Produce CD indefinitely towards E, and through A draw AF parallel to CE. Through the centre C, and each degree of the quadrant, draw lines intersecting AF, and it will become a *line of tangents*. From C as a centre through every intersection of AF, describe arches intersecting DE, and CE will be a *line of secants*. And lastly, through every half degree in the line of tangents, draw parallels to CD, and it will be a *line of semitangents*.

For practical purposes, the lines, after being divided in this manner, are transferred to flat rulers of different sizes, where they are drawn parallel to one another, generally in the following order, chords, sines and secants in one line, tangents, and semitangents. In using them, nothing more is necessary, than to extend the compasses from the extremity of the line, to the number denoting the degrees of the given arch: thus the distances from A to 40 on AD, from C to 40 on AC, from A to 40 on AF, from C to 40 on DF, and from C to 40 on CD, will give respectively the chord, sine, tangent, secant, and semi-tangent of an arch of 40°, the radius of the arch being equal to AC. In any set of lines, the chord of 60°, is always equal to the radius of the quadrant, from which the lines are constructed.

SECT. II. *Construction of Maps by Projection.*

General principles of projection.

IN projecting an object upon a plane, according to the rules of perspective, the *plane of projection*, or that on which the object is to be delineated, is generally supposed to be transparent, and situated between the eye and the object to be projected. The position of the eye is called the *projecting point*, and the straight line drawn from this point, perpendicular to the plane of projection, is termed the axis of that plane. The projection of any point of the object, is the point which it is to occupy, when transferred to the plane of projection, and is always determined from the intersection of that plane, by the ray of light coming from the given point to the eye.

Mathematical Geography.

Different methods of projecting the sphere.

Gnomonic.

Orthographic.

Stereographic.

Globular.

Varieties arising from the position of the sphere.

Polar.

Equatorial.

Horizontal.

The different methods of projecting the sphere, arising from the different distances of the projecting point, are generally reckoned four, the *gnomonic* or *central*, the *orthographic*, the *stereographic*, and the *globular*. In the gnomonic projection, the eye is supposed to be placed in the centre, and the plane of projection is tangent to the pole of the hemisphere to be projected. In the orthographic, the eye is supposed to be at an infinite distance from the sphere, so that the rays of light coming from every point of the hemisphere, may be considered as parallel to one another. In the stereographic projection, the eye is situated on the surface of the sphere, in the pole of the circle of projection. And in the globular, its distance from the sphere is equal to the sine of 45°. In each of these methods of projection as applied to the globe, there may be three different cases, according to the position of the sphere, with regard to the projecting point. These are called the *polar, equatorial*, and *horizontal* projections. In the first, the plane of projection or *primitive circle*, coincides with the equator, and one of the poles is in the centre of the map. In the second, the primitive is a meridian, and a point of the equator is in the centre; and in the last, the horizon is the primitive, of which the given place occupies the centre. We shall now proceed to the mechanical construction of a planisphere or map of the world, according to these different methods, referring to the article PROJECTION, for the investigation of the principles of each.

I. *By Gnomonic Projection.*

General properties.

This method, as its name implies, constitutes the foundation of dialling, but is very seldom used in the construction of maps. The disadvantages with which it is attended in its application to the latter, are the distorted appearance which it gives to countries at a distance from the centre of projection, and the difficulty of describing parallels of latitude, which in the *equatorial* and *horizontal* projections are parabolas, ellipses, or hyperbolas. In the *polar* projection, however, where the primitive is parallel to the equator, this difficulty is removed, the parallels of latitude being projected into concentric circles, while the meridians, which in every case of this method are represented by straight lines, intersect one another in the centre of the projection, forming at that point, the same angles that they do on the surface of the sphere. By this method, therefore, we obtain a very simple and expeditious projection, of the northern or southern parts of the globe, and at the same time a tolerably accurate representation, at least of the polar regions. This projection is shewn in Fig. 10. which is constructed thus.

Construction of a gnomonic polar map.

From the centre P, with 60 from the line of chords, describe the circle WLEM for the primitive, and draw the diameter LM to represent the first meridian. From M set off successively towards E and W the chord of 5, 10, or 15 degrees, according to the number of meridians wanted; and through these points, draw diameters for the meridians required. To find the parallels of latitude, take the tangents of their respective co-latitudes, or distances from the pole, and with these radii, describe concentric circles about the centre P. Thus the tangent of 10°, is the radius of the parallel of 80°, the tangent of 20°, is the radius of the parallel of 70°, &c.; that is, PM is converted by the intersections of the parallels into a line of tangents to radius PM. The parallel of 45° corresponds with the primitive WLEM, after which the radii increase with great rapidity as they approach the equator, which becomes infinite. Hence, a whole hemisphere cannot be projected by this method, and it is obvious from inspection, that of what *can* be projected, the countries farther from the pole than the 60th parallel of latitude, must be very inaccurately represented.

Having drawn the meridians, and described the parallels of latitude as above, the continents, seas, islands, &c. which it is intended to represent, are to be delineated according to their relative situations and extent, the position of every point being determined by the intersection of its meridian and parallel of latitude. This may be considered as a general rule for determining the position of places in all projections; but as meridians and parallels of latitude cannot be described through every degree, the position of any intermediate point in the preceding method, may be found readily thus: Transfer to the edge of a flat ruler the divisions of the line of tangents, then by laying the commencement of this scale on P, and the graduated edge on the degree of the primitive denoting the longitude, the division of the scale corresponding to the co-latitude of the place, will shew the position required.

II. *By Orthographic Projection.*

General properties.

Though this method of projection is more frequently employed in geography than the preceding, it affords but a very imperfect and inaccurate representation of the whole hemisphere. From the position of the eye, the parts of the sphere are seen more and more obliquely as they approach the primitive, and consequently the countries at a distance from the centre of projection are contracted far below their natural limits. The orthographic projection, therefore, though the reverse of the gnomonic as to its defects, is like the latter best adapted for representing countries at a moderate distance from the centre of projection. The representations of the hemisphere on orthographic principles, usually employed in geography, are the polar and equatorial, which are constructed as follows:

Construction of an orthographic polar map. PLATE CCLXV. Fig. 11.

1. *The Polar.* From the centre P, (Fig. 11.) with 60° from the line of chords, describe the primitive WLEM, which will represent the equator, and draw the meridians as in Fig. 10. To find the parallels of latitude, take the sines of their respective co-latitudes, and with these radii describe circles about the centre P. Thus the sine of 10° is the radius of the parallel of 80°, the sine of 20° is the radius of the parallel of 70°, &c. or PM is converted by the intersections of the parallels into a line of sines to radius PM. Hence, to find the radii of the parallels without the help of lines previously constructed, divide ME into as many equal parts as the parallels wanted, and let fall perpendiculars from these divisions on MP; the distances between P and these perpendiculars will be the radii required.

In this projection, the whole hemisphere is represented within the primitive, which in the gnomonic is occupied by the zone of 45° round the pole; but the countries near the equator are very much distorted from their true dimensions.

An orthographic equatorial map. PLATE CCLXVI. Fig. 1.

2. *The Equatorial.* From Æ (Fig. 1. Plate CCLXVI.), with the chord of 60°, describe the meridian WNES for the primitive, and draw the diameters WE, NS at right angles to one another; the former to represent the equator, and the latter a meridian at right angles to the primitive. From Æ towards E, set off Æ*h*, Æ*g*, Æ*f*, &c. equal to the sines of 5°, 10°, 15°, or of 10°, 20°, 30°,

Mathematical Geography.

&c. according to the number of meridians wanted; then elliptic arches described through N *a* S, N *b* S, N *c* S, &c. will represent the meridians, in this case, 10° distant from each other, or whose angles of inclination to the primitive, measured by the arches of the equator intercepted between them, are 10°, 20°, 30°, &c. respectively. Of these ellipses, NS is always the transverse axis, and Æ *a*, Æ *b*, Æ *c*, &c. the semiconjugates. Hence, to find the foci of any given arch N*f*S; from *f* the extremity of the semiconjugate, as a centre, with the radius ÆN, half the transverse, describe an arch intersecting NS in F and F′: these points will be the foci required. The foci being found, the ellipse may be described according to the method explained under CONIC SECTIONS, vol. vii. p. 137, or by any of the elliptic instruments described under the article DRAWING INSTRUMENTS, vol. viii. p. 130. If the whole ellipse N*f*S be described, the other semicircumference will represent the corresponding meridian on the opposite side of NS. The points *a*, *b*, *c*, *d*, &c. may also be found by dividing EN or ES into nine equal parts, and letting fall perpendiculars from every division on EÆ. Straight lines drawn through the divisions of EN, and parallel to EW, will represent parallels of latitude.

PLATE CCLXVI. Fig. 1.

Analemma.

When this projection is made upon the solstitial colure, the planisphere is distinguished by the name of *Analemma*, and is the foundation of a simple instrument of the same name used for the solution of various astronomical problems. See ANALEMMA, and PROJECTION OF THE SPHERE.

The orthographical projection of the sphere on the plane of the horizon, is seldom used in constructing maps, partly from the inaccuracy of representation common to it with the preceding methods, but chiefly from the difficulty of construction, both meridians and parallels of latitude being projected into ellipses. It is applied to the projection of solar eclipses. See ASTRONOMY, vol. ii. p. 744.

III. *By Stereographic Projection.*

General properties.

In delineating maps according to the principles of this projection, the defects of the other methods are in a great measure avoided, both as to the accuracy of representation, and the facility of construction. These advantages are chiefly owing to the two following properties, by which the stereographic projection is distinguished from every other. 1*st*, All circles are projected into circles or straight lines; and, 2*dly*, The projections of any two circles intersect one another in the plane of projection, at the same angle that the circles themselves do on the surface of the sphere.

In maps of the world constructed on stereographic principles, the projection is generally made on the plane of a meridian, the eye being successively placed in the poles of that meridian, opposite the hemisphere to be projected. As the method, however, is of very extensive application, we shall give an example of all the three cases.

Construction of a stereographic polar map.

PLATE CCLXVI. Fig. 2.

1. *The Polar.* From P (Fig. 2.) with 60° from the line of chords, describe the primitive WLEM, in this case the equator, and draw diameters for meridians as in the gnomonic polar projection. To project the parallels of latitude, take from the scale the semitangents of their complements of latitude, or distances from the pole, and with these radii describe concentric circles about P. Thus the semitangent of 10° will be the radius of the parallel of 80°, the semitangent of 20° will be the radius of the parallel of 70°, &c. that is, PM by the intersections of the parallels, is converted into a line of semitangents to radius PM. The radii of the parallels may also be found thus: From W draw straight lines to every tenth degree of the quadrant ME, intersecting the line MP in 10°, 20°, 30°, &c. then the distances between P and these intersections will be the radii of parallels for every tenth degree of latitude.

2. *The Equatorial.* In this method, which is most frequently used in constructing terrestrial maps, the meridian of any place may be taken for the primitive, or plane of projection; but for the more convenient representation of the earth in two hemispheres, it is usual to take one of those meridians, which nearly separate the eastern and western continents. In British maps, the projection is generally made on the plane of the meridian 20° west from the meridian of London, that is, the projecting points are in the equator 70° east and 110° west from the first meridian. The projection of meridians and parallels of latitude, according to this method, is represented in Fig. 3. which is constructed thus.

A stereographic equatorial map.

PLATE CCLXVI. Fig. 3.

From Æ with the chord of 60° describe the meridian WNES for the primitive, and through the centre draw WE and NS at right angles to one another, the former representing the equator, and the latter a meridian at right angles to the primitive. From Æ, set off on Æ, Æ *a*, Æ *b*, Æ *c*, &c. the tangents of 5°, 10°, 15°, &c.; or of 10°, 20°, 30°, &c. according to the number of meridians wanted, and from these divisions as centres, describe arches of circles passing through the poles P and S; these arches will be the projections of meridians between Æ and W. In the same manner may be described meridians on the other side of NS. In Fig. 3. Æ *a*, Æ *b*, &c. are the tangents of 10°, 20°, &c. therefore the arch described from *a*, viz. N *m* S next to W, is 80° from N Æ S, the meridian passing through the projecting point, that described from *b*, viz. the second from W is 70° from the same meridian, and so of the others, always measuring the distance between two meridians, or the angle which they make with each other, by the arch of the equator intercepted between them. If the second from W be taken to represent the meridian of London, the primitive WNES will embrace the whole of the eastern continent, or old world, except a small part of the north-east point of Asia, without including any part of America, and the other meridians will be reckoned both ways towards the east and west. In the present case, however, as our object is not to exhibit an actual map of the earth's surface, but only the imaginary lines with which it is supposed to be intersected, we shall assume NÆS as the first meridian, by which means our references to the Figure will be more obvious and distinct.

Before proceeding to the projection of the parallels of latitude, it may be proper to notice another method, besides that already explained, of describing meridians, viz. by determining the points in which these circles must intersect the equator WE (Fig. 4.) This is done by setting off from Æ towards W and E, Æ 10, Æ 20, Æ 30, &c. equal to the semitangents of these arches respectively. Then three points being given, viz. N, S, and 10, 20, or 30, in the equator WE, a fourth may be found, which shall be the centre of a circle passing through the other three. To determine this fourth point or centre, draw lines from N and S to the point in the equator through which the meridian is to pass, bisect these lines, and erect perpendiculars at the points of bisection; these perpendiculars will meet WE in the point required. See GEOMETRY, SECT. II. PROB. XI.

Fig. 4.

Though both these methods of describing meridians imply the use of lines of tangents, or semitangents,

Mathematical Geography.

yet the projection may be performed without the assistance of these lines. Thus, in the first method, divide the quadrants WN and ES, Fig. 3. into degrees, and from S, through every tenth degree of each, draw straight lines intersecting WE on both sides of Æ; then the parts of WE contained between every two corresponding points of intersection, will be the projected diameters of the meridians, whose distance from the first meridian, is equal to the distance of the points in the quadrants from the poles. Thus the straight line drawn from S to 10 in the quadrant WN, will intersect ÆW in *m*, and the line joining S and 10 in the quadrant ES, will intersect ÆE produced in *e*, wherefore *m e* is the projected diameter of the meridian, 80° distant from NÆS. If then *m e* be bisected, the point of bisection will be the centre, and half the line bisected will be the radius of the meridian N *m* S. In the same manner may be described the other meridians on either side of NÆS.

Plate CCLXVI. Fig. 3.

In the second method, where it is required to find the points of the equator through which any given meridian is to pass, draw a straight line from S, Fig. 4. to the point of the quadrant WN, or EN, whose distance from N is equal to the distance of the given meridian from the first meridian, and it will intersect ÆW or ÆE in the point required. Thus the line joining S and 10 in the quadrant WN will intersect ÆW in 80, the point through which the meridian must pass, whose distance from the first meridian is 80°. This point being determined, the centre may be found as before.

Instrument for describing meridians.

In projecting maps on a large scale, it becomes extremely difficult to determine the centres, and still more so to describe, with accuracy, the arches of meridians at small distances from the first meridian. To remedy this inconvenience, an instrument has been invented of a very simple construction, by which these arches may readily be described, the extremities and one intermediate point being given.* When this intermediate point is determined, as in the preceding paragraph, and the circle described by means of the instrument now mentioned, the operation is perhaps as much simplified as the nature of the subject will admit of.

To describe the parallels of latitude in this projection, set off from Æ (Fig. 3.) on ÆN produced, the secants of the co-latitudes of the parallels, and from these points as centres, with radii equal to the distances between them and the points in the quadrants WN, EN, denoting the latitudes, describe arches, and they will be the parallels required. Thus the secant of 30° set off from Æ to *f*, on ÆN produced, will be the centre of the parallel of 60° north latitude, and the distance between that point and 60 in the quadrant WN, or EN will be the radius of the parallel.

The centre of any given parallel, as 60, may also be determined thus: From E, draw straight lines through 60 in each of the quadrants EN, WN, intersecting ÆN, and ÆN produced, in the points *g* and *h*, then the part of ÆN contained between these points will be the projected diameter of the parallel of 60. If, therefore, this line be bisected, the point of bisection will be *f*, the centre; and half the line bisected will be the radius of the parallel.

If the semi-tangents of 10°, 20°, 30°, &c. be set off from Æ towards N, they will give the points in which the parallels of 10°, 20°, 30°, must intersect ÆN. Thus the semitangent of 60° set off from Æ towards N, gives the point *g*. In every parallel, there will thus be given three points, viz. the extremities in the quadrants WN and EN, and an intermediate point in ÆN; and consequently the parallel may be described either by finding its centre, or applying the instrument formerly mentioned, in the projection of meridians. The intermediate points in ÆN may also be found without a line of semitangents, as in the last paragraph, viz. by drawing lines from E to every tenth degree of WN. In the same manner may be described the parallels on the other side of the equator.

3. *The Horizontal.* Though this projection is not so frequently used as the preceding in constructing a map of the world, it is more convenient, as we shall afterwards shew, for some particular purposes, and is therefore not to be omitted in a system of mathematical geography. The projection of the equator, meridians, and parallels of latitude on the horizon of any given place, as Edinburgh, Lat. 56° N. is as follows.

A stereographic horizontal map.

Plate CCLXVI. Fig. 5.

From C (Fig. 5.) with 60 from the line of chords, describe the circle WNES for the primitive or horizon of the place C, and draw NCS, WCE at right angles to each other, the former representing the meridian of the place, and the other a great circle 90° distant from it, and which, on the celestial sphere, is called the Prime vertical. From C set off on CN, the semitangent CP of the co-latitude, in this case 34°, and P will be the projection of the north pole. From the same point set off on CN and CS, CÆ equal to the tangent of the co-latitude (34°), and CQ equal to the semitangent of the latitude (56°); then a circle described from Æ as a centre with the radius ÆQ will pass through W, E, and represent the equator. To project the meridians, set off from C on CS, or CS produced, CA equal to the tangent of the latitude (56°), and through A draw BD at right angles to CA. From P, with 60 from the line of chords, describe the quadrant *v w*, and from *v* set off on this arch the chords of 10, 20, 30, &c.; then a ruler laid between P and each of these divisions, will intersect AD in *a*, *b*, *c*, *d*, &c. the centres of the meridians between S and W. Thus AP will be the radius of the meridian WPE, 90° distant from the first meridian NPS; *a* P will be the radius of 80 P 100, the meridian 10° distant from the last, or 80° from the first meridian, and so of the others. In the same manner may be described the meridians on the other side of NS from centres in the line AB. In determining the centres of the meridian, it is convenient to describe the quadrant *v w* with 60 from the line of chords, because the chords of 10, 20, 30, &c. may be set off from the same line, without the trouble of dividing the quadrant. It is not necessary, however, nor indeed is it always proper, to take that particular radius, as any other will answer the same purpose; and the greater it is, the more accurately will the points in BD be determined, particularly such as are at a great distance from A.

In the preceding method, the points P, Q, Æ, A, are determined by the lines of tangents and semitangents; but they may also be found without the help of these lines thus: Having described WNES, and drawn NS, WE as before, set off from N towards E, the arch NP′ equal to the latitude of the place (56°), and join P′W; the line P′W will intersect CN in P, the projec-

* This instrument consists of two rulers AB, CB (Fig. 12. Plate CCLXV.) fastened together by a joint B, so as to form any required angle ABC, a pen or pencil being fixed in the angular point B. In using the instrument, this pen is placed on the intermediate point of the arch to be described, and pins being fixed, or weights laid at the extremities of the arch, the limbs AB, CB are extended so as to touch these pins or weights. In this state the whole instrument is moved round, the two sides being always pressed against the pins or weights, and the point at B describes the arch required. The principle of the instrument depends on the property of the circle, that all angles in the same segment are equal to one another. See Geometry, Sect. II. Prop. XVII. and Drawing Instruments.

tion of the north pole. From P′ draw the diameter P′C p′, and at right angles to this diameter draw another æ′ C q. From W through the extremities of this diameter, draw W q and W æ, intersecting CS in Q and CN produced in æ, and bisect æ Q; the point of bisection will be Æ the centre, and half the line bisected will be ÆQ the radius of the equator WQE. To find the centres of the meridians, join W p′, and produce the line till it meet CS produced in p; bisect P p, and the point of bisection will be A the centre; and half the line bisected will be AP, the radius of the meridian WPE at right angles to the first meridian NPS. The centres of the other meridians are found as before in BD, drawn through A, at right angles to AN.

In this, as in the equatorial projection, it becomes difficult to describe the meridians that make small angles with the first meridian, their centres being at a great distance from the point A. This inconvenience, however, will be in a great measure remedied by the following construction.

Plate CCLXVI. Fig. 6.

From C, (Fig. 6.) describe WNES, find Æ, P, Q and A, and draw P′ p′ and BD, all as in Fig. 5. From A draw A f perpendicular to P′p′, and on AC set off Ag, equal to A f. From g as a centre, with any radius as gA, describe a quadrant AG, and divide it into degrees from A towards G. Through g, and every tenth degree of AG, draw straight lines intersecting AD in a, b, c, d, &c. and from these points draw straight lines through C: these lines will intersect the primitive in the points through which the corresponding meridian is to pass. Now, as every meridian must pass through P, there will be given three points in each, viz. 10, P, 170 in the meridian 10° from NS, 20, P, 160 in the next, and so on; the circle may therefore be described by the instrument formerly mentioned in the equatorial projection. In this construction, the point in AD, next to A, gives the intersections of the meridian nearest to NS, and in the method explained in last paragraph the point next to A is the centre of the meridian farthest from NS. By a combination of the two methods therefore, all the meridians may be determined by means of points at a moderate distance from A.

To project the parallels of latitude, set off from C, (Fig. 5.) on NS, the semitangents of the greatest and least distances of the parallel from C, and bisect the part of NS contained between these points; the point of bisection will be the centre, and half the line bisected will be the radius of the parallel. Thus let it be required first to project a parallel to the north of the given place, as of 70° north latitude. Since the parallel extends 20° on each side of the pole P, and C is 34° distant from P, the nearest point of the parallel to C is between C and P $34°—20°=14°$ from the former, and the opposite or most distant $34°+20°=54°$. From C therefore, set off towards N the semitangents of 14° and 54° to r and s, and bisect r s; then the middle point of r s will be the centre, and half the line will be the radius of the parallel required. Secondly, let the parallel to be projected be the 56th, or that whose distance from the pole is equal to the co-latitude of the place. In this case it is obvious, that the circle must pass through C on the one side, and on the opposite it will cut CN in Æ, at the distance of the semitangent of $34°+34°=68°$. The distance therefore between C and that point being bisected, it will give the centre of the parallel. Lastly, let the parallel be to the south of the given place, as, for example, that of 30°. Here the distance of the circle from P is greater than PC by $60°—34°=26°$, or its nearest distance from C is 26° towards S, while its greatest distance is $60°+34°=94°$. From C therefore, set off towards S the semitangent of 26° C f, and from C towards N the semitangent of 94° C g, and bisect the distance between these points as before.

Parallels of latitude may also be projected, without the line of semitangents, thus: Divide the primitive into degrees from P′ (Fig. 6.) in both directions, and through the degree denoting the co-latitude of the parallel to be projected, draw lines to W, intersecting NS or NS produced in two points. Bisect the portion of NS contained between these intersections, and the circle described from the point of bisection with a radius equal to half the line bisected, will be the parallel required. Thus, if straight lines be drawn from the 20th degree on each side of P′ to W, the intersection of these lines with NS, will give the points r and s, as in Fig. 5.

IV. *By Globular Projection.*

General properties.

Plate CCLXV. Fig. 7.

Though we have classed this method of projection under a separate head, it is, strictly speaking, to be considered as a modification of the stereographic. As originally proposed by its inventor De Lahire, it is not indeed very frequently employed, but it has given rise to a mechanical method, which, from the facility of construction, is likely to become more and more common in projecting maps of the world, on the plane of a meridian. According to Lahire's method, the projecting point, as was formerly observed, is distant from the surface of the sphere, the sine of 45°, that is, if the diameter or meridian NS (Fig. 7.) be equal to 200, the distance NP of the projecting point P is equal to 70. Having determined P, divide SW, SE into degrees, and from P draw straight lines to every tenth division, intersecting ÆW and ÆE. Through these points of intersection, and the two poles N, S, describe ellipses, and they will be projections of meridians. By this construction, it is found, that the straight line from P to 45 in the quadrant SW or SE divides the radius ÆW or ÆE into two equal parts; but to render the other division of these radii nearly equal, the projecting point P must be only at the distance of 59½ from N, NS being equal to 200. This equality, however, may be obtained mechanically thus, without regard to the position of the projecting point.

Construction of a globular quatorial map. Fig. 8.

From C, (Fig. 8.) with 60 from the line of chords, describe the primitive WNES representing a meridian, and draw the diameters NS, WE at right angles to one another, the former representing a meridian at right angles to the primitive, and the latter the equator. From W and E set off in both directions towards N and S, the chords of 10°, 20°, 30°, &c. and divide each of the semidiameters CN, CE, CS, CW into 9 equal parts, in the points 10, 20, 30, &c. then circles passing through the poles N, S, and the divisions of the semidiameters CW, CE, will be meridians 10° distant from each other, and circles passing through the divisions of the quadrants WN, EN, and the semidiameter CN, or through the divisions of WS, ES, and the semidiameter CS, will be parallels, the former of north and the latter of south latitude, 10° distant from one another. These circles may be described, either by finding the centres, which will always be in the diameters WE, NS, or in these diameters produced, and which may be determined from the three given points in the circumference; or if the centres be at a great distance from C, by employing the instrument formerly mentioned in the stereographic projection. Upon this principle is constructed the planisphere, Plate CCLXVIII.

Plate CCLXV

Having thus briefly explained the various methods usually employed by geographers, for delineating on a plane the imaginary lines with which they suppose the surface of the earth to be intersected, we might go on to apply the same principles to the projection of the celestial sphere, or the construction of a map of the heavens. As this, however, does not properly apply to geography, we shall proceed to take a short view of the comparative defects and merits of the projections now explained, as applicable to the construction of terrestrial maps.

As the principal object of a planisphere, or map of the world, is to determine the longitude and latitude of particular places, with their distances and bearings from each other, and to exhibit a view of the figure, extent, and relative positions of the different countries, that projection is to be preferred, which determines all these particulars most accurately, and with the greatest facility. In none of the preceding methods, however, nor indeed in any other method, are all these properties united. In the gnomonic polar projection, as we formerly observed, the position of any place to be projected, and consequently the situation of a place after it has been projected, is easily determined, by applying a line of tangents to the centre, and making its graduated edge fall on the degree of the primitive denoting the longitude. The distance between two places that are in the same meridian, or under the same parallel of latitude, may also be easily and accurately determined from this projection. In the former case, lay the extremity of the line of tangents on the centre, and make its graduated edge pass through the two places, then the difference of the numbers on the scale between the two places will shew their difference of latitude in degrees, or the arch of a great circle intercepted between them, from which their distance in miles may be easily ascertained. In the second case, when the places are under the same parallel of latitude, by laying the ruler successively over each, and referring to the divisions in the primitive, the arch of the parallel of latitude intercepted between them will be determined, and the latitude being known, the length of that arch may be found in miles by means of the Table, at page 151. Of the latter, indeed, it is to be observed, that the rule holds only in the case of short distances, when the arch of a parallel of latitude intercepted between two points does not sensibly differ from an arch of a great circle intercepted between the same points. With these advantages, however, the projection is in other respects very defective. The distance between two places, not under the same meridian or parallel of latitude, can only be found by an operation far too tedious and complicated for ordinary use, while countries at a distance from the pole are very much extended beyond their true figure and dimensions.

In the orthographic polar projection, the advantages and disadvantages are nearly the same as in the gnomonic. The situation of places, and their distance from each other, when under the same meridian or parallel of latitude, are found by means of a line of sines instead of tangents; but the figure and dimensions of countries at a distance from the pole, are as much contracted below the truth, as in the former case they were extended beyond it. In the equatorial projection, it is more difficult than in the preceding methods to determine the longitude of any given point, the circles of longitude or meridians being ellipses. To the young geographer, however, this method will be found extremely useful, as calculated to convey a very distinct idea of the earth's sphericity.

The stereographic polar projection affords the same facility of finding the positions of places, by means of a line of semitangents, that the gnomonic and orthographic polar projections do, by means of tangents and sines. By the former may also be readily found the distance between places under the same meridian, or if they are not far from each other, under the same parallel of latitude, and it possesses the additional advantage of representing the different countries more nearly, according to their true figure and dimensions. In other respects, it does not materially differ from the other polar projections.

Equatorial. In the stereographic projection on the plane of a meridian, the principal advantages compared with the corresponding orthographic projection, are the simplicity of its construction, and greater accuracy of its representations. In neither, however, is it easy to find the distance between places not under the same meridian; nor is it possible to exhibit exactly the different portions of the globe according to their true figure and dimensions. In the orthographic, the countries at a distance from the centre of the map are very much contracted, and in the stereographic they are considerably, though not in the same proportion, expanded. The convenience formerly mentioned regarding the division of the globe into the eastern and western hemispheres, is common to both; and, indeed, to all projections in which the primitive coincides with the plane of a meridian.

Horizontal. The principal recommendation of the stereographic projection on the plane of the horizon, is the facility it affords of solving a problem which, in all the preceding methods, can only be effected by an operation too abstruse for the purposes of practical geography. The problem alluded to is, to find the distance between any two places on the surface of the globe, whatever may be their positions relatively to one another. Thus, if it were required to find the distance between Edinburgh and any other place, project the sphere on the horizon of Edinburgh, and construct a line of semitangents to the radius of the projection; then laying the extremity of the scale on the centre of the map, with its graduated edge on the given place, the number of the scale over the place will be the distance required in degrees of a great circle. If the place does not lie within the primitive, that is if it be more than 90° distant from Edinburgh, the map may be extended beyond the primitive so far as to include it; or, what is perhaps better, the opposite hemisphere may be projected, and the distance of the place from the centre of this hemisphere subtracted from 180, will give the distance required. By this projection may also be found the angle of position which any given place makes with the place in the centre, thus: Divide the primitive or horizon into degrees from the north and south points towards the east and west; then applying the scale as before, its graduated edge will cut the horizon in the angle required. But though the solution of these problems may in some cases be very desirable, the horizontal projection is, upon the whole, very inconvenient for a map of the world, particularly from the difficulty of determining, on such a map, the longitude and latitude of places which do not happen to lie under any of the meridians or parallels of latitude. This defect, indeed, is common to it with the equatorial projections, and it may be observed of them all in general, that as it is impossible to combine in one the whole, or even the principal properties of each, we must be satisfied with gaining one advantage by the sacrifice of another. *Globular.* For ordinary purposes, the globular projection is, after all, perhaps the best in constructing a map of the world. Simplicity of construction, tolerable accuracy in the

Mathematical Geography.

representation of different countries, and facility in finding the longitude and latitude of any given place, are the characteristic properties of this projection; and, to the majority of those who have most occasion to consult such maps, these properties are by far the most important.

SECT. III. *Construction of Maps by Developement.*

Developement of different bodies.

IN the various methods of projecting the sphere, as explained in the preceding Section, the reader cannot fail to observe, that, besides the inaccurate representation of different portions of the earth's surface, common in some measure to them all, they are also attended in practice with considerable difficulty and inconvenience. This difficulty increases with the scale of the projection; and, in the delineation of small portions of the earth's surface, it becomes so great as almost to prevent the application of any of them, to the construction of such maps. To remedy this defect, geographers have had recourse to the method of *developement*, or that which supposes the earth's surface to be spread out on a plane. But as a sphere or spheroid is a body that does not admit of its surface being so extended, it must be supposed to be converted into some other body, as much as possible resembling the sphere, and whose surface is at the same time susceptible of such a developement. The only bodies of this kind with which the sphere can be at all compared, are the *cone* and *cylinder;* and accordingly, both have been employed for this purpose.

I. *Of the Cone.*

General principle. PLATE CCLXVI. Fig. 9.

The principle of this developement, or projection as it is sometimes called, may be shortly explained thus. Let WNES (Fig. 9.) be the sphere of which it is proposed to develope any portion, as the fourth part WNE, WE the equator, SN the meridian at right angles to WNES, and ML the radius of the middle parallel, or that which divides the part to be developed into two equal parts in the direction of latitude, in this case 45°. Draw MA and M′A at right angles to the radii CM and CM′, and meeting SN produced in A; that is, make MA and M′A the cotangents of the latitude of the middle parallel; then AM and AM′ will be the sides of a cone, tangent to the sphere at M and M′, and of which any zone, extending to a moderate distance on each side of MM′, may, without any sensible error, be considered as equal to the corresponding zone of the sphere. From A with the radius AM describe the arch M *m* M′; then, if the radius CN and the arch M *m* M′ be both divided into equal parts, arches described from A through the former will be the projected parallels of latitude, and straight lines drawn from the same point through the latter will represent meridians, both at greater or less distances from one another, according to the number of divisions. The arch M *m* M′ will be the parallel of 45°.

By this projection may be obtained a tolerably accurate representation of a small portion of the globe; but when it is extended to a considerable space, as the fourth part of the whole sphere, the countries towards the pole and the equator are extended a great deal beyond their true limits, in the direction of their latitude. Various methods of remedying this defect have been adopted or recommended by different geographers; but the simplest, as well as the most successful, is that known by the name of *Flamstead's projection.* It was so denominated at first from its inventor, and it still retains the name, though since his time it has undergone various alterations. In its most improved form, the construction is as follows.

Flamstead's projection. Fig. 10.

Draw an indefinite straight line NS (Fig. 10.) to represent the middle meridian of the map, and from the point M, near the middle of the line, set off on both sides towards N and S equal distances of any convenient length, to represent degrees of latitude. Suppose, for example, that the map is to contain 60 degrees of latitude, viz. from the 20th to the 80th parallel, and that this extent is to be equal to three inches; then each degree will be equal to $\frac{1}{20}$ or .05 *in.*; the point M will be in the parallel of 50°, and the distance of $\frac{1}{2}$ or .5 *in.* set off towards N and S will give the points through which the parallels of 40°, 30° and 20° must pass on the one side, and those of 60°, 70° and 80° on the other. The centre C of these parallels will be in the line NS towards N, and may be found thus.

Let d be the length of the assumed degree of latitude,
l the latitude of the middle parallel, or M, and
d' the length of an arch of 1° to radius 1; then

$$d' : \text{cotan. } l :: d : \text{MC} = \frac{\text{cot. } l \times d}{d'}.$$

Now, in this example, $d = .05$ *in.*, $l = 50°$, and $d' = \frac{3.14159}{180} = .01745329$; therefore,

$$\text{MC} = \frac{.05 \times \text{cotan. } 50}{.01745329} \text{ inches.}$$

The computation is performed most conveniently by logarithms, thus:

Log. .05	$\bar{2}.698970$
Log. cot. 50° to Rad. 1	$\bar{1}.923813$
	$\bar{2}.622783$
Log. .01745329	$\bar{2}.241876$
Log. MC	0.380907

and MC = 2.4038 inches.

From M, therefore, set off towards N, MC = 2.4 *in.* and from C as a centre through each of the divisions in NS, describe arches for the parallels of latitude.

To find the meridians, take any parallel, as the middle one passing through M, and from the table of degrees of longitude, p. 151, take the length corresponding to the latitude of the parallel, multiply it by the length of the assumed degree, and that product again by the number of degrees to which the map is to extend on each side of the middle meridian; the last product will express the distance from M at which the extreme meridian will intersect the middle parallel. Thus, in the present example, let the map extend 40° on each side of NS; that is, let it include 80° of longitude, and the calculation becomes—

Degree of longitude in lat. 50	.64279
Length of the assumed degree in inches .	.05
	.0321395
Half longitude of the map	40
	1.2855800

From M, therefore, set off on the middle parallel both ways, 1.285 *in.* and it will give the limits of the map on that parallel. Corresponding points being determined, in the same way, on each of the other parallels, the curves passing through these points will be the meridians bounding the map on the east and west. To find the other meridians, divide the arch of each parallel between the middle and extreme meridians, into as hemati- Geogra- phy.

many equal parts as the number of meridians wanted on each side of NS, and curves drawn through the corresponding points will be the meridians required. In the above example, each of the arches being divided into four equal parts, will give a meridian for every tenth degree. If the parallels are at such a distance from one another as to render it difficult to describe the meridian curves with sufficient accuracy, intermediate parallels may be described with a pencil point, and afterwards erased.

eding nod not accu-

It may be proper to observe, that the preceding method of determining the limits of the map on each parallel, gives the extent somewhat too great, the chord of the arch M*m*, instead of the arch itself, being assumed equal to 1.285 *in.* In ordinary cases, indeed, this difference is too small to affect the accuracy of the map, and therefore an expeditious and convenient method of construction is not to be abandoned, on account of an error which is scarcely, if at all, sensible. The truth of this remark will be obvious from the following method of determining the arch of the middle parallel, by which the length of the chord is obtained with perfect accuracy.

ount of rror de- ined.

As the arch of the middle parallel of latitude M*m*, (Fig. 9.) is terminated on the sphere, and in the projection by the same points, but has for a radius, in the former case the cosine, and in the latter the cotangent of the latitude, the number of degrees which the arch contains in the projection, will be less than the number which it contained on the globe, or which it represents in the projection, in the same proportion as the cosine of the latitude is less than the cotangent. Hence, if a denote the amplitude of the arch of the middle parallel l on the sphere, or the number of degrees to be represented between the middle and extreme meridian of the map, and a' the amplitude of the same arch in the projection, as described from the centre of the parallel, or the angle which a straight line, drawn from the extremity of the parallel to the centre, makes with the middle meridian, we have

$$\text{cotan.}\, l : \cos.\, l :: a : a' = a \times \frac{\cos.\, l}{\cot.\, l}.$$

But $\frac{\cos.\, l}{\cot.\, l} = \sin.\, l$ to radius $1 = \frac{\sin.\, l}{r}$ to radius r; therefore $a' = \frac{a \times \sin.\, l}{r}$, and by logarithms,

$$\log.\, a' = \log.\, a + \log.\, \sin.\, l - \log.\, r.$$

Let now half the longitude of the map be as above 40°, and let it be required to find the extremity of the middle parallel M*m*, (Fig. 10.)

In this case $a = 40$ and $l = 50°$, therefore

$$\log.\, a' = \log.\, 40 + \log.\, \sin.\, 50° - \log.\, r.$$

Log. 40	1.602060
Log. sin. 50°	9.884254
	11.486314
Log. r	10.000000
Log. a'	1.486314
a'	30°.641 = 30° 38′ 27″

therefore a straight line drawn from C, and making an angle with MC = 30° 38′ 27″, will intersect M*m* in the point through which the meridian must pass, whose distance from NS = 40°. By a similar, though a more tedious calculation, the amplitudes of the other parallels may be determined: but without entering upon these calculations, we shall proceed to find what is the real difference between the two methods in point of accuracy. In the case of the middle parallel, it has been shewn, that the angle MC*m* = 30° 38′ 27″, and joining *m*M, we have in the isosceles triangle CM*m* an angle C, and a side *m*C. If the triangle therefore be resolved, the base *m* M, or the chord of the arch *m* M, will be found to be 1.27 *in.* which gives for the excess of the former method .015 *in.*: an error which in almost all cases may be safely overlooked.

Mathematical Geography.

The characteristic property of this projection is, that all the quadrilaterals formed by meridians and parallels of latitude have nearly the same ratio to one another on the map, that the corresponding quadrilaterals have to each other on the sphere. It is also a consequence of this property, that distances on the map may be readily and correctly measured by a scale of equal parts. This scale may be constructed as follows.

Scale of the map. PLATE CCLXVI. Fig. 11.

From any point A (Fig. 11.), draw a straight line AB, equal to any number of the assumed degrees of latitude, as for example 60, and from the same point draw an indefinite straight line AC, making any angle with AB. Then, suppose the scale is to be divided so as to represent English miles, the whole will contain 69.045 × 60 = 4142.7, or nearly 4140. From any scale of equal parts, set off from A towards C 4 divisions, and .14 of another division, and let them terminate at D. Join DB, and through the divisions of AD draw straight lines parallel to DB, and intersecting AB in the points 1, 2, 3, 4; each of these divisions will represent 1000 English miles, except the last, which will be 140, and the distance between two places on the map applied to this scale will give their distance in miles.

II. *Of the Cylinder.*

General principle. PLATE CCLXVII. Fig. 1.

The principle of this developement may be explained in a manner analogous to that of the cone. Let WNC, (Fig. 1. Plate CCLXVII.) be the eighth part of a sphere, a portion of which it is proposed to develope, and let M*m* be the radius of the middle parallel of that portion. Then if a cylinder ABCN, equal in diameter to the radius of the middle parallel, be partly inscribed in the sphere, and partly circumscribed about it, a zone of the cylinder to a short distance, on each side of M*m*, may be considered as very nearly coinciding with the corresponding zone of the sphere. If the former, therefore, be developed, or spread out, the parallels of latitude will be straight lines parallel and equal to M*m*, and the meridians will also be straight lines, cutting the parallels of latitude at right angles; that is, they will be parallel to one another, and equal in length to the breadth of the zone. Upon this principle is constructed the *Plane Chart*, as follows.

Plane chart.

Suppose the chart is required to extend from 40° to 60° north latitude, and from 10° west to 10° east longitude; that is, to contain 20° of latitude and 20° of longitude. Describe a parallelogram ABCD, (Fig. 2,) making BC of any convenient length, and AB : BC :: cos. of the middle latitude (50°) : radius. Divide AB and BC each into four equal parts, and straight lines drawn through these points parallel to BC and AB, will be meridians and parallels of latitude five degrees distant from one another. If necessary, intermediate parallels and meridians may be drawn in the same way.

Fig. 2.

Mathematical Geography.

Mercator's chart.

It is obvious, from inspecting Fig. 1, that a chart constructed on this principle may, for a few degrees on each side of the equator, be tolerably correct; but that the inaccuracy increases with the distance from the equator, and in high latitudes becomes excessive. To obviate this inconvenience, another method of develepement has been invented, known by the name of *Mercator's projection.* In this method, as in the former, meridians and parallels of latitude are straight lines cutting one another at right angles, the degrees of longitude being of course the same in all latitudes; but in order that the degrees of latitude and longitude may preserve their true proportions to one another, the former are made to increase on the map, in the same ratio that the latter diminish on the sphere. The distances from the equator, or from one another, at which the parallels of latitude ought to be drawn according to this principle, can only be determined accurately by the application of the fluxional calculus: (see FLUXIONS, vol. ix. p. 463); but an approximation to these distances may be found as follows:

General principle of Wright's method.

PLATE CCLXVIII. Fig. 3.

Let PE (Fig. 3.) represent the quadrant of a meridian, CE the equator, and DE any arch of PE; then DG will be the sine, CG or DH the cosine, EF the tangent, and CF the secant of the arch DE. Now by similar triangles (see GEOMETRY) CG : CD : : CE : CF, or taking l for the latitude of D, cos. l : rad. : : rad. : sec. l. But since circles, or arches of circles, are to one another as their radii, rad. : cos. l : : an arch of the equator : a corresponding arch of the parallel l; or supposing the earth to be a sphere, rad. : cos. l : : an arch of the meridian : a corresponding arch of the parallel l. Hence if d represent the length of a degree of the meridian, and d' the length of a degree of the parallel l on the globe,

$$\text{sec. } l : \text{rad.} :: d : d'.$$

But on the map, the natural degree of the meridian d, must be increased in the same ratio as d' is diminished on the sphere; that is, taking ∂ to denote the lengthened degree of the meridian.

$$\text{rad.} : \text{sec. } l :: d : \partial = \frac{d \times \text{sec. } l}{\text{rad.}}.$$

When d and rad. are both $=1$, the formula becomes $\partial = \text{sec. } l$; that is, when the natural degree of the meridian and radius are both assumed $=1$, the length of any degree of latitude will be expressed by the secant of that latitude. But no degree of the meridian, nor indeed any arch of a definite length, can have all the same latitude l, and therefore in the equation $\partial = \text{sec. } l$ ∂ is to be understood as the projection of an indefinitely small arch d, assumed equal to unity. Now any arch of the meridian DE, is made up of an indefinite number of such arches, and therefore the projection of DE, or the distance of the parallel l from the equator, is equal to the sum of the secants of an indefinite number of arches, each of which is assumed equal to unity. This distance, as was formerly observed, can only be found accurately by fluxions, but an approximation is obtained by dividing DE into a number of small arches, each being reckoned unity, and finding the sum of their secants. The greater the number of parts, the greater also will be the accuracy of the approximation. This principle was first explained, and applied to the construction of charts, by Mr Wright in 1599, who determined the distance of each parallel to 1 minute of the quadrant, by finding the sum of the secants, of all the arches of 1 minute, from the equator to that parallel. These distances he arranged in a table which is denominated a table of *meridional parts,* and which is still employed in constructing charts, as in the following examples.

Chart of the world on Mercator's projection.

1. Let it be required to construct a chart of the world, according to Mercator's projection.

Through the point C (Fig. 4.) intended to be the centre of the map, draw two indefinite straight lines WE, NS at right angles to one another, the former representing the equator, and the latter the first meridian. From C by means of any convenient scale of equal parts, set off towards W and E, 18 equal parts, each representing 10 degrees of longitude. Find then, in the Table, the meridional parts, corresponding to 10°, 20°, 30°, &c. divide each by 60, and taking the quotients from the same scale of equal parts, set them from C towards N and S; then straight lines drawn through the divisions of WE parallel to NS will be meridians, and straight lines through the divisions of NS parallel to WE will be parallels of latitude, 10° distant from one another. Upon this principle is constructed the chart of the world, Plate CCLXIX.

PLATE CCLX[...]

Chart of a portion of the earth.

2. Let it be required to represent only a portion of the earth's surface, as for example from 0° to 50° W. longitude, and from 30° to 60° N. latitude.

Draw AB (Fig. 5.) to represent the parallel of 30°, and from the extremity, erect the perpendicular BC for the first meridian. From B, by means of any convenient scale of equal parts, set off five divisions, towards A, and from these points erect perpendiculars for the other meridians, 10° distant from each other. Take then from the Table the meridional parts corresponding to 40°, 50°, and 60°, subtract from each the meridional parts corresponding to 30°, the lowest parallel of the chart, and divide the remainders by 60°; the quotients taken from the same scale of equal parts, and set from B to C, will give the distances of the respective parallels. Thus, to find the distance of the parallel of 40°:

Meridional parts of 40°	2622.7
Meridional parts of 30°	1888.4
	734.3

and $\frac{734.3}{60} = 12,24$ parts of the scale from which the divisions of AB were taken.

To facilitate the construction of charts according to this projection, the flat rulers commonly called Gunter's scales, are provided with two lines adjacent and parallel to one another marked Mer. and E : P, the first being meridional parts, previously divided by 60, so as to reduce them to degrees, and the second a scale of equal parts, or degrees of longitude, corresponding to the latitudes on the other. Hence, if the longitude of a chart be taken from the line E : P, the distance of any parallel from the equator is found by extending the compasses from the extremity of the line Mer. to the number denoting the latitude, and applying that distance from the commencement of the line E : P. In like manner to find the distance between any two parallels, take the distance between the latitudes on Mer. and apply it to E : P. Thus the distance between the parallels of 30° and 40° on Mer. will be equal to 12.24 on E : P, the same as in the preceding example.

Improvement of Gregory, Halley, &c.

Such is the principle of the method, originally invented by Wright, and still frequently employed, in constructing a chart, according to Mercator's projection. It was soon discovered, however, and subsequently demonstrated by Gregory and Halley, that the meridian line, divided according to this principle, becomes a line of logarithmic cotangents, to half the co-

Mathematical Geography.

latitudes of the different parallels, deducting radius from each; that is, C 20 (Fig. 4.) reckoning from C towards N, is the log. cot. $\frac{90^\circ - 20^\circ}{2}$ or 35°, = log. tan. 55°;

C 40 = log. cot. $\frac{90^\circ - 40^\circ}{2}$ or 25°, = log. tan. 65°, &c.

always deducting radius. Advantage has accordingly been taken of this principle, by adapting a line of such tangents to the construction of charts. This line is to be found on the common Gunter's scale, adjacent to the line Mer. and marked Tan. Like the former, it commences on the right hand, and is constructed on the following principle.

Construction of the line of logarithmic tangents.

As radius is to be deducted from each tangent, before transferring it to the scale, and as all tangents below 45° are less than the radius, none less than that of 45° can be exhibited on the line. Nor, indeed, is any less tangent necessary, as half the colatitude never can be greater, or, which is the same thing, the complement of half the colatitude, never can be less than 45°. From the extremity of the line, therefore, which is marked 45°, the logarithmic tangents of all the arches greater than 45°, deducting radius, are set off towards the left hand, and numbered at every tenth division, 50, 60, 70, &c. But the logarithmic tangent of any arch, as 50° = log. cot. $90^\circ - 50^\circ$ or 40° = log. cot. $\frac{90^\circ - 10^\circ}{2}$ = log. cot. of half the colatitude of 10°. In like manner, tan. 55° = cot. 35° = cot. $\frac{90^\circ - 20^\circ}{2}$ = cot. of half the colatitude of 20°, and so of others. To facilitate, therefore, the application of the line, the divisions marked 50, 60, 70, &c. are also numbered 40, 30, 20, &c. by which means they exhibit at once the half colatitudes, to which the tangents 50, 60, 70, &c. are cotangents. Hence the following simple rule, for finding the projected distance of any parallel of latitude, from the equator.

Extend the compasses from the extremity of the line 45, to the number denoting half the colatitude of the parallel, and it will be the distance required. Thus, the distance of the parallel of 20° is found by extending the compasses from 45 to $\frac{90 - 20}{2} = 35$, and so of any other. Hence also, to find the projected distance between any two parallels, take the distance between the numbers denoting half the colatitudes of each; thus the distance between the parallels of 20° and 40° on the chart = the distance between 35 and 25 on the scale.

But though the distances of the parallels, or the lengths of the degrees of latitude, are thus readily found, it is obvious that these distances must correspond to some particular scale of longitudes. In order, therefore, to construct a chart by the line of tangents, it becomes necessary to determine the length of the degree of longitude which corresponds to that line, and which may be found thus.

Construction of a line of longitudes.

Take from the line Mer. any latitude whatever, as 37° 6′, and applying that distance to the line E : P, mark the corresponding length, which in this case will be 40; or divide the number opposite to 37° 6′ in the table of meridional parts, which is 2400, by 60, and mark the quotient, viz. 40. From 45 on the line Tan. extend the compasses to half the colatitude of 37° 6′, the assumed latitude, which is 26° 27′; apply this distance to any scale of equal parts, as of 1 inch, and divide the corresponding distance, which in this case will be about 3.4 *in.* by 40, the number found on E : P, or from the table corresponding to the assumed latitude; the quotient, in the present instance .085, will be the length of a degree of longitude, corresponding to the above latitudes, in terms of the unit of the scale of equal parts, viz. inches. Hence, if the distances of every tenth parallel be taken from a line of tangents of the dimension supposed above, every tenth meridian will be found by setting off on the equator, or on any parallel of latitude, divisions each equal to .85 *in.*

It follows, from the meridians in this projection being parallel to one another, that the rhumb-lines, which on the globe are spirals continually approaching the poles, are represented on the chart by straight lines; a property which renders this construction of vast importance in navigation. See NAVIGATION.

Construction of gores for covering globes.

The only other projection that we shall notice, as connected with the subject of the present Section, is the construction of *gores*, for covering globes, each of which may be considered as a developement of a small portion of the surface of the sphere, extending longitudinally, in the direction of the meridian. We formerly observed, in treating of the construction of globes, that in an indefinitely small portion of the sphere, ÆNQS (Plate CCLXV. Fig. 7.), ÆQ and *ac*, portions of the equator and a parallel of latitude, may be regarded as straight lines, perpendicular to MN. In practice, however, the gore is not taken so small as to warrant this assumption; and therefore these lines are really portions of circles. The following method of projecting gores, has been recommended by several eminent artists, as well as astronomers.

Plate CCLXV. Fig. 7.

Draw a straight line ÆQ, equal to the breadth of the intended gore at the equator, which is generally $\frac{1}{12}$ of the whole circumference, and bisect it by a perpendicular MN, equal to $\frac{1}{4}$ of the circumference. Divide MN into 9 equal parts, and through each, from points in MN produced, with radii equal to the cotangents of their respective latitudes, to rad. MN, describe arches for the parallels of every 10th degree. From each of the divisions in MN, and with radii equal to the fractions opposite their respective latitudes in the Table, p. 151, multiplied into the length of MÆ, describe arches intersecting the parallels, on both sides of MN; then the curves N *a* Æ, N *c* Q drawn through these divisions, will be the meridians distant from one another $\frac{1}{12}$ of the circumference, or 30°, that is the segment of the gore Æ *a* N *c* Q applied to the globe will cover $\frac{1}{12}$ of a hemisphere. The same operation repeated will give the other gores, after which the different portions of the earth's surface, or celestial sphere, are to be delineated as on any other maps. The globe, as was formerly observed, is generally covered in this way, from the equator to the parallel of 70° or 80°; but the space round the pole is projected on one circular piece, whose radius is equal to the sine of its distance from the pole. It is hardly necessary to observe, that neither by this, nor any other method, can gores be constructed, so as accurately to cover any given portion of a sphere. It is even found that the dimensions of the different pieces, undergo a considerable alteration in consequence of their being moistened, for the purpose of being fixed on the globe. The best method of correcting these irregularities, is by enlarging or diminishing, as may be necessary, the size of the globe itself.

SECT. IV. *Construction of Maps representing small Portions of the Earth's Surface, and the Method of filling up the Outlines of Maps in general.*

THOUGH the various methods of projection, explained in the course of this article, are sufficient for the con-

Mathematical Geography.

struction of any kind of maps, yet when it is required to represent a small portion of the earth's surface, and to exhibit the different parts nearly in their true proportions, the following is perhaps the most convenient, as well as the most accurate of any.

Suppose it is required to construct a map, extending from 50° to 60° N. Latitude, and from 3° E. to 7° W. Longitude.

Plate CCLXVII. Fig. 6.

Draw an indefinite straight line AB (Plate CCLXVII. Fig. 6.) for the parallel of 50°, and from a point C near the middle of the map, erect a perpendicular for the middle meridian, or that of 2° W. longitude. From C set off to D 10 equal parts, taken from a scale of any convenient length, as inches, to denote degrees of latitude, and through D draw EF parallel to AB, for the parallel of 60°. Take from the Table, p. 151, the fraction corresponding to 50°, which is .64279 or .643 nearly, and it will be the length in parts of the same scale, in this case inches, to be set off from C towards A, and from C towards B for degrees of longitude. In like manner, take the fraction opposite to 60° in the Table, which is .5, and it will give the length to be set off from D to E and from D to F. Then lines drawn through the divisions of CD, parallel to AB, will be parallels of latitude, and lines joining the corresponding divisions in AB and EF will be meridians. A scale of miles adapted to the map, may be constructed as formerly explained under Flamstead's projection.

Natural divisions of the globe.

Of the objects to be delineated on a map, or of the method of representing them, it will not be necessary to say much, as such details must be familiar to all our readers. The great natural division of the globe, is into *land* and *water*. The subdivisions of the former are *continents*, or large tracts containing several kingdoms and states, as Europe, Asia, Africa, and America, and *islands*, or smaller tracts, wholly surrounded by water, as Britain. A tract of land, surrounded with water on all sides but one, whatever be its extent, is called a *peninsula*, as Spain and Africa; and the side by which it is united to other land, is called an *isthmus*, as the isthmus of Suez, which joins Africa to Asia. A point of land running into the sea is called a *cape*, *promontory*, or *head-land*. The subdivisions of the water are *oceans*, or those large collections which surround the continents, and which are usually reckoned five, viz. the Northern, Southern, Atlantic, Pacific, and Indian; and *seas*, or those branches of the ocean which intersect the continents, as the Baltic and Mediterranean. When a narrow branch of the sea, or ocean, projects far into the land, it is called a *gulf*, as the Arabian Gulf, and a *bay*, when its entrance is wider, as the Bay of Biscay. The canal that unites a gulf with a sea or an ocean, is called a *strait*, as the Straits of Babelmandel and Gibraltar.

Continents. Islands. Peninsula. Isthmus. Cape. Oceans. Seas. Gulf. Bay. Strait.

Method of representing these subdivisions.

All these divisions are traced out on the map, by a crooked or waving line representing the coast, from which small parallel lines are drawn towards the water, of about a tenth, or sometimes two tenths of an inch in length. These lines, while they render the separation more distinct, have also the effect of making the sea appear to project from the surface of the map. In charts, or maps chiefly intended for representing coasts, harbours, &c. the direction of the parallel lines is reversed, which gives to the land the appearance of projecting. The latter seems to be the most natural representation. In modern maps, the parallel lines are generally drawn quite across the sea, from coast to coast, by which the division of land and water is rendered still more distinct. In representing mountains, geographers formerly employed vertical sections, as A (Fig. 7.) but of late, the *bird's eye view* is more frequently used. This consists in small waving lines, as B, diverging from a point, the point representing the summit, and the lines the declivity of the mountain. Rivers are represented by waving lines, roads by crooked lines, either single or double, and towns by small circles, varying in magnitude, according to the size of the towns themselves, and the scale of the map.

Plate CCLXVII. Fig. 7.

As the reduction of maps from one scale to another, is frequently a problem of importance in practical geography, we shall point out a method of making such a reduction, which, if not extremely accurate, deserves to be noticed for its simplicity.

Method of reducing maps. Fig. 8.

Let ABCD (Fig. 8.) be a given map, and *a b c d* a similar figure of a reduced size, upon which it is required to lay down points corresponding to E, F, G, H, and to trace a line corresponding to the line LMN. Divide ABCD into any number of equal squares, or parallelograms, by straight lines parallel to AB and AD, and divide *a b c d* also into the same number, by lines parallel to *a b*, *a d*; then, by comparing the corresponding parallelograms, points *e*, *f*, *g*, *h* may easily be found occupying very nearly the same positions in *a b c d*, that the points E, F, G, H do in ABCD, and a line *l m n* may also be traced, differing little in its direction from LMN. This method may be advantageously employed for filling up the details of a map, after the principal points have been determined by some more accurate method. For the use of the pentagraph, in reducing maps, see the article Drawing Instruments, vol. viii. p. 129. See, for the construction of maps, *Precis de la Geographie Universelle*, par M. Malte Brun, tom. ii. Paris 1812; *Memoires sur la Projection des Cartes Geographiques*, par M. Henry, Paris 1810; Lorgna, *Principii di Geografia*, Verona 1789; Playfair, *Outlines of Natural Philosophy*, vol. ii. p. 66, &c.

Sect. V. *On the Determination of the Longitudes and Latitudes of Places on the Earth's Surface.*

In the preceding Sections, we have pointed out the various methods which may be employed in delineating the whole or a part of the earth's surface, either upon a sphere or upon a plane. Before a map, however, can be completed, it is necessary to have the exact position of various places in reference to the equator, and to some fixed meridian; and hence the determination of the longitudes and latitudes of places by astronomical, trigonometrical, or chronometrical observations, is one of the most important operations in geography.

We have already pointed out in our article Astronomy, the method of making these observations by the aid of the planets or the fixed stars; and in our articles Navigation, Surveying, and Timekeeper, we shall have occasion to consider the method of determining longitudes and latitudes by trigonometrical instruments, and by chronometers. We shall, therefore, conclude this article with a Table of geographical positions, exhibiting the latitude of the principal points on the earth's surface, and their longitudes, or difference of meridians, in relation to the observatory of Greenwich.

This Table, which is by far the most correct that has ever been published, has been taken principally from the *Connoissance des Tems* for 1816, and contains the results of the best observations which have been made by astronomers and navigators, and by those eminent individuals who have from time to time been employed in measuring degrees of the meridian. We have corrected many of the positions, and have added more than two hundred new places in England and Scotland, from the accurate observations of Colonel Mudge and Captain Coleby. No place is inserted, unless its position has been actually determined either by astronomical, trigonometrical, or chronometrical observation.

Geology, Geometrical Analysis.

GEOLOGY, or GEOGNOSY, is that branch of mineralogy which relates to the arrangement and mode of formation of the different mineral substances of which the earth is composed. We originally proposed to discuss this subject under the present article, but it has been thought proper to include it under the general head of MINERALOGY.

GEOMETRICAL ANALYSIS, is the particular form of proceeding, employed by the ancient geometers in the investigation of geometrical truth. It originated in the school of Plato, and was alike applicable to the demonstration of theorems, and the investigation of problems. We learn from the writings of Pappus Alexandrinus, that in his time there existed thirty-three books relating to this subject; many of these have been lost, and their restoration has afforded an exercise to the ingenuity of mathematicians of modern times.

We have sufficiently indicated the nature of the geometrical analysis, and the mode of its application in our article ANALYSIS. When at that part of our work, it was our intention to have treated at some length on the subject in this place; but as we dvanced, we have, with a view to give sufficient room to other oranches of knowledge, found it necessary to limit somewhat our views. The history of its origin and progress will be found in the introduction to the article GEOMETRY, and it will be noticed again under the words INCLINATION, LOCUS, PORISM, TANGENCY, and SECTION. Works which treat on the subject are enumerated in the introduction to GEOMETRY. (ξ)

GEOMETRY.

History.

Geometry is that branch of mathematics which treats of the properties of extension and figure. The name is derived from γεωμετρία, the *science of land measuring.*

There is a certain degree of geometrical knowledge which naturally arises out of the wants of man, in every state of society. It is impossible to build houses and temples, or to apportion territory, without employing some of the principles of geometry. Hence we cannot expect to find a period of society, or a country in which it was altogether unknown.

[Or]igin of [Ge]ometry.

Ancient writers have generally supposed that it was first cultivated in Egypt; and, according to some, it derived its origin from the necessity of determining every year the just share of land that belonged to each proprietor, after the waters of the Nile, which annually overflowed the country, had returned into their ordinary channel. It may however be remarked, that the obliteration of the landmarks, by the inundation, is quite a conjecture, and not a very probable one.

Some writers, among whom is Herodotus, fix the origin of geometry at the time when Sesostris intersected Egypt by numerous canals, and divided the country among the inhabitants. Sir Isaac Newton has adopted this opinion in his chronology, and has supposed that this division was made by Thoth the minister of Sesostris, who, according to him, was the same as Osiris; and this conjecture is supported by some ancient authorities. Aristotle has however attributed the invention to the Egyptian priests, who, living secluded from the world, had leisure for study. Thus, various opinions have been entertained respecting the origin of geometry, but all have agreed in fixing it in Egypt.

[Ge]ometry [bro]ught to [Gr]eece by [Th]ales, [A.] C. 640.

The celebrated philosopher, Thales of Miletus, transplanted the sciences, and particularly mathematics, from Egypt into Greece. He was born about 640 years before Christ, and being unable to gratify his ardent desire for knowledge at home, he travelled into Egypt, at an advanced period of life, where he conversed with the priests, the only depositories of learning in that country. Diogenes Laertius relates, that he measured the height of the pyramids, or rather the obelisks, by means of their shadow; and Plutarch says, that the king Amasis was astonished at this instance of sagacity in the Greek philosopher; which is a proof that the Egyptians had made but little progress in the science. It is also stated by Proclus, that Thales employed the principles of geometry to determine the distance of vessels remote from the shore. On his return to Greece, his celebrity for learning drew the attention of his countrymen: he soon had disciples, and hence the foundation of the Ionian school, so called from Ionia his native country.

[Ion]ian [sch]ool [fou]nded.

There were some slight traces of what may be called natural geometry in Greece, before the time of Thales: Thus, Euphorbus of Phrygia is said to have discovered some of the properties of a triangle; the square and the level have been ascribed to Theodorus of Samos; and the compasses to the nephew of Dædalus. But these can only be considered as a kind of instinctive geometry; the origin of the true geometry among the Greeks must be fixed to the period of the return of Thales. It was he that laid the foundation of the science, and inspired his countrymen with a taste for its study; and various discoveries are attributed to him, concerning the circle, and the comparison of triangles. In particular, he first found that all angles in a semicircle are right angles; a discovery which is said to have excited in his mind that lively emotion, which is perhaps only felt by poets and geometers: he foresaw the important consequences to which this proposition led, and he expressed his gratitude to the muses by a sacrifice. This, however, is but a small part of what geometry owes him; and it is much to be regretted that the loss of the ancient history of the science should have left us in uncertainty as to the full extent of the obligation.

Early geometers. Ameristus and Anaximander. Born 610 A. C.

It is probable that the greater number of the disciples of Thales were acquainted with geometry; but the names of Ameristus and Anaximander only have reached our times. The first is said to have been a skilful geometer; the other composed a kind of elementary treatise or introduction to geometry, the earliest on record. Thales was succeeded in his school by Anaximander, who is said to have invented the sphere, the gnomon, geographical charts, and sun-dials; he was succeeded by Anaximenes; and this philosopher again was succeeded by his scholar Anaxagoras, who, being cast into prison on account of his opinions relating to astronomy, employed himself in attempting to square the circle. This is the earliest effort on record, to resolve the most celebrated problem in geometry.

Anaximenes. Born 554 A. C. Anaxagoras. Born 500 A. C.

Pythagoras. Born 580 A. C.

Pythagoras was one of the earliest and most successful cultivators of geometry. He was born about 580 years before the Christian æra; he studied under Thales, and by his advice travelled into Egypt. Here he is said to have consulted the columns of Sothis, on which that celebrated person had engraven the principles of geometry, and which were deposited in subterranean vases. A learned curiosity induced him to travel also into India; and it is far from being improbable, that he was more indebted for his knowledge to the Brahmins, on the banks of the Ganges, than to the priests of Egypt. On his return, finding his native country a prey to tyranny, he settled in Italy, and there founded one of the most celebrated schools of antiquity. He is said to have discovered that in any right angled triangle, the square on the side opposite the right angle, is equal to the two squares on the sides containing it; and, on this account, to have sacrificed one hundred oxen, to express his gratitude to the muses. This, however, was incompatible with his moral principles, which led him to abhor the shedding of blood on any account whatever; and besides, the moderate fortune of a philosopher would not admit of such an expensive proof of his piety. The application which the Pythagoreans made of geometry gave birth to several new theories, such as the incommensurability of certain lines, for example, the side of a square, and its diagonal, also the doctrine of the regular solids, which, although of little use in itself, must have led to the discovery of many propositions in geometry. Diogenes Laertius has attributed to Pythagoras the merit of having discovered, that of all figures having the same boundary, the circle among plane figures, and the sphere among solid figures, are the most capacious: if this was so, he is the first on record that has treated of isoperimetrical problems.

Pythagorean school founded about 550 A. C.

History.

The Pythagorean school sent forth many mathematicians; of these Archytas claims attention, because of his solution of the problem of finding two mean proportionals; also on account of his being one of the first that employed the geometrical analysis, which he had learnt from Plato, and by means of which he made many discoveries. He is said to have applied geometry to mechanics, for which he was blamed by Plato; but probably it was rather for applying, on the contrary, mechanics to geometry, as he employed motion in geometrical resolutions and constructions.

Democritus.

Democritus of Abdera studied geometry, and was a profound mathematician. From the titles of his works, it has been conjectured that he was one of the principal promoters of the elementary doctrine respecting the contact of circles and spheres, and concerning irrational numbers and solids. He treated besides of some of the principles of optics and perspective.

Hippocrates, 380 A. C.

Hippocrates was originally a merchant, but having no turn for commerce, his affairs went into disorder; to repair them, he came to Athens, and was one day led by curiosity to visit the schools of philosophy. There he heard of geometry for the first time; and as probably there is a natural adaptation of certain minds to particular studies, he was instantly captivated with the subject, and became one of the best geometers of his time. He discovered the quadrature of a space bounded by half the circumference of one circle, and one fourth the circumference of another, their convexities being turned the same way. This figure, called a *lune*, he shewed to be equal to a right angled triangle having its sides about the right angle equal, and the remaining side equal to the common chord of the two arcs; and thus he was the first that proved a curvilineal to be equal to a rectilineal space. But although a kind of quadrature, it cannot be compared as a discovery with the quadrature of the parabola found afterwards by Archimedes: the former is merely a geometrical trick, which leads to nothing further; but the latter was an important step in the progress of the science. Hippocrates attempted the quadrature of the circle, but if his mode of reasoning has been correctly handed down to us, he committed a blunder: this is the oldest paralogism in geometry upon record. On the other hand it must be mentioned to his credit, that he first proved the duplication of the cube to depend on the finding of two mean proportionals between two given lines: (See Introduction to Conic Sections.) He was also the first that composed Elements of Geometry, which, however, have been lost, and are only to be regretted, because we might have learnt from them the state of the science at that period. It has been said that, notwithstanding his want of success in commerce, he retained something of the mercantile spirit: he accepted money for teaching geometry, and for this he was expelled the school of the Pythagoreans. This offence we think might have been forgiven, in consideration of his misfortunes.

Bryson and Antiphon.

Two geometers, Bryson and Antiphon, appear to have lived about the time of Hippocrates, and a little before Aristotle. These are only known by some animadversions of this last philosopher on their attempts to square the circle. It appears that before this time, geometers knew that the area of a circle was equal to a triangle whose base was equal to the circumference, and perpendicular equal to the radius.

Having briefly traced the progress of geometry during the two first ages after its introduction into Greece, we come now to the origin of the Platonic school, which may be considered as an æra in the history of the science. Its celebrated founder had been the disciple of a philosopher (Socrates) who set little value on geometry; but Plato entertained a very different opinion of its utility. After the example of Thales and Pythagoras, he travelled into Egypt, to study under the priests. He also went into Italy, to consult the famous Pythagoreans, Philolaus, Timæus of Locris, and Archytas, and to Cyrene to hear the mathematician Theodorus. On his return to Greece, he made mathematics, and especially geometry, the basis of his instructions. He put an inscription over his school, forbidding any one to enter, that did not understand geometry; and when questioned concerning the probable employment of the Deity, he answered, that *he geometrized continually*, meaning no doubt that he governed the universe by geometrical laws.

History.

Platonic school founded about 400 A. C.

Invention of geometrical analysis.

It does not appear that Plato composed any work himself on mathematics, but he is reputed to have invented the Geometrical Analysis: (See Analysis.) The theory of the Conic Sections originated in this school; some have even supposed that Plato himself invented it, but there does not seem to be any sufficient ground for this opinion. See Conic Sections.

Of geometrical loci.

A third discovery due to the Platonic school was that of the *geometrical loci*; when the conditions which determine the position of a point are such as to admit of its being any where in a line of a particular kind, but do not admit of its being out of that line, then the line is called the *locus* of the point: Thus, if one end of a straight line of a given length be at a given point, the *locus* of the other end will be the circumference of a given circle: Again, if the base of a triangle of a given area be given in position and magnitude, the *locus* of its vertex will be a given straight line, which will be parallel to the base; also, if the base of a triangle be given in position and magnitude, and its vertical angle be given in magnitude, the *locus* of its vertex will be the circumference of a given circle: all this is evident from the elements of geometry. *Geometrical loci*, considered merely as speculative truths, are interesting; but their chief value arises from their utility in the resolution of problems, of which, in general, they suggest the most elegant solutions. See Locus.

Duplication of the cube.

The celebrated problem concerning the duplication of the cube, acquired its celebrity about the time of Plato. Its origin, however, was earlier; for it appears, that Hippocrates had reduced it to the determination of two mean proportionals between two given lines; but it had not then excited much attention among geometers. We have already given its history in the introduction to Conic Sections. Plato himself gave a solution, and it was also resolved by Archytas, Eudoxus, Eratosthenes, and Menæchmus. The solutions of eleven of the ancient geometers, are preserved in Eutocius' commentary on Archimedes, *de Sph. et Cyl.*

Trisection of an angle.

It is probable that the *trisection of an angle*, a problem of the same difficulty as the duplication of the cube, was likewise considered in the Platonic school. There is no absolute testimony of its being so ancient; but, according to the natural progress of the human mind, it must have occurred as soon as geometry assumed the form of a science; for the transition from the bisection of an arc to its division into three, or any number of equal parts, or into parts which have a given ratio to one another, is easy. The quadratrix, a curve almost as old as the time of Plato, appears to have been invented with a view to the solution of the problem in its most general form. One difficulty in the problems

History.

of doubling a cube, and trisecting an angle, must have arisen from the impossibility of resolving them by straight lines and circles alone; and of this the ancient geometrical analysis gave no certain indication. The modern analysis teaches how to resolve every such problem, and also shews by what lines it may be effected.

These discoveries must be attributed to the Platonic school in general; for it is impossible to say with whom each originated. Some of advanced years frequented the school, as friends of its celebrated head, or out of respect for his doctrines; and others, chiefly young persons, as disciples and pupils. Of the first class were Laodamus, Archytas, and Theætetus. Laodamus was one of the first to whom Plato communicated his method of analysis, before he made it public; and he is said by Proclus to have profited greatly by this instrument of discovery. Archytas was a Pythagorean of extensive knowledge in geometry and mechanics. He had a great friendship for Plato, and frequently visited him at Athens; but in one of his voyages he perished by shipwreck. Theætetus was a rich citizen of Athens, and a friend and fellow-student of Plato under Socrates, and Theodorus of Cyrene, the geometer. He appears to have cultivated and extended the theory of the regular solids.

Laodamus, Archytas, Theætetus.

The progress that geometry had then made, from the time of Hippocrates of Chios, required that the elements of the science should be new modelled. This was done by Leon, a scholar of Neoclis, or Neoclide, a philosopher who had studied under Plato. To Leon has been ascribed also the invention of that part of the solution of a problem called its *determination*, which treats of the limits, or the cases in which it is possible. Eudoxus of Cnidus was one of the most celebrated of the friends and contemporaries of Plato. He generalized many theorems, and thereby greatly advanced geometry. It is believed that he cultivated the theory of the conic sections; and its invention has been attributed to him. He resolved the problem of the duplication of the cube; and it is to be regretted that Eutocius, who despised his solution, has not thought fit to record it with the others, in his Commentary on Archimedes. Diogenes Laertius has attributed to him the invention of curve lines in general; from which we may infer, that other curves than the conic sections were known in the school of Plato. Archimedes says, in the beginning of his treatise on the sphere and cylinder, that Eudoxus found the measure of the pyramid and cone, and that he had treated of solids; and others again have supposed, that he was the author of the theory of proportion as given in the fifth book of Euclid's Elements.

Leon.

Eudoxus. Died 368 A. C.

Passing over various geometers who are said to have distinguished themselves, but of whom hardly any thing more than the names are now known, we shall only mention Menæchmus, and his brother Dinostratus. The former extended the theory of conic sections, insomuch that Eratosthenes seems to have given him the honour of their discovery, calling them *the curves of Menæchmus*. His two solutions of the problem of two mean proportionals, are a proof of his geometrical skill. Several discoveries have been given to Dinostratus; but he is chiefly known by a property which he discovered of the *quadratrix*, a curve supposed to have been invented by Hippias of Elis.

Menæchmus, Dinostratus.

After the death of Plato, his school was divided into two, which, upon some points, held opposite sentiments, but agreed in regarding a knowledge of the mathematics as absolutely necessary to such as would study philosophy. Thus the geometrical theories which had been cultivated with so much ardour in his lifetime, still continued to make progress. Xenocrates, the successor of Plato after Speusippus, wrote on geometry and arithmetic. The principal geometers were all bred in the Platonic school, and among these probably we ought to reckon Aristæus, who is now little known, because his works are lost: we learn, however, from Pappus, that he was one of the ancients who had made the most progress in their *sublime geometry*. He composed a treatise on solid *loci*, in five books, and another on conic sections, also in five books, which last contained the greatest part of what was afterwards given by Apollonius in the first four books of his work. Pappus placed this work after the conics of Apollonius, in the order of study which he prescribed to his son: This shews that it was a profound theory, and supposed the doctrine of conics to be previously known. He is reputed to have been the friend and preceptor of Euclid.

Xenocrates.

Aristæus.

The progress of geometry among the Peripatetics was not so brilliant as it had been in the school of Plato, but the science was by no means neglected. The successor of Aristotle composed several works relating to mathematics, and particularly a complete history of these sciences down to his own time: there were four books on the history of geometry, six on that of astronomy, and one on that of arithmetic. What a treasure this would have been, had we now possessed it!

The next remarkable epoch in the history of geometry, after the time of Plato, was the establishment of the school of Alexandria, by Ptolemy Lagus, about 300 years before the Christian æra. This event was highly propitious to learning in general, and particularly to every branch of mathematics then known; for the whole was then cultivated with as much attention as had been bestowed on geometry alone in the Platonic school. It was here that the celebrated geometer Euclid flourished under the first of the Ptolemies: his native place is not certainly known, but he appears to have studied at Athens, under the disciples of Plato, before he settled at Alexandria. Pappus, in the introduction to the seventh book of his Collections, gives him an excellent character, describing him as gentle, modest, and benign towards all, and more especially such as cultivated and improved the mathematics. There is an anecdote recorded of Euclid, which seems to shew he was not much of a courtier: Ptolemy Philadelphus having asked him whether there was any easier way of studying geometry than that commonly taught; his reply was, "there is no royal road to geometry." This celebrated man composed treatises on various branches of the ancient mathematics, but he is best known by his Elements, a work on geometry and arithmetic, in thirteen books, under which he has collected all the elementary truths of geometry, which had been found before his time. The selection and arrangement have been made with such judgment, that, after a period of 2000 years, and notwithstanding the great additions made to mathematical science, it is still generally allowed to be the best elementary work on geometry extant. Numberless treatises have been written since the revival of learning, some with a view to improve, and others to supplant the work of the Greek geometer; but in this country, at least, they have been generally neglected and forgotten, and Euclid maintains his place in our schools.

School of Alexandria founded 300 A. C.

Euclid flourished 280 A. C.

Of Euclid's Elements, the first four books treat of the properties of plane figures; the fifth contains the theory of proportion; and the sixth its application to

Euclid's Elements.

History.

Euclid's Elements of Geometry.

plane figures; the seventh, eighth, ninth, and tenth relate to arithmetic, and the doctrine of incommensurables; the eleventh and twelfth contain the elements of the geometry of solids; and the thirteenth treats of the five regular solids, or *Platonic bodies*, so called because they were studied in that celebrated school: two books more, viz. the fourteenth and fifteenth, on regular solids, have been attributed to Euclid, but these rather appear to have been written by Hypsicles of Alexandria.

It is only the first six, and the eleventh and twelfth books, that are now commonly taught in the schools; for the books on arithmetic have been superseded by the modern theories of algebra, and the regular solids have long ceased to be particularly interesting: they may be compared to mines which have been abandoned because the produce was not equal to the expence of working them. Euclid's Elements have had a number of commentators; the earliest was Theon of Alexandria, who lived about the middle of the fourth century. Proclus also has given a commentary on the first book, which is only valuable on account of the information it contains respecting the history and metaphysics of geometry. After the revival of learning, the Elements of Euclid were first known in Europe, through the medium of an Arabic translation; from this it was deciphered and translated into Latin, by Athelard in England, and Campanus in Italy, about the same time, in the 12th or 13th centuries. Athelard's translation exists only in manuscript, in some libraries; that of Campanus served as the basis of the greater part of the Latin translations, made about the end of the 15th and the beginning of the 16th centuries. The *editio princeps* is that which Ratdolt of Augsburg, a celebrated printer, gave in 1482, at Venice, in folio; the Greek text did not appear until 1533, when it was printed at Basle, by J. Hervage, under the care of J. Grynæus. The earliest English edition is that of Bilingsley, in 1570: But the history of the various editions of this work, either in whole or in part, that have been published in all countries, in which science has been cultivated, is far too extensive to find a place here. The curious reader may find a copious list in the second volume of the *Bibliotheca Mathematica*, by Murhard. At present, the edition of Euclid most esteemed in this country, is that of the late Dr Simson of Glasgow, which contains the first six and the eleventh and twelfth books, and the book of Euclid's Data. We have lately seen the first volume of an edition in the original Greek, accompanied with a Latin and French translation by Peyrard, a French professor of mathematics, and author of a French translation of Archimedes; it gives the original text as exhibited in a great number of manuscripts, and on this account it must be extremely valuable.

Euclid's commentators.

Euclid's Data.

Besides the Elements, the only other entire geometrical work of Euclid that has come down to the present times, is his Data. This is the first in order of the books written by the ancient geometers to facilitate the method of resolution or analysis. In general, a thing is said to be given, which is actually exhibited, or can be found; and the propositions in the book of Euclid's Data, shew what things can be found from those which by hypothesis are already known.

We learn from Pappus of Alexandria, that there existed four books by Euclid on Conic Sections, and two concerning *Loci ad Superficiem*; these were curves of double curvature. But his most profound work, and that of which the loss is most regretted, was his three books on Porisms, which Pappus says were a most artful collection of many things that relate to the analysis of the more difficult and general problems. We shall explain this subject under the word PORISM. Proclus cites another work of Euclid's, which he entitles, *De Divisionibus*. This probably treated of the division of figures. These are all the known geometrical writings of Euclid:—his other works do not belong to this place. See EUCLID.

Archimedes. Born 287 A. C.

In the order of time, Archimedes is the next of the ancient geometers that has drawn the attention of the moderns. He was born at Syracuse, about the year 287 A. C. He cultivated all the parts of mathematics, and in particular geometry. The most difficult part of the science is that which relates to the areas of curve lines, and to curve surfaces. Archimedes applied his fine genius to this subject, and he laid the foundation of all the subsequent discoveries relating to it. His writings on geometry are numerous. We have, in the first place, two books on the sphere and cylinder; these contain the beautiful discovery, that the sphere is two-thirds of the circumscribing cylinder, whether we compare their surfaces, or their solidities, observing that the two ends of the cylinder are considered as forming a part of its surface. He likewise shews, that the curve surface of any segment of the cylinder between two planes perpendicular to its axis, is equal to the curve surface of the corresponding segment of the sphere. Archimedes was so much pleased with these discoveries, that he requested after his death that his tomb might be inscribed with a sphere and cylinder.

His book on the *Measure of the Circle*, is a kind of supplement to those on the sphere and cylinder. In this, he demonstrates that any circle is equal to a triangle having its base equal to the circumference, and its height equal to the radius; and he proves, that if the diameter of a circle be reckoned unity, the circumference will be between $3\frac{10}{70}$ and $3\frac{10}{71}$. The principles laid down by Archimedes were sufficient to carry the approximation to any degree of nearness; but he appears to have aimed at nothing more than a simple rule, sufficiently accurate for the common concerns of life.

His treatise on *Conoids* and *Spheroids* relates to the solids generated by the conic sections revolving about their axes: those produced by the rotation of the parabola and hyperbola, he called *Conoids*; and such as are generated by the revolution of the ellipse about either axis are his *Spheroids*. Here he compares the area of an ellipse with that of a circle; he also proves that the sections of conoids and spheroids are conic sections, and he treats of their tangent planes. He proves, for the first time, that a parabolic conoid is equal to three times the half of a cone of the same base and altitude, and he also shews what is the ratio of any segment of a hyperbolic conoid, or of a spheroid to a cone of the same base and altitude. His reasoning is a model of accuracy; and it exhibits the true spirit of the ancient synthetic method; it is however exceedingly prolix and difficult, insomuch that few will have patience to follow the steps of the venerable mathematician, more especially as the same conclusions may be found with equal certainty by the modern analysis, at an infinitely less expence of thought.

Conon.

His treatise on *Spirals* treats of a curve which was the invention of his friend Conon, who it seems had found its properties, but died before he had time to investigate their demonstrations: these Archimedes has supplied. The whole subject is, however, so much his own, that what is properly the spiral of Conon, is usually called the spiral of Archimedes. He has also treated *Of the Equilibrium of Planes, or of their centres of gravity*, in two books; and next *Of the Quadrature of the Parabola*. This is the first complete quadrature of a curve that was ever found. He here shews, that the area of any segment of a parabola cut off by a chord, is two-thirds of the circumscribing parallelogram, and this he proves by two different methods. His *Arenarius* was written to evince the possibility of expressing, by numbers, the grains of sand that might fill the whole space of the universe. Here he introduces a property of a geometrical progression, that has since been made the foundation of the theory of logarithms; but it would be going too far to suppose that Archimedes had made any approach to that valuable invention. This tract is valuable, not on account of the subject on which he treats, but because of the information it contains respecting the ancient astronomy, and the application which it gives of the Greek arithmetic. In addition to the works we have enumerated, there is a treatise *on bodies which are carried on a fluid*, in two books, and a book of *Lemmas*, which is a collection of theorems and problems, curious in themselves, and useful to the geometrical analysis. These are all the writings of Archimedes now extant, but many have been lost.

The writings of Archimedes are the most precious relict of the ancient geometry: they shew to what an extent such a genius as his could carry its method of demonstration; but they likewise prove, that there were certain limits beyond which it became inapplicable, on account of the unwieldiness of the machinery. In general, the progress of discovery is slow; but Archimedes took up the subject where men of ordinary capacities were at a stand, and, by the vigour of his mind, anticipated the labour of ages: he was undoubtedly the Newton of antiquity.

Eutocius has written a commentary on a part of the works of Archimedes, viz. on the books *De Sphæra et cylindro, de dimensione circuli et de æquiponderantibus*. In the year 1543, Nicolas Tartalea translated from Greek into Latin, and published at Venice, the treatises 1. *De Centris Gravium, &c.* 2. *Quadratura Parabolæ*. 3. *De Insidentibus aquæ, liber primus*; and, in 1555, the two books *De Insidentibus aquæ* appeared at Venice. In 1543, an edition of the works of Archimedes was published at Basle, with the Latin translation of John of Cremona, and revised by Regimontanus. In this, the two books *De Insidentibus in Fluido*, and the *Lemmata* were wanting, but it contained the commentary of Eutocius in Greek and Latin. Other editions of his works, or parts of them, have been given by Commandinus, Renault, Greaves and Foster, Borelli, Barrow, Maurolicus, Wallis, some with commentaries; but these are in a manner superseded by the Oxford edition of Torelli in Greek and Latin, printed in 1792, and the French translation of Peyrard in 4to and 8vo, the latter printed in 1808. For farther information respecting this geometer, see ARCHIMEDES.

Eratosthenes. Born 2?7 A. C.

Eratosthenes flourished in the Alexandrian school, about the time of Archimedes: his extensive acquirements in all branches of knowledge induced the third Ptolemy to make him his librarian. As a geometer, he might rank with Aristæus, Euclid, and Apollonius. His construction of the duplication of the cube, has come down to us in Eutocius' Commentary on Archimedes; and we find it recorded in Pappus, that he wrote two books on a branch of the geometrical analysis, which were entitled *De Locis ad medietates*; these appear to have been conic sections. There is an arithmetical invention attributed to him, by which the prime numbers may be determined. Its nature has been described in our article ARITHMETIC, page 372. It may be presumed that Eratosthenes composed many works; one is said to have been on the conic sections, and others on astronomy, but these are now completely lost.

Apollonius, 240 A. C.

About the time that Archimedes finished his career, another geometer of the highest order appeared. This was Apollonius of Perga, a town in Pamphylia. He was born towards the middle of the third century, before the Christian era, and he flourished principally under Ptolemy Philopater, or towards the end of that century. He studied in the Alexandrian school under the successors of Euclid; and so highly esteemed were his discoveries, that he acquired the name of the *Great Geometer*. It is mortifying to reflect, that sometimes consummate abilities are alloyed with great moral defects; Apollonius had a mind of the highest order, yet he was vain, jealous of merit in others, and always disposed to detraction. He was, however, one of the most inventive and profound writers that has treated of the mathematics, and it was in a great measure from his works that the true spirit of the ancient geometry was to be learnt. In the introduction to our article CONIC SECTIONS, we have had occasion to speak of his treatise on that subject; which contributed principally to his celebrity. The most material of his other works were the following treatises: 1. On the Section of a Ratio; 2. On the Section of a Space; 3. On Determinate Section; 4. On Tangencies; 5. On Inclinations; 6. On Plane Loci: The nature and contents of each of these has been particularly described in our article on ANALYSIS. We have understood that Peyrard, the learned French editor of the works of Euclid and Archimedes, had it in contemplation to give French translations of the writings of Apollonius, as well as the other ancient geometers, as far as they have been preserved; but we fear that the state of France is not likely to be soon favourable to the execution of his views.

The names of several mathematicians of antiquity contemporary with Archimedes and Apollonius, have come down to us. Apollonius has addressed the three first books of his conics to Eudemus of Pergamus, and speaks of him as a good judge in these matters, but he being dead before the fourth book was finished, Apollonius addressed it to Attalus. He says, in his first address to Eudemus, that Naucrates had instigated him to study the conics; and in that which precedes the second book, he requests Eudemus to communicate it to Philonides of Ephesus.

It appears that there was a geometer named Trasideus, who corresponded with Conon of Samos on the conic sections, and another Nicoteles the Cyrenean, who animadverted on some mistakes committed by Conon. Here, then, are five or six geometers besides Apollonius, who all cultivated the theory of conics. The regret which Archimedes expressed for the loss of Conon, gives us reason to think highly of him; but this is almost the only ground upon which we can form an idea of his skill as a geometer.

Dositheus was also a friend of Archimedes, who addressed to him several of his works. It is probable that Nicomedes, the inventor of the conchoid, lived about the period at which we are now arrived. This curve, and the application he made of it to the finding of two mean proportionals, are the only vestiges that now remain of his labours.

Nicomedes.

History.

As we descend towards the commencement of the Christian æra, we find a numerous list of mathematicians, most of whom are chiefly known as cultivators of astronomy, and some as writers on geometry. In this number were Geminus of Rhodes, who composed a work called *Enarrationes Geometricæ,* which consisted of six books; Philo, who gave a solution of the problem of two mean proportionals; Possidonius, who was a geometer, an astronomer, a mechanician, and a geographer. Dionysiodorus, who resolved a difficult problem of Archimedes, namely to divide a hemisphere in a given ratio by a plane parallel to its base; and Theodosius, the author of an excellent treatise on Spherics, in three books, which has been preserved, and which constitutes a part of the precious remains of the ancient geometry.

Possidonius.

Theodosius, 50 A. C.

Menelaus.

The astronomer and geometer Menelaus of Alexandria, lived in the second century of the Christian era: he composed a treatise on Trigonometry, in six books; and another on Spherics, in three books, which is still extant. He appears also to have treated of the geometry of curve lines.

Ptolemy. Born 70 A. D. Died 147.

The astronomer Ptolemy must be reckoned among the geometers of the second century. His work on Optics, which however is now lost, * is supposed to have contained some beautiful applications of geometry.

There were several geometers who flourished in the period of the three or four first centuries of the Christian era; but the exact time of each is not certainly known; as Serenus of Antissensis, who wrote on cylinders and cones; Hypsicles of Alexandria, who wrote two books on regular solids; Perseus Citticus, the inventor of certain lines called *spiriques,* which were curves made by the section of a plane and a solid, formed by the revolution of an arc of a circle about a given axis. Philo of Thyaneus, who appears to have treated of certain curves, which were also considered by Menelaus, but whose nature is not now known. Pappus also mentions Demetrius of Alexandria, as the author of a work which treated of curves, and hence it has been conjectured that the ancients had gone farther into this subject than has been generally supposed.

Serenus

Hypsicles.

We are now come to the period when learning began to decline, so that instead of brilliant discoveries, and original treatises, we have only commentaries and annotations on the works of former times, a presage of the approach of ignorance and barbarism. Of this nature were the works of Pappus, and Theon of Alexandria, two mathematicians who lived towards the end of the fourth century. The former of these, however, ranks in a higher class, on account of the genius displayed in his writings. Geometry is particularly obliged to him for his *Mathematical Collections,* which originally consisted of eight books; but of these, the first and half of the second are now lost. He seems to have intended to collect, into one body, several scattered discoveries, and to illustrate and complete, in many places, the writings of the most celebrated mathematicians, in particular Apollonius, Archimedes, Euclid, and Theodosius; for this purpose he has given a multitude of lemmas, and curious theorems, which they had supposed known; and he has also described the different attempts which had been made to resolve the more difficult problems, as the duplication of the cube, and the trisection of an angle. The preface to his seventh book is inestimably precious, for it has preserved from oblivion many analytical works on geometry, of which we should otherwise have been entirely ignorant. The abridgment which he has given of these is all that remains of the greater number; yet it has served to give a continuity to the history of geometry, and to inspire modern mathematicians with a high opinion of the theories of the ancients. In fact, such of their geometrical writings as have descended to our times are merely elementary; their more recondite works have either been entirely lost, or are only known by the account which Pappus has given of them. The books that remain of Pappus have suffered much from the injuries of time; there are many inaccuracies, and some passages so mutilated as to be hardly intelligible. The original Greek, except some extracts, has never been published. The only translation that has been given, which is by Commandinus, was published at Pesara in 1588, and again, with little variation, in 1660, at Bologna. Commandinus appears to have had access to only one manuscript, which wanted the first two books, and throughout was very faulty. There are, however, several manuscripts of Pappus in the libraries; the university of Oxford possesses two; one has half of the second book, and this part was published, with a Latin translation, in 1688, by Dr Wallis. It treats of arithmetic, so that probably the first two books treated of this subject. The university has already conferred a great favour on geometrical science, by the elegant editions it has given of Euclid, Apollonius, and Archimedes; and it is to be wished that the obligation were increased by an edition of Pappus. Our limits will not admit of a detailed statement of the contents of this valuable work; some account of it may be seen in Dr Hutton's Mathematical Dictionary, and also in Dr Traill's Life of Simson.

Pappus, A. D. 380.

Theon, the associate of Pappus in the Alexandrian school, wrote Scholia, or Notes on Euclid, which Commandinus has given in one of his Latin editions of that author. He is supposed, however, to have greatly vitiated the text; and Dr Simson, the learned editor of Euclid, has bestowed great labour in freeing it from what he supposed to be Theon's interpolations.

Theon.

Theon had a beautiful and accomplished daughter, named Hypatia, who cultivated geometry; and so learned was she in the science, that she was judged worthy to succeed her father in the Alexandrian school. She wrote commentaries on Apollonius and Diophantus, which are now lost. It is infinitely to be lamented that so exalted a being should have had so tragical a fate. This woman, the ornament of her sex and of human nature, fell a sacrifice to the blind fury of a fanatical mob, about the beginning of the fifth century.

Hypatia. Died

The philosopher Proclus, the chief of the Platonics at Athens, transferred thither, in some degree, the seat of the mathematical sciences, towards the middle of the fifth century; although he did not extend geometry, yet he held it in esteem. His very prolix commentary on the first book of Euclid, has made us acquainted with many traits in the history of the ancient geometry, and excited a regret that he did not extend it to the remaining books. Proclus was succeeded in his school by Marinus of Neapolis, who formed with Isidore of Miletus and Eutocius of Ascalon, a kind of succession, which brings the history of geometry down to the reign of Justinian. Marinus wrote a preface to Euclid's book of Data, which Dr Simson has rejected in his edition

Proclus.

Marinus.

Eutocius.

* A Latin translation of the Optics of Ptolemy has lately been discovered in the Royal Library at Paris. M. Le Chevalier Delambre, who mentioned to the Editor this curious fact, has given an analysis of the work in the *Connoissances des Tems* for 1816. See our article OPTICS. ED.

istory.

as of no use. Isidore is said, by Eutocius, to have invented an instrument for describing a parabola, by continued motion.

cles.

It would appear that Diocles lived about this period; he was the inventor of the *cissoid*, a curve contrived for the purpose of finding two mean proportionals. Eutocius also attributes to this geometer a solution of the Archimedean problem concerning the division of a sphere, which we have already noticed; it is highly creditable to him, and shews that he was skilful in the ancient analysis. We may place Sporus, and his master Philo, about this period; the former gave a solution of the problem of two mean proportionals, and the latter extended Archimedes' approximation of the ratio of the diameter to the circumference of a circle, as far as 10,000th parts.

rus.
lo.

The labours of Proclus, and the geometers that followed him, were the last rays which the ancient mathematics scattered upon Greece. The long night of ignorance which elapsed from this time, until the destruction of the Greek empire, produced merely elementary writers, such as in better times would scarce have deserved the name of mathematicians. The school of Alexandria, however, yet existed, and the brilliant times of Euclid and Apollonius might have been renewed, had it not been for the troubles which agitated the East. The taking of Alexandria by the Saracens, gave a mortal blow to the sciences, not only in that celebrated capital, but also throughout the Greek empire. This happened in the year 640 A.D. The Alexandrian library, a treasure of inestimable value, was delivered to destruction, and the finest monument of human genius, the accumulated store of knowledge produced by the exertion of the most enlightened minds in many ages, was expended in heating the public baths of the city. See ALEXANDRIA.

ian
etry.

It is consoling to reflect, that although the followers of Mohammed, at this period, destroyed the sciences, yet they afterwards were entitled to the gratitude of posterity, for the care with which they cherished them. Within less than a century, we find the Arabs cultivating astronomy and geometry. Many of the Greek mathematicians, chiefly such as treat of astronomy, as Euclid, Theodosius, Hypsicles, Menelaus, were translated into Arabic in the reign of Almamon, or soon after; they even then began to study the more sublime geometry, for the four first books of the conics of Apollonius were translated by order of that enlightened prince. At a later period, the remaining books were translated, also Archimedes' treatise on the sphere and cylinder, and probably his other works; and it deserves to be remarked, that the Arabs cite several works of the Greek geometers, concerning which we know nothing; as a treatise on parallel lines, another on triangles, and a third on the division of the circle. We are indebted to the Arabs for the form under which trigonometry is now known. Ptolemy had greatly simplified the theory of Menelaus, yet he employed a laborious rule, called the *rule of six quantities*.

ben
a.

Geber ben Aphla, who lived in the 11th century, substituted, instead of the ancient method, three or four theorems, which are the foundation of modern trigonometry. The Arabs also simplified trigonometrical calculation, by substituting the sines of arcs, instead of the chords of the double arcs; and this was even one of their earliest inventions, for it is found in the writings of Albatenius, who flourished about the year 880 of our era. The names of many Arabian geometers are known, we shall, however, only mention Bagdadin, or Mahomet Al-Bagdadi, (of Bagdad,) the author of an elegant work on mensuration, which has been translated and published in 1570; and Alhazen, the celebrated author of a work on optics, which shews him to have been an excellent geometer. In general, the Arabian geometers had little invention, they were almost all compilers or commentators on the ancients.

History.

Bagdadin.

Alhazen, 1100.

Persian geometry.

Nassir-Eddin, 1270.

Persia has also had its geometers. The most celebrated was Nassir-Eddin Al-Tussi; he wrote a learned commentary on Euclid, which was printed in 1590 at the press of the Medici. He also revised the conics of Apollonius, and wrote a commentary on the subject; this was useful to Dr Halley, in restoring the fifth, sixth, and seventh books of that precious work. The geometer next in esteem was Maimon-Reschid: he wrote a commentary on Euclid, and is said to have indulged in a singular whim: he had conceived such an affection for one of the propositions of the first book of the Elements, that he wore the diagram as an ornament embroidered on his sleeve. Geometry has, in modern times, been respected among the Persians, but they have not made any improvements in the science. The traveller Chardin has given some traits of the pedantry of their literati. "They have given," says he, "a name to every proposition of the Elements. They call the 47th proposition of the first book of Euclid *the figure of the bride*, probably because it is to become the mother of a numerous progeny of other theorems. The 48th proposition, again, they call the *bride's sister*; and they, with reason, denominate geometry *the difficult science*.

Turkish geometry.

The Turks have not altogether neglected geometry. In the libraries of Constantinople, the greater number of the Greek mathematicians may be found translated into Arabic, and some into the Turkish language; but it does not appear that they pay attention to any thing beyond what is contained in Euclid's Elements, and inindeed they have never made one discovery in the sciences.

Hebrew geometry.

There are hardly any traces of geometry among the ancient Hebrews. Every one knows that when Solomon's temple was built, Hiram king of Tyre furnished architects and navigators, a proof that geometry must then have been very little known in Palestine. It was not until the second dispersion among the nations that they began to cultivate the sciences. In the ninth century, the Jews, after the example of the Arabians, began to translate the Greek geometers into their language; but they have discovered nothing whatever in geometry.

Geometry of India.

The researches of the learned have brought to light astronomical tables in India, which must have been constructed by the principles of geometry; but the period at which they have been formed has by no means been completely ascertained. Some are of opinion, that they have been framed from observations made at a very remote period, not less than three thousand years before the Christian æra; and if this opinion be well founded, the science of geometry must have been cultivated in India to a considerable extent, long before the period assigned to its origin in the West: so that many of the elementary propositions may have been brought from India to Greece. The Hindoos have a treatise called the *Suryá Sidhánta*, which professes to be a revelation from heaven, communicated to Meya, a man of great sanctity, about four million of years ago; but setting aside this fabulous origin, it has been supposed to be of great antiquity, and to have been written at least two thousand years before

History.

the Christian era. Interwoven with many absurdities, this book contains a rational system of trigonometry, which differs entirely from that first known in Greece or Arabia: In fact, it is founded on a geometrical theorem, which was not known to the mathematicians of Europe before the time of Vieta, about two hundred years ago. And it employs the sines of arcs, a thing unknown to the Greeks, who used the chords of the double arcs. The invention of sines has been attributed to the Arabs, but it is possible that they may have received this improvement in trigonometry, as well as the numeral characters, from India.

According to the natural progress of knowledge, the sciences of astronomy and geometry must have been long cultivated, and carried to some degree of perfection, before a system of trigonometry would be formed; we may therefore infer, that geometry had an earlier origin in India than the *Suryâ Sidhânta*. It is, however, proper we should state, that the high antiquity both of the Indian astronomy and the *Suryâ Sidhânta* has been controverted; but we cannot find room to enter on this point here. The antiquity of the Indian geometry has been asserted by Bailly in his *Astronomie Indienne*, and Professor Playfair in his *Remarks on the Astronomy of the Brahmins*, Edin. Trans. vol. ii. and *Observations on the Trigonometry of the Brahmins*, Edin. Trans. vol. iv. with great eloquence and strength of reasoning: (See our article ASTRONOMY, p. 585.) On this side of the question, the *Edinburgh Review*, vol. x. p. 455, may also be consulted. And on the opposite side, La Place, *Systeme du Monde*, 2d edit. p. 239; Bentley *On the Hindoo Systems of Astronomy*, in the *Asiatic Researches*, vol. viii.; *Edinburgh Review*, vol. xviii. p. 210; Leslie's *Geometry*, 2d edit. p. 456. Mr Leslie is of opinion, that the Hindoos derived their knowledge of mathematics from the West. In opposition to this, consult Strachey, in the Preface to *Bija Ganita;* and a review of the work in *Edinburgh Review*, vol. xxi. p. 364.

Chinese geometry.

The Chinese are well known to have observed the heavens from the most remote ages, yet they appear to have made little progress in geometry. When the Europeans came among them, it consisted of little more than the rules of mensuration: it is true, they have long known the famous property of a right angled triangle, and in this they have even gone before the Greeks; but this property, which, on account of its various applications, well deserved the sacrifice said to have been offered by Pythagoras to the Muses, has remained sterile in their hands. They did not become acquainted with spherical trigonometry before the 13th century; and then they probably learned it from the Arabs or Persians.

Roman geometry.

The Romans fell far short of the Greeks in their attention to the sciences. The mathematics, in particular, were greatly neglected at Rome; so that geometry, hardly known, went little beyond the measuring of land and the fixing of boundaries. The celebrated Varro, although no mathematician, had some knowledge of geometry, and wrote a treatise on the science, which has been cited by Frontinus and Priscianus under the title of *Mensuralia*. Cicero was not unacquainted with mathematics; although he did not write on the subject, his works contain expressions of esteem for the science. The pains he took to discover the tomb of Archimedes, in Sicily, was a proof that he could estimate the high merit of that illustrious man.

Vitruvius has displayed considerable knowledge in mathematics, particularly in the ninth book of his architecture. We owe to him many notices relating to the mechanics and gnomonics of his time.

Boetius, 500 A.

The fifth, sixth, and seventh centuries, present hardly any mathematicians. The senator and Roman consul Boetius, so well known by his misfortunes and his *Consolations of Philosophy*, was, in regard to the time, one of the most versed in mathematics. It was by his care that the Greek authors, as Nicomachus, Ptolemy, Euclid, &c. begin to be a little known in the Latin tongue. His geometry is a kind of free translation of Euclid.

Beda, 70

Alcuin, 750.

The beginning of the eighth century was brightened by the learning of Beda; he understood all the branches of mathematics, then so little known, but he attended chiefly to astronomy. It is a curious fact, that at this period mathematics were more cultivated in Britain than in any other part of Europe. This country produced Alcuin, who studied under Beda; he was well skilled in mathematics, and master to Charlemagne. The exertions of Alcuin and his exalted pupil to revive the sciences were unavailing: the light of science was almost extinguished, and the human mind enveloped in the darkness of ignorance; insomuch, that there is no trace of a single mathematician to be found during a period of 150 years preceding the middle of the tenth century. However, about that period a few scattered rays shot across the gloom. The monk Abbo, a man eminently endowed with a taste for knowledge, and in particular for mathematics, then hardly known, had made the monastery of Fleuri a school celebrated for its learning. Among his scholars was Gerbert, afterwards elevated to the pontificate by the name of Silvester II. His desire for learning could not be gratified by what was known among the Christians; he therefore travelled into Spain, and studied among the Arabs, in their celebrated schools of Cordova and Grenada. He soon went beyond his masters in mathematics, and on his return to France he wrote a book on geometry, which has been published by the learned authors of *Thesaurus Anecdotorum Novissimus*, and from which it appears that he was acquainted with the geometry of Euclid and Archimedes. It is a work on practical geometry, in which he gives rules for measuring heights and distances, by means of an instrument which he calls *Horoscopus*.

Abbo.

Gerbert 960 A.

Adelbo

Herm

Gerbert had imitators in his own age, and in that which followed it. Among the first was Adelbold, who wrote a small treatise on the solidity of the sphere. It appears he knew what had been done in this matter by Archimedes, but his own reasoning is vague and ungeometrical. About the year 1050, Hermann Contractus wrote several treatises on mathematics, and in particular one on the quadrature of the circle.

Adhel. 1130.

Robert Readi 1143.

Bacon Born Died

The twelfth century, notwithstanding the ignorance of the period, presents some mathematicians. The English monk Adhelard travelled into Spain and Egypt; and on his return he translated Euclid from Arabic into Latin. He appears to have been the first that made this author known in the West; but his work exists only in the libraries. Adhelard had various imitators among his countrymen, as Daniel Morlay, Robert of Reading, William Shell, Clement Langtown: They lived towards the end of this century, as did also Robert, bishop of Lincoln, called *Grotshead*, the author of a short treatise on the sphere, and his brother Adam Marsh. Roger Bacon, himself a mathematician, and their cotemporary in his youth, speaks highly of their skill in geometry. Passing over various writers on astronomy, we shall only farther mention Plato of Tivoli, who, about the year 1120, translated the Spherics of Theodosius from the Arabic into barbarous Latin.

Sacro-Bosco. Died 1256.

Campanus.

The thirteenth century was brilliant when compared with the ages that had gone before; it was the twilight of that bright day which has enlightened Europe for upwards of 200 years. Among the mathematicians of this time may be reckoned John of Halifax, called also *Sacro-Bosco*, who wrote a treatise on the sphere, and Campanus of Navarre, the celebrated translator of Euclid, and the author of a treatise on the quadrature of the circle; in which he has supposed that the approximate ratio found by Archimedes was quite exact; and proceeding on this, he has resolved some problems relating to the circle: His paralogism is excusable in consideration of the time in which he lived. The celebrated Albertus Magnus wrote on geometry in this century.

Albertus Magnus. Died 1280.

It is instructive to reflect upon the principles in human nature, by which, after ignorance has debased the mind, knowledge is again renovated. In the dark ages, when the true causes which bring about natural events were unknown or but little understood, the principle in the mind, by which men are led to suppose co-existing events as somehow connected, made them conjecture that the motions of the heavenly bodies, the most striking phenomena of nature, were closely connected with the common events of life. In this way, probably, astrology became a disease of the mind in the absence of genuine knowledge; but in pursuit of this delusion, it was necessary to cultivate astronomy, and this science again required the immediate aid of geometry. Thus we see, that from the very nature of the human understanding, it has a tendency to emerge from ignorance, and that probably we are indebted for the restoration of the ancient astronomy and geometry to the vain speculations of judicial astrology.

Wallingfort.

During the 14th century, England was fertile in mathematicians. They wrote treatises on arithmetic and geometry, but chiefly on astronomy. Their works, however, have chiefly remained in the public libraries. The most remarkable was Richard Wallingfort, who raised himself from an obscure condition by his merit. The science of geometry claims also the poet Chaucer as one of its cultivators. Even at this time, Britain gave indications of the approach of that brilliant æra of discovery, which will for ever render her illustrious among the nations.

Purbach. Born 1423. Died 1461.

Muller. Born 1436. Died 1475.

The period now approached in which geometry was to recover more than its original splendour. Its principal promoters were then Purbach and John Muller, called also Regiomontanus. They greatly improved trigonometry, and formed the resolution of travelling together into Italy, to study the Greek tongue; but Purbach dying, Regiomontanus went alone, and accomplished his purpose. Thus prepared, he translated the Almagest of Ptolemy from the original. He also gave Latin versions of the spherics of Menelaus, those of Theodosius, and his other astronomical treatises: besides, he corrected, by the Greek text, the ancient version of Archimedes made by Gerrard of Cremona. He translated the Conics of Apollonius, the Cylindrics of Serenus, and others of the ancient mathematicians. He commented on certain books of Archimedes, which Eutocius had passed over: he defended Euclid's definition of proportionals against Campanus; and he refuted a pretended quadrature of the circle by Cardinal Cusa.

Purbach rejected the ancient sexagesimal division of the radius, and instead of it he supposed it to be divided into 600,000. Regiomontanus, again, improved on Purbach; and, dividing the radius into 1,000,000 parts, he calculated new tables for every degree and minute of the quadrant, adding, for the first time, the tangents. It was Purbach that invented the geometrical square, and he appears to have been the first that applied the plumb line to mark the divisions on instruments.

De Burgo. 1480.

Lucus Pacciolus, or De Burgo, must be reckoned one of the distinguished cultivators of geometry of this period. He revised Campanus's translation of Euclid, but his labours did not appear until 1509. His work, *Summa de Arithmetica Geometria*, &c. 1494, contains a tolerable treatise on geometry. The progress which had now been made in the Greek tongue, and the invention of printing, contributed greatly to the dissemination of geometrical knowledge. The Greek mathematicians began now to be known in Europe; and Euclid was printed for the first time at Venice in 1482, in a folio volume, by Erhard Ratdolt, one of the first printers of the age: its title was, *Præclarissimus liber Elementorum Euclidis perspicacissimi in artem geometriæ incipit quam felicissime.* And at the end we read, *Opus Elementorum Euclidis Megarensis in geometricam artem; in id quoque Campani perspicassimi commentationes. Erhardus Ratdolt, Augustensis impressor Solertissimus, Venetiis impressit, anno salutis* MCCCCLXXXII. *Oct. cal. Junii. Lector vale.* On the back of the title-page, there is a dedication to the reigning Doge.

Commandinus. Born 1509. Died 1575.

Campanus's translation of Euclid was made from an Arabic manuscript; but in 1505, Zamberti gave a translation from the original Greek. In the year 1518, the spherics of Theodosius appeared for the first time; and in 1537, there came out a translation of the first four books (the only ones then known) of Apollonius by Memmius. But although Zamberti and Memmius might be good Greek scholars, they had little geometrical knowledge; and hence their translations were in some measure imperfect. Commandinus possessed both qualifications, and on that account succeeded better. He translated into Latin, and published in 1558, a part of the works of Archimedes, with a commentary. The two books on floating bodies, of which the Greek text has never been found, were published by him in 1565. He gave, in the following year, the first four books of Apollonius's conics, with the commentary of Eutocius, and the lemmas of Pappus. His Latin translation of Euclid appeared in 1572. Geometry is also indebted to him for a treatise on *Geodesia*, or the divisions of figures, by an Arabian geometer: the original was furnished by John Dee, an English mathematician. But his last and most important work was his translation of the mathematical collections of Pappus, the only one that has yet appeared. It is probable that, had it not been for his zeal in the cause of mathematics, this treasure of geometrical knowledge would still have been buried in the dust of libraries. Commandinus died in 1575, and his Pappus was printed after his death in 1588.

Maurolycus. Born 1495. Died 1575.

Maurolycus of Messina distinguished himself both by his editions of the ancients and his original works. In 1558, he published a new translation of the spherics of Theodosius from the Greek; to this he joined the spherics of Menelaus from the Arabic, and two new books as a supplement. He prepared an edition, or rather imitation of Archimedes, which was printed after his death; and he treated of the conic sections, deducing them elegantly from the cone itself. He made the

History.

useful remark in dialling, that the shadow of the top of a style describes a conic section on a plane.

Tartalea. Born 1479. Died 1557.

Tartalea, one of the earliest cultivators of algebra, contributed likewise to the revival of geometry. He made a translation of Euclid's Elements into Italian, which appeared in 1547. He also gave a Latin translation of part of Archimedes in 1543; he demonstrated the rule for finding the area of a triangle from its three sides; but the rule itself is probably of great antiquity, as it occurs in the Geodesia of Hero the younger.

The very prolix commentary of Proclus on Euclid, was given in a Latin translation by two mathematicians, Napolitain and Barozzi. And there were many other translators that would deserve notice in a history of geometry, if our limits would permit; but we cannot find room to notice particularly all the cultivators of the science in the 16th century. We shall therefore only mention a few; as Clavius, whose translation and commentary on Euclid are still esteemed; Benedictus, or Benedetto, mathematician to the Duke of Savoy, whose writings shew that he was well acquainted with the ancient geometrical analysis; Wolfius, who wished to demonstrate even the axioms of geometry; and Ramus, the author of various esteemed works on the science.

Clavius. Born 1537. Died 1612.

Ramus. Born 1515. Died 1572.

Vieta. Born 1540. Died 1603.

The celebrated Vieta, who flourished in France towards the end of the 15th century, deserves particular notice. He was profoundly skilled in the ancient geometry, and he restored the book of Tangencies of Apollonius, in his *Apollonius Gallus*, an exquisite model of geometrical elegance. He was the first that carried the approximate value of the ratio of the diameter of a circle to its circumference as far as eleven figures; and to him we owe the doctrine of angular sections, one of the most elegant theories in geometry.

Metius. Died 1636.

Romanus. Died 1625.

The Low Countries produced several geometers of distinguished merit; as Metius, who found a very convenient approximation to the ratio of the diameter of a circle to its circumference, viz. that of 113 to 355; and Adrianus Romanus, a geometer much esteemed in his time. He carried the approximation to the circumference of the circles as far as 17 decimal figures; and hence he was the plague of all the pretenders to its quadrature; for he was in every case able to shew, that the lines which they supposed equal to the circumference, were either greater than a polygon described about the circle, or else less than a polygon inscribed in it. In this way he refuted Joseph Scaliger, who imposed upon himself the task of squaring the circle as an amusement, just to shew his superiority to the plodding mathematicians, who had long sought it in vain. He wrote a treatise on Trigonometry, and was very successful in simplifying the number of cases.

Nonius. Born 1497. Died 1577.

Spain and Portugal can number only two geometers of note; the one was Nonius, or Nunez, who determined elegantly the time of the shortest twilight, a problem which seems for a long time to have puzzled James Bernoulli. The other was John of Royas, a Castilian, the inventor of a projection of the sphere.

Record. Died 1558.

Dee. Died 1608.

Wright. Died 1615.

At this period, England abounded in mathematicians. Robert Record, John Dee, Leonard and Thomas Digges, and H. Billingsley, all concurred in cultivating geometry. We are particularly indebted to Edward Wright for the invention of his chart, which is improperly called Mercator's. His book on the correction of certain errors in navigation, indicates a geometry beyond that of his time.

Werner. Born 1468. Died 1528.

Germany then produced but few geometers; it might, however, boast of John Werner of Nuremberg. He wrote on the conic sections; he attempted to restore Apollonius's treatise on the section of a ratio; he also translated Euclid from Greek into German, and cultivated trigonometry. His writings, however, have not been printed. Other German mathematicians did not cultivate so sublime a geometry. Rheticus extended the trigonometrical tables, and improved them by inserting the secants; and Pitiscus still farther extended them in his *Thesaurus Mathematicus sive Canon Sinuum*, &c. which contains the sines of every tenth second of the quadrant to 16 figures, and for every second of the first and last degree to 26 figures, together with the first, second, and in some cases the third differences. This is one of the most remarkable monuments of human patience, and is so much the more meritorious, that it was not accompanied with much renown.

Rheticus. Born 1514. Died 1576.

Pitiscus. Died 1613.

We now enter upon the 17th century, the most fertile of any in mathematical discoveries: in fact, the progress since made in the science is little more than their expansion; and whatever perfection it may attain in future ages, a great share of the glory will belong to the period at which we are now arrived.

L. Valerius 1604.

One of the earliest geometers of the 17th century was Lucas Valerius, an Italian, and Professor of Mathematics at Rome. He determined the centre of gravity in complete conoids and spheroids, as well as in their segments cut off by planes parallel to the base. Archimedes had resolved this problem only in the case of the parabolic conoid; and Commandinus had extended the subject a little farther, to the easiest cases; but Valerius went beyond them both.

Ghetaldus. Died 1609.

Marinus Ghetaldus, a native of Ragusa, was well acquainted with the ancient geometry. Guided by the indications of Pappus, he attempted to restore the lost book of Apollonius on *Inclinations*, in a work called *Apollonius Redivivus*. He also wrote a supplement to the *Apollonius Gallus* of Vieta. He died on a mission to Turkey in 1609.

Anderson.

Alexander Anderson was one of the earliest of the Scottish geometers. He appears to have been a friend or scholar of Vieta, some of whose posthumous works he published. He was well acquainted with the geometrical analysis; and of this he has given proof in his *Supplementum Apollonii Redivivi*, where he endeavours to supply what Ghetaldus has left incomplete in his work. See ANDERSON.

Ceulen. 1619.

The Low Countries produced in this period several mathematicians, whose labours were conducive to the progress of geometry. Ludolph Van Ceulen claims attention, on account of the immensely long calculation by which he determined that the diameter of a circle being supposed 1, the circumference will be between the number

$$3.14159,26535,89793,23846,26433,83279,50288,$$

and the same number increased by unity in the last figure. It must be acknowledged that there was more patience than genius displayed in this effort; for he proceeded simply after the manner of Archimedes, inscribing polygons in a circle, and describing others of an equal number of sides about it, until he found an inscribed and circumscribing polygon to agree in 36 figures. After the example of Archimedes, he desired that this, his greatest discovery, should be inscribed on his tomb. Geometry, however, derived more real service from his other labours.

Snellius Born 15.. Died 16..

Willebrod Snellius was another of the Dutch mathematicians: At the age of seventeen, he undertook to restore Apollonius's book of *Determinate Sections*, and

History.

he published his divination with the title *Apollonius Batavus.* He also treated of the approximate value of the circumference of a circle in his *Cyclometria.* He here shewed how Van Ceulen might have greatly shortened his labour by two limits nearer to the circumference than the circumscribing and inscribed polygons; and he verified the calculation, by computing the perimeter of a polygon of 1073741824 sides, which, according to the other method, would have given only 20 figures of the number.

Girard. Died 1633.

Albert Girard, another Fleming, was highly estimable as a geometer. He was the first that found the surface of a spherical triangle, or of a polygon bounded by great circles on the sphere. He deserves still more honour, however, for his divination of the *Porisms* of Euclid, if, as he asserted, he really had succeeded in restoring the work of the ancient geometer. Unfortunately his labours on this subject have never been published.

Kepler. Born 1571. Died 1630.

Want of room obliges us to pass over several whose reputation as geometers is excelled by that which they acquired in other branches of mathematics: we must not, however, omit the celebrated Kepler; he was the first that had the boldness to introduce the name and the idea of infinity into the language of geometry. The circle he considered as composed of an infinite number of triangles, having their vertices at the centre, and of which the bases form the circumference; and the cone, as made up of an infinite number of pyramids, whose bases formed its base, and which had with it a common vertex.

By the aid of these, and similar views, Kepler, in his *Nova Stereometria,* a work on gauging, demonstrated, in a direct manner, and with great brevity, those truths which the ancients had established by tedious and very peculiar modes of reasoning. Kepler opened in this book a vast field for speculation; for, passing beyond the views of Archimedes, he formed a multitude of new bodies, and he investigated their solidities. Archimedes limited his enquiries to those generated by the rotation of conic sections about an axis, but Kepler treated of solids generated by the rotation of these curves about any line whatever in their plane. He thus considered ninety solids besides those handled by the Sicilian geometer. Upon the whole, this book contained views which appear to have had great influence on the improvements that soon afterwards took place in geometry.

Guldin. Born 1577. Died 1643.

The problems proposed by Kepler probably led to the invention of the methods of Guldin and Cavallerius. The principal discovery of Guldin consisted in an application which he made of a property of the centre of gravity, to the measure of solids produced by revolution. "Every figure," says he, "formed by the rotation of a line, or a surface about an immoveable axis, is the product of the generating quantity by the line described by its centre of gravity. This principle, certainly one of the most beautiful discoveries in geometry, was however known in the days of Pappus; for it is distinctly stated at the end of the preface to his seventh book; yet Guldin takes no notice of the circumstance.

Cavallerius. Born 1598. Died 1647.

To Cavallerius we are indebted for the doctrine of indivisibles, which he published in 1635. In this, he considered a line as made up of an infinite number of points, a surface, of an infinite number of lines, and a solid, of an infinite number of surfaces: these elements of magnitudes he called *Indivisibles.* The introduction of so bold a postulate into geometry, was opposed by some of his contemporaries; but in answer, the Italian geometer explained that this hypothesis was by no means an essential part of his theory, which, in fact, was the same as the ancient method of exhaustions, but free from its tedious and indirect modes of reasoning.

In the first place, he considered such figures as had their increasing or decreasing elements at equal heights above the base, always in a given ratio; and he shewed that the figures themselves were to each other in the same given ratio. Next, he compared figures composed of an increasing or decreasing series of elements, with others in which the elements were all equal: for example, a cone, which he considered as composed of an infinite number of circles, increasing from the base to the vertex, with a cylinder, which is composed of an infinite number of circles, all of the same size; and to determine the ratio of the contents of the two solids, he found the ratio of the sum of the decreasing circles in the cone, to the sum of the circles which were equal to one another in the cylinder. In the cone, these circles decrease from the base to the vertex as the squares of the terms of an arithmetical progression. In other solids, they form other progressions: for example, in the parabolic conoid, it is simply that of an arithmetical progression. The general object of the method is to assign the ratio of this sum of an increasing or decreasing series of terms with that of the equal terms which form an uniform and known figure of the same base and altitude. The method of indivisibles is now superseded by the more extensive doctrine of fluxions; yet it was of immense importance at the time it was invented, and in fact was one step towards that grand discovery.

Fermat. Died 1665. Roberval. Born 1602. Died 1675.

The French geometers pursued the same career of discovery, and almost at the same time as Cavallerius; they even resolved more difficult problems. In 1636, Fermat had found the area of a spiral, of a different nature from that which Archimedes had handled; and soon afterwards, he proposed to Roberval to determine the areas of parabolic curves of the higher orders, (See FERMAT.) Roberval quickly resolved the problem; and he also determined their tangents. Fermat, again, on his part, found their centres of gravity. Roberval claimed the merit of having invented for himself a theory altogether similar to that of Cavallerius, before the latter had made his known; but as his selfish views led him to conceal it, that he might triumph over his contemporaries, he has but little claim on the gratitude of posterity as a discoverer, although he deserves credit for his skill as a geometer. Roberval did not venture to deviate so much from the common language of geometry as Cavallerius; he conceived his surfaces and solids to be made up of an indefinite number of very narrow rectangles and thin prisms, which decreased according to a certain law.

Descartes. Born 1596. Died 1650.

The celebrated Descartes contributed in no small degree to the developement of these new and brilliant discoveries in geometry. When Mersennus had sent him an account of Fermat's method of finding the centre of gravity of conoids, Descartes quickly sent him the determination of the centres of gravity of all parabolas, also their general quadrature, their tangents, and the ratios of their conoids.

It was in this period that the logarithmic spiral and cycloid were brought into discussion; the former was suggested by Descartes, the latter was first noticed by Galileo. See EPICYCLOID.

Pascal. Born 1623. Died 1662.

Passing over many geometers of ordinary merit, we must notice Pascal, who, at the age of twelve, had such a turn for geometry, that he undertook to construct a system for himself, guided by the recollection of the conversations which he had heard among the mathematicians that visited his father, who was himself a mathematician. He had gone as far as to discover that the three angles of any triangle were equal to two right angles, when he was observed by his father. At the age of 16, he is said to have composed a treatise on conic sections, in which all that Apollonius had demonstrated was elegantly deduced from a single proposition: this was shewn to Descartes, but the philosoper could not believe it to be the work of so young a geometer. The hopes he had so early excited, and the elegance of his disquisitions on the cycloid, gave geometers reason to regret that a larger portion of his short life was not dedicated to the science. He died in 1662, aged 39.

Gregory St Vincent. Born 1584. Died 1667.

Gregory St Vincent, a Flemish mathematician, held a respectable place among the geometers of his day. The main object of his researches was the quadrature of the circle, which he sought with the most persevering industry through all the difficulties of the geometry of his time. He even believed he had succeeded; but in this he was wrong: his researches, however, procured him a rich harvest of other geometrical truths.

Tacquet. Died 1660.

Andrew Tacquet, another Flemish mathematician, was a respectable geometer. He endeavoured to extend the boundaries of the science by a treatise on the mensuration of the surface and solidity of bodies formed by cutting a cylinder in different ways by a plane, and of different solids formed by the revolution of segments of circles and conic sections. In treating of these, he has affected the rigorous style of the ancient demonstration, a thing not entitled to commendation, considering that it was by adopting a more brief style, and new views, that the science was then receiving great improvement.

Huygens. Born 1629. Died 1695.

The celebrated Huygens was one of the brightest ornaments of that period. At an early age, he published his *Theoremata de Circuli et hyp. quad.* He completed what Snellius had done concerning approximations to the circle, in his work *De Circuli Magnitudine inventa*; these were the labours of his youth: afterwards he found the surface of conoids and spheroids, a problem which, on account of its difficulty, had not been attempted before his time. He determined the measure of the cissoid; he shewed how to reduce the problem of the rectification of curve lines to that of quadratures; and he invented the theory of involutes and evolutes. His treatise *De Horologio Oscillatorio*, is the finest specimen that has ever been given of the application of the most profound geometry to mechanics. In short, his name is associated in the history of geometry with some of the most brilliant discoveries that have been made in the science.

J. Gregory. Born 1638. Died 1675.

Our countryman, James Gregory, also stands in the very highest class as a geometer. He treated of the quadrature of the circle, and gave better methods of approximating to it than were known before his time. He attempted to shew that the complete solution of the problem was a thing impossible; but the correctness of his reasoning was questioned by Huygens. In 1668, Gregory published his *Geometriæ pars Universalis*, which gave the first idea of the logarithmic curve, and contained many curious theorems useful for the transformation and quadrature of curvilineal figures, for the rectification of curves, and for the measure of their solids of revolution, &c. He wrote various other works, some of which belong rather to the modern analysis than to the ancient geometry. The excellence of his writings, and their rareness, has induced Mr Baron Maseres to reprint them at his sole expence, as a testimony of his estimation of the author's merit, and to make the elegance of his views, and the extent of his claims as a discoverer, better known. Our mathematical readers will readily recollect, that this is not the only obligation of the kind that this worthy man has conferred upon science. See GREGORY.

Barrow. Born 1630. Died 1677.

Dr Barrow next claims our attention by his admirable geometrical writings; his geometrical lectures are composed partly in the style of the ancient, and partly in that of the modern geometry. He had the high honour of being the geometrical tutor of Newton, to whom he resigned his mathematical professorship, with a view to dedicate his time to theological studies; but seduced from his purpose by his favourite science, he did homage to it, by giving an edition of the writings of Archimedes, Apollonius, and Theodosius. Such was this excellent man's estimation of geometry, that he considered the contemplation of it as not unworthy of the Deity. The beginning of his Apollonius was inscribed with the words, Θεος γεωμετρει, *Tu autem Domine quantus es geometra*, "God himself geometrizes; O Lord, how great a geometer thou art!"

Torricelli. Born 1608. Died 1647.

In Italy, Torricelli, the disciple of Galileo, cultivated geometry: with such a master, it is easy to conceive any degree of excellence in the scholar. Among other geometrical enquiries, he treated of the solid formed by the rotation of a hyperbola about its asymptote; and he shewed that it had a finite magnitude, a thing which may appear paradoxical, when it is considered that the generating surface is infinitely great.

Borelli. Born 1608. Died 1679.

Borelli also claims attention on account of his editions of Euclid, Apollonius, and Archimedes, works remarkable for their brevity and perspicuity; and also because of his efforts in translating from the Arabic three books of the Conics of Apollonius, which were then supposed to have been lost. See CONIC SECTIONS.

Viviani. Born 1622. Died 1703.

Viviani, another disciple of Galileo, must here also be noticed. His geometrical writings were of the most elegant and valuable kind. We have spoken, in our treatise on CONIC SECTIONS, of his restoration of the Conics of Apollonius; and in our treatise on FLUXIONS, (art. 165.) of his beautiful problem concerning the quadrature of a portion of the surface of a sphere.

We have already noticed some of Descartes's geometrical labours, but his main effort, for which his name will be handed down to posterity with honour, was his application of algebra to geometry; an invention by which the properties of geometrical figures were represented by equations. His *Geometry*, which contains his views on this subject, was published first in 1637. The union of geometry and algebra promoted very much the discovery of the new calculus, the germ of which lay concealed in the method of exhaustions of the ancients, was partly evolved by Cavallerius, and still farther in the arithmetic of infinites of Dr Wallis, and, lastly, fully expanded by Newton and Leibnitz. The history of geometry becomes now interwoven with that of the modern analysis, and is chiefly interesting by the extent to which the science has been carried by that powerful instrument of invention.

Newton. Born 1642. Died 1727.

Although the ancient geometry was thus in a manner supplanted by the modern theories, the science by no means lost its interest. Sir Isaac Newton held it in such esteem, that he delivered his sublime discovery. ries in its language, and established their truth by its peculiar mode of demonstration. The conic sections, one of its earliest and most profound theories, acquired a value by its application to astronomy, far beyond what it ever had when considered merely as an object of intellectual speculation; and the learning and genius of Halley and Gregory were employed in restoring and bringing into view the precious remains of Euclid and Apollonius

1656. 1742. gory. 1661. 1710.

For upwards of a century, the physico-mathematical sciences have very much engaged the attention of mathematicians; but in these, the ancient geometry affords a very limited degree of aid in comparison to the modern: hence no doubt it has happened, that the venerable theories of the ancients have been less noticed. There have, however, been some who have sedulously cultivated them, and endeavoured to restore them to their former importance; and this spirit has been particularly manifested in Britain. It is a curious circumstance, that when the subtile reasonings of the ingenious Bishop of Cloyne had raised doubts as to the justness of the high claims of the doctrine of fluxions, the boast of the modern analysis; the ingenious Maclaurin thought the safest course he could follow, was to call geometry to its aid, and to explain its principles in the clear style, although circuitous manner, of the ancients.

rin. 1698. 1746.

Passing over several foreigners who have cultivated geometry in the 18th century, as well as natives of Britain, for whose particular labours we cannot find room, we must notice the celebrated Scottish geometer Dr Robert Simson. To him we are indebted for a treatise on conic sections, composed on the model of the ancients; also for restorations of the *Plane Loci* of Apollonius, and the books of determinate sections; but more especially for his restitution of the *Porisms* of Euclid: a task which we are not certain was ever accomplished by any geometer before his time; although Albert Girard, as we have already observed, claimed a like honour. His edition of the first six, and the eleventh and twelfth books of Euclid's Elements, has now in a manner superseded all others in this country, and is almost universally taught in our schools.

1687. 1768.

Dr Matthew Stewart, the friend of Simson, was another geometer, whose writings and example have greatly contributed to establish a correct taste for this study in Scotland. His first essay was, a *Collection of General Theorems;* the most elegant of any that are known in the whole compass of mathematics. They were given without demonstrations, except a few of the more simple, which he has proved with a degree of elegance that renders them the finest models of geometrical reasoning. His tracts, physical and mathematical, his essay on the sun's distance, and his solution of Kepler's problem, are attempts to apply pure geometry to the sublimest inquiries in astronomy. His partial success has shewn what may be accomplished by the force of genius; and the points in which he has failed serve also to shew, that even in such a masterly hand, the geometrical method is still limited in its application, and can by no means be compared in power with the modern geometry. This excellent geometer published also a work entitled *Propositiones Geometricæ, More Veterum demonstratæ, ad Geometriam Antiquam illustrandam et promovendam idoneæ,* which we reckon one of the most valuable that could be put into the hands of a student that is previously acquainted with the elements, and is desirous of learning the true spirit of the ancient geometry. To such of our readers as wish to appreciate the high

n 17. d 85.

3

merit of these two geometers, we recommend the Rev. Dr Traill's excellent life of Dr Simson (1812), and an elegant biographical account of Dr Stewart, composed by Mr Playfair, and read before the Royal Society of Edinburgh, (*Edin. Phil. Trans.* vol. i.) See also the articles SIMSON and STEWART in our Work. History.

Regretting that our limits oblige us to omit many British geometers, whose names deserve preservation, we shall yet mention two; the Rev. Mr Lawson, author of a Dissertation on the Geometrical Analysis of the Ancients, and English editions of the Tangencies and Determinate Section of Apollonius; and Dr Horsley, Bishop of St Asaph. This learned prelate has given a restoration of Apollonius' work on Inclinations, also a neat edition, in Latin, of Euclid's Elements, besides other works on geometry. For farther information relative to the history of geometry, the reader may consult the articles ANALYSIS, ARITHMETIC OF SINES, CONIC SECTIONS, CURVES, DIALLING, EPICYCLOID, and other branches of mathematics that are to follow the present article; also the biographical accounts of mathematicians contained in our work. We shall now give a select catalogue of the principal works which have been written on geometry, particularly those which exhibit the progress of its improvement. Such as relate to conics have been already enumerated in CONIC SECTIONS, and those that treat of TRIGONOMETRY, will be indicated in that article.

Lawson. Horsley. Born 1732. Died 1806.

On the history of geometry, consult Montucla, *Histoire de Mathematiques,* (2d edit.) Bossut's General History of Mathematics in French, of which there is an English translation, and Dr Hutton's Dictionary, (2d edit. 1815.)

List of Writers on Geometry.

Euclid, *The Elements of Geometry.* Of this there are very many editions; the first is that of Ratdolt, 1482. There is an elegant Greek and Latin edition of his works by Dr Gregory, Oxford 1703. Perhaps the most valuable is that of Peyrard, in Greek, Latin, and French, of which the first six books are now published. Dr Barrow's edition of all the books, and the *Data,* and Dr Horsley's of the first 12, from the Latin versions of Commandine and Gregory, and the *Data,* are valuable. Simson's edition of the first six, and the 11th and 12th books, and the *Data;* and Playfair's edition, the first six, (the same as Simson's,) and three additional books on solids, are most commonly used.

Euclid's *Porisms* have been restored by Dr Simson in his *Opera Reliqua,* 1776.

Archimedes; the best editions are Torelli's in Greek and Latin, Oxford, 1792; and Peyrard's French translation, Paris, 1808. The first edition of the Greek text was that of Venatorius in 1544.

Apollonius; the writings that have been recovered of this celebrated geometer are:—

1. *The Section of a Ratio;* and, 2. *The Section of a Space.* These have been restored by Snellius, 1607; and by Dr Halley, 1706.

3. *Determinate Section;* Snellius restored these in his *Apollonius Batavus,* 1601. There is an English translation by Lawson, to which is added a new restoration by Wales, 1772. Simson has restored this work in his *Opera Reliqua,* 1776; and Giannini, an Italian geometer, in 1773.

4. *Tangencies;* Vieta restored this in his *Apollonius Gallus,* 1600. Some additions were made by Ghetaldus, and others by Alexander Anderson, in 1612. The labours of Vieta and Ghetaldus have been given in English by Lawson, 1771.

5. *The Plane Loci;* these have been restored by

History.

Schooten, 1656; and Fermat, 1679; but the best restoration is that of Dr Simson, 1749.

6. *The Inclinations*; these were restored by Ghetaldus, in his *Apollonius Redivivus*, 1607: To this there is a Supplement by Anderson, 1612. There is also a restoration by Dr Horsley, 1770; and another by Reuben Burrow, 1779.

Theodosius and Menelaus: These were published by Maurolicus in 1558, and Burrow gave Theodosius in 1675. There is also an Oxford edition by Hunter, in 1707.

Proclus, *Commentariorum in Primum Euclidis librum Libri* iv. *Latine vertit F. Baroccius*, 1560. Proclus has also been given in English by Taylor, 1788.

Eratosthenes, *Geometria, &c. cum annot.* 1672.

Veterum Mathematicorum Athenæi, Bitonis, Apollodori, Heronis, Philonis, et aliorum, Opera Gr. et Lat. 1693.

Carnot, *Geometrie de Position*, 1803.

Legendre, *Elements de Geometrie*, ninth edit. 1812.

Leslie, *Elements of Geometry, Geometrical Analysis, and Plane Trigonometry*, 2d edit. 1811.

The three books which Mr Leslie has given on the Geometrical Analysis, are a great acquisition to elementary geometry.

Creswell, *On Geometrical Maxima and Minima.*

To such as are entering on the study of geometry, we would recommend any one of the following works: Simson's Euclid, Playfair's Geometry, Legendre *Geometrie*, Leslie's Geometry. Indeed, we would recommend the perusal of Legendre's work with any of the others. We have chiefly kept it in view in drawing up the following article.

Every one has a distinct idea of a body, or *solid*. It is extended in three directions, that is, it has length, breadth, and thickness. We easily conceive that there is something which bounds a solid, or which separates the space it fills from space in general; that boundary is a *surface*, which can manifestly have only two dimensions, viz. length and breadth.

A surface again has a boundary, or something that may separate a portion of it from the remainder, that is a *line*, which can have but one dimension.

Again, there is something that terminates a line, or which indicates where one portion of it ends, and another begins; this is a *point*, which can neither have length, breadth, nor thickness. Here, then, we have three different species of magnitude, viz. solids, surfaces, and lines, which form the object of geometrical discussion.

The elements of geometry are commonly divided into two Parts; one treats of the properties of lines and figures described upon a *plane* surface; and the other relates to the properties of solids: the former is sometimes called *Plane*, and the latter *Solid* geometry.

Part I. OF LINES AND FIGURES UPON A PLANE.

ples.

We have seen how the general ideas of a surface, a line, and a point, may be acquired from the consideration of a solid. The *elements* of geometry admit of only two lines, the *straight line*, and the *curve*. The straight line serves to determine the nature of the surface called a *plane;* and from both we get a correct notion of a circle. But the nature of these, and the other things to be discussed, will be particularly explained in the following Sections by precise definitions.

SECTION I.

The Principles of Geometry.

Definitions.

itions.

1. A *point* is that which has position, but not magnitude.

2. A *line* is length without breadth.

Cor. The extremities of a line are points, and the intersections of one line with another are also points.

3. A straight line is the shortest way from one point to another.

4. Every line which is neither straight, nor composed of straight lines, is a curve line.

E XX.

Thus, in Fig. 1. Plate CCLXX. AB is a straight line, and ACB a curve line.

5. A *surface,* or *superficies,* is that which has only length and breadth.

Cor. The extremities of a superficies are lines, and the intersections of one superficies with another are also lines.

6. A *plane* superficies is that in which any two points being taken, the straight line between them lies wholly in that superficies.

7. Every surface which is neither a plane, nor composed of plane surfaces, is a *curve* surface.

8. A *plane rectilineal angle* is the inclination of two straight lines to one another, which meet together, but are not in the same straight line. The point in which the lines meet one another is called the *vertex* of the angle; and the lines are called its *sides.* *

N. B. When several angles are at a point A (Fig. 6.) any one of them is expressed by three letters, of which the letter that is at the *vertex* of the angle is put between the other two, and one of these is somewhere upon one of the straight lines, and the other upon the other line. Thus, the angle which is contained by AB and AC is named the angle CAB or BAC; that which is contained by AB and AD is named the angle DAB or BAD; and that which is contained by AC and AD is called the angle CAD or DAC. But if there be only one angle at a point, as in Fig. 2. it may be expressed by a letter placed at that point, as the angle at A, or the angle A.

Principles.

Fig. 7.

9. When a straight line standing on another straight line makes the adjacent angles equal to one another, each of the angles is called a *right* angle; and the straight line which stands on the other is called a *perpendicular.* (Fig. 7.)

Figs. 8. and 9.

10. An *obtuse* angle is that which is greater than a right angle (Fig. 8.); and an *acute* angle is that which is less than a right angle (Fig. 9.)

Fig. 10.

11. *Parallel* straight lines are such as are in the same plane, and which being produced ever so far both ways, do not meet. (Fig. 10.)

Figs. 11, 12, &c. to Fig. 22.

12. A *plane figure* is that which is enclosed by one or more lines on a plane. If the lines are straight, the space they enclose is called a *rectilineal* figure, and the lines themselves are called its *perimeter.* See Fig. 11, 12, &c. to Fig. 22.

13. A rectilineal figure having three sides is named a *triangle;* a figure of four sides is called a *quadrilateral;* that of five sides is a *pentagon;* that of six sides is a *hexagon,* and so on. Figures of more than four sides are likewise called *polygons.*

Figs. 11, 12, and 13.

14. An *equilateral* triangle is that which has its three sides equal (Fig. 11.) An *isosceles* triangle is that which has only two equal sides (Fig. 12.), and a *scalene* triangle that which has all its sides unequal. (Fig. 13.)

Fig. 14.

15. A *right angled* triangle is that which has a right angle. The side opposite to the right angle is called the *hypothenuse* (Fig. 14.)

Fig. 15.

An *obtuse angled triangle* is that which has an obtuse angle (Fig. 15.)

Fig. 16.

An *acute angled* triangle is that which has all its angles acute (Fig. 16.)

16. Among four-sided figures the following are distinguished by particular names:

Fig. 17.

A *square* is that which has all its sides equal, and all its angles right angles (Fig. 17.)

Fig. 18.

A *rectangle* is that which has its angles right angles, but its sides not equal (Fig. 18.)

Fig. 19.

A *rhombus* is that which has all its sides equal, but its angles are not right angles (Fig. 19.)

Fig. 20.

A *parallelogram,* or *rhomboid,* is that which has its opposite sides parallel (Fig. 20.)

Fig. 21.

A *trapezium* is that of which the opposite sides are not parallel (Fig. 21.)

Fig. 22.

A *trapezoid* is that of which only two of the opposite sides are parallel (Fig. 22.)

Fig. 48.

17. The *diagonal* of a figure is a straight line which joins the vertices of two angles which are not adjacent. Thus, in Fig. 48. AC, AD, AE, &c. are diagonals of the figure ABCDEFG.

18. An *equilateral* polygon is that which has all its

* To get an accurate notion of the nature of an angle, we may suppose that the angle contained by the straight lines AB and AC (Fig. 2.) is successively compared with the angles contained by the lines DE and DF (Fig. 3.); and D′E′ and D′F′ (Fig. 4. and 5.) First, suppose that the line AC (Fig. 2.) is placed on the line DF (Fig. 3.), so that the point A may fall on D; then, if AC coincide with DF, the angle contained by AB and AC is equal to the angle contained by DE and DF. But if, when AC is placed on D′F′ (Fig. 4. and Fig. 5.) and A on D′, the line AB do not fall on D′E′, but has another position DG; then the angle contained by AB and AC is not equal to the angle contained by D′E′ and D′F′: It is greater if D′E′ fall between DG and D′F′, as in Fig. 4; but it is less if DG fall between D′E′ and D′F′, as in Fig. 5.

An angle may be made up of several angles; thus, in Fig. 6. the angle contained by the lines AB and AD is the sum of the two angles contained by AB and AC, and by AC and AD. If these are equal, it is double any one of them.

Hence it appears, that like other quantities, angles admit of addition, subtraction, multiplication, and division.

Principles

sides equal; an *equiangular* polygon is that of which all the angles are equal.

19. Two polygons are *equilateral* between themselves when their sides are equal each to each, taken in the same order; that is, when going round the two figures, a side of the one is equal to a side of the other, the next side of the one to the next side of the other, and so on. In a like sense, polygons are *equiangular*. In either case, the equal sides or angles are called *homologous* sides or angles.

Explanation of Terms and Signs.

An *axiom* is a self-evident truth.

A *theorem* is a truth which becomes evident by a process of reasoning called a *demonstration.*

A *problem* is something proposed to be done; or it is a question that requires a solution.

A *lemma* is a truth premised to facilitate the demonstration of a theorem, or the solution of a problem.

The common name *proposition* is given indifferently to a theorem, a problem, or a lemma.

A *corollary* is a consequence which follows from one or several propositions.

A *scholium* is a remark upon one or several propositions going before, tending to explain their connection, their utility, their restriction, or their extension.

A *hypothesis* is a supposition made either in the enunciation of a proposition, or in the course of a demonstration.

For the sake of brevity, it is convenient to employ, to a certain extent, the signs of algebra in geometry. Those we shall chiefly employ are of the most simple nature, viz. the signs $+$, $-$, $=$, $>$, $<$. Their meaning is fully explained in the beginning of ALGEBRA, articles 19, 20, 21, 22, and 23; and to that place we refer the reader. Others that may occur will be explained as we proceed.

AXIOMS.

1. Things which are equal to the same thing are equal to one another.
2. If equals be added to equals, the wholes are equal.
3. If equals be taken from equals, the remainders are equal.
4. If equals be added to unequals, the wholes are unequal.
5. If equals be taken from unequals, the remainders are unequal.
6. Things which are double of the same, are equal to one another.
7. Things which are halves of the same are equal to one another.
8. Magnitudes which coincide with one another, that is, which exactly fill the same space, are equal to one another.
9. The whole is greater than its part.
10. Only one straight line can be drawn from one point to another.
11. Two straight lines cannot be drawn through the same point parallel to the same straight line, without coinciding with one another.

POSTULATES.

1. Let it be granted, that a straight line may be drawn from any one point to any other point.
2. That a terminated straight line may be produced to any length in a straight line.
3. And that a circle may be described on any centre at any distance from that centre. *

NOTE. The references in the following treatise are to be understood thus: (4.) means the 4th Prop. of the section in which it occurs. (Cor. 4.) means the corollary to the 4th Prop. (2. Cor. 4.) means the 2d Cor. to Prop. 4. (4. 3.) means the 4th Prop. in the 3d section of the Part in which it occurs. Again, (5. 4. P. I.) means the 5th Prop. of the 4th section of Part I. and so on.

PROPOSITION I. THEOREM.

All right angles are equal among themselves.

Let the straight line CD be perpendicular to AB, and GH to EF; the angles ACD, EGH shall be equal to one another. Take the four equal distances CA, CB, GE, GF; then AB shall be equal to GF. Suppose now the line EF to be placed upon AB, so that E may coincide with A, and F with B; the lines EF, AB must coincide; for otherwise, two different straight lines might be drawn from one point to another, which is impossible, (Ax. 10.) Therefore the point G, the middle of EF, will fall upon the point C, the middle of AB. Now, the line GE thus coinciding with the line CA, the line GH will coincide with CD; for if it could have any other position, as CK, then because the angle EGH is equal to HGF, by hypothesis, (Def. 9.), it would follow that the angle ACK would be equal to KCB, and consequently the angle ACD would be less than BCK, and therefore much less than BCD, which is impossible, because the angle ACD ought to be equal to the angle BCD, (Def. 9.) Therefore it would be absurd to suppose that GH did not coincide with CD, consequently the angle ACD is equal to EGH. Fig.

PROP. II. THEOR.

Any straight line CD which meets another straight line AB makes with it two adjacent angles ACD, BCD, which taken together are equal to two right angles. Fig.

At the point C, let a straight line CE be drawn perpendicular to AB. The angle ACD is the sum of the angles ACE, ECD; therefore, ACD $+$ DCB shall be the sum of the three angles ACE, ECD, DCB, (axiom 2); the first of these is a right angle, and the two others make together a right angle: therefore, the sum of the two angles ACD, BCD is equal to two right angles.

COROLLARY 1. If one of the angles ACD, BCD is a right angle, the other is also a right angle.

COR. 2. (Fig. 25.) All the angles BAC, CAD, DAE, EAF, which any number of straight lines make with another line BF are together equal to two right angles. Fig. 25.

* According to the strict method of Euclid, before any line is supposed to be drawn, or any figure constructed, the manner of doing it should be shewn. There is, however, some convenience in abating a little of this rigour, so far as to take for granted, that, for the purpose of demonstrating a theorem, lines may be drawn in a proposed manner, and certain figures constructed, although the manner of drawing the lines and constructing the figures may not have been explained. This concession, however, is to be confined entirely to the theorems, and by no means to be extended to the problems.

The three postulates in the text are all that are absolutely requisite in a system of geometry.

Principles.

For their sum is equal to the two angles BAD and DAF, which together make two right angles.

Fig. 26. Cor. 3. (Fig. 26.) All the angles which any number of lines AB, AC, AD, AE, &c. make about a point, are equal to four right angles. For through A draw a straight line PQ, then all the angles which the lines make on each side of PQ, are equal to two right angles: therefore, all the angles on both sides, which make up the angles about A, are equal to four right angles.

Prop. III. Theor.

Fig. 27. If two adjacent angles ACD, DCB are together equal to two right angles, the two exterior sides AC, CB form one continued straight line.

For, if CB be not the continuation of CA, suppose CE to be its continuation; then the sum of the angles ACD, DCE is equal to two right angles, (2.) But by hypothesis, the sum of the angles ACD, DCB is equal to two right angles; therefore ACD + DCE = ACD + DCB (Ax. 1.) And taking from each the angle ACD, there remains the angle DCE equal to the angle DCB (Ax. 3.), a part equal to the whole, which is impossible, (Ax. 9.)

Prop. IV. Theor.

Fig. 28. If two straight lines AB, DE cut each other, the vertical or opposite angles shall be equal.

For because DE is a straight line, the sum of the two angles ACD, ACE is equal to two right angles, (2.); and because AB is a straight line, the sum of the angles ACE. ECB is equal to two right angles, (2.); therefore the sum of the angles ACD, ACE is equal to the sum of the angles ACE, ECB; and taking away from each the common angle ACE, there remains the angle ACD equal to the vertical or opposite angle ECB.

Prop. V. Theor.

Two straight lines which have two common points coincide entirely throughout their whole extent, and form but one and the same straight line.

Fig. 29. Let A and B be the common points; in the first place, the two lines can make but one, from A to B (Ax. 10.) If it were possible that they could separate at C, let us suppose that the one takes the direction CD, and the other the direction CE. At the point C, suppose CF to be drawn perpendicular to AC; then, because ACD is by hypothesis a straight line, the angle FCD is a right angle, (Def. 9.); in like manner, because ACE is supposed a straight line, the angle FCE is a right angle; therefore, the angles FCD, FCE are equal, (1.); but this is impossible, (Ax. 9.); therefore, the straight lines which have two common points A, B cannot separate, but must form one continued line.

Prop. VI. Theor.

Two triangles are equal, when an angle, and the two sides which contain it in the one are equal to an angle, and the two sides which contain it in the other, each to each.

Let the angle A be equal to the angle D, the side AB equal to the side DE, and the side AC equal to the side DF; the triangles ABC, DEF shall be equal. Fig. 30.

Suppose the triangle ABC to be placed upon the triangle DEF, so that AB may be on DE; then, because the angles A and D are equal, AC will fall on DF, and because AB = DE, and AC = DF, the points B, C will fall on the points E, F; therefore the base BC will coincide with the base EF (5.); and the triangles will coincide entirely; therefore they are equal, (Ax. 8.)

Cor. Hence it follows, that the bases or third sides BC, EF are equal, and that the remaining angles B, C of the one, are equal to the remaining angles E, F of the other, each to each, viz. those to which the equal sides are opposite.

Prop VII. Theor.

Two triangles are equal, when a side and two adjacent angles of the one are equal to a side and two adjacent angles of the other, each to each.

Let the side BC be equal to the side EF, the angle B equal to the angle E, and the angle C equal to the angle F; the triangles shall be equal. Fig. 30.

For suppose the triangle ABC to be placed upon DEF, so that their equal bases BC, EF may coincide; then because the angles B, E are equal, the line BA will fall on ED; and because the angles C, F are equal, the line CA will fall on FD; therefore the three sides of the one triangle will coincide with the three sides of the other, and the triangles will be equal.

Cor. Hence it appears that the remaining angles A, D of the triangles are equal, and that the remaining sides AB, AC of the one are equal to the remaining sides DE, DF of the other each to each, viz. those to which the equal angles are opposite.

Prop. VIII. Theor.

Any two sides of a triangle are together greater than the third.

For, in the triangle ABC, the straight line BC is the shortest line that can be drawn from B to C, therefore BC is less than BA + AC. Fig. 30.

Prop. IX. Theor.

If from any point O within a triangle ABC, straight lines OB, OC are drawn to the extremities of the base BC, their sum is less than the sum of the two sides AB, AC. Fig. 31.

Produce BO until it meet AC in D; the line OC is less than OD + DC, (8.), and adding to these unequals BO, we have $BO + OC < BO + OD + DC$, (Ax. 4.); that is $BO + OC < BD + DC$.

In like manner, $BD < BA + AD$; and adding DC, $BD + DC < BA + AD + DC$, that is $BD + DC < BA + AC$; but we have found $BO + OC < BD + DC$; much more then is $BO + OC < BA + AC$.

Prop. X. Theor.

If two sides AB, AC of a triangle ABC are equal to Figs. 32, 33, 34.

Principles. two sides DE, DF of another triangle DEF, each to each, and if the angle BAC contained by the former be greater than the angle EDF contained by the latter; the base BC of the triangle which has the greater angle, shall be greater than the base EF of the other triangle.

Make the angle CAG = D, take AG = DE or AB, and join CG; and because the triangles CAG, DEF have an angle of the one equal to an angle of the other, and the sides which contain these angles equal; CG shall be equal to EF, (6.) Now there may be three cases, according as the point G falls without the triangle ABC, or on the side BC, or within the triangle.

Fig. 32. Case 1st, (Fig. 32.) Because GC is less than GI + IC, and AB less than AI + IB, therefore GC + AB is less than GI + AI + IC + IB, that is, GC + AB $<$ AG + BC; from these unequal sums take away AB, or its equal AG, and there remains GC $<$ BC; but GC = EF, therefore EF $<$ BC.

Fig. 33. Case 2d, (Fig. 33.) If the point G fall on BC, it is evident that GC, or its equal EF, is less than BC.

Fig. 34. Case 3d, (Fig. 34.) Lastly, if the point G fall within the triangle, by Prop. 9. we have AG + GC $<$ AB + BC; and taking away AG from one of these unequals, and AB = AG from the other, we have GC $<$ BC.

Prop. XI. Theor.

Two triangles are equal when the three sides of the one are equal to the three sides of the other, each to each.

Fig. 30. Let the side AB = DE, AC = DF, and BC = EF, then shall the angle A = D, B = E, C = F. For if the angle A were greater than D; then, as the sides AB, AC are equal to the sides DE, DF, each to each, it would follow (10.) that the side BC would be greater than EF: And if the angle A were less than D, then BC would be less than EF: but BC is equal to EF, therefore the angle A can neither be greater nor less than D; therefore A = D. In like manner it may be proved that B = E and that C = F.

Scholium. It appears that in two equal triangles, the equal angles are opposite to the equal sides, for the equal angles A and D are opposite to the equal sides BC, EF.

Prop. XII. Theor.

In an isosceles triangle, the angles opposite to the equal sides are equal.

Fig. 35. Let the side AB = AC, then shall the angle C = B. For suppose AD to be drawn from the vertex A to D, the middle of the base BC: Then the two triangles ADB, ADC will have the sides of the one equal to the sides of the other, each to each, viz. AB = AC, BD = CD, and AD common to both; therefore (11.) the angle ABD shall be equal to the angle ACD.

Cor. An equilateral triangle is also equiangular.

Scholium. It appears by the demonstration, that the angles BAD, CAD are equal; also that the angles BDA, CDA are equal, and consequently right angles (Def. 9.): Therefore *a straight line drawn from the vertex of an isosceles triangle to the middle of the base bisects the vertical angle, and is perpendicular to the base.*

Note. In a triangle not isosceles, any side is taken for the *base*, and the opposite angle is the *vertex*; but in the isosceles triangle, the base is the side which is not equal to the others. Principles.

Prop. XIII. Theor.

Conversely, if two angles of a triangle are equal, the opposite sides are equal, and the triangle is isosceles.

Let the angle ABC = ACB; the side AC shall be equal to the side AB. Fig. 36.

For if the sides are not equal, let AB be the greater of the two. Take BD = AC, and join DC: The angle DBC is by hypothesis equal to ACB, and the two sides DB, BC are equal to the two sides AC, CB; therefore (6.) the triangle DBC is equal to ACB: now this is impossible, (Ax. 9.) for the triangle DBC is only a part of the triangle ACB, therefore AB is not unequal to AC, that is AB = AC.

Prop. XIV. Theor.

Of two sides of a triangle, that is the greater which is opposite to the greater angle; and conversely, of two angles of a triangle, that is the greater which is opposite to the greater side.

1. Let the angle ACB be greater than B; the side AB opposite to the angle C is greater than the side AC opposite to B. For make BCD = B; then in the triangle BCD, because the angles DCB and B are equal, we have DC = DB (12.); but AC is less than AD + DC (8.), and AD + DC = AD + DB = AB; therefore AB is greater than AC. Fig. 37.

2. Next let the side AB be greater than AC; the angle ACB opposite to AB shall be greater than B which is opposite to AC. For if ACB could be less than B; then AB would be less than AC, which is contrary to the hypothesis of the proposition: And if ACB could be equal to B, then AB would be equal to AC, which is also contrary to the hypothesis; therefore ACB must be greater than ABC.

Prop. XV. Theor.

From a point A without a straight line DE, only one perpendicular can be drawn to that line. Fig. 38.

For suppose it possible to draw two, AB, AC; produce one of them, so that BF may be equal to AB, and join FC; and because AB = BF, and BC is common to the triangles ABC, FBC, and the angles ABC, FBC are equal; the angle ACB is equal to FCB (6.) therefore AC and CF must form one continued line (3.); and so, through two points A, F, two straight lines AF and ACF may be drawn, that do not coincide, which is impossible: Therefore it is equally impossible that two perpendiculars can be drawn from the same point to the same straight line.

Scholium. Through the same point C, in a straight line AB (Fig. 24.), it is impossible to draw two perpendiculars to that line: For if CE and CD could be both perpendicular to AB; then ECB and DCB would be both right angles, and equal to one another (1.) which is absurd (Ax. 9.) Fig. 24.

Prop. XVI. Theor.

If from a point A without a straight line DE, a per- Fig. 39.

Principles.

pendicular AB be drawn to that line; and different oblique lines AE, AC, AD, &c. to different points of that line.

1st, The perpendicular AB is shorter than any oblique line.

2d, The two oblique lines AC, AE on opposite sides of the perpendicular, and at equal distances BC, BE, are equal.

3d, Of any two oblique lines AC, AD, or AE, AD, that which is farther from the perpendicular is the greater of the two.

Produce the perpendicular, so that BF = AB, and join FC, FD.

1. The triangles BCF, BCA are equal (6.), for BF= BA, and BC is common, and the angles at B are right angles; therefore CF = CA. Now AF is less than AC+CF, (8.) therefore, taking the halves, AB is less than AC; that is, the perpendicular is the shortest line that can be drawn from A to DE.

2. Next suppose BE=BC; then the triangles ABE, ABC will be equal (6.); for they have also BA common, and the angles ABE, ABC equal, therefore AE=AC; that is two oblique lines equally distant from the perpendicular on opposite sides are equal.

3. In the triangle ADF, the sum of AC and CF is less than the sum of AD and DF (9.); therefore AC the half of AC+CF, is less than AD, the half of AD+DF; that is the oblique line farther from the perpendicular is greater.

Cor. 1. The perpendicular from a point on a line measures its distance from the line.

Cor. 2. From the same point no more than two equal straight lines can be drawn to terminate in that line.

Prop. XVII. Theor.

Fig. 39. If through the point C, the middle of the straight line AB, a perpendicular be drawn to that line.

1st, Every point in the perpendicular is equally distant from the extremities of the line AB.

2d, Every point out of the perpendicular, is unequally distant from the extremities of the line.

1. Because AC=CB, the two oblique lines AD, DB, which are equally distant from the perpendicular, are equal (16). The same is also true of the two oblique lines AE, EB, and of the two oblique lines AF, FB, &c. Therefore, every point in the perpendicular is equally distant from the ends of the line.

2. Let I be a point out of the perpendicular. If IA, IB be joined, one of them will cut the perpendicular in D; therefore, drawing DB, we have DB=DA. But IB is less than ID+DB, and ID+DB=ID+DA=IA, therefore IB is less than IA; that is, any point out of the perpendicular is unequally distant from the extremities A, B.

Prop. XVIII. Theor.

Two right angled triangles are equal, if the hypothenuse and a side of the one be equal to the hypothenuse and a side of the other.

Fig 40. Let the hypothenuse AC=DF, and the side AB=DE; the right angled triangle ABC shall be equal to the right angled triangle DEF.

The proposition will evidently be true, if it can be proved that BC=EF (11). Let us suppose, if it be possible, that these sides are unequal, and that BC is the greater. Take BG=EF, and join AG. The triangles ABG, DEF, having AB=DE, and BG=EF (by hypothesis), and also having the angle ABG equal to DEF, they will be equal (6); therefore AG=DF, but DF=AC; therefore AG=AC; that is, two oblique lines, one more remote from the perpendicular than the other, are equal, which is impossible (16); therefore BC is not unequal to EF: and hence the triangle ABC is equal to the triangle DEF.

Principles.

Prop. XIX. Theor.

If two straight lines AC, BD, are perpendicular to a third AB, these two lines are parallel; that is, although produced ever so far both ways, they will not meet, (Def. 11.) Fig. 41.

For if they could meet in a point O, on either side of AB, then two perpendiculars OA, OB might be drawn from the same point O, to the same straight line AB, which is impossible, (15.)

Prop. XX. Theor.

If two straight lines AC, BD, make with a third AB two interior angles CAB, ABD, the sum of which is equal to two right angles, these two straight lines are parallel. Fig. 42.

From G, the middle of AB, draw EGF perpendicular to AC; then, because the sum ABD+ABF is equal to two right angles (2.), and by hypothesis the sum ABD+BAC is equal to two right angles, therefore ABD+ABF=ABD+BAC; and taking away the common angle ABD, there remains ABF=BAC; that is GBF =GAE. Besides, the angles BGF, AGE are equal (4.), and BG=GA; wherefore the triangles BGF, AGE have a side and two adjacent angles of the one equal to a side and two adjacent angles of the other; they are therefore equal (7.), and the angle BFG= AEG; but AEG is by construction a right angle; therefore BFG is a right angle; and since GEC is a right angle, the straight lines EC, FD are perpendicular to EF, and are therefore parallel to one another. (19.)

Cor. 1. If two straight lines AC, BD make with a third HK the alternate angles AHK, HKD equal, the two lines are parallel. For then, adding KHC, we have AHK + KHC = HKD + KHC; but the former sum is equal to two right angles (2.), therefore the latter is equal to two right angles; and consequently AC is parallel to BD. Fig. 43.

Cor. 2. If two straight lines AC, BD are cut by a third FG, so as to make the exterior angle FHC equal to the interior and opposite angle HKD on the same side; the two lines are parallel: For since FHC=AHK (4.), then we have AHK = HKD; that is, the alternate angles equal, therefore AC is parallel to BD.

Prop. XXI. Theor.

If a straight line EF meet two parallel straight lines AC, BD, the sum of the inward angles CEF, EFD on the same side, will be equal to two right angles. Fig. 44.

For if not, suppose EG to be drawn through E, so that the sum of GEF and EFD may be two right angles; then EG will be parallel to BD (20.); and thus through the same point E two straight lines EG, EC

Principles are drawn, each parallel to BD, which is impossible, (Ax. 11.); therefore no straight line that does not coincide with AC is parallel to BD, therefore the straight line AC is parallel to BD.

Cor. 1. If a straight line is perpendicular to one of two parallel straight lines, it is also perpendicular to the other.

Fig. 43. Cor. 2. (Fig. 43.) If a straight line HK meet two parallel straight lines AC, BD, the alternate angles AHK, HKD shall be equal.

For the sum CHK+HKD is equal to two right angles; and the sum CHK+AHK is also equal to two right angles (2.), therefore the angle HKD must be equal to AHK.

Cor. 3. (Fig. 43.) If a straight line FG cut two parallel straight lines AC, BD, the exterior angle FHC is equal to the interior and opposite angles HKD.

For since FHC = AHK (4.), and AHK = HKD; therefore FHC = HKD.

Fig. 44. Scholium. If a straight line EF meet two other straight lines EG, FD, and make the two interior angles EFD, FEG on the same side less than two right angles, the lines EG, FD meet, if produced, on the side of EF, on which the angles are less than two right angles. For if they do not meet on that side, they are either parallel, or else they meet on the other side. Now they cannot be parallel, for then the two interior angles would be equal to two right angles, instead of being less. Again, to shew that they cannot meet on the other side, suppose EA to be parallel to DFB; then because the sum EFD + FEG is (by hypothesis) less than two right angles, that is, less than FEK + FEG (2.); and EFD = FEA (Cor. 2. of this Prop.); therefore the sum FEA + FEG is less than FEK + FEG; and, taking FEG from both, FEA is less than FEK; hence FB and EK must be on opposite sides of EA, and therefore can never meet.

The truth of this proposition is assumed as an axiom in the Elements of Euclid, and made the foundation of the theory of parallel lines.

Prop. XXII. Theor.

Fig. 45. Two straight lines AB, CD, parallel to a third EF, are parallel to one another.

Draw the straight line PQR perpendicular to EF. Because AB is parallel to EF, the line PR shall be perpendicular to AB (1. Cor. 21.) And because CD is parallel to EF, the line PR is also perpendicular to CD; therefore AB and CD are perpendicular to the same straight line PQ; hence they are parallel. (19.)

Prop. XXIII. Theor.

Two parallel straight lines are every where equally distant.

Fig. 46. Let AB, CD be two parallel straight lines. From any points E and F in one of them, suppose perpendiculars EG, FH to be drawn; these, when produced, will meet the others at right angles in H and G (1. Cor. 21.): Join FG; then, because FH and EG are both perpendicular to AB, they are parallel, (19.); therefore the alternate angles HFG, FGE which they make with FG, are equal, (2. Cor. 21.): And because AB is parallel to CD, the alternate angles GFE, FGH are also equal; therefore the triangles GEF, FHG have two angles of the one equal to two angles of the other, each to each; and the side FG adjacent to the equal angles common; the triangles are therefore equal, (7.); and FH is equal to EG, that is, any two points F, E, on one of the lines, are equally distant from the other line. Principles.

Prop. XXIV. Theor.

In any triangle, if one of the sides be produced, the exterior angle is equal to both the interior and opposite angles; and the three interior angles are equal to two right angles.

Let ABC be a triangle; produce any one of its sides, AC towards D, and from the point A, let AE be drawn parallel to BC: And because of the parallels CB, AE, the angle EAD = C, and the angle EAB = B, (Cor. 2. and 3. of Prop. 21.); therefore EAD + EAB = C + B; that is, BAD = B + C: Hence the outward angle is equal to the two inward and opposite angles. Fig. 47.

Again, because BAD = B + C, to each add BAC, and we have BAD + BAC = B + C + BAC, that is, equal to the sum of the three angles of the triangle; but the sum BAD + CAB is equal to two right angles (2.); therefore the sum of the three angles of the triangle ABC is equal to two right angles.

Cor. 1. If two angles of one triangle are equal to two angles of another triangle, each to each, the third angle of the one shall be equal to the third angle of the other, and the triangles shall be equiangular.

Cor. 2. A triangle can have only one right angle.

Cor. 3. In any right angled triangle, the sum of the two acute angles is equal to a right angle.

Cor. 4. In an equilateral triangle, each of the angles is one-third of two right angles, or two-thirds of one right angle.

Prop. XXV. Theor.

The sum of all the interior angles of a polygon is equal to twice as many right angles, wanting four, as the polygon has sides.

Let ABCDE, &c. be a polygon; if from the vertex of any one of its angles A, diagonals AC, AD, AE, &c. be drawn to the vertices of all the other angles, it is evident that the polygon will be divided into five triangles if it have seven sides; and into six triangles if it have eight sides; and, in general, the number of triangles will be two less than the number of sides. It is also evident, that the sum of all the angles of these triangles make up all the angles of the polygon; now, all the angles of each triangle are together equal to two right angles; therefore all the angles of the triangles, that is all the angles of the polygon, will be equal to two right angles taken as often, except two, as the figure has sides, and consequently all the angles of the polygon will be equal to twice as many right angles wanting four as the figure has sides. Fig. 48.

Cor. The sum of the angles of a quadrilateral will be four right angles.

Scholium. The proposition will only apply to such polygons as have their angles *salient*, that is when the straight line that joins any two adjacent angles falls within the polygon. When some of the angles are *re-entrant*, the proposition must have a different form.

Prop. XXVI. Theor.

The opposite sides of a parallelogram are equal, as well as the opposite angles.

Draw the diagonal BD. The triangles ADB, DBC have the common side DB; also because of the parallels AB, CD, the angle ABD = CDB, (2 Cor. 21.) and because of the parallels AD, BC, the angle ADB = DBC; therefore the triangles are equal, (7.); and the sides AB, DC, which are opposite the equal angles, are equal. In like manner AD and BC are equal; therefore the opposite sides of a parallelogram are equal.

Again, from the equality of the triangles, it follows that the angle at A is equal to the angle at C; and it has been shewn, that the angles ADB, BDC are respectively equal to the angles CBD, DBA; therefore the whole angle ADC is equal to the whole angle ABC; thus the opposite angles are equal.

Cor. Two parallels AB, CD comprehended between two other parallels AD, BC are equal.

Prop. XXVII. Theor.

If in a quadrilateral ABCD, the opposite sides are equal, so that AB = CD, and AD = BC; the sides are parallel, and the figure is a parallelogram.

For, drawing the diagonal DB, the triangles ABD, BDC have the three sides equal, each to each; therefore the angle ADB, opposite to the side AB, is equal to the angle CBD, opposite to the side CD, (11.); hence the side AD is parallel to BC, (1. Cor. 20.) For a like reason AB is parallel to CD; therefore the quadrilateral ABCD is a parallelogram.

Prop. XXVIII. Theor.

If two opposite sides AB, CD of a quadrilateral are equal and parallel; the other two sides are equal and parallel, and the figure ABCD is a parallelogram.

For, having drawn the diagonal BD, since AB is parallel to CD, the angle ABD = BDC (2. Cor. 21.); besides the side AB = DC, and the side DB is common; therefore the triangle ABD is equal to the triangle DBC, (6.); therefore the side AD = BC, the angle ADB = DBC; and consequently AD is parallel to BC; therefore the figure ABCD is a parallelogram.

SECT. II.

Of a Circle.

Definitions.

1. The *circumference of a circle* is a curve line, every point of which is equally distant from a certain point within it called the *centre*. The *circle* is the space bounded by that curve line.

Note. Sometimes the circumference of a circle is called *the circle*; but it is easy to avoid ambiguity, by recollecting that the circumference is a *line*, and the circle a *space*.

2. Every straight line, CA, CE, CD, &c. drawn from the centre to the circumference, is called a *radius* or *semidiameter*; and every straight line, as AB, which passes through the centre, and is terminated both ways by the circumference, is called a *diameter*. Of the Circle.

Cor. All the radii are equal; also the diameters are all equal, and each is double of the radius.

3. An *arc* of a circle is any portion of the circumference, as FHG.

The *chord* or *subtense* of an arc is the straight line FG which joins its extremities.

4. A *segment* is the space comprehended between an arc and its chord.

Note. The same chord FG corresponds to two arcs FHG, FKG, also to two segments; but it is always the least of the two that is meant, unless otherwise expressed.

5. A *sector* is a part of a circle comprehended by an arc DE, and the two radii CD, CE drawn to its extremities.

6. A straight line is said to be *placed* in a circle, when its extremities are in the circumference, as FG.

7. An angle is said to be in a segment of a circle, when its vertex is on the arc of the segment, and the lines which contain it terminate in the extremities of the chord.

8. A rectilineal figure is said to be *inscribed* in a circle, when all its angles are on the circumference of the circle. The circle is then said to be *described* about the figure.

9. A straight line is said to *touch* a circle, and is called a *tangent*, when it meets the circumference, and being produced does not cut it; as the line IKL. The point K in which the straight line meets the circle is called the *point* of *contact*.

10. Two circumferences of circles are said to touch each other, when they meet in one point only.

11. A rectilineal figure is said to *circumscribe* a circle, when all its sides are tangents to the circumference; the circle is then said to be *inscribed* in the figure.

Prop. I. Theor.

Any diameter AB of a circle, divides the circumference into two equal parts. Fig. 51.

For if the figure AEB be applied upon AFB, so that they may coincide in their common base AB; it is manifest that they must entirely coincide; for were it otherwise, some parts of the circumference would be farther from the centre than others, contrary to the definition of a circle. (Def. 1. Sect. 2.)

Prop. II. Theor.

Every chord is shorter than the diameter.

For if the radii AC, CD be drawn to the extremities of the chord AD, then AD will be less than AC + CD (8. 1.) that is less than the diameter. Fig. 51.

Prop. III. Theor.

A straight line cannot cut a circle in more than two points.

For if it could cut it in three, these would be all equally distant from the centre; and so three equal straight lines might be drawn from the same point to terminate in the same straight line, which is impossible, (16. 1.)

Of the Circle.

Prop. IV. Theor.

In the same circle, or in equal circles, equal arcs are subtended by equal chords; and conversely, equal chords subtend equal arcs.

Fig. 52. If the radii AC, EO are equal, and the arc AMD is equal to the arc ENG; the chord AD shall be equal to the chord EG. For the semicircle AMDB may evidently be applied exactly upon the semicircle ENGF; and then the curve line AMDB will coincide entirely with the curve ENGF; but we suppose the arc AMD = arc ENG; therefore the point D will fall on G, and the chord AD on the chord EG.

Conversely, if the chord AD be equal to the chord EG, then the arc AMD = arc ENG. For, drawing the radii CD, OG; the triangles ACD, EOG have AC = EO, CD = OG, AD = EG; therefore they are equal, (11. 1.); and the angle ACD = EOG; consequently, if the semicircle ADB be placed on the equal semicircle EGF; so that AC may coincide with EO; the point D will manifestly fall on G, and the arc AMD will be equal to ENG.

Prop. V. Theor.

In the same, or in equal circles, a greater arc is subtended by a greater chord, and conversely; provided that the arcs are each less than a semicircumference.

Fig. 52. Let the arc AH be greater than the arc AD, and let the chords AD, AH, and the radii CD, CH be drawn. The two sides AC, CH of the triangle ACH are equal to the two sides AC, CD of the triangle ACD; and the angle ACH is greater than the angle ACD; therefore AH > AD (10. 1.) Thus it appears, that the chord that subtends the greater arc is the greater.

Conversely, if the chord AH is supposed greater than AD, it may be inferred from the same triangles, that the angle ACH is greater than the angle ACD, and therefore that the arc AH is greater than AD.

Scholium. If the arcs, instead of being less, were greater than a semicircumference, the opposite property would hold true; that is, the greater the arc, the smaller the chord.

Prop. VI. Theor.

Fig. 53. The radius CG, which is perpendicular to a chord AB, bisects the chord, and the arc it subtends; that is, divides each into two equal parts.

Draw the radii CA, CB; these, with respect to the perpendicular CD, are two equal oblique lines; therefore they meet AB at equal distances from the perpendicular (16. 1.); that is, AD = DB.

Next, if AD = DB; then, because CG is a perpendicular to AB, every point in CG is equally distant from A and B (17. 1.); therefore, if AG and BG be drawn, the chord AG = chord BG; hence the arc AG = arc BG (4.)

Scholium. From this proposition, it appears that the centre C, the middle D of the chord, and the middle G of the arc, are three points situated in a straight line perpendicular to the chord. Now, two points are sufficient to fix the position of a straight line. Therefore, any straight line which passes through two of these points will necessarily pass through the third, and be perpendicular to the chord.

Hence it also follows, *that the perpendicular to the middle of a chord passes through the centre and the middle of the arc subtended by the chord.*

Prop. VII. Theor.

One circle, and only one, can be described through three given points A, B, C, which are not in a straight line. Fig. 5

Join AB, BC, and divide these lines each into two equal parts by the perpendiculars DE, FG. Now, if ABC, or DBF, be a right angle; then, if the points D, F be joined, DBF will be a right angled triangle, and therefore each of the angles BFD, BDF will be less than a right angle (2. Cor. 24. 1.); and consequently, each of the angles FDE, DFG will be less than a right angle, and their sum will be less than two right angles: hence DE, FG will meet, if produced in a point O (Schol. 21. 1.) But if DBF is not a right angle, the two lines GF, AB will make with BF two angles on one side, which will be less than two right angles; therefore those lines will meet in a point K; and as BFK is a right angle, BKF will be less than a right angle (2. Cor. 24. 1.); therefore EDK and GKD will be together less than two right angles, and consequently will meet at a point O, as in the other case. Now this point O, considered as in the perpendicular DE, will be equally distant from A and B (17. 1.); and considered as in the perpendicular FG, it will be equally distant from C and B: therefore it will be equally distant from A, B, and C, and these three points will be in the circumference of a circle, of which O is the centre.

Again, every circle that passes through A and B must have its centre in DE; and every circle that passes through C and B must have its centre in FG (Schol. 6.); but these two lines can only have one common point; therefore only one circle can pass through the points A, B, C.

Cor. Two circles cannot cut each other in more than two points; for, if they could have three common points, they would have the same centre, and would coincide.

Prop. VIII. Theor.

Two equal chords are equally distant from the centre; and of two unequal chords, the shortest is farthest from the centre.

1. Let the chord AB=DE; suppose them divided into two equal parts by the perpendiculars CF, CG from the centre; and draw the radii CA, CD. The right angled triangles CAF, CDG have equal hypothenuses CA, CD; also AF, the half of AB, equal to DG, the half of DE; therefore the triangles are equal (18. 1.), and CF=CG; therefore AB, DE are equally distant from the centre. Fig.

2. Next let the chord AH be greater than the chord DE, so that the arc AKH is greater than the arc DME. In AKH take AKB equal to DME; draw the chord AB, and CF a perpendicular from the centre upon AB, meeting AH in O; and CI a perpendicular upon AH. It is evident that CF is greater than CO, and CO greater than CI (16. 1.); much more then is CF > CI: But CF=CG, since the chords AB, DE are equal;

therefore CG > CI; therefore of two unequal chords, the smaller is the farthest of the two from the centre.

Prop. IX. Theor.

A straight line BD, drawn perpendicular to the extremity of a radius CA, is a tangent to the circumference.

For every oblique line CE is longer than the perpendicular CA (16. 1.); therefore the point E must be without the circle; and as this holds true of every point in the line BD, except the point A, the line BD is a tangent (9. Def.)

Scholium. Only one tangent AD can be drawn from a point A in the circumference. For if it were possible to draw another tangent, as AG, then as CA would not be perpendicular to AG, another line CF would be perpendicular to AG; and so, CF would be less than CA (16. 1.); therefore F would fall within the circle, and AF, if produced, would cut the circumference.

Prop. X. Theor.

Two parallel chords AB, DE in a circle intercept equal arcs AD, BE.

Draw the radius CH perpendicular to AB; it will also be perpendicular to DE (1. Cor. 21. 1.) Therefore H will be at the same time the middle of the arcs AHB and DHE: Hence we have DH=HE and AH=HB; and therefore DA=BE.

Prop. XI. Theor.

If two circumferences cut each other, the straight line which passes through their centres shall be perpendicular to the chord which joins the points of intersection, and shall divide it into two equal parts.

For the line AB, which joins the point of intersection, being a common chord of the two circles; if, through the middle of this chord, a perpendicular be drawn, it will pass through C and D, the centres of both the circles. But only one line can be drawn through two given points; therefore the straight line which passes through the centres is a perpendicular at the middle of the common chord.

Prop. XII. Theor.

If the distance of the centres be less than the sum of their radii; and if, at the same time, the greater radius is less than the sum of the lesser and the distance of the centres, the two circles will cut each other.

For that the circles may intersect each other, the triangle CAD must be possible; therefore, it is necessary not only that CD be less than AC+AD, but also that the greater radius AD be less than AC+CD (8. 1). Now it is evident, that when the triangle CAD can be constructed, the circles described on C and D as centres will intersect on A and B.

Prop. XIII. Theor.

If the distance CD of the centres of two circles be equal to the sum of their radii CA, AD, the two circles touch each other externally.

It is evident that they will have a common point A, but they cannot have another common point; for if they had two common points, (as in Fig. 58.) it would be necessary that the distance of their centres should be less than the sum of their radii. Of the Circle.

Prop. XIV. Theor.

If the distance of the centres be equal to the difference of the radii CA, AD, the two circles will touch each other internally. Fig. 61.

In the first place, it is evident that they have a common point A, and they cannot have another; for, that this might be possible, it would be necessary that the greater radius AD should be less than the sum of the lesser and the distance of the centres C, D, which is inconsistent with the hypothesis.

Cor. Therefore, if two circles touch each other, either externally or internally, their centres and the point of contact are in the same straight line.

Prop. XV. Theor.

In the same circle, or in equal circles, equal angles ACB, DCE at the centre, intercept equal arcs AB, DE on the circumference; and conversely, if the arcs AB, DE be equal, the angles ACB, DCE are also equal. Fig. 62.

1. If the angle ACB=DCE, these two angles may be placed on each other, and as their sides are equal, the point A will fall on D, and the point B on E; but then the arc AB must also fall on the arc DE; for if the two arcs did not coincide, there would be in the one or the other points unequally distant from the centre, which is impossible: therefore the arc AB=DE.

2. Next if the arc AB=DE, the angle ACB shall be equal to DCE; for if they are not equal, let ACB be the greater. Take ACI=DCE, then by what has been demonstrated AI=DE; but by hypothesis, the arc AB=DE; therefore the arc AI=AB, which is impossible; wherefore the angle ACB=DCE.

Prop. XVI. Theor.

An angle ACB at the centre of a circle, is double of the angle ADB at the circumference, upon the same arc AB. Figs. 63, 64.

Draw DC, producing it to E. First, let the angle at the centre be within the angle at the circumference, (Fig. 63,) then the angle ACE=CAD+CDA, (24. 1); but because CA=CD, the angle CAD=CDA, (12. 1,) therefore the angle ACE=2 CDA. For the same reason, the angle BCE=2 CDB: Therefore, the whole angle ACB is double the whole angle ADB. Fig. 63.

Next, let the angle at the centre be without the angle at the circumference, (Fig. 64). It may be demonstrated as in the first case, that the angle ECB=2 EDB; and that the angle ECA a part of the first, is equal to 2 EDA a part of the second; therefore the remainder ACB is double the remainder ADB. Fig. 64.

Prop. XVII. Theor.

The angles ADB, AEB, in the same segment AEB of a circle, are equal to one another. Figs. 65, 66.

Let C be the centre of the circle, and first let the seg-

Of the Circle.

ment AEB be greater than a semicircle, (Fig. 65). Draw CA, CB to the ends of the base of the segment, then each of the angles ADB, AEB will be half of the angle ACB, (16.); therefore the angles ADB, AEB are equal.

Fig. 65.

Fig. 66.

Next, let the segment AEB be less than a semicircle; draw the diameter DCF, and join EF; and because the segment ADEF is greater than a semicircle by the first case, the angle ADF=AEF. In like manner, because the segment BEDF is greater than a semicircle, the angle BDF is equal to the angle BEF; therefore the whole angle ADB is equal to the whole angle AEB.

Prop. XVIII. Theor.

Fig. 67.

The opposite angles of any quadrilateral ABCD inscribed in a circle, are together equal to two right angles.

Draw the diagonals AC, BD. In the segment ABCD, the angle ABD=ACD; and in the segment CBAD, the angle CBD=CAD, (17.); therefore the whole angle ABC is equal to the sum ACD+CAD; and adding ADC, we get the sum ABC+ADC equal to the sum ACD + CAD + ADC; now these three angles are the angles of the triangle ADC, and therefore equal to two right angles, (24. 1.): Therefore the sum of the angles ABC, ADC is equal to two right angles. In like manner it may be demonstrated, that the sum of the angles BAD, BCD is equal to two right angles.

Prop. XIX. Theor.

Fig. 68.

An angle ABD in a semicircle is a right angle; an angle BAD in a segment greater than a semicircle, is less than a right angle; and an angle BED in a segment less than a semicircle, is greater than a right angle.

Produce AB to F, and draw BC to the centre; and because CA=CB, the angle CBA=CAB, (12. 1.), in like manner, because CD=CB, the angle CBD=CDB, therefore the sum CBA+CBD=CAB+CDB; that is, ABD=CAB+CDB; but this last sum is equal to the angle DBF, (24. 1.) therefore the angle ABD=DBF. Hence each is a right angle, (9. def 1.); therefore the angle ABD in a semicircle is a right angle.

And because in the triangle ABD the angle ABD is a right angle; therefore BAD, which is manifestly in a segment less than a semicircle, is less than a right angle, (2. Cor. 24. 1.). Again, because ABED is a quadrilateral in a circle, we have A+E= two right angles, (18.); but A is less than a right angle; therefore E, which is in a segment greater than a semicircle, is greater than a right angle.

Prop. XX. Theor.

Fig. 69.

The angle BAE, contained by a tangent AE to a circle, and a chord AB drawn from the point of contact, is equal to the angle AGB in the alternate segment.

Let the diameter ACF be drawn, and GF be joined; and because FGA and FAE are right angles, (19. and 9.), and of these, FGB a part of the one, is equal FAB a part of the other, (17.). The remainders BAE, BGA are equal.

Problems relating to the two First Sections.

Prob

Geometrical problems, like geometrical theorems, may be multiplied without end. They are divided into classes, according to the nature of the lines employed in their solution. The most simple, called *Plane Problems*, require only straight lines, and circles, and they may be all ultimately reduced to three.

1. To draw a straight line from one given point to another given point.
2. To prolong a straight line.
3. To describe a circle on any point as a centre, with any given radius.

These are resolved by the mechanical contrivances of a ruler and compasses, which are commonly known; and they belong rather to mechanics than to geometry, which does not teach how to resolve them, but takes for granted that the manner of solving them is known. This assumption is formally made in the *postulates*, (beginning of Sect. I.)

The elements of geometry treat only of the more simple plane problems, to which the complex may be reduced. Some of these are now to be considered.

Problem I.

From the greater CD of two unequal lines AB, CD, to cut off a part equal to the less. Fig.

From C as a centre, with a radius equal to AB, let the circumference of a circle be described cutting CD in E, (3d Postulate), and the thing is done.

Prob. II.

At a given point A to draw a line equal to a given line CD. Fig

Draw the indefinite line AF (Post. 1. and 2.); from which cut off AB=CD, (Prob. 1.)

Prob. III.

To bisect a given straight line AB, that is to divide it into two equal parts. Fig

On A and B as centres, with any radius greater than the half of AB, describe two arcs of circles to meet in D, (Post. 3. and Prop. 12.), this point will be equally distant from A and B. In like manner, find another point E, either on the same or on the other side of the line, which may be equally distant from A and B. Through D and E draw a straight line to meet AB in C; the point C will be the middle of AB.

For the points D and E are in a straight line, perpendicular to the middle of AB (17. 1.); therefore the line DCE is that perpendicular, and C is the middle of the line.

Prob. IV.

To draw a perpendicular to a given line BC from a given point A in that line. F

Take the points B and C at equal distances from A; and on B and C as centres, with a radius greater than BA, describe arcs to meet in D. Draw AD, which will be the perpendicular required.

Problems.

For D being equally distant from B and C, it must be in a line perpendicular to the middle of BC. Therefore AD is the perpendicular required.

PROB. V.

Fig. 74. To draw a perpendicular to a given line BD from a given point A without that line.

On A as a centre, with a sufficiently great radius, describe an arc to cut the line in B and D. Find next a point E equally distant from A and B; join AE, meeting BD in C, and AC will be the perpendicular required.

For the two points A, E are each equally distant from B and D; therefore AE is perpendicular to BD.

PROB. VI.

Fig. 75. At a given point A in a given line AB to make an angle equal to a given angle K.

On K as a centre, with any radius, describe an arc IL, to terminate in the sides of the angle. On A as a centre, with the same radius, describe an indefinite arc BO. On B as a centre with a radius equal to the chord of the arc LI, describe an arc to cut the arc BO in D; draw AD, and the angle DAB shall be equal to the given angle K.

For IL, BD are equal chords in equal circles, therefore the arc IL = arc BD (4.), and the angle K = angle A, (15.)

PROB. VII.

To divide a given angle, or an arc, into two equal parts.

Fig. 76. 1. If it is an arc AB whose centre is C, which is to be divided, on A and B as centres, with the same radius describe arcs to meet in D; through C and D draw a straight line CD, which will bisect the arc AB at the point E.

For C and D are each at the same distance from the extremities of the chord AB; therefore CD is perpendicular at the middle of the chord (17. 1.), and consequently must bisect the arc AEB, (Schol. 6.)

2. If the angle ACB is to be bisected; in the first place, an arc AEB is to be described on C the vertex of the angle as a centre; then a point D must be found equally distant from A and B as before, and a line drawn from C through D will bisect the angle.

For if the chord AB be drawn, CD will be perpendicular at the middle of AB; therefore CD bisects the arc AB (6.), and consequently bisects the angle ACB, (15.)

PROB. VIII.

Fig. 77. Through a given point A, to draw a straight line parallel to a given line BC.

On A as a centre, with a radius sufficiently great, describe an indefinite arc EO; on E as a centre, with the same radius, describe an arc AF; also on E as a centre with the chord of the arc AF as a radius, describe an arc to meet EO in D; draw a line from A through D, and AD will be the parallel required.

For AF and DE are manifestly equal arcs of equal circles; therefore the angles BEA, DAE are equal; and hence BC is parallel to AD, (Cor. 1. 20. 1.)

Problems.

PROB. IX.

To describe a triangle, the sides of which shall be equal to three given straight lines A, B, C. Fig. 78.

Draw a straight line DE equal to one of the lines A; on E as a centre, with a radius equal to another of the lines B, describe an arc; on D as a centre, with a radius equal to the remaining line C, describe another arc, cutting the former in F; draw DF, EF; and DEF shall be the triangle required, as is sufficiently evident.

SCHOLIUM. The problem is only possible when the sum of any two of the given lines is greater than the third, (8. 1.)

PROB. X.

To construct a parallelogram, the adjacent sides of which may be equal to two given lines A, B, and the angle which they contain equal to a given angle C. Fig. 79.

Draw a straight line DE = A; at the point D, make an angle FDE = C, and take DF = B; describe two arcs, one on F as a centre, with DE or A as a radius, and the other on E as a centre with B as a radius. From the point G, where these arcs cut each other, draw GF, GE, and DEGF will be the parallelogram required.

For by the construction, the opposite sides are equal; therefore the figure is a parallelogram, (27. 1.)

COR. If the given angle were a right angle, the figure would be a rectangle; and if the sides were equal, the figure would be a square.

PROB. XI.

To find the centre of a circle, or of a given arc.

Take any three points A, B, C in the circumference of the circle, or in the arc; join them by the lines AB, BC, (or suppose these lines drawn), and bisect AB, BC by the perpendiculars DE, FG (Prob. 3.); the point O where these lines meet each other shall be the centre sought, as is evident from Prop. 7. Fig. 80.

SCHOLIUM. By this construction, a circle may be described through three given points; or may be described about a given triangle ABC.

PROB. XII.

Through a given point A, to draw a tangent to a given circle. Figs. 81, 82.

If the given point A is in the circumference (Fig. 81.), draw the radius CA, and draw AD perpendicular to CA; and DA shall be the tangent required, (9. 2.) Fig. 81.

If the point A is without the circle, (Fig. 82.), draw AC to the centre, bisect AC in O; and on O as a centre, with OC as a radius, describe a circle which may cut the given circle in B; draw AB, and AB shall be the tangent required. Fig. 82.

For join CB, and the angle ABC in a semicircle will be a right angle (19.); therefore AB, a perpendicular to the radius at its extremity B, is a tangent to the circle, (9.)

Problems.

SCHOLIUM. When the point A is without the circle, there may be two equal tangents AB, AD drawn, which shall pass through the point A. For the right angled triangles ABC, ADC have a common hypothenuse AC, and a side BC equal a side CD; therefore AB = AD, (18. 1.)

PROB. XIII.

Fig. 83. To inscribe a circle in a given triangle ABC.

Bisect the angles A and B, (Prob. 7.) by the straight lines AO, BO, which will meet at a point O, because the angles CBA and BAC are less than two right angles; and therefore OAB and OBA are also less than two right angles, (Schol. 21. 1.) Draw OD, OE, OF, perpendicular to the sides of the triangle: And because the triangles OAD, OAF have the angle OAD = OAF, and the angle ODA = OFA; the remaining angle AOD shall be equal to the remaining angle AOF, (1 Cor. 24. 1.) Besides the side AO, adjacent to the equal angles, is common to both; therefore the triangles are equal, (7. 1.) and OD = OF: In like manner it may be demonstrated, that the triangles BOD and BOE are equal, and therefore OD = OE; therefore the three lines OD, OE, OF are equal; and a circle described on O as a centre, with any one of them as a radius, will pass through the extremities of the other two; and because the angles at D, E, F are right angles, the circle will touch the sides of the triangle (9.), and be inscribed in it.

PROB. XIV.

Fig. 84. Upon a given straight line AB, to describe a segment of a circle that may contain an angle equal to a given angle C.

Produce AB towards D, and at the point B make the angle DBE = C; draw BO perpendicular to BE, and GO a perpendicular upon the middle of AB. On the point of concourse O as a centre, with the radius OB, describe a circle which will evidently pass through A; the segment required shall be AMB. For since BE is perpendicular to the extremity of the radius OB, BE is a tangent; therefore the angle EBD, which is equal to C by construction, is equal to any angle AMB in the alternate segment.

SCHOLIUM. If the given angle were a right angle, the segment sought would be a semicircle described on the diameter AB.

SECT. III.

OF PROPORTION.

Of proportion.

THE theory of proportion treats of the *ratios* of quantities; that is, the relations they have to each other in respect of magnitude. As it applies alike to quantities of every kind, we have explained it in our article ALGEBRA, Sect. III.; and some foreign writers on geometry, particularly Legendre, even regard this subject as altogether an arithmetical or algebraical theory. In this country it has been usual to introduce it into geometry, just before its application is wanted; although perhaps it might with propriety be inserted, rather as a preliminary theory, than as forming a part of geometry. However, in compliance with custom, we shall treat it, (but somewhat differently,) also in this place.

Proport.

Definitions.

Definitio

1. When one quantity contains another, a certain number of times exactly, the former is called a *multiple* of the latter; and the latter is said to be a *part* of the former.

2. When several magnitudes are multiples of as many others, and each contains its part the same number of times, the former are called *equimultiples* of the latter, and the latter *like parts* of the former.

3. If there be four quantities, which we shall call A, B, C and D, and if A contain some part of B, exactly as often as C contains a like part of D, then A is said to have to B the same *ratio* that C has to D; or the *ratio* of A to B is said to be *equal* to the ratio of C to D.

COR. Hence if A contain B exactly as often as C contains D, then the ratio of A to B is equal to the ratio of C to D.

Note. Each pair of quantities is supposed to be of the same kind as both lines or both surfaces, &c. but A and B may be of one kind, and C and D of any other kind.

4. Each set of quantities compared, as A and B, is called the *terms* of the ratio; the first is called the *antecedent*, and the second the *consequent*.

5. The terms of two equal ratios are called *proportionals*.

To indicate that the ratio of A to B is equal to the ratio of C to D, they are usually written thus; A : B :: C : D; and sometimes thus, A : B = C : D; also thus $\frac{A}{B}=\frac{C}{D}$; each expression is read thus; A *is to* B *as* C *to* D, and is called a *proportion*.

6. Of four proportional quantities, the last term is called a *fourth proportional* to the other three taken in order

7. When there is any number of quantities greater than two, of which the first has to the second the same ratio which the second has to the third, and the second to the third the same ratio which the third has to the fourth, and so on, the magnitudes are said to be *continual proportionals*.

8. When three quantities are continual proportionals, the second is said to be a *mean proportional* between the other two; and the last a *third proportional* to the first and second.

9. In proportionals, the antecedent terms are called *homologous* to one another, and also the consequents to one another.

10. When there is any number of quantities of the same kind, the first is said to have to the last of them the ratio *compounded* of the ratio which the first has to the second, and of the ratio which the second has to the third, and so on unto the last magnitude. For example, if there be four quantities A, B, C, D, the first A is said to have to the last D the ratio compounded of the ratio of A to B, and of the ratio of B to C, and of the ratio of C to D.

And if A : B :: E : F, and B : C :: G : H; and C : D :: K : L; then, since the ratio of A to D is compounded of the ratios of A to B, B to C, C to D; A may also be said to have to D the ratio compounded of the ratios, which are the same with the ratios of E to F, G to H, and K to L.

11. A ratio which is compounded of two equal ratios, is said to be *duplicate* of either of these ratios.

COR. Hence if three magnitudes A, B, and C are continual proportionals, the ratio of A to C is *duplicate* of that of A to B. For the ratio of A to C is compounded of the ratios of A to B, and of B to C; but by Def. 7. the ratio of A to B is equal to the ratio of B to C; therefore, by this definition, the ratio of A to C is duplicate of the ratio of A to B, or of B to C.

12. A ratio which is compounded of three equal ratios, is said to be *triplicate* of any one of them. By a like mode of proceeding, a ratio *quadruplicate* of another is formed, and so on.

Cor. If four magnitudes A, B, C, D be continual proportionals, the ratio of A to D is triplicate of the ratio of A to B, or of B to C, or of C to D.

13. *Ratio* of *equality* is that which equal magnitudes bear to each other.

Geometers make use of the following technical words to signify certain ways of changing either the order or magnitude of proportionals, so that they still continue to be proportional.

14. If four quantities be proportionals, they are said to be proportionals by *inversion*, when it is inferred that the second is to the first as the fourth to the third. (See Prop. 2.)

15. They are said to be proportionals by *alternation*, when it is inferred that the first is to the third as the second to the fourth. (Prop. 3.)

16. They are proportionals by *composition*, when the sum of the first and second is to the second as the sum of the third and fourth is to the fourth. (Prop. 4.)

17. And by *division*, when the difference of the first and second is to the second as the difference of the third and fourth is to the fourth. (Prop. 5.)

18. They are proportionals by *conversion*, when the first is to the difference of the first and second, as the third to the difference of the third and fourth. (Prop. 6.)

In this Section, the letters A, B, C, &c. are used to denote quantities of any kind; the letters m, n, p, q, &c. are used to denote numbers only.

In addition to the characters which denote addition and subtraction, we shall now also employ those which express multiplication and division; they are explained in Algebra, Art. 27, 28, and 29.

Axioms.

1. Equal quantities have the same ratio to the same quantity; and the same quantity has the same ratio to each of any number of equal quantities.

2. Quantities having the same ratio to the same quantity, or to equal quantities, are equal among themselves; and these quantities, to which the same quantity has the same ratio, are equal.

3. Ratios equal to one and the same ratio, are also equal one to the other.

4. If two quantities be composed of parts that are equal among themselves, then will the whole of the one have the same ratio to the whole of the other, as the number of parts in the one has to the number of equal parts in the other.

Prop. I. Theor.

Quantities have to one another the same ratio which their equimultiples have.

Let A and B be two quantities, and supposing m to denote any number, let mA and mB, (that is m times A, and m times B,) be any equimultiples of these quantities; the ratio of A to B shall be equal to the ratio of mA to mB, or $A : B :: mA : mB$.

For let us suppose that A contains three such parts, each equal to X, as B contains four, so that

$$A = X + X + X; \qquad B = X + X + X + X;$$

Then $mA = mX + mX + mX$;

$$mB = mX + mX + mX + mX;$$

because a whole quantity taken any number of times, is manifestly equivalent to the aggregate of each of its parts taken the same number of times: Now as A contains one-fourth of B three times, and mA evidently contains one-fourth of mB also three times, A contains a part of B exactly as often as mA contains a like part of mB; therefore (Def. 3.) the ratio of A to B is equal to the ratio of mA to nB.

If instead of supposing A to contain three such parts as B contains four, we had taken general symbols, and suppose A to contain p, such equal parts as B contained q, the reasoning and result would have been exactly the same. A like remark is to be made on the subsequent propositions.

Cor. Like parts of quantities have to each other the same ratio as the wholes; for A and B are like parts of mA and mB.

Prop. II. Theor.

If four quantities be proportionals, they shall also be proportionals by inversion.

Let A, B, C, D be four quantities, such that $A : B :: C : D$; then also $B : A :: D : C$.

For suppose that A contains two such equal parts as B contains three, and consequently, (Def. 3.) that C contains two such equal parts as D contains three; then B will contain three such parts as A contains two, and D will contain three such parts as C contains two; so that B will contain a part of A, exactly as often as D contains a like part of C, therefore (Def. 3.) $B : A :: D : C$.

Prop. III. Theor.

If four quantities of the same kind be proportionals, they shall also be proportionals by alternation.

Let $A : B :: C : D$; then, alternately, $A : C :: B : D$.

For let us suppose that A contains three such equal parts as B contains four, then, (Def. 3.) C will also contain three such equal parts as D contains four: let each of the equal parts contained in A and B be X, and let each of the equal parts contained in C and D be Y; then

$$A = 3X \qquad B = 4X$$
$$C = 3Y \qquad D = 4Y$$

Because X is contained three times in A, and Y is contained three times in C; A and C are equimultiples of X and Y, (Def. 2.): and in like manner, it appears that B and D are equimultiples of X and Y; threfore (Prop. 1.) $A : C :: X : Y$; also, $B : D :: X : Y$; and since the ratios of A to C, and of B to D are each equal to the ratio of X to Y, it follows, (Ax. 3.) that $A : C :: B : D$.

Cor. If the first of four proportionals be greater than the third, the second is greater than the fourth; and if the first be equal to the third, the second is equal to the fourth; and if the first be less than the third, the second is less than the fourth.

PROP. IV. THEOR.

If four quantities be proportionals, they shall also be proportionals by composition.

Let A : B : : C : D; then by composition A : A + B : : C : C+D.

For let us suppose that A contains five such equal parts as B contains three, then also, (Def. 3.) C will contain five such equal parts as D contains three. Let each of the parts in A and B be X, and let each of the parts in C and D be Y; then because

$A=5X$; $B=3X$; $C=5Y$; $D=3Y$.

It follows that

$A+B=8X$ $\quad C+D=8Y$.

Here it is evident that A+B contains one third of B eight times; and that C + D contains one third of D also eight times; and in general, that A+B will contain some part of B exactly as often as C+D contains a like part of D; therefore (by Def. 3.) A+B : B : : C+D : D.

PROP. V. THEOR.

If four quantities be proportionals, they will also be proportionals by division.

Let A : B : : C : D; then by division, A—B : B : : C—D : D.

For making the same supposition as in last proposition, so that

$A=5X$, $B=3X$, $C=5Y$, $D=3Y$; we have $A-B=2X$, and $C-D=2Y$, therefore A—B contains one third of B twice, and C—D contains one-third of D also twice: and in general, it is evident that A—B will in every case contain a part of B exactly as often as C—D contains a like part of D: therefore (Def. 3.) A—B : B : : C—D : D.

PROP. VI. THEOR.

If four quantities be proportionals, they are also proportionals by conversion.

Let A : B : : C : D; then, by conversion, A : A—B : : C : C—D.

For, making the same supposition as in the two last propositions, because

$A=5X$, $B=3X$, $C=5Y$, $D=3Y$;
therefore $A-B=2X$, and $C-D=2Y$;

Hence it appears that A contains one half of A—B five times, and that C contains one half of C—D also five times, therefore A contains a part of A—B as often as C contains a like part of C—D; therefore A : A—B : : C : C—D. (Def. 3.)

PROP. VII. THEOR.

If four quantities be proportionals, and there be taken any equimultiples of the antecedents, and also any equimultiples of the consequents; the resulting quantities will also be four proportionals.

Let A : B : : C : D; and supposing *m* and *n* to be any two numbers, let the antecedents A and C be taken each *m* times, and the consequents B and D each *n* times; then shall *m* A : *n* B : : *m* C : *n* D.

For suppose that A contains two such equal parts as B contains three: and consequently that C contains two such equal parts as D contains three. (Def. 3.) Let each of the parts contained in A and B be X, and each of the parts contained in C and D be Y; so that

$A=2X$, $\quad B=3X$,
$C=2Y$, $\quad D=3Y$;

Then, multiplying the antecedents by the number *m*, and the consequents by *n*, and observing that $m\times 2=2\times m$, and that $n\times 2=2\times n$, we have

$mA=2\times mX$, $\quad nB=3\times nX$,
$mC=2\times mY$, $\quad nD=3\times nY$.

Here it is evident that *m* A contains one third of *n* B twice; and that *m* C contains one third of *n* D also twice; therefore *m* A : *n* B : : *m* C : *n* D. (Def. 3.)

PROP. VIII. THEOR.

If there be any number of magnitudes, and as many others, which taken two and two have the same ratio; the first shall have to the last of the first series, the same ratio which the first has to the last of the other series.

A, B, C.
H, K, L.

First, let there be three magnitudes A, B, C, and other three H, K, L, such, that A : B : : H : K, and B : C : : K : L, then, A : C : : H : L.

For let us suppose that A contains 2 such parts, each equal to X, as B contains 3, and as C contains 7; then, (Def. 3.) H will contain 2 such parts (each of which we shall denote by Y) as K contains 3, and as L contains 7; so that we have

$A=2X$, $B=3X$, $C=7X$,
then, $H=2Y$, $K=3Y$, $L=7Y$.

Here it is evident that A will contain one seventh of C twice, and that H will contain one seventh of L also twice; therefore (Def. 3.) A : C : : H : L.

A, B, C, D.
H, K, L, M.

Next, let there be four quantities A, B, C, D, and other four H, K, L, M, such, that A : B : : H : K, and B : C : : K : L, and C : D : : L : M; then shall A : D : : H : M. For by the first case it is evident that A : C : : H : L; and because C : D : : L : M; therefore, as before, A : D : : H : M. The demonstration applies in the same manner to any number of quantities.

Note. Quantities which are proportionals, according to the hypothesis of this theorem, are said to be so from *equality of distance directly*, and the theorem is usually cited by the words *ex æquali*, or *ex æquo*.

PROP. IX. THEOR.

If there be any number of quantities, and as many others, which taken two and two in a cross order have the same ratio; the first shall have to the last of the first series the same ratio that the first has to the last of the other series.

A, B, C.
H, K, L.

First, let there be three quantities A, B, C, and other three H, K, L, such, that A : B : : K : L, and B : C : : H : K; then A : C : : H : L.

For suppose A to contain two such equal parts as B contains three, then K will contain two such equal parts as L contains three, (Def. 3.); let each of the equal parts contained in A and B be X, and let each of the equal parts contained in K and L be Y, so that

$A=2X$, $B=3X$, $K=2Y$, $L=3Y$.

Also let Z be the same part of C that Y is of L, and let V be the same part of H that X is of A; so that we have

$C=3Z$, $H=2V$.

Then, because B : C : : H : K; that is 3X : 3Z : : 2V :

 2Y, and because 3X : 3Z : : X : Z, and 2V : 2Y : : V : Y, (1.); therefore X : Z : : V : Y, (Ax. 3.); hence, (by Prop. 7.) 2X : 3Z : : 2V : 3Y; but 2X=A, 3Z=C, 2V =H, 3Y=L; therefore A : C : : H : L.

Next, let there be four quantities, A, B, C, D, and other four H, K, L, M, such that A : B : : L : M, and B : C : : K : L, and C : D : : H : K; then A : D : : H : M; for it is evident by the first case, that A : C : : K : M; and because C : D : : H : K, therefore, as before, A : D : : H : M. The same mode of demonstration will apply to any number of quantities.

A, B, C, D.
H, K, L, M,

Note. The quantities in this proposition are said to be proportional from *equality of distance*, but in a cross order; and the theorem is usually cited by the words *ex æquali in proportione perturbata*, or *ex æquo perturbate.*

PROP. X. THEOR.

If the first have to the second the same ratio which the third has to the fourth, and the fifth have to the second the same ratio which the sixth has to the fourth; the first and fifth together shall have to the second the same ratio which the third and sixth together have to the fourth.

Let A : B : : C : D, and also E : B : : F : D, then A+E : B : : C+F : D.

Because E : B : : F : D, by inversion B : E : : D : F, (2.) But by hypothesis A : B : : C : D; therefore *ex æquali*, (8.) A : E : : C : F, and by composition A+E : E : : C+F : F. Now again by hypothesis, E : B : : F : D, therefore *ex æquali*, (8.) A+E : B : : C+F : D.

PROP. XI. THEOR.

If four quantities be proportionals, as the sum of one antecedent and its consequent is to their difference, so is the sum of the other antecedent and consequent to their difference.

Let A : B : : C : D, then A+B : A—B : : C+D : C—D.
For by composition, A+B : B : : C+D : D (4.)
And by Div. and Inver. B : A—B : : D : C—D (5 and 2.)
Therefore *ex æquo* A+B : A—B : : C+D : C—D (8.)
Note. Proportionals formed in this manner, are said to be so by *mixing*.

PROP. XII. THEOR.

If there be any number of proportionals, as one antecedent is to its consequent, so is the sum of all the antecedents to the sum of all the consequents.

Let A : B : : C : D : : E : F, then A : B : : A+C+E : B+D+F.

For suppose that A contains two such parts, each = X, as B contains three; and that C contains two such parts, each =Y, as D contains three; and that E contains two such parts, each = Z, as F contains three; and so on, then

$$A = 2X,\ B = 3X,$$
$$C = 2Y,\ D = 3Y,$$
$$E = 2Z,\ F = 3Z.$$

Hence by addition,

$$A+C+E = 2X+2Y+2Z = 2(X+Y+Z),$$
$$B+D+F = 3X+3Y+3Z = 3(X+Y+Z).$$

Thus it appears, that A contains a third part of B twice, and that A + C + E contains a third part of B+D+F also twice; therefore A : B : : A+C+E : B+D+F.

PROP. XIII. PROB.

To find the numerical ratio of two straight lines AB, CD, supposing them to have a common measure. Fig. 85.

Take the lesser of the two lines on the greater as often as possible; for example twice, with a remainder EB.

Take the remainder BE on the line CD as often as possible; once, for example, with a remainder DF.

Take the second remainder DF on the first BE as often as possible; once, for example, with a remainder BG.

Take the third remainder BG on the second DF as often as possible, and continue this process until a remainder is found, which is contained an exact number of times in that going before it. Then the last remainder shall be the common measure of the proposed lines; and considering it as unity, we shall easily find the values of the preceding remainders, and at last those of the two proposed lines; that is, we shall know how often each contains the unit, so that if AB contain it *m* times, and CD contain it *n* times, then AB : CD : : *m* : *n*.

For example, if it is found that GB is contained exactly twice in FD, BG shall be the common measure of the two lines. Let BG=1, then FD=2; but EB=FD+GB, therefore EB=3; CD=EB+FD, therefore CD=5; lastly, AB=2 CD+EB, therefore AB=13: therefore the ratio of AB to CD is that of 13 to 5.

SCHOLIUM. This operation is evidently the same as that by which the common measure of two numbers is found. Its demonstration is given in ALGEBRA, Art. 72. and 73. If the operation terminate, and the lines have a common measure, they are said to be *commensurable*; but the lines may be such that the operation will never terminate, and as then the quantities have no common measure, they are said to be *incommensurable*. The side of a square AB, and its diagonal AC, are of this nature, (Fig. 86.) For if we take AD=AB, and draw DE perpendicular to AC, to meet CB in E, and join AE, the triangles ABE, ADE will be equal, (18. 1.) and BE=DE. But the angle DEC=DAB (1 Cor. 24. 1.) =DCB, (12. 1.) therefore DE=DC, (13. 1.) and hence BE=DC. Now to determine whether AB and AC have a common measure, we first take AB out of AC, and DC will remain; we next take DC out of CB, and get it once, with a remainder CE; but as CE is still greater than DC, we must again take CD out of CE, and then proceeding exactly as before, we must take the last remainder out of CD as often as we can, and so on. Now CE is evidently the diagonal of a square, of which DC is a side; therefore it appears, that in seeking the common measure, we must make the very same kind of construction in this second square that was made upon the first; and again, in pursuing the operation, we must make a like construction on a third square, and so on continually, so that the operation can never come to an end: therefore the quantities AC, AB can have no common measure. Fig. 86.

On the subject of incommensurable quantities, see also ALGEBRA, Sect. VI.

In the theory of proportion, we have, with a view to brevity and perspicuity, treated only of commensurable ratios; that is, such as can be accurately expressed by numbers. Although the ratio of incommensurable quantities cannot be so expressed, yet a ratio may be always assigned in numbers, which shall be as near to the true ratio as we please. For let A and B be any two

Proportion of Figures.

quantities whatever, and suppose that X is such a part of A, that $A=mX$; then, if n denote the number of times that X can be taken from B, and D the remainder, we have $B=nX+D$, and $B-D=nX$; and because $m:n::mX:nX$, therefore $m:n::A:B-D$. Now as D is less than X, by taking X sufficiently small, D may be less than any proposed quantity, and B—D may differ from B by less than any given quantity; therefore such values may be given to m and n, as shall make the ratio of m to n as near to the ratio of A to B as we please. Hence we may, with perfect confidence, apply whatever has been delivered in this Section concerning commensurable quantities to such as are incommensurable.

SECTION IV.

The Proportion of Figures.

Definitions.

Definitions. 1. *Equivalent* figures are such as have equal surfaces. Two figures may be equivalent, although dissimilar. For example, a circle may be equal to a square; a triangle to a rectangle, &c.

We shall apply the term *equal* to such figures only as would coincide entirely, if placed the one upon the other.

2. Two figures are *similar*, when the angles of the one are equal to the angles of the other, each to each, and the homologous sides proportional. By the homologous sides, we mean those that have the same position in the two figures, or which are adjacent to equal angles: the angles themselves may be called *homologous angles.*

Fig. 87. 3. In two circles, similar sectors, similar arcs, similar segments, are those which have equal angles at the centre. Thus, if the angle A=O, the arc BC is similar to the arc DE, and the sector ABC to the sector ODE (Fig. 87.)

Fig. 96. 4. The *altitude* of a triangle ABC, (Fig. 96,) is a perpendicular drawn from any one of its angles A upon the opposite side BC its base.

Fig. 94. The *altitude* of a parallelogram ABCE, (Fig. 94,) is the distance AD between any two of its parallel sides.

Fig. 95. The *altitude* of a trapezoid ABCD, is the distance EF between its parallel sides. (Fig. 95.)

5. The *area* and the *surface* of a figure, are terms of nearly the same import. The area, however, is more particularly the quantity of superficies, as expressed by some other superficies taken a certain number of times.

Prop. I. Theor.

Parallelograms which have equal bases and equal altitudes are equivalent.

Fig. 88. Let AB be the common base of the two parallelograms ABCD, ABEF; since they are supposed to have the same altitude, their sides DC, FE, opposite to their bases, will be in the same straight line parallel to AB. But by the nature of parallelograms AD=BC, and AF=BE; also DC=AB, and FE=AB, (26. 1.) and therefore DC=FE; and taking away DC and FE from the same straight line DE, there remains DF=CE: Hence the triangles DAF, CBE have the three sides of the one equal to the three sides of the other, each to each, therefore they are equal (11. 1.): Now if the former be taken away from the quadrilateral ABED, there will remain the parallelogram AFEB; and if the latter be taken from the same quadrilateral, the parallelogram ABCD will remain; therefore the parallelogram ABCD is equivalent to the parallelogram ABEF.

Cor. Every parallelogram ABCD is equal to a rectangle FBCE of the same base and altitude. (Fig. 89.) Fig. 10[illegible]

Prop. II. Theor.

Any triangle ABC is half of a parallelogram ABCD of the same base and altitude. Fig. 89

For the triangles ABC, ACD are equal, (26. 1.)

Cor. 1. Therefore a triangle ABC is half of a rectangle BCEF, which has the same base BC and the same altitude AO.

Cor. 2. Triangles which have equal bases and equal altitudes are equivalent.

Prop. III. Theor.

Two rectangles of the same altitude are to one another as their bases.

Let ABCD, AEFD be two rectangles, which have a common altitude AD; they are to one another as their bases AB, AE.

For suppose that the base AB contains seven such parts as the base AE contains four; then, if AB be divided into seven equal parts, AE will contain four of them. At each point of division draw a perpendicular to the base; these will form seven equal rectangles (1.); and as AB contains seven such parts as AE contains four, the rectangle AC will also contain seven such parts as the rectangle AF contains four; therefore AB has to AE the same ratio that the rectangle AC has to the rectangle AF. Fig. 9[illegible]

Prop. IV. Theor.

Any two rectangles are to one another as the products of the numbers which express their bases and altitudes.

Let ABCD, AEGF be two rectangles, and let some line taken as an unit be contained m times in AB the base of the one, and n times in AD its altitude; also p times in AE the base of the other, and q times in AF its altitude; the rectangle ABCD shall be to the rectangle AEGF as the product mn to the product pq. Fig. [illegible]

Let the rectangles be so placed, that their bases AB, AE may be in a straight line, then their other sides AD, AF shall also form a straight line (3. 1.) Complete the rectangle EADH, and because this rectangle has the same altitude as the rectangle ABCD when EA, AB are taken as their bases, and the same altitude as the rectangle AEGF when AD, AF are taken as their bases, we have

$$ABCD : ADHE :: AB : AE :: m : p \quad (3.)$$
$$\text{but } m : p :: mn : pn \quad (1.\ 3.)$$
$$\text{therefore } ABCD : AEHD :: mn : pn.$$

In like manner, it appears that

$$AEHD : AEGF :: AD : AF :: n : q :: pn : pq.$$

Therefore, *ex æquo,* $ABCD : AEGF :: mn : pq$.

Scholium. If ABCD, one of the rectangles, (Fig. 92.) be a square having the measuring unit for its side, this square may be taken as the measuring unit of surfaces; and because the linear unit AB is contained p times in EF, and q times in EH, by the proposition Fig. 92.

$$1 \times 1 : pq :: ABCD : EFGH;$$

hence the rectangle EFGH will contain the superficial unit ABCD as often as the numeral product pq contains unity, consequently the product pq will express the *area* of the rectangle, or will indicate how often it contains the unit of superficies. Thus, if EF contain the linear unit AB four times, and EH contain it three times, the area EFGH will be $3 \times 4 = 12$, that is, twelve times a square whose side is $AB = 1$.

In consequence of the surface of a rectangle EFGH being expressed by the product of its sides, the rectangle, or its area, may be denoted by the symbol $EF \times FG$; or thus, EF.FG, in conformity to the manner of expressing a product in arithmetic.

However, instead of expressing the area of a square made on a line AB thus, $AB \times AB$, it is thus expressed, AB^2.

Note. A rectangle is said to be *contained* by two of its sides about any one of its angles.

PROP. V. THEOR.

The area of a parallelogram is equal to the product of its base by its altitude.

Fig. 93. For the parallelogram ABCD is equivalent to the rectangle ABEF, which has the same base AB and the same altitude (1.); and this last is measured by $AB \times BE$, or $AB \times AF$; that is, by the product of the base of the parallelogram and its altitude (4.)

COR. Parallelograms of the same base are to one another as their altitudes; and parallelograms of the same altitude are to one another as their bases. For in the former case, put B for their common base, and A and A′ for their altitudes; then we have $B \times A : B \times A' :: A : A'$. And in the latter, put A for their common altitude, and B and B′ for their bases; then $B \times A : B' \times A :: B : B'$.

PROP. VI. THEOR.

The area of a triangle is equal to the product of its base by half its altitude.

Fig. 94. For the triangle ABC is half the parallelogram ABCE, which has the same base BC, and the same altitude AD (2.); but the area of the parallelogram is $BC \times AD$ (5.); therefore the area of the triangle is $\frac{1}{2}BC \times AD$, or $BC \times \frac{1}{2}AD$.

COR. Two triangles of the same base are to one another as their altitudes, and two triangles of the same altitude are to one another as their bases.

PROP. VII. THEOR.

Fig. 95. The area of a trapezoid ABCD is equal to the product of half the sum of its parallel sides AB, DC by its altitude EF.

Through I, the middle of the side BC, draw KL parallel to the opposite side DA, and produce DC until it meet KL. In the triangles IBL, ICK, the side $IB = IC$, the angle $B = C$ (2 Cor. 21. 1.), the angle $BIL = CIK$; therefore the triangles are equal (7. 1.), and the side $CK = BL$. Now, the parallelogram ALKD is the sum of the polygon ALICD and the triangle CIK, and the trapezoid ABCD is the sum of the same polygon and a triangle equal to BIL; therefore the trapezoid ABCD is equal to the parallelogram ALKD, and has for its measure $AL \times EF$. And because $AL = DK$ and $BL = CK$, therefore $AB + CD = AL + DK = 2AL$; and hence AL is half the sum of the parallel sides AB, CD: therefore the area of the trapezoid is equal to $\frac{1}{2}(AB + CD) \times EF$.

PROP. VIII. THEOR.

If a straight line AC be divided into any two parts AB, BC, the square made on the whole line AC is equal to the squares on its two parts AB, BC, together with twice the rectangle contained by these parts. Or the proposition may be briefly expressed thus; AC^2 or $(AB + BC)^2 = AB^2 + BC^2 + 2\,AB \times BC$. Fig. 97.

Construct the square ACDE; take $AF = AB$; draw FG parallel to AC, and BH parallel to AE.

The square ACDE is composed of four parts; the first ABIF is the square on AB, because $AF = AB$; the second IGDH is the square on BC; for since $AC = AE$, and $AB = AF$, the difference $AC - AB$ is equal to the difference $AE - AF$, that is, $BC = EF$; but because of the parallels, $BC = IG$, and $EF = HI$, therefore HIGD is the square on BC. These two parts being taken from the whole square, there remains the two rectangles BCGI, EFIH, which are each equal to $AB \times BC$; so that the truth of the proposition is evident.

PROP. IX. THEOR.

If a line AC be the difference of two lines AB, BC, the square of AC shall be equal to the excess of the squares of AB and BC above twice the rectangle contained by AB and BC; that is, Fig. 98.

$$AC^2 \text{ or } (AB - BC)^2 = AB^2 + BC^2 - 2\,AB \times BC.$$

Construct the square ABIF, take $AE = AC$, draw CG parallel to BI, HK parallel to AB, and complete the square FEKL.

The two rectangles CGIB, GLKD are each equal to $AB \times BC$. If these be taken from the figure ABILKEA, which is equal to $AB^2 + BC^2$, there will evidently remain the square ACDE, that is, the square of $AB - BC$.

PROP. X. THEOR.

The rectangle contained by the sum and the difference of two lines, is equal to the difference of the squares of these lines; that is, Fig. 99.

$$(AB + BC) \times (AB - BC) = AB^2 - BC^2.$$

Construct upon AB and AC the squares ABIF, ACDE, produce AB so that $BK = BC$, and complete the rectangle AKLE.

The base AK of the rectangle is the sum of the two lines AB, BC; the altitude AE is the difference of the same lines; therefore the rectangle $AKLE = (AB + BC) \times (AB - BC)$. But the same rectangle is made up of two parts $ABHE + BHLK$; and the part BHLK is equal to the rectangle EDGF; for $BH = DE$, and $BK = EF$; therefore $AKLE = ABHE + EDGF$. But these two parts form the excess of the square ABIF above the square DHIG, which is the square of BC; therefore $(AB + BC) \times (AB - BC) = AB^2 - BC^2$.

PROP. XI. THEOR.

In any right angled triangle, the square which is described on the side opposite to the right angle is equal

Proportion of Figures.

to the sum of the squares on the two sides containing the right angle.

Fig. 100. Let ABC be a right angled triangle, of which A is the right angle. Having formed squares on the three sides, draw AD perpendicular to the hypothenuse, producing it to E; draw also the lines AF, CH.

The angle ABF is made up of the angle ABC and a right angle CBF; the angle HBC is made up of the same angle ABC and a right angle ABH; therefore the angle ABF = HBC: but AB = BH, because they are sides of the square, and BF = BC for a like reason; therefore the triangles ABF, HBC are equal (6. 1.) Now the triangle ABF is half of the rectangle BDEF, or BE, because they have the same base BF and the same altitude (2.); and the triangle HBC is in like manner half of the square BL, for they have the same base BH, and the same altitude; for, because the angles BAC, BAL are right angles, the lines CA, AL form a continued straight line (3. 1.), which is parallel to BH; therefore the rectangle BE is equivalent to the square BL. In like manner, by joining AG and BI, it may be demonstrated that the rectangle CE is equivalent to the square CK; therefore the two rectangles BE, CE are together equal to the two squares BL, CK: but these rectangles make up the whole square on BC, the side opposite to the right angle, and BL, CK are the squares on BA, and AC, the sides containing the right angle; therefore the square on the side subtending the right angle is equal to the sum of the squares on the sides containing the right angle.

Prop. XII. Theor.

Fig. 101. In any triangle ABC, the square of AB, the side opposite to any one of its acute angles, is less than the sum of the squares of the sides AC, CB, which contain that angle; and if a perpendicular AD be drawn to either of these BC from the opposite angle, the difference shall be equal to twice the rectangle BC × CD, so that

$$AB^2 = AC^2 + CB^2 - 2\,BC \times CD.$$

There are two cases, according as the perpendicular falls within or without the triangle. In case first, BD = BC − CD; and in case second, BD = DC − BC. In either case, $BD^2 = BC^2 + CD^2 - 2\,BC \times CD$ (9.) To each of these equals add DA^2, and we have

$$BD^2 + DA^2 = BC^2 + CD^2 + DA^2 - 2\,BC \times CD;$$

but $BD^2 + DA^2 = BA^2$ (11.), and $CD^2 + DA^2 = CA^2$; therefore $BA^2 = BC^2 + CA^2 - 2\,BC \times CD$.

Prop. XIII. Theor.

Fig. 102. In any obtuse angled triangle ABC, the square of AB, the side opposite to the obtuse angle, is greater than the squares of AC, BC, the sides containing the obtuse angle; and if a perpendicular AD be drawn on either of these sides, the excess will be equal to 2 BC × CD; so that we have

$$AB^2 = AC^2 + CB^2 + 2\,BC \times CD.$$

For BD = BC + CD; therefore $BD^2 = BC^2 + CD^2 + 2\,BC \times CD$ (8.); to each of these equals add DA^2, and we have

$$BD^2 + DA^2 = BC^2 + CD^2 + DA^2 + 2\,BC \times CD.$$

But $BD^2 + DA^2 = BA^2$; and $CD^2 + DA^2 = CA^2$; therefore $BA^2 = BC^2 + CA^2 + 2\,BC \times CD$.

Prop. XIV. Theor.

Fig. 1 In any triangle ABC, if a straight line AE be drawn from its vertex to the middle of the base, the sum of the squares of the sides is equal to twice the square of that line, and twice the square of half the base.

Draw AD perpendicular to the base. Then

$$AB^2 = AE^2 + EB^2 + 2\,BE \times ED \quad (13.)$$

$$AC^2 = AE^2 + EC^2 - 2\,CE \times DE \quad (12.)$$

Hence, by adding, and observing that BE = CE, and therefore $BE^2 = CE^2$, and BE × ED = CE × ED, we get $AB^2 + AC^2 = 2\,AE^2 + 2\,BE^2$.

Prop. XV. Theor.

Fig. A straight line DE drawn parallel to the base of a triangle ABC, divides the sides AB, AC proportionally; or so that AD : DB :: AE : EC.

Join BE and DC; the two triangles BDE, CDE have the same base DE; they have also the same altitude, because BC is parallel to DE; therefore they are equivalent, (2.) Again, because the triangles ADE, BDE have manifestly the same altitude, they are to one another as their bases, that is ADE : BDE :: AD : BD. Also because the triangles ADE, CDE have the same altitude, they are to each other as their bases, that is ADE : CDE :: AE : CE; but we have seen that the triangle BDE = triangle CDE; therefore, because of the common ratio in the two proportions, it follows that AD : BD :: AE : CE.

Prop. XVI. Theor.

Fig. Conversely, if the sides AB, AC be cut proportionally by the line DE, so that AD : DB :: AE : EC, the line DE shall be parallel to the base BC.

For if DE be not parallel to BC, some other line DO will be parallel to BC: then, by the preceding theorem, AD : DB :: AO : OC, but by hypothesis, AD : DB :: AE : EC; therefore, AO : OC :: AE : EC; and by composition, AC : OC :: AC : EC; hence OC must be equal to EC, which is impossible, unless the point O fall at E; therefore no line besides DE can be parallel to BC.

Prop. XVII. Theor.

Fig. If a straight line BD be drawn from the vertex of a triangle, so as to make equal angles with its sides BA, BC, the distances of the point D, in which it cuts the base from A and C, the extremities of the base, shall have to each other the same ratio as the adjacent sides BA, BC of the triangle: that is AD : DC :: AB : BC.

From C, one extremity of the base, draw CE parallel to BD, meeting AB in E. The angle ABD = BEC and the angle CBD = BCE (2 and 3 Cor. 21. 1.), but by hypothesis the angle ABD = CBD, therefore the angle BEC = BCE; hence the side BC = side BE, (13.) Again, because ABD is a triangle, and CE is drawn parallel to one of its sides, AD : DC :: AB : BE; but it has been shewn that BE = BC; therefore AD : DC :: AB : BC.

Scholium. There may be two cases, in one the line

Proportion of Figures.

BD meets the base between its extremities; and in the other, it meets the base produced.

Prop. XVIII. Theor.

Two equiangular triangles have their homologous sides proportionals, and the triangles are similar.

Fig. 106. Let ABC, DCE be two triangles which have their angles equal, each to each, viz. BAC=CDE, ABC=DCE, and ACB=DEC; the homologous sides, or the sides adjacent to the equal angles, shall be proportionals: that is, BC : CE : : AB : DC : : AC : DE.

Place the homologous sides BC, CE in the same direction, and because the angles B and E are together less than two right angles, the lines BA, ED shall meet if produced, (Schol. 21. 1.); let them meet in F. Then since BCE is a straight line, and the angle BCA=E; AC is parallel to FE (2 Cor. 20. 1.) In like manner, because the angle DCE = B; CD is parallel to FB; therefore ACDF is a parallelogram.

In the triangle BFE, the line AC is parallel to FE, wherefore BC : CE : : BA : AF (15.); or since AF = CD, BC : CE : : BA : CD. Again, in the same triangle BFE, CD is parallel to BF, therefore BC : CE : : FD : DE; that is, because FD = AC, BC : CE : : AC : DE. Since then it appears that the ratio of BC to CE is equal to the ratio of BA to CD, and also to the ratio of AC to DE, it follows that BA : CD : : AC : DE; therefore the homologous sides are proportionals; and because the triangles are equiangular, they are similar, (Def. 2.)

Scholium. It may be remarked that the homologous sides are opposite to the equal angles.

Prop. XIX. Theor.

Two triangles which have their homologous sides proportionals, are equiangular and similar.

Fig. 107. Suppose that BC : EF : : AB : DE : : AC : DF; the triangles ABC, DEF have their angles equal, viz. A=D, B=E, C=F.

At the point E, make the angle FEG = B, and at F, make the angle EFG = C, then G shall be equal to A (1 Cor. 24. 1.), and the triangles GEF, ABC shall be equiangular; therefore, by the preceding theorem, BC : EF : : AB : EG; but by hypothesis, BC : EF : : AB : DE; therefore EG = DE. In like manner we have BC : EF : : AC : FG; but by hypothesis, BC : EF : : AC : DF; therefore FG = DF. Thus it appears that the triangles DEF, GEF have their three sides equal, each to each; therefore they are equal (11.1.) But, by construction, the triangle GEF is equiangular to the triangle ABC; therefore also the triangles DEF, ABC, are equiangular and similar.

Prop. XX. Theor.

Two triangles which have an angle of the one equal to an angle of the other, and the sides about them proportionals, are similar.

Fig. 108. Let the angle A = D, and suppose that AB : DE : : AC : DF; the triangle ABC is similar to DEF.

Take AG = DE, and draw GH parallel to BC; the angle AGH shall be equal to ABC (3 Cor. 21.1.) and the triangle AGH equiangular to the triangle ABC; therefore AB : AG : : AC : AH; but by hypothesis, AB : DE : : AC : DF, and by construction, AG = DE, therefore AH = DF. The two triangles AGH, DEF have therefore an angle of the one equal to an angle of the other, and the sides containing these angles equal; therefore they are equal (6. 1.); but the triangle AGH is similar to ABC; therefore DEF is also similar to ABC.

Prop. XXI. Theor.

In a right angled triangle, if from the right angle A a perpendicular AD be drawn to the hypothenuse. Fig. 109.

1. The two triangles ABD, ADC are similar to the whole triangle ABC, and to each other.

2. Each side AB or AC is a mean proportional between the hypothenuse BC, and the adjacent segment BD or DC.

3. The perpendicular AD is a mean proportional between the two segments BD, DC.

First, The triangles BAD and BAC have the common angle B; and, besides, the right angle BDA is equal to the right angle BAC; therefore the third angle BAD of the one, is equal to the third angle C of the other (1 Cor. 24. 1.); therefore the two triangles are equiangular and similar. In like manner it may be demonstrated, that the triangle DAC is equiangular, and similar to the triangle BAC; therefore the three triangles are equiangular, and similar to one another.

Secondly, Since the triangle BAD is similar to BCA, their homologous sides are proportionals, that is, CB : BA : : BA : BD (18.) In like manner, because of the similar triangles CAD, CBA, we have BC : CA : : CA : CD; therefore each side is a mean proportional between the hypothenuse and its segment adjacent to that side.

Thirdly, Because of the similar triangles BDA, ADC, we have BD : DA : : DA : DC; so that the perpendicular is a mean proportional between the segments of the hypothenuse.

Prop. XXII. Theor.

If four straight lines be proportionals, the rectangle contained by the extremes is equal to the rectangle contained by the means; and conversely, if the rectangle contained by the extremes be equal to the rectangle contained by the means, the four straight lines are proportionals.

Let HA, HB, HC, HD be four straight lines, proportionals; the rectangle HA × HD = rectangle HB × HC. Fig. 110.

Let HA, HB be placed in a straight line, and HC, HD also in a straight line perpendicular to AB, and construct the rectangles P=HA × HD, Q=HC × HB, and R=HD × HB; then HA : HB : : P : R, and HC : HD : : Q : R, (3.) but by hypothesis, HA : HB : : HC : HD; therefore P : R : : Q : R, and hence P=Q, that is HA × HD=HB × HC.

Again, if P=Q, that is, if HA × HD=HB × HC, then HA : HB : : HC : HD; for the same construction being made, we have P : R : : Q : R; but P : R : : HA : HB; and Q : R : : HC : HD; therefore HA : HB : : HC : HD.

Cor. If three straight lines be proportionals, the rectangle contained by the extremes is equal to the square

Proportion of Figures.

of the mean; and if the rectangle contained by the extremes be equal to the square of the mean, the three straight lines are proportionals.

PROP. XXIII. THEOR.

Fig. 111.

If four straight lines be proportionals, and also other four, the rectangles contained by the corresponding terms shall be proportionals; that is, if A : B : : C : D, and E : F : : G : H; then supposing rectangles constructed, having these lines for their sides, as in the figure,

$A \times E : B \times F : : C \times G : D \times H.$

On the line B construct another rectangle which shall have E for its altitude; and on the line D construct a second rectangle that shall have G for its altitude. Then, by Prop. 3,

$A : B : : A \times E : B \times E$, and $C : D : : C \times G : D \times G$;

but A : B : : C : D, by hypothesis,

therefore $A \times E : B \times E : : C \times G : D \times G$;

Now, $B \times E : B \times F : : E : F$, and $D \times G : D \times H : : G : H$, and by hypothesis E : F : : G : H;

therefore $B \times E : B \times F : : D \times G : D \times H$;

but it was shewn that

$A \times E : B \times E : : C \times G : D \times G$

therefore, *ex æquo*, $A \times E : B \times F : : C \times G : D \times H$.

COR. Hence the squares of four proportional straight lines are also proportionals.

PROP. XXIV. THEOR.

Fig. 112.

Two triangles which have an angle of the one equal to an angle of the other, are to each other as the rectangle of the sides about the equal angles: That is, the triangle ABC is to the triangle ADE as $AB \times AC$ to $AD \times AE$.

Draw BE; the triangles ABE, ADE have a common vertex E, therefore ABE : ADE : : AB : AD (Cor. 6.); but $AB : AD : : AB \times AE : AD \times AE$ (3.) therefore,

trian. ABE : *trian.* ADE : : $AB \times AE : AD \times AE$.

In like manner it may be demonstrated, that

trian. ABC : *trian.* ABE : : $AB \times AC : AB \times AE$;

therefore (8. 3.)

trian. ABC : *trian.* ADE : : $AB \times AC : AD \times AE$.

COR. 1. Therefore the two triangles are equivalent, if $AB \times AC = AD \times AE$; or if AB : AD : : AE : AC (22.)

COR. 2. Two parallelograms which have an angle of the one equal to an angle of the other, will be to each other as the rectangles contained by the sides about these angles: For the parallelograms are the doubles of triangles which have an angle and two sides common with those of the parallelogram.

PROP. XXV. THEOR.

Similar triangles are to each other as the squares of their homologous sides.

Fig. 108.

Let the angle A=D, and the angle B=E, then,

AB : DE : : AC : DF (18.)

and AB : DE : : AB : DE,

for the terms of the two last ratios are identical, therefore,

$AB^2 : DE^2 : : AC \times AB : DF \times DE$ (23.)

But *trian.* BAC : *trian.* EDF : : $AC \times AB : DF \times DE$ (24.)

Therefore *trian.* ABC : *trian.* EDF : : $AB^2 : DE^2$.

PROP. XXVI. THEOR.

Similar polygons are composed of the same number of triangles, which are similar, each to each, and similarly situated.

In the polygon ABCDE, draw from an angle A the diagonals AC, AD, and in the other polygon FGHIK, draw in like manner from the angle F, which is homologous to A, the diagonals FH, FI. And since the polygons are similar, the angle B is equal to its homologous angle G, (Def. 2.) and besides, AB : BC : : FG : GH; therefore the triangles ABC, FGH are similar, (20.), and the angle BCA = GHF; these equal angles being taken from the equal angle BCD, GHI, the remainders ACD, FHI are equal; but since the triangles ABC, FGH are similar, we have AC : FH : : BC : GH, and because of the similitude of the polygons we have BC : GH : : CD : HI; therefore AC : FH : : CD : HI. Now it has been shewn that the angle ACD = FHI; therefore the triangles ACD, FHI are similar (20.) In like manner, it may be demonstrated, that the remaining triangles of the two polygons are similar; therefore the polygons are composed of the same number of similar triangles similarly situated. Fig. 113.

PROP. XXVII. THEOR.

The circumferences or perimeters of similar polygons are to one another as their homologous sides; and their areas are as the squares of their homologous sides.

1. For by the nature of similar figures, AB : FG : : BC : GH : : CD : HI, &c. Therefore, AB is to FG as AB + BC + CD, &c. the perimeter of the first figure to FG + GH + HI, &c. the perimeter of the second figure (12. 3.) Fig. 113.

2. And because the triangles ABC, FGH are similar, ABC : FGH : : $AC^2 : FH^2$ (25.), and in like manner, because the triangles ACD, FHI are similar, ACD : FHI : : $AC^2 : FH^2$; therefore, ABC : FGH : : ACD : FHI. In the same way it may be shewn that ACD : FHI : : ADE : FIK, and so on, if the polygons consist of more triangles. Hence, by Prop. 12. 3. the triangle ABC is to the triangle FGH as the sum of the triangles ABC, ACD, ADE, or the polygon ABCDE, to the sum of the triangles FGH, FHI, FIK, or the polygon FGHIK: But the triangle ABC is to the triangle FGH as AB^2 to FG^2 (25.); therefore the similar polygons are as the squares of their homologous sides.

COR. 1. If three similar figures have their homologous sides equal to the three sides of a right angled triangle; the figure made on the side opposite to the right angle shall be equal to the other two. For the figures are proportional to the squares on their homologous sides; and since the square on the side opposite to the right angle is equal to the squares on the other two sides, the figure on the former shall be equal to those on the latter.

COR. 2. Similar polygons have to each other the duplicate ratio of their homologous sides. For let L be a third proportional to the homologous sides AB, FG, then (Def. 11. 3.) AB has to L the duplicate ratio of AB to FG; but AB : L : : $AB^2 : AB \times L$ (3.); or, since $AB \times L = FG^2$ (Cor. 22.), AB : L : : $AB^2 : FG^2$: : ABCDE : FGHIK; therefore the figure

Proportion of Figures.

ABCDE has to FGHIK the duplicate ratio of AB to FG.

Prop. XXVIII. Theor.

Fig. 114. The segments of two chords AB, CD, which cut each other within a circle, are reciprocally proportionals, that is, AO : DO : : CO : OB.

Join AC and BD: In the triangles AOC, BOD, the vertical angles at O are equal; also the angle A = D, and C = B (17. 2.); therefore the triangles are similar, and the homologous sides proportionals, that is, AO : OD : : CO : OB.

Cor. Hence the rectangle AO × OB is equal to the rectangle CO × OD (22.) That is, the rectangle contained by the segments of the one chord is equal to the rectangle contained by the segments of the other.

Prop. XXIX. Theor.

Fig. 115. If two chords BA, CD in a circle be produced to intersect each other without it; the distances of the extremities of the chords from their mutual intersection are reciprocally proportionals, that is, AO : DO : : CO : BO.

For, joining BD and AC, the triangles OAC, OBD have the angle O common, and besides, the angle B=C (17. 2.), therefore the triangles are similar, and the homologous sides proportional; that is, AO : OD : : CO : OB.

Cor. Hence the rectangle AO × OB is equal to the rectangle CO × OD (22.)

Prop. XXX. Theor.

Fig. 116. If from any point O in the prolongation of a chord CD, a tangent OA be drawn to the circumference, the tangent is a mean proportional between the distances of the intersection from the extremities of the chord. That is, CO : OA : : OA : OD.

For if DA and AC be joined, the triangles OAD and OAC have the angle at O common, besides the angle OAD=C (20. 2.); therefore the two triangles are similar, and hence CO : OA : : OA : OD.

Cor. Hence we have AO^2=CO × OD, (Cor. 22.)

Scholium. The three preceding propositions have a great affinity. In fact, they constitute an individual property of the circle; for when two of the intersections unite, the chord becomes a tangent.

Prop. XXXI. Theor.

Fig. 117. In the same circle, or in equal circles, any angles ACB, DEF at the centres are to each other as the arcs AB, DF of the circles, intercepted between the lines which contain the angles.

Let us suppose that the arc AB contains three such equal parts as DF contains five. Let A*p*, *p q*, *q* B be the equal parts in AB, and D *r*, *r s*, &c. the equal parts in DF; draw the lines C*p*, C*q*, E*r*, E*s*, &c.; the angles AC*p*, *p*C*q*, *q*CB, DE*r*, &c. are all equal (15.2.) therefore as the arc AB contains ⅕th of the arc DF three times, the angle ACB will evidently contain ⅕th of the angle DEF also three times; and, in general, whatever number of times the arc AB contains some part of the arc DF, the same number of times will the angle ACB contain a like part of the angle DEF.

Problems to Sect. IV.

PROBLEMS RELATIVE TO SECT. IV.

Problem I.

To divide a given straight line into any number of equal parts, or into parts proportional to given lines.

1. Let it be proposed to divide the line AB into five equal parts. Through the extremity A draw an indefinite straight line AG; and in this line, take five equal distances AC, CD, DE, EF, and FG, of any length. Join BG, and draw CI parallel to GB, then AI will be the fifth part of AB, and the distance AI being set off five times from A, the line AB will be divided into five equal parts at the points I, K, L, M, as required. For the sides AG, AB are cut proportionally in C and I, (15. 4.); and as AC is one-fifth of AG, AI will also be one-fifth of AB. Fig. 118.

Next let it be proposed to divide the line AB into parts proportional to the lines P, Q, R, (Fig. 119.) From the extremity A, draw the indefinite straight line AE, and take AC=P, CD=Q, DE=R. Join the extremities E and B, and draw CI, DK, parallel to EB; then the line AB shall be divided into parts AI, IK, KB proportional to the given lines P, Q, R. Fig. 119.

For because of the parallels AC:CD:: AI:IK(15.4.), and by composition, AD : DC : : AK : KI; again, DE : AD : : KB : KA; therefore, *ex æquo*, DE : DC : : KB:KI, and so on; since then it appears that AC:AI:: CD : IK : : DE : KB, the parts of the line AB have to each other the ratios of the lines AC, CD, DE, that is of P, Q, and R.

Prob. II.

To find a fourth proportional to three given lines A, B, C. Fig. 120.

Draw the two indefinite lines DE, DF, making any angle. On DE take DA = A, and DB = B; and on DF take DC = C; join AC, and through B draw BX parallel to AC; then shall DX be the fourth proportional required. For since BX is parallel to AC, DA : DB : : DC : DX (15. 4.); therefore DX is the fourth proportional required.

Cor. By this problem, a third proportional to two given lines may be found; for it will be the same as a fourth proportional to A, B and B.

Prob. III.

To find a mean proportional between two given lines A and B. Fig. 121.

On the indefinite line DF take DE=A, and EF=B; on DF as a diameter describe a semicircle DGF; at the point E draw EG perpendicular to the diameter, meeting the circumference in G; then shall EG be the mean proportional required. Join GD and GF; the triangle DGF is right angled at G, for G is an angle in a semicircle (19. 2.); therefore the perpendicular GE

Problems to Sect. IV.

on the hypothenuse is a proportional between DE and EF, (21.) that is between A and B.

PROB. IV.

Fig. 122. To divide a straight line AB into two parts, so that one of them shall be a mean proportional between the whole line and the other part.

At B, one extremity of the line, erect a perpendicular BC equal to half AB; on C as a centre, with CB as a radius, describe a circle; draw AC to meet the circumference in D, and take AF = AD; then the line AB shall be divided at the point F in the manner required, that is, AB : AF :: AF : FB.

For AB being perpendicular to the extremity of the radius BC, is a tangent to the circle (9. 2.); therefore if AC be produced until it meet the circumference again in E, we shall have AE : AB :: AB : AD; hence, by division, AE—AB : AB :: AB—AD : AD; but since BC $=\frac{1}{2}$ AB, therefore DE = AB, and consequently AE — AB = AD = AF; also, because AF = AD, we have AB — AD = FB; therefore AF : AB :: FB : AD, or AF, and by inversion, AB : AF :: AF : FB.

SCHOLIUM. A line divided in this manner is said to be cut in *extreme and mean ratio*; and it may be remarked, that AE is also divided into extreme and mean ratio at the point D, for since AB = DE, we have AE : DE :: DE : AD.

PROB. V.

Fig. 123. Through a given point A in a given angle BCD, to draw a straight line BD, so that the parts AB, AD contained between the point A and the two sides of the angle shall be equal.

Through the point A, draw AE parallel to CD; take EB = EC, and draw AB to meet CD in D, and the thing is done. For AE being parallel to CD, we have BE : EC :: BA : AD; but BE = EC, therefore BA = AD.

PROB. VI.

To make a square equivalent to a given parallelogram, or to a given triangle.

Fig. 124. 1. Let ABCD be the given parallelogram, AB its base, and DE its altitude. Between AB and DE find a mean proportional XY (Prob. 3.); the square made on XY shall be equivalent to the parallelogram ABCD. For since by construction, AB : XY :: XY : DE; therefore, (Cor. 22.) XY^2 = AB × DE = the parallelogram ABCD, (Cor. 1.)

Fig. 125. 2. Let ABC be the given triangle, BC its base, and AD its altitude. Take a mean proportional between BC and the half of AD; and let XY be that mean. The square made on XY shall be equivalent to the triangle ABC.

For since BC : XY :: XY : $\frac{1}{2}$ AD; therefore XY^2 = BC × $\frac{1}{2}$ AD = triangle ABC.

PROB. VII.

Fig. 126. Upon a given straight line AD, to make a rectangle DAEX equivalent to a given rectangle ABFC.

Find AX a fourth proportional to the three lines AD, AB, AC, (Prob. 2.); the rectangle contained by AD and AX will be that required.

For since AD : AB :: AC : AX, it follows that AD × AX = AB × AC (22.); therefore the rectangle ADEX is equivalent to the rectangle ABFC.

PROB. VIII.

Having given any rectilineal figure to make another equivalent to it, that shall have one side fewer.

Let ABCDE be the given figure. Draw a diagonal CE so as to cut off from it a triangle CDE; through D, the vertex of the triangle, draw DF parallel to its base CE, to meet AE, one of the adjacent sides of the figure (produced if necessary) in F; join CF, and the figure ABCF shall be equal to the figure ABCDE, and have one side fewer. For the triangle CFE is equivalent to CDE (6.), therefore, adding the common space ABCE, the figure ABCF is equal to the figure ABCDE. Fig. 127.

SCHOLIUM. By this problem, a triangle may be found that shall be equivalent to a rectilineal figure of any number of sides. Thus, the five-sided figure ABCDE having been reduced to the quadrilateral ABCF, if we join CA, and draw BG parallel to CA, to meet FA produced in G, and then join CG, the quadrilateral will be transformed into an equivalent triangle CGF, which will also be equal to the original figure ABCDE.

It has been already shewn that a square may be found equivalent to any triangle; therefore by this, and Prob. 6. any rectilineal figure whatever may be transformed into an equivalent square.

PROB. IX.

To make a square that shall be equal to the sum, or to the difference of two given squares.

Let A and B be the sides of the two given squares. Fig. 128.

1. To make a square equal to the sum of two squares, draw two indefinite lines ED, EF, containing a right angle; take DE=A and EG=B; join DG, and DG is evidently the side of the square required, (11.)

2. If a square is to be found equal to the difference of two squares; form a right angle FEH; take EG equal to the lesser of the two sides A, B, and on G as a centre, with a radius equal to the greater, describe an arc, to meet EH in H; then EH shall be the side of a square equal to the difference of the squares on GH and GE, or on A and B, as is evident from Prop. 11. Sect. 4.

SCHOLIUM. By this problem, a square may be made equal to any number of given squares.

PROB. X.

On a given straight line FG, homologous to AB, to describe a polygon similar to a given polygon ABCDE. Fig. 113

Draw the diagonals AC, AD: at the point F make the angle GFH equal to the angle BAC, and at G make the angle FGH equal to ABC; the lines FH, GH will meet in H, and form a triangle FGH similar to ABC. In like manner, on FH, which is homologous to AC, construct a triangle FHI, similar to ACD; and on FI, homologous to AD, construct a triangle FIK similar to ADE. The polygon FGHIK shall be similar to ABCDE. For hese two polygons are composed ular rons. of the same number of triangles, similar and similarly situated, (26.)

SECT. V.

Of Regular Polygons, and the Measure of the Circle.

ir po- , and ·asure circle. Definition. A polygon, which is at the same time equilateral and equiangular, is called a *regular polygon.*

Prop. I. Problem.

To inscribe a square in a given circle.

29. Draw two diameters AC, BD, at right angles to each other; join their extremities A, B, C, D; and the figure ABCD shall be the inscribed square. For the angles ABC, BCD, &c. are right angles, (19. 2.), and the chords AB, BC, &c. are equal.

Prop. II. Prob.

To inscribe a regular hexagon and an equilateral triangle in a given circle.

30. From any point B in the circumference, apply BA and BC each equal to the radius BO; draw the diameters AD, BE, CF, and join their adjoining extremities, and the figure ABCDEF, thus formed, will be the hexagon required.

For the triangles AOB, COB being equilateral, each of the angles AOB, BOC will be one third of two right angles (4. Cor. 24. 1.); therefore COD will also be one-third of two right angles (2. 1.); therefore the angles AOF, FOE, EOD, vertical to these, will be each one-third of two right angles, and the six angles at O will be equal; and hence the straight lines AB, BC, CD, DE, EF, FA will be all equal (15. 2.), and the hexagon will be equilateral. It will also be equiangular; for the angles FAB, ABC, &c. stand each on two-thirds of the whole circumference; therefore they are all equal (17. 2.) If straight lines be drawn joining A, C, E, the vertices of the alternate angles of the hexagon, there will be formed an equilateral triangle inscribed in the circle, as is sufficiently evident.

Scholium. In the same way as we have proved that every equilateral hexagon is equiangular, it may be proved that any equilateral polygon whatever in a circle is also equiangular.

Prop. III. Prob.

To describe a regular decagon in a circle, also a regular pentagon.

1. Divide the radius AO in extreme and mean ratio at the point M; take the chord AB equal to the greater segment OM, and AB shall be a side of the regular decagon, or figure of ten sides, which may be completely formed by placing straight lines, each equal to AB, round the circumference.

Join BM; and because, by construction, AO : OM : : OM : AM, and AB=OM, therefore AO : AB : : AB : AM; hence the triangles AOB, ABM, which have an angle OAB common to both, have the sides about that angle proportionals; therefore they are similar (20. 4.) And because the triangle AOB is isosceles, the triangle ABM is also isosceles, and AB=BM; but AB=MO, by construction; therefore BM=MO, and the triangle BMO is isosceles. Therefore the angle AMB, which is equal to the sum MOB + MBO (24. 1.), will be double MOB. But the angle AMB = MAB; therefore each of the angles OAB, OBA is double AOB; and the three angles of the triangle AOB will be five times the angle O. Thus the angle O will be one-fifth of two right angles (24. 1.), or one-tenth of four right angles, therefore the arc AB is one-tenth of the circumference; and the chord AB is the side of a regular decagon inscribed in a circle. Regular Polygons.

If every second angle of the decagon be joined by straight lines, there will be formed a regular pentagon ACEGI inscribed in the circle.

Cor. By this and the foregoing problems a regular quindecagon, or polygon of fifteen sides, may be inscribed in a circle. For let AL be the side of a hexagon; then the arc ABL will be $\frac{1}{6}$, or $\frac{5}{30}$ of the whole circumference, and the arc AB $\frac{1}{10}$, or $\frac{3}{30}$ of the circumference, therefore the difference of the two arcs will be $\frac{2}{30}$, or $\frac{1}{15}$ of the circumference, and LB the chord of the arc will be the side of a quindecagon.

Scholium. By bisecting the arc subtended by a side of any polygon, another of double the number of sides may be inscribed in a circle. Hence from a square, we may inscribe polygons of 8, 16, 32, &c. sides; and from a hexagon others of 12, 24, &c.

The square, the regular pentagon and hexagon, and such figures as can be formed from them in the manner we have described, were the only regular figures that th ancients could inscribe in a circle. A mathematician o our own times, Mr Gauss, has however shewn, that a regular polygon of 17 sides may be inscribed in a circle by drawing straight lines and circles only; and tha the same is true of all polygons of which the number of sides is a prime number of the form 2^n+1. This formula includes figures of 3, 5, 17, 257, 65537, &c. sides; but the demonstration, even in the case of 17 sides, has not yet been given on principles purely geometrical. See *Disquisitiones Arithmeticæ*, published at Brunswick, 1801; or a French translation, 1807.

Prop. IV. Prob.

Having given any regular polygon ABCD, &c. inscribed in a circle, to describe a regular polygon of the same number of sides about the circle.

At H, the middle of the arc AB, draw the tangent *a* H *b*; do the same at the middle of each of the other arcs BC, CD, &c. these tangents shall form by their intersections a regular circumscribed polygon *a b c d*, &c. similar to the inscribed polygon. Fig. 132.

Draw the radii OH, OI, and because OH is perpendicular to the tangent *a b*, (9. 2.) and also to the chord AB (schol. 6. 2.), the tangent is parallel to the chord (19. 1.) In like manner it may be shewn that all the other sides of the circumscribing figure are parallel to the sides of the inscribed figure. Draw a line from O to *b*; and because the right angled triangles O *b* H, O *b* I are equal (18.1), for they have a common hypothenuse O *b*, and the side OH=OI, therefore the angle HO *b*= IO*b*, and the line O *b* passes through the middle of the arc HI, that is, a line drawn from the centre to the intersection of any two sides of the circumscribing polygon passes through the intersection of the sides parallel to them of the inscribed polygon: And because the angles *cb*O and *a b* O are respectively equal to CBO and ABO (3 Cor. 21. 1.), the whole angle *c b a* = CBA; in like manner it may be proved, that *b a f* = BAF, &c. therefore the angles of the circumscribing polygon are equal to those of the inscribed polygon. Again, be-

Regular Polygons. cause of the similar triangles OBA, O b a, and OBC, O b c, we have AB : $a\,b$: : (BO : $b\,o$: :) BC : $b\,c$ (18. 4.) but AB = BC, therefore $a\,b = b\,c$: For a like reason $b\,c = c\,d$, &c. therefore the circumscribing polygon is regular and similar to the inscribed polygon.

Prop. V. Theor.

Regular polygons of the same number of sides inscribed in circles are similar, and are to one another as the squares of the radii of the circles.

Fig. 133. Let ABCDEF and $a\,b\,c\,d\,e\,f$ be equilateral hexagons inscribed in circles; these will also be equiangular, (schol. 2.) and consequently regular; and because all the angles of each polygon are together equal to eight right angles (25. 1.), the angle A is $\frac{1}{6}$ of eight right angles; and as the same is also true of a, therefore the angles A and a are equal. In like manner it appears that B = b, C = c, &c. and because the sides of each figure are all equal, we have FA : AB : : $f\,a$: $a\,b$, &c. therefore the polygons are similar (2 def. 4.)

Draw BO, CO, $b\,o$, $c\,o$, to the centres: The triangles BOC, $b\,o\,c$ are similar, for the angles at O and o are equal, each being $\frac{1}{6}$ of four right angles, and CO : OB : : $c\,o$: $o\,b$; therefore COB : $c\,o\,b$: : CO^2 : $c\,o^2$; but the triangles COB, $c\,o\,b$ are manifestly like parts of the whole polygons, therefore (1. 3.) the polygons are to each other as the squares of CO, $c\,o$, the radii of the circles.

Prop. VI. Theor.

A circle being given, two similar polygons may be found, the one described about the circle; and the other inscribed in it, which shall differ from one another by less than any given space.

Fig. 134. Let Q be the side of a square, equal to the given space; bisect AC, a fourth part of the circumference of the circle, and again bisect the half of this fourth, and proceed in this manner, always bisecting one of the arcs found by the former bisection, until an arc is found of which the chord AB is less than Q: As this arc will be an exact part of the circumference, if we place chords AB, BC, CD, &c. in it each equal to AB, the last will terminate at A, and there will be formed a regular polygon ABCDE &c. in the circle:

Next describe about the circle a regular polygon $a\,b\,c\,d\,e$, &c. of the same number of sides as the inscribed polygon, and having its sides parallel to those of the latter (4.) The difference of these two shall be less than the square of the line Q.

For, draw lines from a and b to O the centre, these will pass through A and B, as was shewn in the demonstration of Prop. 4. also a line drawn from O to K, the point in which $a\,b$ touches the circle, will bisect AB in I, and be perpendicular to it (6. 2.): complete the diameter AOE, and join EB. Put P for the circumscribing polygon, and p for the inscribed polygon; then, because the triangles $a\,o\,b$, AOB are manifestly like parts of P and p, we have P : p : : $a\,o\,b$: AOB; (1. 3.) but these triangles being similar, $a\,o\,b$: AOB : : $o\,a^2$: OA^2, or OK^2, (25. 4.); and again, because the triangles O aK, EAB are manifestly similar, we have O a^2 : OK^2 : : EA^2 : EB^2 (18. and 23. 4.); therefore P : p : : EA^2 : EB^2, and by conversion, P : P — p : : EA^2 : $EA^2 - EB^2$ or AB^2. Now, as a square described about a circle will manifestly include within it a polygon of 8, also of 16, and of 32 sides, &c. the polygon P will be less than the square of EA; therefore P — p, the difference of the circumscribing and inscribed polygons, will be less than the square of AB, that is, by construction, less than the given space Q. (cor. 3. 3.)

Cor. 1. Because the polygons differ from each other more than either differs from the circle, we may infer, that a polygon may be described about a circle, and also a polygon may be inscribed in a circle, either of which shall differ from the circle by less than any given space.

Cor. 2. A space that is less than any polygon whatever, described about a circle, and also greater than any polygon whatever, inscribed in the same circle, must be equal to that circle.

Axiom.

Fig. If HBI be any arc of a circle, and b H, b I tangents at its extremities, the sum of the tangents b H, b I is greater than the arc HBI.

Cor. The circumference of a circle is less than the perimeter of its circumscribing polygon.

Prop. VII. Theor.

The area of any circle is equal to a rectangle contained by half the perimeter, and the radius.

Fig. Let ABCD, &c. be a regular polygon inscribed in the circle, and $a\,b\,c\,d$ &c. a similar polygon, described about it, and having the sides ab, bc, &c. parallel to AB, BC, &c. draw OIK perpendicular to AB, ab; and OAa, OBb, through the points A, a, and B, b. Let P be the perimeter of the polygon $a\,b\,c\,d$ &c. p that of the polygon ABCD &c. and Q that of the circle.

The triangle a O b is equal to $\frac{1}{2}a\,b \times$ OK, (6. 4.) and multiplying these equals by n, the number of sides of the polygon, we have $n \times$ trian. a O $b = n \times \frac{1}{2}a\,b \times$ OK; but $n \times$ trian. a O b is manifestly the area of the polygon $a\,b\,c\,d$ &c. and $n \times \frac{1}{2}a\,b$, or $\frac{1}{2} \times n \times a\,b$ is equal to $\frac{1}{2}$ P; therefore the area of the polygon $a\,b\,c\,d$ &c. is $\frac{1}{2}$P $\times$ OK; and similarly, the area of the polygon ABCD &c. is $\frac{1}{2}\,p \times$ OI.

Because $\frac{1}{2}$Q $< \frac{1}{2}$ P, therefore $\frac{1}{2}$ Q $\times$ KO $< \frac{1}{2}$ P $\times$ KO, but $\frac{1}{2}$ P $\times$ KO is the area of the polygon $a\,b\,c\,d$ &c. therefore $\frac{1}{2}$ Q $\times$ KO is less than the area of the polygon $a\,b\,c\,d$ &c. Again, because $\frac{1}{2}$Q $> \frac{1}{2}p$, therefore $\frac{1}{2}$Q $\times$ OK $> \frac{1}{2}p \times$ OK; but OK $>$ OI, and $\frac{1}{2}p \times$ OK $> \frac{1}{2}\,p \times$ OI: much more then is $\frac{1}{2}$ Q $\times$ OK $> \frac{1}{2}p \times$ OI, but $\frac{1}{2}p \times$ OI is the area of the polygon ABCD, &c. therefore $\frac{1}{2}$ Q $\times$ OK is greater than the area of the polygon ABCD, &c. Thus it appears, that the rectangle contained by $\frac{1}{2}$ Q the perimeter of the circle, and OK its radius, is greater than any polygon inscribed in the circle, and less than any polygon described about the circle; therefore it must be exactly equal to the area of the circle, (Cor. 6.)

Prop. VIII. Theor.

The areas of circles are to each other as the squares of their radii.

F. 133. Let ABCDEF, and $a\,b\,c\,d\,e\,f$ be regular, and similar polygons inscribed in the circles; and as OB^2 : $o\,b^2$, so let the circle ABCDEF be to a fourth proportional Q; then because OB^2 : $o\,b^2$: : pol. ABCDEF : pol. $abcdef$, (5.) it follows, that ular gons.

pol. ABCDEF : pol. $abcdef$ :: cir. ABCDEF : Q.

Now the third term of this proportion is greater than the first, therefore the fourth is greater than the second; that is, Q is greater than any polygon inscribed in the circle $abcdef$.

Because the areas of similar polygons described about a circle are also to each other as the squares of the radii, it may be shewn in the same way, that the space Q is less than any polygon described about the circle $abcdef$; therefore Q must be exactly equal to the circle $abcdef$ (2 Cor. 6.) and the circle ABC &c. is to the circle abc &c. as OB^2 to ob^2.

Cor. 1. The perimeters of circles are to each other as their radii. Let P be half the circumference of the circle ABCDEF, and R its radius; also let p and r be half the circumference and the radius of the other circle; then the areas of the circles are equal to the rectangles $P\times R$ and $p\times r$, (7.); and it has been shewn, that $P\times R : p\times r :: R^2 : r^2$; therefore, by alternation, $P\times R : R^2 :: p\times r : r^2$; but $P\times R : R^2 :: P : R$, and $p\times r : r^2 :: p : r$; therefore $P : R :: p : r$; and by alternation, $P : p :: R : r$.

Cor. 2. A circle described with the hypothenuse of a right angled triangle as a radius, is equal to two circles described with the other two sides as radii, (Fig.

135. 135.) Let the sides of the triangle be a, b, and its hypothenuse h; and let the circles described with these lines as radii be A, B, and H; and because

$$A : H :: a^2 : h^2,$$
$$\text{and } B : H :: b^2 : h^2;$$

Therefore $A+B : H :: a^2+b^2 : h^2$ (10. 3.) but $a^2+b^2=h^2$; therefore $A+B=H$.

Prop. IX. Prob.

Having given the surfaces of a regular polygon inscribed in a circle, and of a similar polygon described about it, to find the surfaces of the inscribed and circumscribed polygons of double the number of sides.

136. Let AB be the side of the inscribed polygon, EF parallel to AB, that of the similar circumscribed polygon, and C the centre of the circle. If the chord AM, and the tangents AP, BQ be drawn, the chord AM shall be the side of an inscribed polygon of double the number of sides, and PQ=2 PM, the side of a similar circumscribed polygon. This being supposed, as the same construction may be made in all the different angles equal to ACM, and as the triangles contained in ACM have to each other the ratios of the whole polygons, it will be sufficient to consider these only.

Let A be the surface of the inscribed polygon, of which AB is a side, B the surface of the similar circumscribed polygon, a the surface of the polygon, of which AM is a side, and b the surface of the circumscribed polygon. A and B are supposed known, and it is required to determine a and b.

1. The triangles ACD, ACM, are to each other as their bases CD, CM, (Cor. 6. 4.) besides they are to each other as the polygons A and a, of which they are like parts; therefore $A : a :: CD : CM$. The triangles CAM, CME, are to each other as their bases CA, CE, and also as the polygons a and B; therefore $a : B :: CA : CE$. But because of the similar triangles CDA, CME, we have $CD : CM :: CA : CE$, (18. 4.) therefore $A : a :: a : B$; so that the polygon a, one of those we seek, is a mean proportional between the two known polygons A and B; and if these are expressed by numbers, a will be found by taking the square root of their product; that is, $a=\sqrt{A\times B}$.*

Regular Polygons.

2. Because of the common altitude CM, the triangle CPM is to the triangle CPE as PM to PE; but because the angle ECM is bisected by CP, $PM : PE :: CM : CE$ (17. 4.) $:: CD : CA :: A : a$, therefore $CPM : CPE :: A : a$, and by inversion and composition, $CPM+CPE$, or $CME : CPM :: A+a : A$, and taking the doubles of the consequents, $CME : 2\,CPM :: A+a : 2A$; now CME and 2 CPM, or CMPA, are like parts of the polygons B and b, therefore $A+a : 2A :: B : b$; hence b is known, because it is a fourth proportional to the three known quantities $A+a$, 2 A and B, and $b=\dfrac{2A\times B}{A+a}$.

Therefore, by means of the polygons A and B, it is easy to find the polygons a and b, which have double the number of sides.

Prop. X. Prob.

To find nearly the ratio of the diameter of a circle to its circumference.

The most obvious method, although not the best, is to express the diameter by a number, and compute the areas of two polygons of the same number of sides, one inscribed in the circle, and the other described about it. The area of the circle itself will be some quantity between these two. If the number of sides be considerable, either, or any quantity between them, will be nearly equal to the area of the circle. And since the area is equal to the rectangle contained by the radius and half the circumference, if the approximate value of the area be divided by the radius, twice the quotient will be an approximate value of the circumference.

Let us suppose the radius to be unity, then the diameter will be 2, and the side of a square described about the circle, will be expressed by the number 4; and as the inscribed square A, is evidently half the circumscribed square, the area of the inscribed square will be 2. Employing now the formulæ found in last proposition, viz.

$$a=\sqrt{A\times B},\quad b=\frac{2A\times B}{A\times a},$$

and making A=2, and B=4, we find a, the area of a regular polygon of eight sides inscribed in the circle, $=\sqrt{2\times 4}=\sqrt{8}=2.8284271$, and b the circumscribed polygon $=3.3137085$.

Putting now A=2.8284271, and B=3.3137085, we may hence find a and b the inscribed and circumscribed figures of 16 sides, and so on as in this Table.

Number of Sides.	Inscr. Polygon.	Circum. Pol.
4	2.0000000	4.0000000
8	2.8284271	3.3137085
16	3.0614674	3.1825979
32	3.1214451	3.1517249
64	3.1365485	3.1441184
128	3.1403311	3.1422236
256	3.1412772	3.1417504
512	3.1415138	3.1416321
1024	3.1415729	3.1416025
2048	3.1415877	3.1415951
4096	3.1415914	3.1415933
8192	3.1415923	3.1415928
16384	3.1415925	3.1415927
32768	3.1415926	3.1415926

* The radical sign $\sqrt{}$ placed over the symbol that expresses any quantity, indicates that the square root of the expression which it affects is to be taken. See Algebra, Art. 137.

Regular Polygons.

Hence it appears that the inscribed and circumscribing polygons of 32768 sides agree in the first seven decimal places of the numeral expressions for their value; therefore the numeral expression for the circle itself, which is between these, will be correct in all these figures; so that the radius of a circle being one, its area is 3.1415926 nearly, and this divided by the radius gives 3.14159926 for half the circumference nearly, the radius being one; hence the diameter is to the circumference nearly as 1 to 3.1415926 nearly.

Scholium. By this method, the ratio of the diameter to the circumference may be found to any approximate degree of accuracy. Archimedes, by means of inscribed and circumscribed polygons of 96 sides, shewed that the diameter is to the circumference nearly as 7 to 22; and Metius found, by polygons of a greater number of sides, that the diameter is to the circumference as 113 to 355. The manner of deducing these from the ratio found in the proposition, is explained in Algebra, art. 364.*

Prop. XI. Prob.

To find a straight line nearly equal to any given arc of a circle.

Fig. 137. Let AB be any arc of a circle, of which C is the centre. Draw the radii CA, CB, and draw AH perpendicular to AC, and CD perpendicular to CB, meeting HA in D. Bisect the angle ACB by the straight line CH; again bisect the angle ACH by the line CI, and bisect the angle ACI by the line CK, and bisect the angle ACK by the line CL, and proceed in this manner with any number of bisections; the greater the number, the more accurate will be the result.

Let H, I, K, L, &c. be the points in which the bisecting lines meet the line DA. In AD produced, take DP$=\frac{1}{2}$ of AH, PQ$=\frac{1}{4}$ of AI, QR$=\frac{1}{8}$ of AK, RS$=\frac{1}{16}$ of AL, and so on, if there were more lines intercepted between A and the bisecting lines, but if AL be the last, then take ST$=\frac{1}{3}$ of RS. Draw a straight line now from C to T, and draw Cb perpendicular to CT, meeting AH in b, and the straight line Ab shall be nearly equal to the arc AB of the circle.

This construction is derived from an elegant formula which we have investigated in the conclusion of the Arithmetic of Sines, also in Conic Sections, (Sect. VII.) It is this, putting a for any arc,

$$\frac{1}{a} = \text{cot. } a + \tfrac{1}{2}\text{ tan. } \tfrac{1}{2}a + \tfrac{1}{4}\text{ tan. } \tfrac{1}{4}a + \tfrac{1}{8}\text{ tan. } \tfrac{1}{8}a + \text{\&c.}$$

Now, from the construction and the definition of the trigonometrical lines about a circle, it is manifest that AD is the cotangent of AB or a, and that AH $=$ tan. $\frac{1}{2}a$, AI $=$ tan. $\frac{1}{4}a$, &c. and therefore that DP$=\frac{1}{2}$ tan $\frac{1}{2}a$, PQ$=\frac{1}{4}$ tan $\frac{1}{4}a$, &c. and therefore that AS $=$ cot. $a+\frac{1}{2}$ tan. $\frac{1}{2}a+\frac{1}{4}$ tan. $\frac{1}{4}a+\frac{1}{8}$ tan. $\frac{1}{8}a+\frac{1}{16}$ tan. $\frac{1}{16}a$; the addition of ST $=\frac{1}{3}$ RS is an approximate value of the sum of the remaining terms of the series; and as TCb is a right-angled triangle, of which C is the right angle, $CA^2 = AT \times Ab$ (21. 4.) and

$$\frac{CA^2}{Ab} = AT, \text{ that is } \frac{1}{Ab} = \text{cot. } a + \tfrac{1}{2}\text{ tan. } \tfrac{1}{2}a + \text{\&c.}$$

Hence it is evident that A$b =$ arc a.

Scholium. If we suppose the arc AB a quadrant, then AD $= 0$, and by calculation, (see Arithmetic of Sines, Art. 33), supposing CA$=1$, it will be found that DP $=$ 5000000 PQ $=$ .1035534, QR $=$ .0248640, RS $=$ .0061557, ST $=$ .0020519; hence DT or AT $=$ .6366250; and since AT : AC $=$ 1 :: AC : Ab, we find Ab or AB$=$1.570784, the approximate value of the quadrant. The more correct value is 1.570796, &c. by which it appears that the error is little more than the $\frac{1}{100000}$ part of the radius.

Part II. THE GEOMETRY OF SOLIDS.

Of Planes and solid Angles.

SECT. I.

Of Planes and Solid Angles.

Definitions.

Definitions. 1. A straight line is *perpendicular* or at right angles to a plane, when it makes right angles with every straight line, meeting it in that plane. On the other hand, the plane is perpendicular to the line.

2. A straight line is *parallel* to a plane when they do not meet, to whatever distance both are produced. The plane is also parallel to the line.

3. Two planes are *parallel* to each other, when they do not meet although produced.

4. Admitting what will be afterward demonstrated, (in Prop. 3.) that the common sections of two planes is a straight line, the *angle* or the *inclination* of two planes is the angle contained by two straight lines, drawn from the same point of their common section at right angles to it; the one in the one plane, and the other in the other. This angle may be either acute, right, or obtuse.

5. If this angle is a right angle, the planes are perpendicular.

6. A solid angle is that which is made by the meeting of more than two plane angles, which are not in the same plane, in one point.

Prop. I. Theor.

A straight line cannot be partly on a plane, and partly above it.

For, according to the definition of a plane, when a straight line has two common points with a plane, it is entirely on that plane.

Prop. II. Theor.

Two straight lines, which cut each other in a plane determine its position; that is, a plane which passes through two straight lines, that cut each other, can have only one position.

Let AB, AC be two straight lines which cut each other in A; suppose a plane to pass through AB, and to turn on that line, until it pass through C; then the

* The ratio of 113 and 355 is easily remembered, by observing that the figures of the numbers are 1, 1, 3, 3, 5, 5, viz. the first three odd numbers each repeated.

Of Planes and solid Angles.

points A and C lying on the plane, the whole line AC will be in the plane; therefore the position of the plane is determined by the single condition of its containing the two straight lines AB, AC.

Cor. 1. Any triangle ABC, or three points A, B, C, not in a straight line, determine the position of a plane.

Fig. 141. Cor. 2. Therefore also any two parallels AP, ED (Fig. 141.) determine the position of a plane, for if a straight line AD meet them, the plane of the two lines AP, AD is that of the parallels AP, ED.

Prop. III. Theor.

If two planes cut each other, their common section is a straight line.

Fig. 139. Draw a straight line joining any two points E and F in the common section of two planes AB, CD, this line will be wholly in the plane AB (by the definition of a plane), and also wholly in the plane CD; therefore it is in both planes at once, and consequently is their common section.

Prop. IV. Theor.

Fig. 140. If a straight line AP is perpendicular to two straight lines PB, PC at the point of their intersection P, it is perpendicular to the plane in which these lines are.

Through P draw any straight line PQ in the plane of the lines PB, PC; through Q, any point in that line, draw a straight line to meet PB, PC, so that BQ=QC, (Prob. 5. Sect. 4. Part I.) Join AC, AQ, AB; and because ABC is a triangle, of which the base BC is bisected at Q, therefore

$$AB^2+AC^2=2BQ^2+2AQ^2, \text{ (14. 4. Part. I.)}$$

In like manner, in the triangle PBC, we have

$$PB^2+PC^2=2BQ^2+2PQ^2;$$

therefore, taking equals from equals, we have

$$AB^2-PB^2+AC^2-PC^2=2AQ^2-2PQ^2.$$

But because the triangles APB, APC are right angled at P, $AB^2-PB^2=AP^2$; and $AC^2-PC^2=AP^2$ (11. 4.); therefore

$$AP^2+AP^2=2AQ^2-2PQ^2,$$

that is, $2AP^2=2AQ^2-2PQ^2$, and $AP^2=AQ^2-PQ^2$, and $AQ^2=AP^2+PQ$, hence in the triangle APQ, the angle at P must be a right angle, (11, 12, and 13. of 4. Part I.), and AP is perpendicular to any line whatever on the plane of the lines PB, PC, therefore it is perpendicular to the plane itself, (Def. 1.)

Cor. 1. The shortest line that can be drawn to a plane from A any point above it, is the perpendicular AP.

Cor. 2. Only one perpendicular PA can be drawn to a given plane, from a given point P in that plane: For if two perpendiculars could be drawn, a plane might pass along them, and meet the given plane in PQ; and thus two lines would be perpendicular to PQ, which is impossible.

Cor. 3. It is also impossible to draw more than one straight line perpendicular to a plane, from a point without it. For if there could be two perpendiculars AP, AQ, the triangle APQ would have two right angles, which is impossible.

Prop. V. Theor.

If a straight line AP is perpendicular to a plane MN, every straight line DE, parallel to AP, is perpendicular to the same plane.

Fig. 141. Let a plane pass along the parallels AP, ED, so as to meet the plane MN in the line PD. In this plane draw a line BDC through D, perpendicular to PD, take equal distances DB, DC, and join AB, AC, AD. And because in the triangles DBP, DCP, DB = DC, and DP is common to both, and the angle PDB=PDC, therefore PB = PC (6. 1. Part I.) Again, in the triangles APB, APC, AP is common to both, and it has been shewn that PB = PC, besides the angles APB, APC are right angles, because AP is perpendicular to the plane MN, therefore AB=AC, so that the triangle ABC is isosceles; hence BD is perpendicular to AD (12. 1. Part I.); but BD is also perpendicular to PD, by construction therefore BD is perpendicular to the plane of the triangle APD (4.), and consequently to DE, which is in that plane; since then EDB is a right angle, and also EDP is a right angle (1 Cor. 21. Part I.), the line DE is perpendicular to the two lines DP, DB; it is therefore perpendicular to the plane MN.

Cor. 1. Conversely, if the two straight lines AP, DE are perpendicular to the same plane MN, they are parallel: For if they are not, let a line be drawn through D parallel to AP, this line will be perpendicular to the plane MN; therefore through the same point D, two perpendiculars can be drawn to the same plane, which is impossible, (2 Cor. 4.)

Cor. 2. Two straight lines A and B parallel to a third C, though not in the same plane, are parallel to one another; for suppose a plane perpendicular to the line C, the lines A and B, which are parallel to C, will be perpendicular to this plane; therefore by the preceding corollary, they will be parallel to one another.

Prop. VI. Theor.

Fig. 142. Two planes MN, PQ perpendicular to the same straight line AB, are parallel to each other.

For if they could meet, let O be one of their common points; join OA, OB; then, because AB is perpendicular to the two planes, the angles OAB, OBA are right angles (Def. 1.); therefore OA, OB are two perpendiculars from the same point on the same straight line, which is impossible; therefore the planes cannot meet, that is, they are parallel.

Prop. VII. Theor.

Fig. 143. The intersections EF, GH of two parallel planes MN, PQ, with a third plane FG, are parallel.

For if the lines EF, GH situated in the same plane, be not parallel, they would meet if produced; therefore, the planes in which they are would also meet, and consequently would not be parallel.

Prop. VIII. Theor.

Fig. 142. A straight line AB perpendicular to a plane MN, is also perpendicular to any plane PQ parallel to MN.

From B draw any straight line BC in the plane PQ, and let a plane passing through BC and AB meet the plane MN in AD, then AD will be parallel to BC, Of Planes and solid Angles.

(7.) Now AB is perpendicular to AD one of two parallel lines AD, BC, therefore it is perpendicular to BC the other line, (21. 1. Part I.); and since BC is any line drawn from B in the plane PQ, it follows that AB is perpendicular to the plane PQ, (Def. 1.)

Prop. IX. Theor.

Fig. 143. Parallel straight lines EG, FH intercepted between two parallel planes MN, PQ are equal.

Let a plane EGHF pass through the parallel lines, so as to meet the parallel planes in the lines EF, GH; these are parallel to each other (7.), as well as EG, FH; therefore EFHG is a parallelogram, and hence EG = FH.

Cor. Parallel planes are every where at the same distance from each other; for if EG and FH are perpendicular to the two planes, they are parallel (1 Cor. 5.), and therefore are equal.

Prop. X. Theor.

Fig. 144. If two straight lines CA, EA meeting one another, be parallel to two others DB, FB that meet one another, though not in the same plane with the first two; the first two and the other two shall contain equal angles; and the plane passing through the first two, shall be parallel to the plane passing through the other two.

Take AC = BD, AE = BF, and join CE, DF, AB, CD, EF. Since AC is equal and parallel to BD, the figure ABDC is a parallelogram, (28. 1. Part I.); therefore CD is equal and parallel to AB. For a like reason, EF is equal and parallel to AB; therefore also CD is equal and parallel to EF. The figure CEFD is therefore a parallelogram, and thus the side CE is equal and parallel to DF; therefore the triangles CAE, DBF are equal (11. 1. Part I.) and the angle CAE=DBF.

In the next place, the plane ACE is parallel to the plane BDF; for if the plane passing through A parallel to BDF could meet the two lines DC, FE in any other points than C and E, for example in G and H, then the three lines AB, DG, FH would be equal (9.), and thus DG would be equal to DC, and FH to FE, which is absurd; therefore the plane AEC is parallel to BFD.

Prop. XI. Theor.

Fig. 144. If three straight lines AB, CD, EF not situated in the same plane, are equal and parallel, the triangles ACE, BDF formed by joining the extremities of these lines are equal, and their planes parallel.

For since AB is equal and parallel to CD, the figure ABDC is a parallelogram, therefore the side AC is equal and parallel to BD; in like manner, it may be shewn that the sides AE, BF are equal and parallel, as also CE, DF; therefore the two triangles CAE, BDF are equal; it may be demonstrated, as in the last proposition, that their planes are parallel.

Prop. XII. Theor.

If two straight lines be cut by parallel planes, they shall be cut in the same ratio.

Fig. 145. Let the straight line AB meet the parallel planes MN, PQ, RS in A, E, B; and let the line CD meet the same planes in C, F, and D; then shall AE : EB :: CF : FD.

Draw AD to meet the plane PQ in G, and join AC, EG, GF, BD; the intersections EG, BD of the parallel planes PQ, RS with the plane ABD are parallel (7.), therefore AE : EB :: AG : GD, (15. 4. Part I.) In like manner, the intersections AC, GF are parallel, therefore AG : GD :: CF : FD; hence, because of the common ratio AG : GD, we have AE : ED :: CF : FD.

Prop. XIII. Theor.

Fig. 146. If a straight line AP be perpendicular to a plane MN, every plane APB, which passes along AP, shall be perpendicular to the plane MN.

Let BC be the intersection of the planes AB, MN. In the plane MN draw DE perpendicular to BP; then, because AP is perpendicular to every line drawn from P in the plane MN, the angles APD and APB are right angles; but the angle APD formed by the two perpendiculars PA, PD is the angle of the planes AB, MN (Def. 4.), therefore the two planes are perpendicular to one another, (Def. 5.)

Scholium. When three straight lines, such as PA, PB, PD are perpendicular to each other, each line is perpendicular to the plane of the other two, and the three planes are perpendicular to one another.

Prop. XIV. Theor.

Fig. 14 If a plane AB be perpendicular to a plane MN, and in the plane AB a straight line PA be drawn perpendicular to their common intersection PB, the line PA shall be perpendicular to the plane MN.

In the plane MN, draw PD perpendicular to PB; then because the planes are perpendicular to each other, the angle APD is a right angle; therefore AP is perpendicular to the lines PB, PD; consequently it is perpendicular to their plane.

Cor. If the plane AB be perpendicular to the plane MN, and through P, any point in their common intersection, a perpendicular be drawn to the plane MN, this perpendicular shall be in the plane AB. For if it is not, a line AP might be drawn in the plane AB perpendicular to PB, the common intersection of the planes, which at the same time would be perpendicular to the plane MN; thus, from the same point P, there would be two perpendiculars to a plane MN, which is impossible, (2 Cor. 4.)

Prop. XV. Theor.

Fig. 1 If two planes AB, AD be perpendicular to a third MN; their common intersection AP is perpendicular to the third plane.

For a perpendicular to the plane MN at P, the point in which it meets the two planes AB, AD must be in both these at the same time, therefore it is their common intersection AP.

Prop. XVI. Theor.

If a solid angle be formed by three plane angles, the sum of any two of them is greater than the third.

On Planes and solid Angles.

Fig. 147. It is sufficiently evident, that the sum of the greatest of the three, and either of the other two, is greater than the remaining angle, and it is only necessary to prove that the sum of the angles AVC, BVC, neither of which is the greatest, exceeds the greatest angle AVB.

In the plane AVB, make the angle BVD=BVC; take any two points A, B, in the lines VA, VB, and draw ADB; take VC=VD, and join AC, BC. And because BV is common to the triangles, VBD, VBC, and VC=VD, and the angle BVD=BVC, therefore BD=BC; now AB, or AD+BD, is less than AC+BC, therefore taking away the common side DB, there remains AD < AC. The two triangles AVC, AVD, have AV common, VC=VD and the base AC > AD, therefore (converse of 10. 1. Part I.) the angle AVC > AVD, and AVC+CVB > AVD+DVB, that is > AVB.

Prop. XVII. Theor.

The sum of all the plane angles which form any solid angle is less than four right angles.

Fig. 148. Let the solid angle V be cut by any plane ABCDE; from a point O taken in this plane, draw to all its angles the lines OA, OB, OC, OD, OE. The sum of the angles of the triangles AVB, BVC, &c. formed about the vertex V, is equivalent to the sum of the angles of a like number of triangles AOB, BOC, &c. formed about the point O; but at the point B, the angles OBA, OBC taken together, make the angle ABC less than the sum of the angles VBA, VBC (16.); in like manner at the point C, we have OCB+OCD < VCB+VCD, and so on with all the angles of the polygon ABCDE. Hence it follows, that in the triangles of which the vertex is O, the sum of the angles at the bases is less than the sum of the angles at the bases of the triangles, which have their vertex at V; therefore, by compensation, the sum of the angles about the point O, is greater than the sum of the angles about the point V; but the sum of the angles about O is equal to four right angles; therefore the sum of the plane angles which form the solid angle about the point V, is less than four right angles.

Scholium. This demonstration supposes, that the solid angle is convex, or that the solid angle lies all on one side of the plane of any one of its faces; if it were otherwise, the sum of the plane angles would not be limited.

Prop. XVIII. Theor.

If two solid angles be composed of three plane angles which are equal, each to each, the planes in which these angles are, have the same inclination to one another.

Figs. 149, 150. Let the angle CAD=*c a d*, the angle CAB=*c a b*, and the angle BAD=*b a d*; the two planes CAB, DAB shall have to each other the same inclination as the planes *c a b*, *d a b*.

Take B any point in AB, and in the planes BAC, BAD, draw BC and BD perpendiculars to AB, and join CD; then the angle CBD is the inclination of the planes BAC, BAD, (Def. 4.) Again, take *a b*=AB, and in the planes *b a c*, *b a d* draw *b c* and *b d* perpendiculars to *a b*, and join *c d*; then the angle *c b d* is the inclination of the planes *b a c*, *b a d*.

The triangles BAC, *b a c*, have the angle BAC=*b a c*, the angle CBA=*c b a*, also the side AB=*a b*; therefore the triangles are equal, (7. 1. Part I.) and BC=*b c*, also AC=*a c*. In the same way it may be proved, that the triangles BAD, *b a d* are equal, and therefore that BD=*bd*, also AD=*a d*. The triangles CAD, *c a d*, have therefore CA=*c a*, AD=*a d*, and the angle CAD=*c a d*; hence CD=*c d*. Now the triangles CBD, *c b d* having CB=*c b*, DB=*d b*, and the base CD=*c d*, the angle CBD will be equal to the angle *c b d*; that is, the inclination of the plane BAC to the plane BAD, is equal to the inclination of the plane *b a c* to the plane *b a d*. In the same way it may be proved, that the other planes are equally inclined to one another.

Scholium. If the three plane angles which contain the solid angles, besides being equal each to each, are also *disposed in the same order as in* Fig. 149, the solid angles will coincide when applied the one to the other, and they will be equal. But if the plane angles are *disposed in a contrary order*, as in Fig. 150, the solid angles will not coincide, although the theorem is alike true in both cases. However, in the latter case as well as in the former, the solid angles must be accounted equal, seeing that they are equal in every thing that determines their magnitude. This kind of equality, which does not admit of superposition, and on that account is not absolute, may be distinguished from the other, by calling it *equality by reason of symmetry*; and two solid angles, which are contained by three plane angles, having the same magnitude in each, but placed in a contrary order, may be called *symmetrical angles*. What is here said, will apply to solid angles contained by any number of plane angles.

SECTION II.

Of Solids bounded by Planes.

Definitions.

Definitions. 1. A *solid* is that which has length, breadth, and thickness.

2. A *prism* is a solid contained by plane figures, of which two that are opposite are equal, similar, and parallel to one another, and the others are parallelograms.

Fig. 151. To construct this solid, let ABCDE be any rectilineal figure, (Fig. 151.) In a plane parallel to ABC draw the lines FG, GH, HI, &c. parallel to the sides AB, BC, CD, &c. thus there will be formed a figure FGHIK, similar to ABCDE. Now let the vertices of the corresponding angles be joined by the lines AF, BG, CH, &c. the faces ABGF, BCHG, &c. will evidently be parallelograms, and the solid thus formed will be a prism.

3. The equal and parallel plane figures ABCDE, FGHIK, are called the *bases* of the prism. The other planes, or parallelograms, taken together, constitute the *lateral* or *convex* surface of the prism.

4. The *altitude* of a prism is the distance between its bases; and its *length* is a line equal to any one of its lateral edges, as AF, or BG, &c.

5. A prism is *right*, when the lateral edges AF, BG, &c. are perpendicular to the planes of its bases; then each of them is equal to the altitude of the prism; in every other case the prism is oblique.

6. A prism is *triangular*, *quadrangular*, *pentagonal*, &c. according as the base is a triangle, a quadrilateral, a pentagon, &c.

7. A prism which has a parallelogram for its base, has all its faces parallelograms, and is called a *parallelopiped*, (Fig. 152.) A parallelopiped is *rectangular*, when all its faces are rectangles. Fig. 152.

8. When the faces of a rectangular parallelopiped are squares, it is called a *cube*.

Of Solids bounded by Planes.

Fig. 148. 9. A *pyramid* is a solid formed by several triangular planes, which meet in a point V, (Fig. 148.) and terminate in the same plane rectilineal figure ABCDE.

The plane figure ABCDE is called the *base* of the pyramid; the point V is its *vertex*; and the triangles AVB, BVC, &c. taken together, form the *convex* or *lateral* surface of the pyramid.

10. The *altitude* of a pyramid, is the perpendicular drawn from its vertex to the plane of its base, produced if necessary.

11. A pyramid is *triangular*, *quadrangular*, &c. according as its base is a triangle, a quadrilateral, &c.

12. A pyramid is *regular*, when its base is a regular figure, and the perpendicular from its vertex passes through the centre of its base; that is, through the centre of a circle that may be described about its base.

13. Two solids are *similar*, when they are contained by the same number of similar planes, similarly situated, and having like inclinations to one another.

Prop. I. Theorem.

Two prisms are equal, when three planes, which contain a solid angle of the one, are equal to three planes which contain a solid angle of the other, each to each, and are similarly situated.

Fig. 151. Let the base ABCDE be equal to the base *a b c d e*; the parallelogram ABGF equal to the parallelogram *a b g f*, and the parallelogram BCHG equal to the parallelogram *b c h g*; then shall the prism ABCDE-FGHIK be equal to the prism *a b c d e-f g h i k*.

For if the base ABCDE be placed upon its equal *a b c d e*, they will entirely coincide; and because the three plane angles which form the solid angle B are equal to the three plane angles which form the solid angle *b*, each to each, namely, ABC=*a b c*, ABG=*a b g*, and GBC=*g b c*; and besides, these angles are similarly situated; the solid angles B and *b* shall be equal (18. 1.), and consequently the side BG will fall on *b g*. Also, because of the equal parallelograms ABGF, *a b g f*, the side GF will fall on its equal *g f*, and, similarly, GH on *g h*: Therefore the upper base FGHIK will coincide entirely with its equal *f g h i k*, and the two solids will coincide entirely, and be equal to one another.

Cor. Two right prisms which have equal bases and equal altitudes are equal to one another.

If the equal angles of the lower bases follow each other in the same order, then the three planes which contain each solid angle of the one prism will be respectively equal to three planes which contain a corresponding solid angle of the other, and will be similarly situated; and when the one solid angle is applied to the other, these planes will coincide, and the prisms will exactly coincide. If the equal angles of the lower bases follow each other in a contrary order, then, by inverting one of the prisms, so that its upper may become its lower base, the angles of the two bases will then be placed in the same order, so that in either case the prisms coincide, and are equal.

Prop. II. Theor.

In every parallelopiped, the opposite planes are equal and parallel.

Fig. 152. From the definition of this solid, the bases ABCD, EFGH are equal parallelograms; and their sides are parallel: it remains therefore to demonstrate that the same is true for two opposite lateral faces, such as AEHD, BFGC. Because the figure ABCD is a parallelogram, AD is equal and parallel to BC; and for a like reason AE is equal and parallel to BF; therefore the angle DAE is equal to the angle CBF (10. 1.) and the plane DAE is parallel to the plane CBF; therefore also the parallelogram DAEH is equal to the parallelogram CBFG. In like manner, it may be demonstrated that the opposite parallelograms ABFE, DCGH are equal and parallel.

Cor. Any two opposite faces of a parallelopiped may be taken for its bases.

Prop. III. Lemma.

In every prism ABCDE-FGHIK, the sections NOPQR, STVXY made by parallel planes are equal polygons. Fig. 153.

For the sides NO, ST are parallel, (7.1.) because the two parallel planes are cut by a third plane ABGF; these same sides NO, ST are comprehended between the parallels NS, OT, which are sides of the prism; therefore NO=ST; for a like reason the sides OP, PQ, QR, &c. of the section NOPQR are respectively equal to the sides TV, VX, XY, &c. of the section STVXY: Besides, these equal sides being at the same time parallel, it follows that the angles NOP, OPQ, &c. of the first section are respectively equal to the angles STV, TVX, &c. of the second section. Therefore the two sections NOPQR, STVXY are equal polygons.

Cor. Every section of an upright prism by a plane parallel to the base is equal to that base.

Prop. IV. Theor.

If a parallelopiped AG, be cut by a plane passing through BD, FH, the diagonals of two of the opposite planes, it will be cut into two equivalent prisms, BAD-EFH, BCD-FGH. Fig. 154.

Through B and F, the extremities of one of the sides, draw the planes B *a d c*, F *e h g* perpendicular to BF to meet the three other sides of the solid in *a*, *d*, *c*, and in *e*, *h*, *g*; these sections are equal (3.), because the planes are perpendicular to FB, and therefore parallel. They are also parallelograms (7. 1.), because the opposite sides of the same section, *a* B, *d c* are the intersections of two parallel planes ABFE, DCGH, by the same plane.

For a like reason, the figure B *a e* F is a parallelogram, as also the other lateral faces BF *g c*, *c d h g*, *a d h e*, of the solid B *a d c*-F *e h g*; therefore this solid is a prism (Def. 2.), and it is a right prism, because BF is perpendicular to the plane of its base.

This being premised, and it being observed that the right prism B *h* is divided into two right triangular prisms *a* B *d-e* F *h*, *c* B *d-g* F *h*, we shall now demonstrate that the oblique triangular prism ABD-EFH is equal to the right triangular prism *a* B *d*-*e* F *h*: In fact, these two prisms have a common part ABD-*e* F *h*, therefore it is only necessary to prove that the remainders, viz. the solids B *a* AD *d*, F *e* EH *h*, are equivalent to each other.

Because BAEF, B *a e* F, are parallelograms, we have AE=BF=*a e*, therefore A *a*=E *e*: In like manner, it may be proved that D *d*=H *h*: Conceive now that F *e h*, the base of the solid F *e* EH *h*, is placed on *a* B *d*, the base of the solid B *a* AD *d*; then the point *e* falling on *a*, and *h* on *d*; the lines e E, *h* H will coincide with their equals, *a* A, *d* D, because they are perpendiculars to the same plane: Therefore the two solids in question will coincide entirely, the one with the other, and hence it follows that the oblique prism BAD-FEH is equivalent to the right prism B *a d*-F *e h*.

In the same manner it may be demonstrated, that the oblique prism BCD-FGH is equal to the right prism B *c d*-F *g h*; but the two right prisms are equal (Cor. 1.), since they have the same altitude, and their bases are equal, they being halves of the same parallelogram, therefore the two triangular prisms BAD-FEH, BCD-FGH which are equivalent to these are equivalent to each other.

Cor. Every triangular prism ABD-EFH is half a parallelopiped AG, having the same solid angle A, with the same edges AB, AD, AE.

Scholium. Although the triangular prisms into which the oblique parallelopiped is divided are contained by equal planes, and have their solid angles equal, yet they cannot be made to coincide. The reason is, that the plane angles about the corresponding solid angles in the two prisms are not placed in the same order. These solid angles are therefore *symmetrical*, and cannot be brought to coincide. (18. 1.) Two prisms, or two solids of any kind so constituted, are called *symmetrical solids*. An exact notion of their relation to each other may be acquired by considering that any object and its image reflected from a mirror are *symmetrical* figures. They resemble each other exactly, but every part is placed in a reverse order; thus the reflected image of a right hand is a left hand.

In symmetrical solids, every circumstance upon which the magnitude of either depends, is the very same in both, hence their *equivalence* might even be assumed as an axiom in solid geometry.

Prop. V. Theor.

155. If two parallelopipeds, AG, AL, have a common base ABCD, and their upper bases EFGH, IKLM in the same plane, and between the same parallels EK, HL; these two parallelopipeds are equivalent to each other.

There may be three cases, according as EI is greater or less than EF, or equal to it, but the demonstration is the same for them all. In the first place, the triangular prism AEI-DHM is equal to the triangular prism BFK-CGL; for since AE is parallel to BF, and EH to FG, the angle AEI = BFK, and HEI = GFK, and HEA=GFB; of these six angles, the three first form the solid angle E, and the three others form the solid angle F; therefore, since the plane angles are equal, each to each, and similarly situated, the solid angles E and F are equal: and if the prism AEI-DHM be placed on the prism BFK-CGL, so that the base AEI may be on the base BFK, these being manifestly equal, they will coincide; and since the solid angle at E is equal to the solid angle at F, the side EH will fall on its equal FG, and coincide with it; thus the planes which form the solid angles E and F will coincide, and the prisms will be equal (1.): Now if from the whole solid contained between the trapezoids AEKB, DHLC, there be taken the prism AEI-DHM, there will remain the parallelopiped AIL, and if from the same solid there be taken the prism BFK-CGL, there will remain the parallelopiped AEG; therefore the two parallelopipeds AIL, AEG are equivalent to one another.

3

Prop. VI. Theor.

Two parallelopipeds of the same base and the same altitude are equivalent to one another.

Let ABCD be the common base of the two parallelopipeds AG, AL; since they have the same altitude, their upper bases EFGH, IKLM will be in the same plane; also the sides EF, AB are equal and parallel, and the same is also true of IK and AB; therefore EF is equal and parallel to IK; for a like reason GF is equal and parallel to LK. Let the sides EF and HG be produced, as also the sides LK and IM, so as to form by their intersection the parallelogram NOPQ; it is evident that this parallelogram is equal to each of the bases EFGH, IKLM. Now if we suppose that there is a third parallelopiped, which, with the same lower base as the other two, has for its upper base NOPQ; this third parallelopiped will be equivalent to the parallelopiped AG, (5.) and for a like reason it will be equivalent to the parallelopiped AL; therefore the two parallelopipeds AG, AL, which have the same base, and the same altitude, are quivalent to one another. Fig. 156.

Prop. VII. Theor.

Every parallelopiped is equivalent to a rectangular parallelopiped which has the same altitude and an equivalent base.

Let AG be the proposed parallelopiped; from the points A, B, C, D, draw AI, BK, CL, DM, perpendicular to the plane ABCD, and terminating in the plane of the upper base, and join IK, KL, LM, MI; thus there will be formed a par llelopiped AL equivalent to the parallelopiped AG, and of which the lateral faces AK, DL are rectangles. If the base ABCD is also a rectangle, AL will be a rectangular parallelopiped equivalent to the proposed parallelopiped AG; but if it is not, (Fig. 157.) draw AO and BN perpendicular to CD, and OQ and NP perpendiculars to the upper base, thus there will be formed a solid ABNO-IKPQ, which will be a rectangular parallelopiped. For, by construction, the base ABNO, and its opposite IKPQ are rectangles, as also the lateral faces, because the edges AI, OQ are perpendicular to the plane of the base; therefore the solid AP is a rectangular parallelopiped. But the two parallelopipeds AP, AL may be considered as having the same base ABKI, and the same altitude AO; therefore they are equivalent; wherefore the parallelopiped AG, which was first transformed to the equivalent solid AL (Fig. 156.) is now reduced to the equivalent rectangular parallelopiped AP (Fig. 157.) which has the same height AI, and a base AONB equivalent to the base ABCD. Fig. 156. Fig. 157. Fig. 156. Fig. 157.

Prop. VIII. Theor.

Two rectangular parallelopipeds AG, AL, which have the same base ABCD, are to one another as their altitudes AE, AI. Fig. 158.

Let us suppose that AE contains some part of AI a certain number of times exactly, for example, let it contain the third part of AI five times, and let these equal parts be A *p*, *p q*, *q* I, I *r*, *r* F: Let planes be supposed to pass through *p*, *q*, *r* parallel to the common base; these will divide the solid AG into five parallelopipeds,

Of Solids bounded by Planes.

which will be equal, because they have equal bases (6.) and equal altitudes, and the solid AL will contain three of these parallelopipeds: thus the parallelopiped AG will contain a part of the parallelopiped AL exactly as often as the altitude AE of the former contains a like part of the altitude AI of the latter, therefore the solids AG, AL have to each other the same ratio as their altitudes AE, AI.

When the altitudes are incommensurable, it may still be inferred that the ratio of the solids is the same as that of their altitudes, for the reasons assigned in the conclusion of Sect. III. Part I.

Prop. IX. Theor.

Fig. 159. Two rectangular parallelopipeds AG, AK, which have the same altitude, are to one another as their bases.

Suppose the solids placed side by side, as in the Figure: Produce the plane ONKL, until it meet the plane DCGH in the line PQ; thus there will be formed a third parallelopiped AQ, which may be compared with the other two. The two solids AG, AQ, having the same base AEHD, are to each other as their altitudes AB, AO (8.) In like manner the two solids AQ, AK, having the same base AOLE, are to one another as their altitudes AD, AM: But the rectangles AC, AP, having the same breadth, are also to each other as AB to AO, (3. 4. Part 1.) and similarly, the rectangles AP, AN are to each other as AD to AM; therefore

sol. AG : *sol.* AQ : : *base* AC : *base* AP,
sol. AQ : *sol.* AK : : *base* AP : *base* AN;

therefore, *ex æquo*,

sol. AG : *sol.* AK : : *base* AC : *base* AN.

Prop. X. Theor.

Any two rectangular parallelopipeds are to each other as the products of numbers proportional to their bases and altitudes; or as the products of the numbers which express their three dimensions.

Fig. 159. Let the two rectangular parallelopipeds AG, AZ be so placed, that their surfaces may have a common angle BAE; and let their bounding planes be produced, so as to form a third parallelopiped AK, having the same altitude as the solid AG. By the last proposition,

sol. AG : *sol.* AK : : *base* AC : *base* AN;

and by Prop. 8,

sol. AK : *sol.* AZ : : AE : AX.

Now, if we consider the bases AC, AN as measured by numbers, and also their altitudes AE, AX, we shall have by Prop. 1. Sect. 3. Part 1,

base AC : *base* AN : : AE × *base* AC : AE × *base* AN,
and AE : AX : : AE × *base* AN : AX × *base* AN;
therefore,
sol. AG : *sol.* AK : : AE × *base* AC : AE × *base* AN,
sol. AK : *sol.* AZ : : AE × *base* AN : AX × *base* AN.

From these two proportions, we have, *ex æquo*,

sol. AG : *sol.* AZ : : AE × *base* AC : AX × *base* AN.

By substituting in this proportion instead of the bases AC, AN, their numerical values AD × AB and AM × AO, we have also

sol. AG : *sol.* AZ : : AD × AB × AE : AM × AO × AX.

Scholium. Hence it appears that the product of the numbers which express the base of a rectangular parallelopiped, and its altitude, or the product of the numbers which express its three dimensions, may be taken as its *numerical measure*: For, if the length of the solid be equal to five times a certain line, which is considered as an unit, its breadth three times that unit, and its height seven times the same unit; then the parallelopiped will be to a cube, whose side or edge is that unit, as 5 × 3 × 7 to 1 × 1 × 1, that is as 5 × 3 × 7 to 1: Hence the parallelopiped will be equivalent to 5 × 3 × 7 = 105 times a cube whose side is unity.

The magnitude of a solid, its bulk, or its extension, constitutes what is called its *solidity* or its *content*. Thus we say that the solidity or content of a rectangular parallelopiped, is equal to the product of its base by its altitude; or to the product of its three dimensions.

Prop. XI. Theor.

The solidity of a parallelopiped, and, in general, the solidity of any prism, is equal to the product of its base by its altitude.

1. For any parallelopiped whatever is equivalent to a rectangular parallelopiped of the same altitude, and an equivalent base (7.); and the solidity of this last has been proved to be equal to the product of its base by its altitude; therefore the solidity of the other is also the product of its base by its altitude.

2. Every triangular prism is half a parallelopiped, which has the same altitude, and a base twice that of the prism; but the solidity of this last is equal to the product of its base by its altitude; therefore the solidity of the prism is the product of its base (half that of the parallelopiped) by its altitude.

3. Any prism whatever may be divided into as many triangular prisms of the same altitude, as there can be triangles in the polygon which forms its base: now the solidity of each prism is the product of its base by its altitude, which is common to them all; therefore the sum of their solidities is equal to the sum of their bases multiplied by the common altitude; that is, the solidity of the whole prism is equal to the product of its base by its altitude.

Cor. Two prisms, which have the same base, are to each other as their altitudes; and two prisms, which have the same altitude, are to each other as their bases. Let B and A be the base and altitude of a prism P, and b and a the base and altitude of another prism p; then since $P=B\times A$, and $p=b\times a$, we have $P:p::B\times A:b\times a$, therefore if $A=a$, then $P:p::B:b$; and if $B=b$, then $P:p::A:a$.

Note. The cube of a line AB is sometimes expressed thus, AB × AB × AB, but more commonly thus, $(AB)^3$, or thus, AB^3.

Prob. XII. Theor.

Fig. Similar prisms are to one another as the cube of their homologous sides.

Let P and p be two prisms, of which BC, bc are the homologous sides; the prism P is to the prism p as the cube of BC to the cube of bc. From A and a, homologous angles of the two prisms, draw AH, ah perpendicular to their bases, BCD, bcd. Join BH, take $Ba=ba$, and in the plane BHA draw ah perpendicular to BH; then ah shall be perpendicular to the plane CBD (13. and 14. 1.) and equal to ah, the altitude of the other prism; for if the solid angles B and b were applied the one to the other, the planes which contain them, and consequently the perpendiculars $a\,h$, $a\,h$, would coincide (Schol. 18. 1.)

Now, because of the similar triangles ABH, $a\,b\,h$, and the similar figures AC, $a\,c$, we have

$$AH : ah :: AB : ab :: BC : bc;$$

and because of the similar bases,

$$base\ BCD : base\ b\,c\,d :: BC^2 : b\,c^2 \text{ (25. 4. Part 1.)}$$

From these two proportions, by considering all the quantities as represented by numbers, we get, (by Prop. 1. Sect. 3. Part 1.)

$$AH \times base\ BCD : a\,h \times base\ BCD :: BC^3 : b\,c \times BC^2,$$
$$a\,h \times base\ BCD : a\,h \times base\ b\,c\,d :: b\,c \times BC^2 : b\,c^3;$$

therefore, *ex æquali*,

$$AH \times base\ BCD : a\,h \times base\ b\,c\,d :: BC^3 : b\,c^3.$$

But $AH \times base$ BCD expresses the solidity of the prism P; and $a\,h \times base\ b\,c\,d$ expresses the solidity of the other prism p, therefore,

$$prism\ P : prism\ p :: BC^3 : b\,c^3.$$

Cor. Similar prisms are to one another in the triplicate ratio of their homologous sides. For let Y and Z be two lines, such, that $BC : b\,c :: b\,c : Y$, and $b\,c : Y :: Y : Z$; then the ratio of BC to Z is triplicate of the ratio of BC to $b\,c$ (12. Def. Sect. 3. Part 1.) But since $BC : b\,c :: b\,c : Y$, therefore $BC^2 : b\,c^2 :: b\,c^2 : Y^2$, (23. 4. Part 1.) and, multiplying the antecedents by BC, and the consequents by $b\,c$, $BC^3 : b\,c^3 :: BC \times b\,c^2 : b\,c \times Y^2 :: BC \times b\,c : Y^2$; but $Y^2 = b\,c \times Z$ (22. 4. Part. 1.); therefore $BC^3 : b\,c^3 :: BC \times b\,c : b\,c \times Z :: BC : Z$. But $BC^3 : b\,c^3 :: prism\ P : prism\ p$, therefore the prisms have to each other the ratio of BC to Z, that is, the triplicate ratio of BC to $b\,c$.

Prop. XIII. Theor.

If a triangular pyramid A-BCD be cut by a plane parallel to its base, the section FGH is similar to the base.

161. For because the parallel planes BCD, FGH are cut by a third plane ABC, the sections FG, BC are parallel (7. 1.) In like manner it appears that FH is parallel to BD; therefore the angle HFG is equal to the angle DBC (10. 1.) And because the triangle ABC is similar to the triangle AFG, and the triangle ABD is similar to the triangle AFH, we have

$$BC : BA :: FG : FA,$$
$$\text{and } BA : BD :: FA : FH.$$

Therefore, *ex æquali*, BC : BD :: FG : FH; now the angle DBC has been shewn to be equal to the angle HFG; therefore the triangles DBC, HFG are equiangular (20. 4. Part 1.)

Prop. XIV. Theor.

161. If two triangular pyramids A-BCD, a-$b\,c\,d$, which have equivalent bases, and equal altitudes, be cut by planes that are parallel to the bases, and at equal distances from them; the sections FGH, $f\,g\,h$ will be equal.

Draw AKE, $a\,k\,e$ perpendicular to the bases BCD, $b\,c\,d$, meeting the cutting planes in K and k; then, because of the parallel planes, we have $AE : AK :: AB : AF$, and $a\,e : a\,k :: a\,b : a\,f$ (12. 1.); but, by hypothesis, $AE = a\,e$, and $AK = a\,k$; therefore, $AB : AF :: a\,b : a\,f$; again, because of similar triangles, $AB : AF :: BC : FG$, and $a\,b : a\,f :: b\,c : f\,g$; therefore, $BC : FG :: b\,c : f\,g$; and hence $BC^2 : FG^2 :: b\,c^2 : f\,g^2$ (23. 4. Part 1.) but because of the similar triangles BDC, FHG, $BC^2 : FG^2 :: trian.\ BDC : trian.\ FHG$, and in like manner $b\,c^2 : f\,g^2 :: trian.\ b\,c\,d : trian.\ f\,g\,h$ (25. 4. Part. 1.) therefore

$$trian.\ BCD : trian.\ FGH :: trian.\ b\,c\,d : trian.\ f\,g\,h.$$

Now $trian.\ BCD = trian.\ b\,c\,d$ (by hypothesis) therefore the triangle FHG is equal to the triangle $f\,h\,g$.

Scholium. It is easy to see, that what is proved in this and the preceding Proposition is also true of polygonal pyramids.

Prop. XV. Theor.

A series of prisms of the same altitude may be inscribed in a pyramid, and another series may be circumscribed about it, which shall exceed the other by less than any given solid.

Let A-BCD be a pyramid, and let AC, one of its lateral edges, be divided into some number of equal parts, at the points F, G, H; through these, let planes pass parallel to the base BCD, making with the sides of the pyramid the sections QPF, SRG, UTH; which will be similar to one another and to the base (13.) From B, in the plane of the triangle ABC, draw BK parallel to CF, meeting FP produced in K; in like manner, from D draw DL parallel to CF, meeting FQ produced in L; join KL, and the solid CBD-FKL will evidently be a prism. By the same construction, let the prisms PM, RO, TV be described: Also let the straight line IP, which is in the plane of the triangle ABC, be produced till it meet BC in h, and let MQ be produced till it meet DC in g; join $h\,g$, then C $h\,g$-FPQ will be a prism, and be equal to the prism PM. In the same manner is described the prism m S equal to the prism RO, and the prism q U equal to the prism TV. Therefore the sum of all the inscribed prisms h Q, m S, and q U is equal to the sum of the prisms PM, RO, and TV; that is, to the sum of all the circumscribed prisms, except the prism BL; wherefore BL is the excess of the prisms circumscribed about the pyramid above the prisms inscribed within it. Fig. 162.

Let us now suppose that Z denotes some given solid equal to a prism, which has the same base CBD as the pyramid, and its altitude equal to a perpendicular from E (a point in AC) upon the base. Then, however near E may be to C, it will evidently be possible to divide AC into such a number of equal parts, that one of them, CF, shall be less than CE; and this being the case, the prism BL will evidently be less than the prism whose base is the triangle CBD, and altitude a perpendicular from E on the base BCD; that is, less than the given solid Z: Therefore the excess of the circumscribed above the inscribed prisms may be less than the solid Z.

Cor. Since the difference between the circumscribed and inscribed prisms may be less than any given magnitude, and the pyramid is greater than the latter, and less than the former, it follows that a series of prisms may be circumscribed about the pyramid, and also a series of prisms may be inscribed in it, which shall differ from the pyramid itself by less than any given solid.

Prop. XVI. Theor.

Pyramids that have equal bases and altitudes, are equal to one another.

Let A-BCD, a-$b\,c\,d$ be two pyramids that have equal bases BCD, $b\,c\,d$, and equal altitudes; viz. the perpendiculars drawn from the vertices A and a upon Fig. 163.

Of Solids bounded by Planes.

the planes BCD, *bcd*, the pyramid A-BCD is equal to the pyramid *a-b c d*.

For if they are not equal, let Z represent the solid which is equal to the excess of one of them, *a-b c d*, above the other A-BCD; and let a series of prisms CE, FG, HK, LM, of the same altitude be circumscribed about the pyramid A-BCD, so as to exceed it by a solid less than Z, which is always possible (15.); also let a series of prisms *c e*, *f g*, *h k*, *l m*, equal in number to the other, and of the same altitude, be circumscribed about the pyramid *a-b c d*. And because the pyramids have equal altitudes, and the number of prisms described about each is the same, the altitudes of the prisms will be all equal, and the bases of the corresponding prisms in the two pyramids, as EF, *e f*, will be sections of the pyramids at equal distances from their bases, therefore they are equal (14.), and the prisms themselves are equal (1.), and the sum of all the prisms described about the one pyramid is equal to the sum of all the prisms described about the other pyramid. To abridge, put P and *p* to denote the pyramids A-BCD, and *a-b c d* respectively, and Q and *q* to express the sums of the prisms described about them. Then, because by hypothesis $Z = p - P$, and by construction $Z > Q - P$, therefore $p - P > Q - P$, hence *p* must be greater than Q; but Q is equal to *q*, therefore *p* must be greater than *q*, that is the pyramid *p* is greater than *q*, the sum of the prisms described about it, which is impossible; therefore the pyramids P, *p* are not unequal, that is they are equal.

Prop. XVII. Theor.

Every prism having a triangular base, may be divided into three pyramids that have triangular bases, and that are equal to one another.

Fig. 164. Let ABC, DEF be the opposite bases of a triangular prism; join AE, EC, CD; and because AE is the diagonal of a parallelogram, the triangles ABE, ADE are equal; therefore the pyramids C-ABE and C-ADE, which have a common vertex C, and the triangles ABE, ADE for their bases, will be equal (16.) When these are taken from the whole prism, there remains the pyramid C-DEF, which is equal to the pyramid C-ABE, or E-ABC, for they have equal bases DEF, ABC, and the same altitude, viz. the altitude of the prism ABC-DEF. Therefore the three pyramids C-ABE, C-ADE, and C-DEF, are equal.

Cor. 1. From this it appears, that every pyramid is the third part of a prism, which has the same base and the same altitude with it. For if the base of the prism be any other figure than a triangle, it may be divided into prisms having triangular bases.

Cor. 2. Pyramids of equal altitudes are to one another as their bases; because the prisms upon the same bases, and of the same altitude, are to one another as their bases.

Prop. XVIII. Theor.

Similar pyramids are to one another as the cubes of their homologous sides.

Fig. 161. If two pyramids be similar, it is evident from Def. 13. that the lesser may be placed in the greater, so that they shall have a common solid angle A; and then their bases BCD, FGH will be parallel; for since the homologous faces are similar, the angle AFG = ABC, and the angle AGH = ACD, and so on; therefore the plane FGH is parallel to the plane BCD: Hence, again, it will follow, that a straight line AKE perpendicular to the base of the one, will also be perpendicular to the base of the other, and AE, AK, the altitudes of the two pyramids, will have to each other the ratio of AB to AF, or of BC to FG, &c. Now, let P represent a right prism, having the same base BCD as the pyramid A-BCD, and the same altitude AE, and similarly let *p* represent another right prism, having the same base FGH as the pyramid A-FGH, and the same altitude AK: Then these prisms will manifestly be contained by the same number of similar planes, similarly situated, and having a like inclination to each other, therefore they will be similar (Def. 13.) and consequently P is to *p* as the cube of BC to the cube of FG (12.), but the pyramids A-BCD, A-FGH are like parts of the prisms (1 Cor. 17.); therefore the pyramids are also to one another as the cubes of their homologous sides BC, FG.

Of the three round Solids.

SECT. III.

Of the Three Round Solids.

Definitions.

Definitions.

1. A *cylinder* is a solid figure, generated by the revolution of a right-angled parallelogram, which revolves about one of its sides, that side remaining fixed, (Fig. 165.)

2. The *axis* of a cylinder is the straight line about which the parallelogram revolves.

3. The *bases* of a cylinder are the circles described by the two revolving opposite sides of the rectangle.

4. A *cone* is a solid figure generated by the revolution of a right-angled triangle about one of the sides containing the right angle, which remains fixed.

5. The *axis* of the cone is the straight line about which the triangle revolves.

6. The *base* of the cone is the straight line generated by that side containing the right angle which revolves.

7. A *sphere* is the solid figure generated by the revolution of a semicircle about a diameter, which remains fixed.

8. The *axis* of a sphere is the straight line about which the semicircle revolves.

9. The *centre* of the sphere is the same with that of the semicircle.

10. *Similar cones* and *cylinders* are those which have the diameters of their bases and their axes proportionals.

Prop. I. Theorem.

If from any point E in the circumference of AEB, the base of a cylinder, a straight line EF be drawn perpendicular to the plane of the base, it will be wholly in the cylindric superfices.

Let AGHD be the generating rectangle, and GH the axis. Because in every position of the revolving rectangle, the angle AGH is a right angle, GH is perpendicular to the plane of the base AEB; therefore, AD, the line which generates the cylindric superfices, is in every position perpendicular to the plane of the base (5. 1.), and consequently, when the revolving radius GA comes to the position GE, AD will coincide with EF; therefore EF is in the cylindric superfices.

Of the three round Solids.

Prop. II. Theor.

A cylinder and a parallelopiped having equal bases and altitudes, are equal to one another.

Fig. 166. If the cylinder ABCD and parallelopiped EF, which have equal bases, (viz. the circle AGB and parallelogram EH), and the same altitude, be not equal, let us suppose that they are unequal, and first let the cylinder be less than the parallelopiped. From EF, let a parallelopiped EQ, equal to the cylinder, be cut off by a plane PQ parallel to NF. Let a polygon AGKBLM be inscribed in the circle AGB so as to differ from it by a less space than the parallelogram PH (6. 5. Part I.) and let the parallelogram RO be equal to the polygon AGKBLM; the point R will manifestly fall between P and N. Now, if an upright prism, having the same altitude as the cylinder, be formed on the polygon AGKBLM as a base, and a solid ES be cut off from the parallelopiped EF by a plane RS parallel to NF; the prism and solid ES will be equal (11. 2.) But the prism being entirely contained within the cylinder, is less than it; therefore the prism is also less than the solid EQ; and consequently the solid ES is equal to a solid which is less than EQ; now this is impossible; therefore the cylinder is not less than the parallelopiped EF. In the same way it may be shewn not to be greater, therefore the cylinder and parallelopiped having equal bases and altitudes, are equal or equivalent to one another.

Prop. III. Theor.

If a cone and cylinder have the same base and altitude, the cone is the third part of the cylinder.

Fig. 167. If a cone A-BCD be not the third part of a cylinder BFKG, having the same base and altitude, it will be the third part of a cylinder LMNO, having the same altitude as the other, but a base either less or greater; and first, let the base LIM be less than the base BCD; then, because the circle LIM is less than the circle BCD, a polygon BECFD may be described in the latter, which shall differ from it by less than its excess above the circle LIM (6. 5. Part I.); wherefore this polygon will be greater than the circle LIM. Let an upright prism and pyramid be constituted on the polygon BECFD as a base, and having the same altitude as the cylinders; and because the cone A-BCD is the third part of the cylinder LMNO, and this cylinder is less than the prism BCD-GHK, because it has a less base and the same altitude, therefore the cone A-BCD is less than the third part of the prism BCD-GHK; but the pyramid A-BECFD is the third part of the prism (17. 2.); therefore the cone A-BCD is less than the pyramid A-BCD: Now this is impossible, because the pyramid being contained entirely within the cone, the cone must be greater than the pyramid. Therefore the cone A-BCD is not less than the third part of the cylinder BFKG. In the same manner, by circumscribing a polygon about the base of the cylinder, it may be shewn that the cone is not greater than the third part of the cylinder; therefore it is equal to the third part of the cylinder.

Prop. IV. Lemma.

Fig. 168. Let ABDC be a plane figure, bounded by a straight line CD, a line of any kind AB, which is terminated by perpendiculars at the extremities of CD, and by these perpendiculars AC, BD. Let AB*ba* be a solid generated by the revolution of this figure about CD as an axis; a series of cylinders may be described about the solid, and another series may be inscribed in it, having all the same altitude, and such that the sum of the circumscribed cylinders shall exceed the sum of the inscribed cylinders by less than any given solid S.

Let the solid S be a cylinder, having B*b* for the diameter of its base, and DP for its height. Suppose the fixed axis CD to be divided into a number of equal parts DK, KG, GE, EC, each less than DP. In the plane of the figure ABDC, draw perpendiculars EF, GH, KL to meet the line AB in F, H, L. Construct the inscribed rectangles AE, FG, HK, LD, also the circumscribed rectangles CF, EH, GL, KB. By the rotation of the plane figure about the axis CD, these rectangles will evidently generate a series of cylinders inscribed in the solid, and another series described about it. Let the circumscribed cylinders, reckoned from the bottom of the solid to the top, be denoted by V, X, Y, Z, and the inscribed cylinders by v, x, y, z, then the sums of the circumscribed and inscribed cylinders will be

$$V + X + Y + Z,$$

and $$v + x + y + z.$$

Now by the nature of the figure, each circumscribed cylinder is equal to the inscribed cylinder next below it; therefore $X = v$, $Y = x$, and $Z = y$, and hence the excess of the sum of all the circumscribed above the inscribed cylinders will be the same as the excess of the greatest circumscribed above the least inscribed cylinder: that is, it will be equal to $V - z$, and consequently will be less than V; but the lowest circumscribed cylinder V is less than the solid S, because it has the same base, (viz. the circle having for its diameter B *b*), and a less altitude KD, by construction; therefore the excess of the series of circumscribed above the series of inscribed cylinders is less than the given solid S.

Cor. The difference between the solid AB*ba* and either of the two series of cylinders will be less than the greatest circumscribed cylinder: For the solid AB*b a* is greater than the one series of cylinders and less than the other, therefore it will differ from either series by a quantity less than the difference between the two.

Prop. V. Theor.

If a cone and hemisphere have equal bases and altitudes, and if a series of cylinders be described about the cone, and another series be inscribed in the hemisphere, and the cylinders have all the same altitude, the sum of the two series will be equal to a cylinder having the same base and altitude as the hemisphere.

Let AFB be a semicircle, and CFDA, CFEB, squares described on the radius CF, and let CE be the diagonal of one of the squares BF: Let CF be divided into any number of equal parts CG, GK, KM, MF; and let perpendiculars be drawn through the points of division, meeting the diagonal CE, in the points O, P, Q; the quadrantal arc BF in the points H, L, N; and the side of the square in the points R, S, T: Construct the rectangles CO, GP, KQ, ME, which will circumscribe the triangle CFE; construct also the rectangles CH, GL, KN, which will be inscribed in the quadrant CFB. Suppose now the plane of the square to revolve about its side CF as an axis; the triangle CFE will then generate a cone, which will have DE for the diameter of its base, and C for its vertex; the quadrant CFB will generate a hemisphere, having for its base a circle of which AB is a diameter; and the square CBEF will generate a cylinder, having the same base and altitude as the hemisphere: Also, the rectangles described about

Fig. 169.

Of the three round Solids.

the triangle CFE will manifestly generate a series of cylinders circumscribing the cone; the rectangles inscribed in the quadrant will generate a series of cylinders inscribed in the hemisphere; and the rectangles CR, GS, KT, ME will generate a series of cylinders which will compose a cylinder having the same base and altitude as the hemisphere.

The triangles CFE, CGO are manifestly similar, and CF=FE; therefore CG=GO: In like manner, it may be proved that CK=KP and that CM=MQ.

Join CH, and because CGH is a right angled triangle, a circle described with CH as a radius will be equal to two circles described with CG and GH as radii (2 Cor. 8. 5. Part I.) but CG=GO, and CH=GR, therefore a circle described with GR as a radius will be equal to two circles described with GO and GH as radii; hence again it follows, that the cylinder generated by the rectangle CR will be equal to both the cylinders generated by the rectangles CO and CH, for they have all the same altitude, and the base of the first is equal to the sum of the bases of the other two. It may be demonstrated in the same manner that the cylinder generated by the rectangle GS is equal to the sum of the cylinders, generated by the rectangles GP and GL, and the same of all the rest; therefore the sum of the cylinders, generated by the rectangles CR, GS, KT, ME is equal to the two series of cylinders, one generated by the rectangles CO, GP, KQ, ME, and the other generated by the rectangles CH, GL, KN; that is, a cylinder having the same base and altitude as the hemisphere, is equal to the sum of the two series of cylinders, one described about the cone, and the other described in the hemisphere.

Prop. VI. Theor.

Every sphere is two thirds of the circumscribing cylinder.

Fig. 169.

Let a figure be constructed exactly as in last proposition; and to abridge, let C denote the cone, c the series of cylinders described about it, H the hemisphere, h the cylinders described in it, and K the cylinder having the same base and altitude as the hemisphere, or cone: Moreover, put d for the difference between the cone and its circumscribed cylinders, and d' for the difference between the hemisphere and its inscribed cylinders; then we have

$$C + d = c, \text{ and } H = h + d',$$

and adding equals to equals,

$$C + H + d = c + h + d'.$$

But $c + h = K$ (5.); therefore, $C + H + d = K + d'$, and $C + H + d - d' = K$, also $C + H = K + d' - d$. Hence it appears that the difference between C+H and K is equal to the difference between d and d'. Now d is less than the cylinder generated by the rotation of the rectangle ME (Cor. to prop. 4.), and d' is less than the cylinder generated by the rectangle CR, which is equal to ME, therefore the difference between d and d' must be less than the same rectangle; hence the difference between C+H and K is less than the cylinder generated by the revolution of the rectangle ME, or is less than a cylinder having the same base as the cone, and the line FM for its altitude. From this we may infer, that C+H is exactly equal to K; for if there can be any difference, let it be a cylinder having the same base as the cone, and its altitude equal to FV; then FM must be greater then FV; but the number of parts into which FC is divided may be so great that FM may be less than FV; therefore C+H cannot be unequal to K; and since C+H=K, and $C = \frac{1}{3}K$ (3.), therefore $H = \frac{2}{3}K$; that is, the hemisphere is two-thirds of its circumscribing cylinder; and taking the doubles of these; the whole sphere is two-thirds of its circumscribing cylinder.

An Index to shew the Propositions in the foregoing Treatise, which correspond to the principal Theorems in the first six, and the eleventh and twelfth Books of Euclid's Elements.

Appendix.

APPENDIX

TO THE ELEMENTS OF GEOMETRY.

SECT. I.

Of the Maxima and Minima of Geometrical Quantities.

Definitions.

Maxima and minima geometrical quantities. 1. A quantity is said to be a *maximum*, when it is the greatest; and a *minimum*, when it is the least of all quantities of the same kind.

Thus the diameter of a circle is a *maximum* among all the chords that can be drawn in a circle; and the perpendicular is a *minimum* among all lines that can be drawn from a given point to terminate in a straight line.

2. Figures are called *isoperimetrical*, when they have equal perimeters.

Prop. I. Theor.

Of all triangles having the same base and the same perimeter, the *maximum* triangle is that in which the two indeterminate sides are equal.

Fig. 170. Let ACB, AMB, be two triangles on the same base AB, and such that AC+CB=AM+MB; then if AC=CB, and AM, be greater or less than MB, the triangle ACB is greater than AMB.

Draw CE perpendicular to AB, and MD perpendicular to CE; join AD, BD, and in AD produced take DF=DB, and join MF. Then AE=BE (Geometry, Schol. to 12 of Sect. I. Part I.) and AD=BD (6. 1.) and the angle FDM=DAE (3 Cor. 21. 1.)=DBE (12. 1.)=BDM; hence the triangles FDM, BDM are equal, (6. 1.) and MF=MB, and AM+MF=AM+MB=AC+CB=2AC; but AM+MF is greater than AF, or 2AD; therefore 2AC>2AD, and AC>AD; and hence EC>ED (16. 1.) Now EC and ED are the altitudes of the triangles ACB and AMB respectively; therefore the triangle ACB is greater than the triangle AMB, (Cor. 6. 4).

Prop. II. Theor.

Of all isoperimetrical polygons of the same number of sides, that which is a *maximum* has its sides equal.

Fig. 171. For let ABCDEF be the maximum polygon, if the side BC be not equal to CD on the base BD, make an isosceles triangle BOD, which shall be isoperimetrical to BCD; then the triangle BOD is greater than BCD (I.), and consequently the polygon ABODEF is greater than the polygon ABCDEF; therefore this last is not the greatest of all polygons having the same number of sides and the same perimeter, which is contrary to what we have supposed; hence BC must be equal to CD; and in like manner it may be demonstrated, that any two adjoining sides are equal.

Prop. III. Theor.

Of all triangles constructed with two given sides which contain any angle, that is the greatest, of which the given sides contain a right angle.

Fig. 172. Let BAC, BAD, be two triangles, which have the side AB common, and AC=AD. If BAC be a right angle, the triangle BAC shall be greater than BAD, or BAD′: for the triangles BAC, BAD, are to one another as their altitudes AC, DE, because they have the same base; but DE is less than AD, or its equal AC; therefore the triangle BAD is less than BAC.

Prop. IV. Theor.

If all the sides of a polygon be given, except one, the polygon will be a *maximum* when all its angles are on half the circumference of a circle of which the unknown side is the diameter.

Fig. 173. Let ABCDEF be the greatest polygon that can be formed by the given lines AB, BC, CD, DE, EF, and the indetermined line AF. Draw AD, FD to the vertex of any one of its angles. If the angle ADF be not a right angle, supposing two parts of the polygon, ABCDA and FEDF, to remain the same, the triangle ADF, and consequently the whole polygon, might be increased by making ADF a right angle (3.); but the polygon being by hypothesis a *maximum*, it cannot be increased, therefore the angle ADF must be already a right angle. The same is also true of the angles ACF, ABF, AEF; therefore all the angles of the polygon are in the circumference of a semicircle of which AF is the diameter.

Scholium. This proposition gives rise to a question, whether it be possible to form different polygons which shall each be inscribed in a semicircle, and have all their sides, except that which is the diameter, equal to given lines? Before deciding this question it may be observed, that if one and the same chord AB (Fig. 174.) subtends arcs described with different radii AC, AD, the angle which the chord subtends at the centre of the greater circle shall be less than the angle it subtends at the centre of the less circle: For the angle ADO = ACD + DAC; therefore ADO>ACO, and doubling each ADB>ACB. Fig. 174.

Prop. V. Theor.

Fig. 173. There is only one way of forming a polygon ABCDEF which shall be inscribed in a semicircle, and have all its sides, except the diameter AF, equal to given lines.

For supposing a circle to be found that satisfies the question, if a greater circle would also satisfy it, the chords AB, BC, CD, &c. would subtend lesser angles at the centre of this than at the centre of the other circle; and the sum of these angles would be less in the one than in the other circle; but by the nature of the figure, in each the sum should be the same, viz. two right angles, therefore the polygon cannot be inscribed in two different semicircles.

Scholium. The order of the given sides AB, BC, CD, &c. may be changed, and still the diameter of the circle shall be the same, as well as the area of the polygon; for whatever be the order of the arcs AB, BC, CD, &c. it is sufficient that their sum be a semicircumference. The different polygons will also have equal areas, because by drawing lines to the centre, the triangles which constitute any one polygon will be respectively equal to those which constitute any other, as is evident.

Appendix.

PROP. VI. THEOR.

Of all polygons formed with given sides, the *maximum* is that which can be inscribed in a circle.

Fig. 175. Let ABCDEFG be the polygon inscribed in a circle, and *a b c d e f g* that which cannot be so inscribed. Draw the diameter EM; join AM, MB, and on *a b* = AB make a triangle *a m b* so that *a m*=AM, and *m b*=MB, and join *e m*. Then by Prop. 4. the polygon EFGAM is greater than *c f g a m*, unless this last can be inscribed in a circle of which *e m* is the diameter, because in this case the two polygons would be equal (Prop. 5.) For the same reason the polygon EDCBM is greater than *e d c b m*, excepting the case of the latter admitting of being inscribed in a semicircle, so as to make them equal. Therefore the whole polygon EFGAMBCDE is greater than the whole polygon *e f g a m b c d e*, unless they are entirely equal, which cannot happen, because the one is supposed to admit of being inscribed in a circle, but not the other; therefore the inscribed polygon is the greater of the two, and taking away the equal triangles AMB, *a m b*, there remains the polygon ABCDEFG, inscribed in a circle, greater than the other polygon *a b c d e f g*, which does not admit of such inscription.

SCHOLIUM. It may be demonstrated, as in Prop. V. that there can be only one circle, and consequently only one *maximum* polygon that satisfies the question; and this polygon will have the same surface, in whatever order the sides follow each other.

PROP. VII. THEOR.

The regular polygon is the greatest of all the isoperimetrical polygons, having the same number of sides.

For by Theorem 2, the *maximum* polygon has all its sides equal; and by the last Theorem, it may be inscribed in a circle. Now no other than a regular polygon has these two properties.

PROP. VIII. LEMMA.

Fig. 176. If two circles ADH, ABK, touch each other internally at A, and a straight line CD be drawn from the centre of the inner circle, to cut the circumferences in B and D, the arc AD of the outer circle shall be greater than the arc AB of the inner circle.

In the circumference of the inner circle, take the arc BE=BA; join CE, and through E and D, with a radius equal to the radius of the outer circle, describe an arc ED; then the trilateral figures ACD, ECD, will manifestly be exactly alike, and the arcs EB, ED will touch each other at E. And because the concave line ADE, (formed by the arcs AD, ED,) and the arc ABE, have their concavities turned the same way, by an axiom in geometry, the former is greater than the latter; therefore taking their halves, the arc AD is greater than the arc AB.

PROP. IX. THEOR.

Of two isoperimetrical regular polygons, that which has the greater number of sides is the greater.

Fig. 177. Let AB, DE be half the exterior sides of the two polygons, C their common centre; also CA and CAD those radii of circles inscribed in the polygons, which are perpendicular to their sides. Draw CB, CE, and let CE meet AB in M. Draw BH parallel to CE. On C as a centre, describe the arc AF, meeting CE in G; and on H as a centre, describe the arc AK, meeting CF in I.

Because the polygons have equal perimeters, the lengths of their sides will be reciprocally as their number; and because all the angles at the centre of each polygon make four right angles, the angles which the sides subtend at the centre, will also be reciprocally as their number: hence we have DE : AB : : arc AG : arc AF.

The triangles CAM, HAB, are manifestly similar, also the sectors CAG, HAK, hence

AB : AM : : arc AK : arc AG,

and since DE : AB : : arc AG : arc AF,

therefore, *ex. æq.* DE : AM : : arc AK : arc AF;

but DE : AM : : CD : CA;

therefore arc AK : arc AF : : CD : CA.

Now the arc AK is greater than the arc AI, which again is greater than the arc AF, (preceding Prop.) therefore CD is greater than CA; that is, the radius of the circle inscribed in the polygon having the lesser angle, or greater number of sides, is greater than the radius of the other polygon; but the polygons being isoperimetrical, and the area of each equal to half the rectangle of the perimeter, and the radius of the inscribed circle, the areas will be proportional to these radii; therefore the polygon that has the greatest number of sides, has the greatest area.

PROP. X. THEOR.

The circle is greater than any isoperimetrical polygon.

It has been proved, that if a regular and irregular polygon have equal perimeters, the former has the greater area; therefore it only remains to compare the circle with a regular polygon of the same perimeter. Fig. 178.

Let AI be half the side of the polygon, C the centre. In the isoperimetrical circle, let the angle DOE= ACI, and consequently the arc DE= the side AI: the polygon P is to the circle C as the triangle ACI is to the sector ODE; now the area of the triangle is $\frac{1}{2}$AI × IC, and the area of the sector is $\frac{1}{2}$ DE × EO; therefore P : C : : $\frac{1}{2}$ AI × IC : $\frac{1}{2}$ DE × EO : : IC : EO. Draw the tangent EG to meet OD in G. The triangles ACI, GOE being similar, IC : EO : : AI : GE; therefore, P : C : : AI, or arc DE : GE : : $\frac{1}{2}$ DE × EO : $\frac{1}{2}$ GE × EO; but $\frac{1}{2}$DE × EO=sector DOE; and $\frac{1}{2}$ GE × EO= triangle GOE, therefore P : C : : sector DOE : triangle GOE; now the triangle GOE is greater than the sector DOE; therefore the circle C is greater than the isoperimetrical polygon P.

COR. A circle contains within a given perimeter the greatest possible area.

PROP. XI. THEOR.

Of all polygons, having the same number of sides, and a given area, a regular polygon is that which has its perimeter a *minimum*.

Let A be the given area of a polygon, and v its perimeter; let a similar polygon have its perimeter equal to a given line b, and let its area be X. Because similar figures are as the squares of their perimeters, we have A : X : : v^2 : b^2; hence A × b^2=X × v^2, and v^2= Fig. 179.

Appendix. $\frac{A \times b^2}{X}$; hence it is evident that the greater the value of X, the less will be the value of v; but the perimeter b being given, the area X is the greatest possible when the polygon is regular, (7.), therefore the perimeter of a regular polygon, having a given area, will be less than the perimeter of an irregular polygon of the same number of sides, and the same area.

PROP. XII. THEOR.

Of regular polygons having the same area; that which has the greatest number of sides has the least perimeter.

Fig. 180. Let v and x be the perimeters of two regular polygons, having the same area A; also let Y and Z be the areas of two polygons, similar to them which have the same permeter b: then, because of the similar polygons, we have

$$v^2 : b^2 :: A : Y,$$
$$b^2 : x^2 :: Z : A,$$

hence, *ex æq.* $v^2 : x^2 :: Z : Y$.

Now, if of the two polygons Y and Z, Y be that which has the greater number of sides, then Y will be greater than Z (9.), and consequently $Z \angle Y$; therefore v^2 will be less than x^2, and v less than x; that is, the perimeter of the polygon having the greater number of sides, is less than the perimeter of the other polygon.

PROP. XIII. THEOR.

The perimeter of a circle is less than that of any polygon having an equal area.

This proposition may be proved exactly in the same manner as the last; or else by considering that a circle is the limit of all the regular polygons that can possibly be described about it; and that while the area of the circle may differ from the area of the polygon by less than any assignable quantity, its perimeter will be less than that of the polygon.

COR. A circle contains a given area with the least possible perimeter.

SECT. II.

THE CONSTRUCTION OF GEOMETRICAL PROBLEMS, BY DESCRIBING CIRCLES ONLY.

Construction of geometrical problems by circles only. A geometrical problem is considered as resolved, when it is shewn to be identical with some other known problem, or to be a combination of several, the mode of resolving each of which is known. The decomposition of a problem into others more simple, leads to the question, which problems are the most simple? so as not to admit of farther decomposition.

The ancient geometers assumed, as the most elementary, these three:

1. To draw a straight line from any one point to any other point.
2. To produce a terminated straight line to any length in a straight line.
3. To describe a circle from any centre at any distance from that centre.

They did not propose to resolve these, but took for granted that their resolution was known, and as obvious as the truth of the axioms.

However narrow a foundation these three self-evident problems, or *postulates* as they are called, may appear to afford, when compared with the vast fabric of geometry, attempts have been made to render it still narrower. Tartalea proposed to Cardan, to construct all the problems in Euclid by one and the same opening of the compasses, admitting, however, the use of a rule; and Benedictus composed a work on this problem. Schooten, instead of the postulate, "that a circle may be described from any centre at any distance from that centre," substituted this, "that from a given point in an indefinite straight line, a straight line may be cut off equal to a given terminated straight line;" by this change, he shewed elegantly how all the problems in elementary geometry might be constructed, without employing the circle farther than to cut off from a line a part of a given length, and thus in appearance the problems were constructed by straight lines only. See Schooten, *Exercit. Math.* lib. ii.

Mascheroni. Died 1801. At a later period, an Italian mathematician, Mascheroni, imposed on himself the task of resolving all plane problems whatever, by the circle alone; his success was complete, and the result of his labours is given in his *Geometrie du Compas*, the Geometry of the Compasses. It must be observed, that it is only in the construction of the problem that the straight line is dispensed with; for, in the demonstration, straight lines must be supposed drawn, and their properties introduced, in order to apply the common elements of geometry.

It is an anecdote not altogether without interest in the history of geometry, that the celebrated Bonaparte, late Emperor of the French, studied the geometry of the compasses under Mascheroni; he even condescended to propose to the French mathematicians one of its problems, namely, to divide the circumference of a circle into four equal parts, without employing straight lines.

We shall now give some specimens of this mode of constructing problems. And it is to be observed, that the propositions referred to in the article GEOMETRY, are all in the first Part.

PROP. I. PROB.

To determine a distance in the direction of a straight line passing through two given points A, B that shall be any multiple of the given distance A B.

First, To double the distance AB. On B as a centre, with BA as a radius, describe a portion ACDE of a circle, not less than its half. On A as a centre, with the same distance, describe an arc, to cut the circle in C. In like manner determine the points D and E in the circumference, so that the distances from C to D, and from D to E, may be equal to the distance from A to C, or from A to B. Then, because the chords of the arcs AC, CD, DE are each equal to the radius AB; the arc ACDE will complete a semicircle (2. 5.), and the points A, E will be the extremities of a diameter; therefore the points A, B, E will lie in a straight line, and the distance AE will be double AB. Fig. 181.

2d, To find the triple of the distance AB. Take BF the double of BE, and AF shall be the triple of AB; and proceeding in this way, any multiple whatever of AB may be found.

PROP. II. PROB.

To divide a given distance AB into any proposed number of equal parts. Fig. 182.

Appendix.

Let us suppose that the distance AB is to be divided into three equal parts. Take the distance AC equal to three times the distance AB, (by Prop. 1.), and in general, whatever be the number of equal parts into which AB is to be divided, take AC equal to the same number of times AB; in other respects, the construction is the same in all cases. On C as a centre, with CA as a radius, describe an arc PAp; and on A as a centre, with AB as a radius, describe another arc PBp, meeting the former in P and p. In the circle pBP, beginning from the point p, place three chords pm, mn, nQ, each equal to the radius AB. On P as a centre, with a radius equal to AB or AP, describe the arc AV, and on A as a centre, with a radius equal to the chord of PQ, describe another arc, meeting the former in V; then V shall be in a straight line joining A and B; and the distance AV shall be one third of the distance AB.

Join AP, CP, AQ, PQ, AV, PV. The triangles CAP, PAQ are manifestly isosceles; and because the arcs pm, mn, nQ are each one-sixth of the circumfe- (2. 5.) the arc pBQ is half the circumference; hence it is the measure of the three angles of the triangle CAP, (31. 4. and 24. 1.) that is of the angle C, and twice the angle CAP; but the arc PBp is the measure of twice the angle PAB, because arc BP = arc Bp; therefore the remaining arc PQ is the measure of the angle C. Now the same arc is also the measure of the angle PAQ; therefore the angle C is equal to the angle PAQ; and since PC : CA :: PA : AQ, the triangles PCA, PAQ are similar (20. 4.); hence the angle APQ is equal to the angle PAC; but the angle APQ = PAV, because by construction AP is common to the triangles APQ, PAV, and PQ = AV, and AQ = PV; therefore the angle PAC is equal to the angle PAV, and consequently V is in the straight line AC. And because CA : AP :: AP : AV, that is, CA : AB :: AB : AV, therefore whatever part AB is of AC, the very same part will AV be of AB.

The remaining points of division X, &c. may be found by making AX = 2 AV, &c. as taught in Prop. 1.

Scholium. The point V might also have been found by determining the points P and p as in the above construction, and then describing arcs on P and p as centres to pass through the point A, these would have intersected each other again in the point V. This construction, however, is not so good as the other, as a practical method, because the arcs cut each other obliquely.

Prop. III. Prob.

Having given two points in a straight line, to determine the direction of a perpendicular to it, which shall pass through one of the points.

Fig. 183. Let the given points be A, B. On these points, with any radius greater than half AB, describe arcs to intersect each other in C. On C, as a centre, describe a circle to pass through A and B, and determine the semicircle ABP, as in the former problems, by cutting off successively three arcs Am, mn, nP, with a radius in the compasses equal to that of the circle; then P will be a point in the perpendicular PB. For the angle APB, which is in a semicircle, is a right angle.

Prop. IV. Prob.

Having given two points in a straight line, to determine the direction of a perpendicular drawn from a point without it, and also the point in which the perpendicular meets the line.

Let A, B be the given points in the line AB, and P the point without it. On A and B, as centres, describe arcs to pass through P, and meet each other at p, a point on the other side of AB. Because each of the points A and B is equally distant from P and p, the line AB is perpendicular to the line which passes through P and p, (17. 1). It also bisects Pp at C; therefore C, the intersection of the line AB, and the perpendicular, may be found by Prop. 2. Fig. 18

Prop. V. Prob.

Having given two points A and B in a straight line, and a point P without it, to determine the position of a line that passes through P, and is parallel to AB. Fig. 19

On P as a centre, with a radius equal to AB, describe an arc of a circle; and on B as a centre, with a radius equal to PA, describe another arc, cutting the former in Q; a line passing through P and Q will be parallel to AB. For if AP, BP, BQ, be joined, the triangles PAB, BQP, will be, in all respects, equal; therefore the angles, QPB, PBA, are equal, and PQ is parallel to AB.

Prop. VI. Prob.

To find the side of a square, that shall be equal to the difference of two given squares.

Let AB and AC be the sides of the given squares. In the line AB produced, take Ba = BA, (Prop. I.), and on A and a, as centres, with a radius equal to AC, describe arcs cutting each other in D. The distance from B to D will be the side of the square required. Fig. 1

Because ADa is an isosceles triangle, a straight line drawn from D, the vertex of the triangle, to B, the middle of the base, will be perpendicular to the base, (12.1); therefore $AD^2 = AB^2 + BD^2$, and $BD^2 = AD^2 - AB^2$.

Prop. VII. Prob.

To bisect a given arc of a circle.

Let AB be the given arc, and C the centre of the circle. On B as a centre, with a radius equal to CA, describe an arc of a circle; and on C as a centre, with a radius equal to BA, describe another arc, cutting the former in D. Find m the side of a square, that shall be equal to the difference of the squares of the lines DA, DC, (Prop. 6.) On D, as a centre, with a radius equal to m, describe an arc, to meet the arc AB in V; then V shall be the middle of the arc AB. Fig. 1

Draw AE perpendicular to CD, and CF perpendicular to AB. Because by construction AB = CD, and AC = BD, the figure ABDC is a parallelogram; therefore also AFCE is a rectangle, and CE = AF, but AF = $\frac{1}{2}$ AB (6.2.); therefore CE = $\frac{1}{2}$ AB = $\frac{1}{2}$ CD, and 2 CE = CD. In the triangle ACD, we have $AD^2 = AC^2 + CD^2 + 2\,EC \times CD$ (13. 4.) $= AC^2 + 2\,CD^2$, therefore $AD^2 - CD^2 = AC^2 + CD^2$; but by construction $AD^2 - CD^2 = DV^2$; therefore $DV^2 = AC^2 + CD^2$; and, if a straight line be drawn from V to C, $DV^2 = VC^2 + CD^2$; hence DCV is a right-angled triangle (11. 4.)

Appendix. and CV is perpendicular to CD, and consequently is perpendicular to the chord AB; therefore CV bisects the arc AVB in V.

PROP. VIII. PROB.

Fig. 188. To find the sum or difference of two given distances AB, CD.

On B, one extremity of either of the given distances as a centre, with a radius equal to the other given distance CD, describe a circle. On A, the other extremity, with any radius, describe an arc to cut the circumference in *m* and *n*. Bisect the arcs of the circle between *m* and *n* in E and F, (last Prop.) then AE is the sum of the distances AB, CD, and AF their difference.

For if A *m*, B *m*, E *m*, A *n*, B *n*, E *n* be joined, the triangles on each side of AB will be equal; hence, as the prolongation of AB, and the line drawn from B to E will bisect the angle *m* B *n*, the points A, B, E will be in a straight line. In like manner it appears that the points A, B, F are in a straight line; consequently AE = AB + BE = AB + CD, and AF = AB — BE = AB — CD.

SCHOLIUM. By this problem, a line may be produced to any given distance. Also from the greater of two lines a part may be cut off equal to the less.

PROP. IX. PROB.

To find the centre of a given circle.

Fig. 189. Let ADB be the circle. Take any point B in the circumference, and on B as a centre, with any radius less than the diameter of the given circle, and greater than the fourth of that diameter, describe a circle ADC, cutting the other circle in D. Determine C, the opposite extremity of the diameter AC, as in the former problems. On BC construct the isosceles triangle BEC, having its sides BE, CE each equal to CD. On E as a centre, with EB or EC as a radius, describe an arc, cutting the circle ADC in F; then the distance from A to F shall be the radius of the circle ADB; and arcs described on any two points in its circumference as centres, with AF as a radius, will evidently intersect each other in its centre.

Suppose O the centre of the circle. Draw OA, OB, and the other lines as in the figure. Because the chord AB = chord BD, the arc AB is equal to the arc BD, and the angle BAD = angle BDA; now the angle BAD, or CAD, is half the angle CBD, (16. 2), and the angle BDA is half the angle BOA; therefore the angles CBD, BOA are equal, and since CB = BD and BO = OA, the triangles CBD, BOA are similar; and CD : CB :: BA : BO; that is, CE : CB : : AB : BO.

Again, because the isosceles triangles EBC, EBF are manifestly in all respects equal, the angle CBF is double the angle CBE; but in the isosceles triangle ABF, of which a side AB is produced, the exterior angle CBF is equal to the two angles BAF, BFA, that is, to 2 BAF, therefore the angle CBE = angle BAF, and BCE=BFA. Hence the isosceles triangles EBC, BFA are similar; and CE : CB :: AB : AF. But it was shewn that CE : CB : : AB : BO; therefore AF = BO, that is, AF is the radius of the given circle ABD.

PROP. X. PROB.

Fig. 190, 191. To determine the intersections of a line which passes through two given points A,B, and a circle given by position.

CASE 1. (Fig. 190.) When the line passes through C the centre of the circle. From C, set off CF and C*f*, in opposite directions, each equal to the radius of the circle, so that F and *f* may be in the line AB (by Prop. 8.); and the points F, *f* will manifestly be the intersection of the straight line and circle. Appendix. Fig. 190.

CASE 2. (Fig. 191.) When the line AB does not pass through the centre C. Draw CD perpendicular to AB (Prop. 4.), and produce it, so that DE = DC, (Prop. 1.). On C and E as centres, with the radius of the circle in the compasses, describe arcs to intersect each other in F and *f*; and these points will be the intersection of the straight line and the circle. For the points F and *f* are in the line which bisects CE at right angles (17. 1.); therefore they are in the line AB; and the same points F, *f* are manifestly in the circumference of the circle; therefore they are the intersections of the straight line and circle. Fig. 191.

PROP. XI. PROB.

To find a third proportional to two given lines P, Q. Fig. 192.

On any point C as a centre, with a radius equal to P, the first of the three proportionals, describe an arc ADB. In this arc place the chord AD equal to Q, the second term. On D as a centre, with DA as a radius, describe a circle ABE, and find E, the opposite end of the diameter passing through A, as in the former problems. The distance from B to E shall be the third proportional sought.

For, the isosceles triangles CAD, CBD being equal, the angle ADB is double the angle ADC; but in the isosceles triangle DBE, the outward angle ADB is the sum of the angles DEB, DBE, and therefore is double the angle DEB. Hence the angles ADC, DBE are equal, and consequently the other angles of the triangles CAD, DBE are equal, and the triangles are similar. Therefore CA : AD : : DB : BE, that is P : Q :: Q : BE.

This construction can only apply, when the first term is greater than half the second; when it is not, it may be doubled or quadrupled, &c. by Prop. 1. until a multiple of it be found that exceeds the half of Q, and then a like multiple of a third proportional to this multiple of P, and the line Q will evidently be a third proportional to P and Q.

PROP. XII. PROB.

To find a fourth proportional to three given lines P, Q, R. Fig. 193.

On any point C as a centre, with radii equal to P and R, the first and third terms of the proportionals, describe concentric circles AB, DE. In the first of these, place the chord AB equal to the second term Q. Take any point D in the circumference of the other circle, and from B place between the two circumferences a line BE equal to AD. Then the distance between D and E shall be the fourth proportional sought.

For, by construction, the three sides of the triangle ACD are equal to the three sides of the triangle BCE, each to each. Hence the angle ACD is equal to the angle BCE, and adding the common angle BCD, the angle ACB is equal to the angle DCE; therefore the isosceles triangles ACB, DCE are similar, and CA : AB : : CD : DE; that is, P : Q : : R : DE.

If the third term is more than double of the first, this construction will not immediately apply; but it may be modified, as in last proposition, by taking a multiple of the first, and then, the line required will be a like mul-

Appendix. tiple of a fourth proportional to the multiple so taken of the first, and the second, and third terms.

PROP. XIII. PROB.

Fig. 194. To find a mean proportional between two given lines AB, CD.

Place BE = CD in a line with AB (Prop. 8.) Bisect AE in F (Prop. 2.). Make BG = BF (Prop. 1.) On F and G as centres, with a radius equal to FB, describe arcs intersecting in H; and the distance from B to H will be the fourth proportional required.

It is manifest from the construction, that FBH is a right angle, and that H is in the circumference of a circle of which AE is the diameter; therefore AB : BH :: BH : BE or CD. (Prob. 3. Sect. 4. Part 1.)

PROP. XIV. THEOR.

Having given two points in each of two straight lines, to find the intersection of the lines.

We shall give an analytical solution to this problem. Indeed the whole theory might, with great advantage, be given under the analytical form.

Fig. 195. Let A, B be given points in the line AB, and C, D given points in the line CD. Suppose the intersection of the lines to be found, and that it is the point V. Draw V a on the other side of VC, so that the angles CVa, CVA may be equal; take V a=VA, and Vb=VB, and draw lines from A to a, and from B to b. Then every point in CV will be equally distant from A and a, also from B and b (12, and 17 of Sect 1. Part I.); hence the distance a C = distance AC; and the distance a D = distance AD; but AC and AD are known, because the points A, C, D are given; therefore the distances aC, a D, are also known, and consequently the point a is known. In like manner it appears that the distances b C, b D are equal to the known distances BC, BD; thus the point b is known.

Draw BG parallel to V a, to meet A a in G. The figure BGab is evidently a parallelogram; therefore BG = a b, and a G = B b; now a b, and B b are lines of a given length, because the points a, b, B are known; therefore BG, a G are given distances; and consequently the point G is known.

The triangles AGB, A a V are evidently similar; hence AG : AB :: A a : AV; thus, AV = aV is a fourth proportional to three given lines; therefore it may be found by Prop. 12. And because V is at known distances from given points A, a, the position of the point V is determined.

CONSTRUCTION. On C and D as centres, with radii equal to CA and DA, describe arcs to meet on the other side of the line at a; also on the same centres, with radii equal to CB, DB describe arcs to meet in b. On B as a centre, with a radius equal to a b, describe an arc, and on a as a centre, with a radius equal to B b describe another arc, to cut the former in G. Lastly, on A and a as centres, with a radius equal to a fourth proportional to the distances AG, AB, A a, (found by Prop. 12.) describe arcs to intersect in the point V, which will be the intersection of the lines AB, CD, as is evident from the analysis of the problem.

PROP. XV. PROB.

To divide the circumference of a circle into four, and also into eight equal parts.

This problem might be resolved by the problem for the bisection of an arc, but more elegantly by a construction suited to the particular case. The analysis may be as follows.

Fig. 19 Let ADB be a semicircle, AD one fourth, and AE one eighth of the circumference. Draw the radii CD, CE, and draw EF, a tangent to the circle, meeting CD in F. Because CE bisects the arc AD, it is perpendicular to the chord AD; now CE is also perpendicular to EF; therefore EF is parallel to AD; hence the angles ADC, EFC are equal; now the angles ACD, CEF are also equal, therefore the triangles ACD, CEF are similar; and since AC = CE, therefore AD = CF. Join AF; and in the right angled triangle ACF, we have $AF^2 = AC^2 + CF^2$, but $CF^2 = AD^2 = AC^2 + CD^2 = 2\ AC^2$; therefore $AF^2 = 3\ AC^2$: Now $AB^2 = 4\ AC^2$, therefore $AF^2 = AB^2 - AC^2$. Place in the circle a chord BG equal to the radius, and join AG; then, because $AG^2 = AB^2 - AC^2$, it follows that $AF^2 = AG^2$ and AF = AG. Hence this construction.

Determine the semicircle AGB as usual, and on A and B as centres, with a radius equal to AG, the chord of two thirds of the semicircumference, describe arcs to intersect each other in F. Place in the circle a chord AD equal to the distance from C to F, and D will be the middle of the arc ADB.

Again, on F as a centre, with a radius equal to AC, describe an arc to cut the circle in E, and E will be the middle of the quadrant AD. (ξ)

GEOMETRY, DESCRIPTIVE, the name given to a branch of geometry, which has of late years been much cultivated by the French mathematicians, and in particular by Monge, who may be regarded as its inventor. Its object is to represent on a plane, which has but two dimensions, any object which has three, and which admits of a strict definition. Descriptive geometry admits of a twofold application. First, it is employed by artists, to communicate to each other a knowledge of different objects. Thus it furnishes the means of constructing geographical and topographical charts; also plans of buildings and machines, architectural designs, sun-dials, theatrical decorations, &c. In this point of view, it is the best method that can be employed to describe the forms and the relative positions of objects. In the next place, it serves as an instrument of research, by which we may discover every thing relative to the form, and the position of the various parts of objects which admit of a rigorous definition. It is by the principles of descriptive geometry, that stone-cutters, carpenters, ship-builders, and other artists, find the dimensions of the different parts of the works which they execute, in as far as these dimensions result from the complete definition of the object.

Descriptive geometry formed an essential branch of the education of the French youth in the school of public works established at the beginning of the revolution; and it appears from the journal of the Polytechnic school, that the scholars were, during a certain period of the course, employed six hours every day in tracing the numerous objects which were the subject of their studies. The lessons given in the Normal School form a treatise on the subject by Monge, entitled *Geometrie Descriptive*, printed in 1799. There is also a treatise by Lacroix, entitled *Essais de geometrie sur les plans et les surfaces courbes* (*ou Elemens de geometrie descriptive*). We have already treated this subject under the head of CONSTRUCTIVE CARPENTRY. See CARPENTRY, Part II. (ξ)

Georgia in America.

GEORGIA, one of the United States of America, is situated between 31° and 35° North Lat. and between 5° and 16° West Long.; extending in length about 600 miles, and in breadth 250; and bounded on the east by the Atlantic ocean, on the south by the East and West Floridas, towards the west by the river Mississippi, and on the north and north-east by South Carolina, by the Tennessee State, or by lands ceded to the United States by South Carolina. The face of the country is various. That portion of its eastern division which lies in one direction between the rivers Savannah and St Mary's, in the other between the mountains and the ocean, a tract of territory which, from north to south, is upwards of 120 miles, and from east to west not less than 40 or 50, is entirely level, without a hill or stone. Farther to the westward, the lands begin to be more or less uneven; from ridges that rise gradually one above another, swelling progressively into hills, and thence finally terminating in mountains. The vast chain of the Alleghany or Appalachian mountains, which commences at Katts Kill, near Hudson's river, in the state of New York, terminates here about 60 miles south of the northern boundary, while; from the point where it ends, there spreads a widely extended plain, of the richest soil, in a latitude and climate favourably adapted to the culture even of most of the East India productions, or of those of the south of Europe. The winters in this country are mild and pleasant; snow is seldom or never seen, nor does it often happen that frosts prove injurious to the vegetation. In the flat country the air is rather confined, and being often contaminated by putrid vapours from the rice swamps, is comparatively less healthful than among the hills; and spring water is scarce. From June to September, the mercury in Fahrenheit's thermometer fluctuates here between 76° and 90°, and in winter between 40° and 60°. The most prevalent winds are the south-west and the eastern, and in winter the north-west. The east wind is warmest in winter, and coolest in summer.

Rivers.

Georgia is abundantly watered by numerous rivers, as well as smaller streams, which intersect it in every direction. The Savannah forms a part of the bounding line by which this state is separated from South Carolina. It is formed principally of two branches, the Tugulo and Keowee, which have their origin in the mountains. It is navigable for large vessels up to the town of the same name, and for boats of 100 feet keel as far as Augusta. There is a fall just above this place, beyond which it is farther passible for boats to the mouth of the Tugulo. Tybeebar, at the entrance of the river, in latitude 31° 57′, has at half tide a depth of 16 feet water. The Alalamaka and Ogeechee rivers have their course nearly parallel to the Savannah.

Besides these, with the several waters tributary to them, there are the Turtle River, Little Sitilla, Great Sitilla, Crooked River, and St Mary's, which last forms a part of the southern boundary of the United States, and is navigable for vessels of considerable burden for 90 miles. On the west, it is washed by the Mississippi, which separates it from Louisiana. Of rivers which fall into the Gulf of Mexico, there are the Pearl, the Pascagoula, the Alibama, the Tombegbee or Mobile, the Escambia, the Chatahouchee, with the Apalachicola, and the Flint rivers. The northern part of the state is watered by the Tennessee, Bend, and the Chuccamaga. All these rivers abound with various sorts of fish, among which are rock, mullet, whiting, shad, trout, drum, bap, cat-fish, brim, and sturgeon; and the bays and lakes afford oysters and other shell-fish. The chief lake or marsh in the state is Ekanfanoka, which is 300 miles in circumference.

Islands and coast.

The whole of the sea coast of Georgia is bordered with islands, through the medium of which there is constituted a sort of inland navigation, extending with but few interruptions from the river Savannah to St Mary's. The principal of these islands are Skedaway, Wassaw, Ossabaw, St Catharine's, Sassels, Frederica, Jekyl, Cumberland, and Amelia.

Soil and agriculture.

The soil of Georgia, and the degrees of its fertility, vary according to situation, and the differences that have taken place as to the manner or the extent of its improvement. The islands just mentioned are, in their natural state, covered with a plentiful growth of pine, oak, hiccory, live oak, and some red cedar. The soil is grey, formed by a mixture of sand and black mould. A considerable part of it, that particularly on which are chiefly found the oak, hiccory, and live oak, is very fertile, and yields on cultivation good crops of indigo, corn, cotton, and potatoes. The soil of the main land adjoining to the marshes and creeks, is nearly of the same quality with that of the islands. The portion of it which borders on the creeks and rivers, forms the chief exception, being the ground which furnishes the valuable rice swamps. These begin immediately upon the termination of the salts, and lie most of them on rivers, which, as far as the tide flows, are called tide lands, or on creeks and particular branches of water, flowing in some deeper or lower parts of the lands, which are called inland swamps, and extend back in the country from 15 to 25 miles, beyond which, for the most part, little rice is planted. Those lands immediately adjoining to the rivers are nearly level, continuing so in a breadth from two to three or four miles, for the space, in a direct line from the sea, of not less than 100 miles. In this distance, wherever a piece of high land extends to the bank of the river on one side, there may almost invariably be expected, on the other, a low or swampy ground of proportionable width. The intermediate lands, which are covered chiefly with pine, and a sort of wild grass and small reeds, afford a large range of feeding ground, both summer and winter. The oak and hiccory ranges that are interspersed, and which are of superior quality, yield, when cultivated, good crops of corn, indigo, or other valuable produce. At a distance from the sea, the soil changes from grey to red; in some places it is gravelly but fertile; and farther back into the country its tint is gradually deepened, till it becomes what is called the mulatto soil, consisting of a black mould and red earth. This sort of land is generally strong, and affords abundant crops of wheat, tobacco, corn, &c. It is succeeded in its turn by a soil that is nearly black, and very rich, and on which there grow large quantities of black walnut and mulberry. This sort of succession in the different soils which occur in the state, is throughout pretty regular and uniform. They stretch in the same order, in lines nearly parallel with the sea coast, not only across this state, but all along northwards, as far even as to Hudson's river.

Productions.

The staple commodity of Georgia is its rice. It yields also small quantities of indigo, cotton, and silk, besides Indian corn, potatoes, oranges, figs, pomegranates, with other useful grains or fruits. The forests afford an abundant supply of fine timber, consisting chiefly of oak, hiccory, mulberry, pine, and cedar.

Manufactures.

The manufactures of Georgia have not hitherto been very considerable. The people in the lower part of the

Georgia in America.

state have not been accustomed to prepare even their own clothing, or that worn by their negroes. For almost every article, as well of their wearing apparel as of the tools used by them in their husbandry, they have been indebted to their merchants, who imported them from Great Britain or the northern states. But in the upper parts of the country, the inhabitants themselves manufacture the chief part of their clothing from cotton and from flax. The principal manufactures are those of indigo, silk, and sago. The latter is a kind of sediment or starch, that is obtained by properly macerating and washing potatoes. The large crops of this kind that grow on the dry plains of the country, besides affording wholesome nourishment, have been made to yield, by distillation, a spirituous liquor of a tolerable quality, though inferior to that which is made from rye. The chief articles of export from this state are rice, tobacco, indigo, sago, lumber of various kinds, naval stores, leather, deer-skins, snake-root, myrtle, and bees-wax, corn, live stock, &c. The value in sterling money of the whole amount of those exports in the year 1755, was £15,744; in 1760, £20,852; in 1765, £73,426; and in 1772, £121,677. In 1791, the value of articles in like manner exported, was, in dollars, 491,472; in 1792, 458,973; in 1793, 501,383; in 1794, 676,154; in 1796, 950,658; and in 1801, 1,854,951. The tonnage employed in this state was, in the year 1755, 1899; in 1760, 1457; in 1765, 7685; in 1772, 11,246; and in 1790, 28,540 tons. The number of American seamen, during the last of those years, was 11,235. In return for her exports, Georgia receives West India goods, teas, wines, clothing, and dry goods of all kinds; from the northern states, cheese, fish, potatoes, apples, cyder, and shoes. The imports and exports are principally to and from Savannah, which has a fine harbour, and is the chief emporium of the state.

Commerce.

Political division.

Before the revolution, Georgia, like the rest of the southern states, was divided into parishes; but since that period, the division has been into counties. According to this distribution, Georgia, under two districts, viz. the Upper and the Lower, comprehends 24 counties, of which 15 are included in the former division and nine in the latter. The counties of the upper district are Montgomery, Washington, Hancock, Green, Franklin, Oglethorpe, Elbert, Wilkes, Lincoln, Warren, Jefferson, Jackson, Bullock, Columbia, and Richmond; those of the lower district are Camden, Glynn, Liberty, Chatham, Bryan, M'Intosh, Effingham, Scriven, and Burke. The principal towns are Augusta, formerly the seat of government, Savannah, the former capital of the state, both on the river Savannah, Sunbury, Brunswick, Frederica, Washington, and Louisville, which last is now the metropolis of the state, and the place in which are deposited its records. The situation of these towns is generally advantageous; most of them standing on the banks of considerable rivers, and some of them, as Savannah, Brunswick, Frederica, and Sunbury, having safe and commodious harbours.

Counties.

Towns.

Population.

In the grand convention at Philadelphia in 1787, the inhabitants of Georgia were reckoned to amount in all to 90,000. By the census of 1790, it did not exceed 82,548 persons, of whom 29,264 were slaves. Subsequent to that period, however, there has been a very considerable augmentation. The disposition and character of the inhabitants, collected as they were led by interest, necessity, or inclination, from different parts of the world, are very much diversified. They have been charged with indolence, which is attributed partly to the relaxing heat of the climate, and partly to the want of the necessary motives to the excitement of industry. They are more advantageously distinguished by their open and friendly hospitality, particularly towards strangers. Their diversions are dancing, gaming, horse-racing, cock-fighting, and chiefly hunting. To this latter amusement the nature of the country is sufficiently favourable, the woods abounding with deer, racoons, rabbits, wild turkies, and other game, at the same time that they are commonly so thin and free from obstruction, as to throw no impediment in the way of the chace.

Civil constitution.

The civil constitution of Georgia, which was adopted and ratified by a convention of delegates from the people on the 6th of May 1789, is formed upon a plan similar to the federal constitution of the United States. According to it, all legislative power is vested in two distinct bodies, both of which are chosen by the people at large, and which are styled the General Assembly. These are the senate and the house of representatives; of the former of which the members are chosen for the term of three years, those of the latter annually. The senate consists of one member from each county, and the house of representatives of 34 members. The executive power is vested in a governor, who holds his office for the space of two years. It is decreed, that freedom of the press, and trial by jury, shall remain inviolate in the state, and that the benefits of the writ of habeas corpus shall be open to every one who may choose, or may have occasion to avail himself of these. The free exercise of their religion is at the same time guaranteed to all persons without exception, none moreover being obliged to contribute to the support of any religious profession but his own. A superior court is twice in each year to be held in the several counties, where all causes are to be tried civil and criminal, other than such as may be subject to the federal court, or as may by law be referred to inferior jurisdictions. The judges of the supreme court, and the attorney general, hold their commissions for three years, and have their stated salaries, which are fixed and secured to them by law. For the more convenient administration of justice, the whole state is divided into two districts, which are called the upper and the lower circuits. The number of judges appointed to sit in the superior court are two only, to each of whom it belongs also to try causes in the several circuits. Besides the superior court, there is an inferior one, viz. a court of common pleas, establishsd in each county, that sits twice in a year, with five judges, who are appointed by the legislature. The county courts have a jurisdiction in criminal causes, which are finally determined in the superior court. There are moreover the sheriff's court, and courts which are held by the justices of the peace in every part of the state.

Religious sects.

The religious sects of Georgia, are Baptists, Methodists, Presbyterians, Episcopalians, Roman Catholics, Quakers, and Jews. The two first are the most numerous, and inhabit principally the upper part of the state. The Episcopalians and Presbyterians are nearly equal in number. The Catholics and Jews have each of them one church. There are likewise some German Lutherans, and a society of Congregationalists.

Literature.

The literature of this state may be considered to be still in its infancy, though the measures adopted for its improvement have been such as to afford the most flattering prospects of ultimate success. The charter, containing the system of education to be followed out in it, passed in the year 1785. A college, with ample and liberal endowments, has been instituted at Louis-

Georgia in America.

ville, a high and healthy part of the country near to the centre of the state, and provision made for the institution of an academy in every county, all which seminaries, in subordination to the principal, are to be supported from the same funds, and considered as the parts and members of one great establishment for the instruction of youth.

Diseases.

In the low country of Georgia, in the vicinity of the rice swamps, bilious complaints and fevers have been observed to be pretty general, especially during the months of July, August, and September, which for that reason are called the sickly months. Pleurisies, peripneumonies, and other inflammatory disorders, occasioned by sudden and violent colds, are prevalent, and not unfrequently fatal during the winter and spring. In the county of Wilkes, within a mile and a half of the town of Washington, there is a medicinal spring, which is said to be a sovereign remedy for the scurvy, scrofulous disorders, consumptions, gouts, and various other diseases. There is likewise at the distance from the sea of about 90 miles, on the way towards the mountains, a very remarkable bank of oyster shells. This runs in a direction nearly parallel with the seacoast, in three distinct ridges contiguous to each other, which together occupy a space of seven miles in breadth. These commence at the river Savannah, and have been traced to the northern branches of the Altamaha, furnishing, wherever they pass, an inexhaustible source of wealth and convenience to the neighbouring inhabitants, in the lime which they derive from them for building, for the making of indigo, or for other useful purposes.

Indian tribes.

The original population of the Georgian state consists chiefly of Muskogee or Creek Indians, Seminolas, Chactaws, Chicasaws, and Cherokees. The Muskogees have their residence principally in its middle parts, being the most numerous of the Indian tribes within the limits of the Indian states. Their numbers have been estimated to be little short of 20,000, of which a third is said to consist of fighting men. The country in which they are settled is hilly but not mountainous, the soil fruitful in a high degree, and well watered, their principal towns being situated in the Latitude of about 32°, and in from 86° to 87° W. Longitude. The Seminolas inhabit a level flat country on the Apalachicola and Flint rivers, possessed of similar advantages. The other tribes which have been mentioned, are found chiefly in the western parts of this state, much of which is still in their possession. Of these, the Chactaws, or flat heads, occupy a very fine and extensive tract of hilly country, with large and fertile plains, between the Alibama and Mississippi rivers. The Chicasaws are settled on the head branches of the Tombegbee and Yazoo rivers in the northwest corner of the state, where they have an extensive plain country, tolerably well watered from springs, and of a pretty good soil. The population of the former of these nations has been estimated at from 12,000 to 15,000 souls; and they have upwards of 40 towns and villages. The number of persons in the latter nation has been reckoned to be about 2000. They have seven towns, of which the central one is in Lat. 34° 23′, and in Long. about 90° 10′ W.

History.

It was in the year 1732, that the measure was meditated in England, of settling a colony between the rivers Savannah and Altamaha, with a view as well to the accommodation of poor people in Great Britain and Ireland, as for affording further security to Carolina It was proposed for this purpose to raise a fund, which should be expended in the conveyance of indigent emigrants to that part of America, free of expence. The plan was countenanced by humane and opulent men, through whose contributions and exertions it was quickly carried into effect. On application to his Majesty George II. letters patent were obtained June 9th, 1732. In November of the same year accordingly, 116 settlers were embarked for Georgia, under the conduct of General Oglethorpe, one of the trustees, and an active promoter of the measure; and soon after their arrival, in the beginning of the year 1733, the spot on which Savannah now stands was marked out as the most proper for the foundation of the settlement. Here, therefore, they proceeded to erect a small fort, with a number of huts for their accommodation and defence. A treaty of amity was concluded between them and their neighbours the Creek Indians, and various regulations were framed for their future government. In the formation of these, the general principle assumed was, that each inhabitant was to be considered as at once a planter and a soldier, who was of course to hold his portion of land as a military fief, and to appear in arms when the occasion required it for the public defence. That large tracts of ground might not accordingly, in the course of time, come to be occupied by the same person, nor the inconveniences be felt which in other colonies had been found to arise from great possessions, it was thought proper to limit the allowance of land for each family to 50 acres, which allotment, or any part of it, they were not to be permitted to mortgage nor to dispose of by will to their female issue. It was provided, that no man should depart from the province without a licence. Such parts of the lands granted by the trustees as should not be cleared, fenced round with a warm fence, or pales six feet high, within eighteen years from the date of the grant, were to revert to the trustees for the benefit of the colony. It was forbidden to use negroes, to import rum, or to trade with the Indians, unless in the case of a special licence being previously obtained for that purpose.

Georgia in America. History. A. D. 1732.

In consequence of the sentiments that came to be entertained at home, respecting the probable anticipated future importance of the settlement in Georgia, parliamentary aid had at different times been granted to promote the objects of the corporation. Additional settlers also were obtained, and these, for the most part, of a character and habits better adapted to the situation than those who had been at first introduced into it. The new comers were chiefly persons inured to labour and fatigue, from the Highlands of Scotland and from Germany, not like those who had preceded them, the idle and useless overflowings of cities and large towns. The accession of this valuable population was such, that within the space of three years, Georgia had received above 400 British subjects, and about 170 foreigners. Adventurers from Scotland, Germany, and Switzerland, still continued to follow their countrymen, contributing to sustain the hopes which the trustees had formed as to the permanence and prosperity of the colony. Several towns were built; and in 1739, more than 600 people were employed in trading with the Indians for furs and skins. It was eventually however found, that the system of government which had been formed for this colony, how pure soever might be the intentions of those by whom it was prepared, and how wise soever in their estimation, its provisions were in effect highly injudicious, and altogether incompatible with its prosperity. The alterations which it was judged necessary to introduce into it, though beneficial so far as they went, were not yet sufficient to render it even tolerably supportable; and the wars in which the province was involved with the Spaniards and Indians, and

A. D. 1739.

Georgia in America. the frequent insurrections among the people themselves, added still farther to the general confusion and wretchedness.

History. In 1741, it was notified to the English government,
A. D. 1741. that of the number of persons that had migrated to Georgia, scarcely a sixth part remained; and those who still continued, were so much discouraged, that they seemed to be desirous of fixing themselves in more favourable situations. The distressed and languishing state of the province was, by repeated complaints, represented to the trustees, who, weary of their irksome
A. D. 1752. and thankless charge, at length, in the year 1752, surrendered their charter to the king, and the province became a royal government. Notwithstanding the expence which had been incurred on account of it, the vestiges of cultivation were at this period scarcely perceptible in its forests; and the whole of the annual exports did not exceed £10,000 sterling. It still continued for several years more to struggle under many difficulties, arising from the want of credit with friends, and the frequent molestations of enemies. The benefits
A. D. 1763. of the peace of Paris, which took place in 1763, were, however, very sensibly felt here: the exports of that year
A. D. 1773. were but about £27,000; those of 1773 were little short of £122,000, while the population and agriculture of the state were proportionably increased. Georgia suffered a good deal during the war with Britain; and even after that was concluded, its progress in improvement yet lay under some checks and interruptions, from the disputes and hostilities in which it was involved with the Creek Indians; but a treaty of peace and friend-
A. D. 1790. ship having, in 1790, been entered into with that nation, it has since been rapidly advancing in all public prosperity. In consequence of an act of the legislature passed in 1795, twenty millions of acres of the Georgia western territory were sold to certain companies, and the purchase money, amounting to 500,000 dollars, was paid into the state treasury. This land was afterwards sold at an advanced price by the original purchasers, to various persons, principally of the middle and eastern states. This transaction produced a great degree of discontent: the ferment, however, afterwards subsided, without any thing having taken place which should shake the confidence of the purchasers as to their security, and the goodness of their title to the lands which they had thus acquired. See Morse's *American Geography.* (K)

GEORGIA, a country of Asia, situated between the Caspian and the Black Seas. Under this name were formerly comprehended also the states of Mingrelia and
Boundaries. Immertia; but it is now exclusively applied to the country made up of the four provinces of Cartuel, Kaket, Kisik, and the Georgian provinces of Armenia. Within these limits are contained the ancient Iberia, with a part of Armenia and Albania. On the north it is bounded by Mount Caucasus; on the north-west by a desert which separates it from Immertia; on the west and south by the Karagatich mountains and Mossian hills, which divide it from the Turkish and Persian provinces of Akiska and Erivan; and on the east by Daghestan and Shirvan. The face of the country is mountainous, diversified with extensive plains, and watered by innumerable rivers. The vallies are exceedingly fertile: cotton, and the finest European fruit-trees, grow here spontaneously; and rice, wheat, millet, hemp, and flax, are raised almost without culture. The hills are covered with forests of pine, oak, ash, beech, chesnuts, walnuts, and elms entwined with vines, which grow perfectly wild, and produce vast quantities of grapes. The rivers abound with the most delicious fish; poultry and game are frequent in the woods, and the pastures feed a great number of cattle. The air of this province is dry, very warm in summer, and very cold in winter. The fine weather commences in the month of May, and continues till November. Upon the whole, this may perhaps be truly characterised as one of the most beautiful and highly favoured regions in the world. Even the natives appear to approach nearer to perfection than those of other countries. The men are tall and elegantly formed, while the grace and beauty of the women are celebrated over all the east. — Georgia in Asia.

Of the four provinces which have been mentioned as constituting the state of Georgia, that of Cartuel, or, as it is sometimes called, Kartel, is on the east divided from Kaket by the Araqui; to the west it borders on Immertia; to the south on Akiska and Armenia; and northward it extends as far as the highest ridges of the Caucasus. It occupies both the banks of the Kur, and is known by the names of Semo or Higher Kartel, and Zemo or Lower Kartel. This is the province of the Georgian state which corresponds to the greater part of the ancient Iberia. The fine cities and handsome public buildings with which anciently that province was decorated, no longer remain. In consequence of the repeated revolutions to which it has been subjected since that period, and particularly through the destructive inroads of the Lesghaes, the face of the country has been completely changed, and its population almost exterminated. The few inhabitants who remain, are, as in ancient times, to be found in the southern and middle mountains of eastern Caucasus. They have their houses almost on the very tops of the hills, and live chiefly by agriculture. — Province of Cartuel.

The province of Kaket begins at the end of the plain 30 miles north-east of Teflis, near one of the front ranges of Mount Caucasus, and is bounded on the south by the adjoining province of Kisik. To the south of this latter province is the river Kur, and on the north and east it is encircled by the Alasan, which separates it from Shirvan and Daghestan. These provinces having formerly become subject to the King of Armenia, were given in fief to the noble Jewish tribe of Bargarut, from whom, it is said, are descended the Wallees of Georgia, Immertia, and the illustrious house of Bagration in Russia. Kaket was the only province which withstood the invasions of the Tartars and Lesghaes; hence it is covered with the ruins of villages, fortresses, and towns. The population, notwithstanding, is considerable. Together with the adjacent province of Kisik, it is stated to have contained, in the time of Reineggs, who visited and has given an account of these countries, to the amount of 18,000 families. The numbers have since, it is said, considerably increased, especially since the provinces fell under the dominion of Russia, the government of which has been at pains to repair the injuries sustained from the incursions of the neighbouring predatory tribes, and to collect the people from their scattered habitations. The province of Kaket is greatly in want of water, and the villages are often at such a distance from the springs, that the natives are under the necessity of alleviating their thirst by fruits or wine. This, however, does not affect the fertility of the country, as, unlike several of the other parts of this state, the gardens and fields here require no irrigation. — Of Kaket.

The Georgian province of Armenia has the hills of Karagatich to the west, the Mossian or Sissian hills to the south, and towards the north-east it is watered by — Of Armenia.

the river Kur. This is the best peopled and most flourishing of the provinces of this state, and it contains several towns. It has been long celebrated for its mines of gold, silver, lead, iron, and copper, as well as for its quarries of marble and jasper, the principal of which are those of Quoesch and Tamblutt.

The most noted of the Georgian rivers are the Kur, formerly known by the name of the Cyrus, which has its origin near Akiska. The Araqui, which rises near to the gates of Caucasus, flows to the south, and after dividing the southern range of Mount Caucasus into two equal parts, falls into the Kur at the town of Tagetta; the Kisia or Nachalir, which originates in the mountains of Karagatich; the river Alosan, the same which Strabo mentions under the name of Auxan; it traverses the province of Kaket, and forms part of the boundary between the states of Georgia and Shirvan.

The capital of Georgia is Teflis. This city lies in latitude 42° 45′ N. being at the distance from St Petersburgh of 2627 versts. It is situated on the N. W. side of the great plain at Karajoes, at the foot of a hill, and occupies both banks of the Kur, over which there is a bridge. It is called Thelestokar, (warm town,) from the warm baths in its neighbourhood, and was founded, according to an old inscription in the citadel, by a certain prince Surang in the year 1063. Before it was taken by Aga Mahomed Khan in 1797, it contained 4000 houses, and 22,000 inhabitants. The greater part of the houses are still standing, and are neatly built; but the population has suffered a reduction of not less than 7000 souls. While Georgia was an independent state, Teflis was for many years the residence of its prince Heraclius. It is at present that of the Russian governor and commander in chief, who has at all times a large force stationed in the city. These troops are quartered in the houses of the inhabitants, a circumstance which is far from being agreeable to them, and may lead to the most unpleasant consequences, as having the same ideas with regard to their women as are most generally prevalent among the eastern nations; they are naturally inimical, in an extreme degree, to any arrangement which may have the effect of exposing them to the view and to the familiarity of strangers. This is the only place in Georgia which is worthy of the name of city. There are, however, several other towns and villages, some of which, if of little importance in themselves, have acquired an interest as being the chief military positions occupied by the Russians in the course of their recent rapid encroachments towards the frontiers of Persia. In the province of Kaket, and about 16 miles to the N. E. of Teflis, is Mandropi, an opulent and well inhabited town. Kudala, Melani, and Magara, in the same province, though once flourishing cities, are now reduced to the state of wretched villages. Gori is a small town near the source of the Kur. Suram is situated on the western frontier of Kartel towards Kariska, and stands on the river Surmela, being defended by a strong hill fort. In a plain near the junction of the Kur and the Arakui are the remains of the city of Tsgetta, which has a most advantageous position on the frontiers of Armenia, Albania, and Iberia. It is supposed to have been founded by the Greeks or Romans, and to have been the place chosen by Pompey for keeping in check the restless spirit of the Albanians after that people had become subject to Rome. According to the Georgian histories and traditions, it was also the most ancient city in the kingdom at the time that it was converted to Christianity. Anamer, seated likewise on the banks of the Arakui, contains nothing remarkable but an old stone church, and a convent in ruins. Akdall stands on the river Tebete, a city once famed for its beautiful buildings, and where are still to be seen the splendid remains of the palace of Prince Allodius. Old and New Kremm are well situated towns, of which, however, the population is now greatly diminished. The fortress of Tellow is impregnable to an enemy unprovided with artillery. Bembeek is a small town, capital of a district of the same name, situated in the southern part of the state. About 70 miles farther to the westward is Gaucha. Both of these, from their contiguity to the Persian province of Erivan, are principal military stations of the Russians in Georgia.

The provinces into which the Georgian state is divided formerly constituted different principalities, which were governed by their own princes, in subordination to the Persian empire. Amidst the shocks that were afterwards sustained by that power, these took the opportunity of rendering themselves independent; and the authority which had been for a time lodged in separate hands, was ultimately engrossed by Prince Heraclius alone of the Kakhettian dynasty. This prince or czar, who is celebrated for his bravery and other great qualities, as well as for the important part which he acted during the disturbances that agitated Persia after the death of Tamas Kuli-Khan, submitted, in the year 1783, to the Russian empire, thus voluntarily sacrificing, for the sake of protection, that independence which his exploits seemed to have secured. Notwithstanding, however, his close alliance with this power, he was forced, in 1787, to renounce his connection with it, and to acknowledge himself tributary to the Porte. More recently the Russian interest has again prevailed, and the sons of Prince Heraclius, having been deprived of their inheritance, the whole of this delightful province became subject to the dominion of the Russian emperor. In February 1801 it was, by a public ukase, united to his dominions. On the accession of Alexander, the same year, the annexation was confirmed, and next year (1802) formally announced to the Georgians. The provinces of Kartel and Kaket have, since that period, been divided into five districts, viz. Ghori, Thelawi, Duschethi, Lori, and Ssignachi. The presidencies in the courts of judicature are intrusted to native Georgians, and civil causes decided according to the laws of the country. In 1803 Prince Zizianow took the command of the Russian forces in Georgia, and soon after reduced the Sesgians of Belucan and Dschari. It was in this year that the widow of King Georgi, the last of the Georgian sovereigns, stabbed the Russian major-general Lasarew, when imparting to her the emperor's command to repair to Russia. In 1804 Gandscha was taken by storm, and Solomon, King of Imerethi, placed himself and his dominions under the protection of Russia. About the same time, a small force was detached to occupy Mingrelia, which had submitted in 1803.

An expedition was undertaken against the Persian province of Armenia, and Prince Zizianow, after some important successes, formed the blockade of Erivan. The Persians, however, being suddenly and strongly reinforced, compelled him to abandon the enterprise, and to confine his future operations to the frontiers of Georgia. He chastised the Ossetes, and added Neichi and Schuschi to the imperial dominions.

The annual revenue of the province is 800,000 rubles, which is partly expended in the salaries of civil officers. The surplus has been hitherto generously con-

Georgia in Asia.

signed to the relief of the most necessitous of the inhabitants.

Inhabitants.

The Georgians, or, as they are sometimes called, the Grusinians, have avoided all commixture with the Tartars, and have ever distinguished themselves as the most numerous and powerful body of the mountaineers of Caucasus. Their manners and customs resemble in some degree those of their neighbours the Persians. They are brave but ignorant, and indolent in the extreme, scarcely earning themselves a subsistence, even in their very rich and productive country. They are chiefly in repute as soldiers, in which respect they are, perhaps, not surpassed by any other of the Asiatic nations. They excel particularly in the use of the bow. The only virtue of the men, however, is said to be courage, while the women, so much praised for their beauty, love to adorn themselves with paint, and are not in high estimation for their modesty. Both men and women are said to be addicted to intoxication, and to indulge freely in the use of strong liquors.

It is a principle established by the laws of war recognised in Turkey, that any revolted province should be given up to pillage, and the inhabitants reduced to a state of slavery. In consequence of this custom, which has been generally prevalent throughout Asia, the market of Constantinople has been supplied with slaves from Georgia and Circassia. Those supplies have likewise been, in great part, furnished through the Leaghai Tartars, who, situated between the Caspian and Black Seas, and in the vicinity of both those states, are continually at war with them. They carry over to the eastern coast of the Black Sea, the slaves whom they take in the course of their incursions, and sell them to the Turkish merchants, who come thither at stated times with a view to the traffic. The inhabitants of this same coast, likewise, seize on their countrymen in the neigbouring villages, and sell them. Children also have sometimes been sold by their parents, and wives by their husbands.

Trade.

Georgia has but little trade. A part of the wine which is made in the country is sold into Armenia and Persia, especially to Ispahan, for the king's table; and silk forms a considerable article of commerce with Erzeroom, though the inhabitants are unacquainted with the best method of winding it.

The nobility, which are here numerous, and possess an unlimited power of life and death over their vassals, treat them with the utmost harshness, levying a tax on the farmer to the amount of at least half the produce. This system, in addition to the sanguinary irruptions from the neighbouring states or tribes, has naturally had the effect of checking the prosperity of the country, and wasting its population. The number of its inhabitants is said not to amount to more now than about 320,000 souls.

Religion.

The religion of Georgia, when anciently it formed one distinct and independant kingdom, was Christianity: with this Mahometanism has, since the year 1639, been blended, the king of Persia having at that time conquered the country, and divided it into provinces, obliging the people to embrace the Mahometan faith. From the time that they have been under the protection of Russia, they have again, however, avowed themselves Christians, following in part the rites of the Armenian, but chiefly those of the Greek church. They are represented, indeed, as not being very tenacious as to those matters. The rest of the population consists of Jews, Tartars, and Russians, each tribe having its peculiar dialect. See Kinneir's *Geographical Memoir of the Persian Empire*; Klaproth's *Travels*; and Tooke's *View of the Russian Empire*, vol. I. (K)

Georgia Island.

GEORGIA, (New or South,) an island in the south Atlantic Ocean, discovered by La Roche in 1675; seen by Mr Guyot, in the ship Leon, in 1756; and explored with much attention, in 1775, by Captain Cook, who named it Georgia in honour of his majesty. This island is situated between 53° 57′ and 54° 57′ south latitude, and between 35° 34′ and 38° 13′ west longitude. It extends south-east by east, and north-west by west, being in that direction 31 leagues long, while its greatest breadth is about ten leagues. In the approach to this island by the last mentioned navigator, there was first discovered in south latitude 54°, and west longitude 38° 23′, a high rock of no great extent, to which was given the name of Willis's Isle. In the vicinity of this, there were some other rocky islets; and to the eastward about two miles, nearer to the main, was perceived a separate island, which, from the great numbers of birds that were seen upon it, received the name of Bird Isle. This, which was not so high, was of greater extent than Willis's Isle. The passage between these two islands having been cleared, and after a progress along the coast, first for about nine miles in the direction of east by north, and then for eleven miles more on an east and east-southerly direction, Cape Buller was gained, and at the distance of four or five miles from it, a bay to which was then given the name of Possession Bay, situated in 54° 5′ south latitude, and 37° 18′ west longitude. The land in which this bay lies was at first judged to be part of a great continent, but upon coasting round the whole country, it was found to be an island about 70 leagues in circumference. The first projecting point which had been fallen in with, in making this circuit, was one in the immediate vicinity of Bird Island, to which had been given the name of Cape North. Also between Cape Buller and Possession Bay there intervenes the Bay of Isles, so named from several small isles lying in and before it. To the projecting land, which next occurred after passing Possession Bay, and which lies from Cape Buller at the distance of 11 or 12 leagues, was given the name of Cape Saunders, beyond which is a pretty large bay which was called Cumberland Bay. In several parts in the bottom of this, as also in some other bays lying between Possession Bay and Cape Saunders, there were vast tracts of snow or of ice not yet broken loose. Further onwards a jutting point which terminated in a round hillock, was named Cape Charlotte, the bay to the westward of it Royal Bay, and its most westerly point Cape George. This last is also the east point of Cumberland Bay, lying from Cape Saunders in the direction of south-east by east, at the distance of seven leagues. Its distance from Cape Charlotte is six leagues. In the direction from Cape Charlotte of south by east, and eight leagues distant, is an island which received the appellation of Cooper's Isle. This is a rock of considerable height, and about five miles in circuit. The coast between this and the just named cape forms a large bay, which was denominated Sandwich Bay. At Cooper's Isle the main coast takes a south-west direction, for the space of four or five leagues, to a point which obtained the name of Cape Disappointment. Off this there are three small isles, the southernmost of which is green, low, and flat, and lies at the distance from the cape of one league. Still further onward in the same direction, and at a distance of about nine leagues, there occurs an island which was named Pickersgill Island, beyond which a little way a point came in sight that exactly united with the part of the coast that had been first seen, and from which the departure had been taken in the circumnavigation, by which the insular character of Georgia was now fully proved.

From what was observed of Georgia in the progress around it, it would appear to abound with bays and harbours, particularly on the north-east coast. These, however, from the great quantity of ice, either within themselves, or in the vicinity, must, for the greatest part of the year, be rendered inaccessible, or at least in respect of the occasional breaking up of the ice-cliffs, they can afford but a very insecure station for ships. The whole coast in general, particularly the south-western parts of it, were observed, notwithstanding that it was then the height of summer, to be in a manner wholly covered, even to the depth of many fathoms, with frozen snow. The sides even, and craggy summits of the lofty mountains, were cased with snow and ice, while the coast at the bottom of the bays was terminated by a wall of ice of considerable height, and the quantity of snow that lay in the vallies was quite incredible. There seemed reason to believe, that though a great deal of ice might be formed upon, or around the island during the winter, which in spring might be partly broken off and dispersed over the sea, yet so little of the quantity that was actually seen there could be so produced, that there must be somewhere, at no great distance, a much more extensive tract of land, though not then discovered, or otherwise the ice must be formed independently of any connection with land. The dangerous nature of the navigation in the circumstances alluded to may easily be conceived. Indeed it is mentioned that from the ice-cliffs, situated at the head, and on each side of one of the bays, pieces were continually breaking off, and floating out to sea, and that the noise from a great fall that took place while our navigators were there, was like that of discharged cannon.

It is stated as a remarkable circumstance in regard to this island, that upon the whole of its coast there was not observed any where a single river, or even so much as a stream of fresh water. The conclusion to which this appearance not unreasonably led, was, that there are in the country no perennial springs, while the interior parts, from their great elevation, never enjoy heat enough to admit of the snow being melted in such quantity as to produce a river or stream of water. Indeed, it is on the coast alone that there is, at any season, a sufficiency of warmth to melt the snow, and that too only on the north-east side; for in the other parts, not only are the sun's rays in a great measure excluded by reason of the uncommon height of the mountains, but even the cold south winds, to which they are so much exposed, might almost of themselves be sufficient to prevent this taking place.

So far as the interior parts of Georgia were observed, the appearance which they exhibited was found to be not less savage and horrible than that of its coast. The wild rocks raised their lofty summits till they were lost in the clouds, while the vallies lay covered with everlasting snow. Not the vestige of a tree, or even of the minutest shrub, was to be seen. The only vegetation that was discovered, was a coarse strong-bladed grass, growing in tufts, wild burnet, and a plant like moss, which sprung from the rocks.

Of animals, seals or sea bears were observed to be pretty numerous; the shores, indeed, even swarming with their cubs. There were also seen several flocks of penguins, of a very large size; some of them that were killed weighing not less than from 29 to 38 pounds. These were of the class of penguins which had previously been noticed at Falkland islands. The oceanic birds were albatrosses, common gulls, likewise that sort of them to which has been given the name of Port Egmont hens, terns, shags, divers, the new white bird, and a small bird like those of the Cape of Good Hope, called yellow birds, which were found to be most delicious food. The only land birds that were observed, were a few small larks. No quadrupeds were seen, nor any vestige met with of the existence in the island of any, except some dung, which it was judged might have proceeded from a fox or some such animal. Though the lands, or rather the rocks, bordering on the sea-coast, were not like the inland parts, entirely covered with snow, the only vegetation that could be seen on the clear places, was the grass already mentioned. These rocks seemed to contain iron. They are of blackish horizontal slate, probably approaching to hornblende. See Cook's *Second Voyage*, vol. ii. (K)

GEORGIUM SIDUS. See ASTRONOMY, page 649. The new discoveries relative to this planet will be found under URANUS, the name which is now universally adopted among astronomers to designate this celestial body.

GERA, is a town of Saxony, and capital of the estates of the count of Reuss. It is situated in a pleasant meadow on the right bank of the river Elster. The town, which is well built, was destroyed by a dreadful fire, but has been rapidly recovering its importance. The manufactures of this town are so numerous and flourishing, that it has received the name of *Little Leipsic*. They consist principally in woollen stuffs, and of stuffs made of wool and silk, which are well known by the name of stuffs of Gera. The musical instruments manufactured here by M. Frederici, have been greatly esteemed. The house and residence of the Count of Reuss is near the town. The baths of Rennebourg are about 1¼ leagues from Gera, and are situated in a charming country, in which both nature and art have combined their embellishments.

The meadow on which the town stands, is surrounded on the east and the west by fertile mountains, and profitable forests, which produce plenty of wood both for carpentry and fuel, as well as excellent building and paving stones, lime, gypsum, and other valuable minerals. Game and fish abound in the neighbourhood. Gera is a great thoroughfare, as the great roads of Leipsic pass through the town.

GERMAIN EN LAYE, ST. a town of France, in the department of the Seine and the Oise, situated on high ground on the western bank of the Seine. The chateau or palace, which was erected by Francis I. and enlarged by several succeeding kings, is an ugly building surrounded with a fosse, and built chiefly of brick. It has for some time been used as a military school; but in 1814, when visited by the writer of this article, this establishment was removed to some other place. On one side of the palace is the front of a superb church, which has never been completed. The view from the terrace is most extensive and magnificent, the ground before it up to Maisons sloping beautifully down to the river. The principal manufactures in this town are those of leather and skins, similar to those of Liege and Rheims. Population 9000.

GERMANY.

Germany.

GERMANY is divided among such a number of sovereigns native and foreign, and its natural boundaries are so obscurely marked, that it is difficult, and at first sight seems improper, to describe it as a single country. But when it is considered, that, in respect to name, language, and inhabitants, it possesses a unity of character, from which it derives a fair and solid claim to occupy a separate place among the divisions of Europe, and that although its extreme limits are not easily ascertained, the great mass of which it is composed is sufficiently identified, we trust we shall be justified in making it the subject of a separate though short article.

Division of the subject.

In order, however, that this article may not repeat or anticipate what the reader will naturally look for under the heads of AUSTRIA, BAVARIA, HANOVER, PRUSSIA, SAXONY, and the other states of Germany, we shall confine it to the three following points: I. A brief description of ancient Germany, and of the manners, &c. of its inhabitants; II. The principal revolutions and events of the Germanic empire, as separate and distinguished from the respective histories of Austria, Prussia, &c.; and lastly, an outline of the statistics of Germany.

Ancient Germany.

I. Ancient Germany was divided on the west by the Rhine, from the Gallic provinces of the Roman empire; and on the south by the Danube, from the Illyrian provinces of the same empire. It was divided and protected from Dacia or Hungary, by a ridge of hills called the Carpathian mountains, which rose from the Danube. The Hercynian Forest, at that time reckoned impenetrable, and a frozen ocean, described by the ancients as lying beyond the Baltic, if by it they did not mean the Baltic itself, were the limits of Germany on the north and north-west. On the east the boundary was still more faintly marked, or rather, it was frequently varying and confounded, by the mixture of the wavering and confederate tribes of the Germans and Sarmatians. From this description of the boundaries of ancient Germany, it will be seen, that, independently of the province westward of the Rhine, which appears to have been a colony of Germans settled within the limits of Gaul, it extended itself over a third part of Europe.

Tribes that inhabited it.

Our most accurate, full, and important information respecting ancient Germany, is derived from Tacitus. This author first mentions two colonies, the Helvetii and Boii, which had returned from Gaul into Germany. The Vangiones he describes as living on the west side of the Rhine; and the Batavi, in the isle formed by the outlets of that river. Beyond the people between the head of the Danube and the Rhine, he places the Catti; and further up on the Rhine, the Usipii, &c.; next the Bructeri; behind them the Dulgubini; and in front the Frisii. After this he mentions, that the coast of Germany turns to the north, which it does at Friezeland and Groningen. This circumstance sufficiently determines the positions of the tribes hitherto mentioned. Next he mentions the Chauci; then the Cherussi and Fosi; the remains of the Cimbri, so formidable and numerous before the time of Tacitus, but when he wrote *parva civitas*, seem to have inhabited the country near the mouth of the Elbe. The Suevi, divided into many tribes, occupied the greatest part of Germany, viz. all from the Danube to the ocean, south and north; and from the Elbe to the Vistula, west and east. The first tribe were the Semnones, who inhabited Brandenberg; then the Longobardi, in Lunenberg. Seven small tribes follow next, who seem to have occupied the peninsula of Jutland. Among these were the Angli. Having thus proceeded to the utmost north of the west parts of Germany, Tacitus proceeds to the description of the nations along the banks of the Danube: the principal of which were the Hermundurii; then the Narisci about Nuremberg; the Marcomanni, whose country anciently reached from the Rhine to the head of the Danube, and to the Necker, but who afterwards went and settled in Bohemia and Moravia, and some of them in Gaul, whence they forced the Boii to return into Germany. The Quadi were situated next to Bohemia, extending from the Danube to Moravia, and the northern part of Austria. After mentioning the remotest nations in this direction, Tacitus returns northward, informing us that a large chain of mountains divided Suevia, beyond which were the Lygii, consisting of many nations. They inhabited the present Silesia; above these were the Gotthones, at the mouth of the Vistula; next from thence on the ocean, were the Rugii, in Rugen; then the Lemovii, who appear to have dwelt to the west of the Rugii, and hence probably near Lubec. After this Tacitus proceeds to the Suiones, who, by most geographers, are considered as the Swedes, but, as Pinkerton contends, more probably the inhabitants of the Danish islands in the Baltic. After the Suiones, Tacitus passes to the Estii, whom he describes as situated on the right hand, as you sail up the *Suevicum Mare*, or probably in the peninsula beyond the present Dantzic. The Sitones seem to have been the present Swedes; and the Fenni, the inhabitants of Livonia. Such, according to Tacitus, were the principal tribes that inhabited ancient Germany in his time.

The ancient Germans were distinguished by their blue eyes, red hair, and large stature. Their children were always kept naked and dirty; every mother suckled her own infants, and did not commit them to the care of maid-servants or nurses. There was no distinction in the mode of rearing the master and slave. They lived among the same cattle, and lay on the same ground, till age caused them to be separated, and superior valour marked out the free born. They were not permitted to marry early in life: the more numerous a person's kinsmen and relations by marriage were, the more comfortable and respectable was his old age: it was no advantage, but rather considered a misfortune and disgrace, to be childless. The uncle, by the mother's side, regarded his nephews with the same affection as their father: every man's children were his heirs and successors, without any testament: if there were no issue, the brothers of the deceased inherited the property, and then his uncles, by his father's or mother's side. The ancient Germans were utterly ignorant of arts and agriculture. Tacitus expressly says, that in his time they had no cities; and though Ptolemy reckons up 90 places, which he calls cities, in all probability they were only rude fortifications, erected to secure the women, children, and cattle, while the men were engaged in warfare. They had not even regular and connected villages, but each individual fixed his dwelling where it suited his convenience, or pleased his fancy. Neither stones, nor bricks, nor tiles, were employed in erecting their habitations. They were equally rude and ill supplied with respect to their government. The clothing used by all the Germans was a loose mantle, fastened with a clasp, or, when that could not be procured, with a thorn. The rich, however, sometimes were clothed in a garment, girt close, and shewing the shape of every limb. The tribes who dwelt towards the north, clothed themselves in furs: the dress of the women was not different from that of the men, except that they sometimes wore linen robes of their own manufacture, and adorned them with purple. The principal employment of the men, in time of peace, consisted in hunting the various sorts of game, with which the forests of Germany were plentifully stocked: their herds of cattle formed the principal object and source of their wealth. The country, though considerably varied, was in general covered with woods, or deformed by marshes; and the indolence and ignorance of the inhabitants prevented them from rendering any large portion of it fit for the growth of corn. Gold, silver, and iron, were extremely scarce: the scarcity of iron appeared from their weapons, which, for the most part, were spears tipt with a short and narrow piece of iron. With this spear, and with a shield, their cavalry went to battle. The infantry had also missile weapons, which they threw to a great distance, with wonderful force and unerring aim. Their warriors were either naked, or dressed in a loose and light mantle. Their shields of wood, or osier, were distinguished and ornamented with a variety of colours; some of the chiefs wore cuirasses, and a few helmets. Their horses were slow, unmanageable, and not remarkable for their beauty. On their cavalry, therefore, they seldom placed much reliance in the hour of battle, their principal strength in general consisting in their infantry, which were drawn up either mixed with the cavalry, or in several deep columns by themselves. They fought by families and clans; and while they fought, they were encouraged by the presence of their wives and children. Their mothers and wives dressed their wounds; carried refreshments to them while fighting; and exhorted them to deeds of bravery. Their armies were totally devoid of discipline; they rushed to battle with dissonant shouts. Sometimes, by their native valour, they prevailed over the disciplined troops of the Romans; but they knew not how to rally or retire; a repulse was a sure defeat; and when they were defeated, the destruction of their army almost inevitably followed.

The ancient Germans in general enjoyed great freedom; there were, however, some exceptions. Tacitus informs us, that among the Suiones riches were held in honour; and that they were therefore subjects to an absolute monarch, who, instead of entrusting his people with the free use of arms as in the rest of Germany, committed them to the custody of slaves. The same historian mentions, that the Sitones were sunk even below servitude; they obeyed a woman! The rest of the German tribes either had no king, or chose their kings solely on account of their nobility and valour. The power of the former was restrained and defined by law or usage; and the latter commanded rather by example than authority. As soon as a youth, born of free parents, attained the age of manhood, he was admitted into the general council of his nation, invested with a spear and shield, and henceforth regarded as a member of the commonwealth. This general council met either at stated periods, or on sudden emergencies. To it was entrusted the trial of public offences, the election of magistrates, and the concerns of peace and war. Sometimes a select council prepared the business for the assembly; but the executive power was vested exclusively in the people. The applause of the assembly was generally signified by a loud clashing of shields and spears. The magistrates were chosen from a regard to birth and merit. To each was assigned a guard, and a council of one hundred persons. The disposal of the landed property within their district was absolutely vested in their hands, and they distributed it every year according to a new division; but they were not permitted to punish with death, to imprison, or even to strike a private citizen, except such magistrates as had the command in time of war. None but the priests were permitted to put to death, to bind or to scourge, in order that punishment might appear to proceed from the gods, and not from their fellow-citizens.

Their chiefs were desirous of being surrounded by youths of noble birth, and tried valour; and the youths of this description were no less anxious to be numbered among the faithful companions of some renowned chief. In the hour of danger, it was shameful for the chief to be surpassed in valour by his companions, and disgraceful to them not to emulate the behaviour of their chief. To outlive his fall in battle was infamy; while to protect his person was their pride and honour. In time of peace, the chiefs sent their companions into some distant country to acquire renown. The horse, or the lance, were the rewards of valour and enterprise, which the companions expected and received. At his board they were entertained; this was their only pay.

Religion.

The ancient Germans had no temples, but performed their religious rites in groves, or in woods, forests, and desert places. They adored the sun, the moon, the fire, and the earth. Jupiter was worshipped under the name of Thor, or Thoran, the Thunderer. Odin, or Wodin, appears to have been their Mars, or god of battle. The supreme deity was worshipped under the name of Esus, or Hesus, and under the emblem of an oak, which was consecrated to him. They had no druids, though their priests bore some resemblance to them in several points of their authority. The priests exerted the influence which they possessed over the fears and superstition of their countrymen, frequently to very useful purposes. They maintained silence and decency in the popular assemblies; and during a solemn procession of the goddess Ertha, the sound of war was hushed, quarrels were suspended, arms laid aside, and the blessings of peace and harmony were enjoyed. In war too, the influence of the priests was conspicuous. The consecrated standards, which during peace were kept concealed from the vulgar eye in the recesses of the sacred groves, were placed in the front of the battle; and the army of their enemies was devoted in the most solemn manner to the gods of war and of thunder. They were taught by their priests, that a brave man was the favourite of their gods; while the coward, who had lost his shield, was devoted equally to contempt and banishment in this world, and shut out from the enjoyments of a future state. A life spent in arms, and a glorious death in battle, they were taught assuredly led to a happy futurity, either in this or in another world. The Germans paid the greatest attention to omens, particularly to that species of divination that was performed by means of twigs, marked in a particular manner, and laid on a white cloth. One presage of futurity, Tacitus says, was peculiar to them, that derived from the neighing of horses; but this was also much

Germany.

regarded by the Persians; and perhaps may be regarded as an additional proof of the opinion, that the Goths, and consequently the Germans, originated in Persia. Another kind of divination, to which they had recourse in wars of doubtful issue, was to oblige a captive of the enemy to fight with one of their countrymen: the event of the war was supposed to be foretold by the issue of this single combat.

Marriages.

The ancient Germans in general did not practise polygamy; and even when their princes married more wives than one, it was done only for the sake of multiplying their alliances. There was no law prohibiting divorces, but the force of example and customs rendered them extremely rare. The adultress was whipped through the village; and neither wealth nor beauty could save her from this punishment, or procure her a second husband. The Germans treated their women very differently from other barbarous and ancient nations; regarding them with esteem and confidence; consulting them on every occasion of importance, and believing that they were inspired by the gods with a larger portion of sanctity and wisdom than had been bestowed upon the men. The funerals of the Germans were remarkable for their plainness, and freedom from pomp and show; only the bodies of illustrious men were burnt with certain kinds of wood. The funeral pile was not, as among the Romans, covered with garments and rich perfumes. The arms of the deceased, and sometimes his horse, were committed to the flames. A mound of earth was reared for his tomb: they then deposited the ashes in urns. The passion of the ancient Germans for play was extremely powerful. In their sober moments they applied to dice, as to a serious and important concern, and with such resolved and blind eagerness to gain or lose, that when every thing else was gone, they risked their liberty and persons on the last throw. The loser, though more powerful or more noble than the winner, submitted to voluntary slavery, and suffered himself to be bound and sold. Still, however, notwithstanding the strong and general prevalence of the spirit of gaming, some shame was attached to it, which induced the winner, as speedily as possible, to dispose of the slave he had acquired in this way, by commerce, in order to wipe off the scandal of the transaction. The slaves of the Germans were much better treated, and of a higher class than the slaves of the Romans; each had his own dwelling; he was indeed bound to give his master, from the fruits of his own labour, a certain portion of grain, and a certain number of cattle; but when he had given these, his labour was his own. As soon as the ancient Germans rose from sleep, which they seldom did till broad daylight, they first bathed, generally in warm water; they then sat down to their meal, each on a distinct seat, and at a separate table. Their drink was a liquor extracted with very little art, from wheat or barley, and fermented to a spirit. Those bordering on the Rhine, purchased wine: their food was simple, consisting of wild apples, venison, or coagulated milk. They were temperate in what they ate, but quite the reverse in what they drank.

Funerals.

Fondness for gaming.

Slaves, &c.

Such were the ancient Germans; and their manners are not only interesting, as exhibiting the state of a people before they emerged from barbarism; but the contemplation of them is instructive in more than one respect. In the first place, we may clearly trace among the Germans that respect for the female sex, which so decidedly and honourably distinguishes the modern nations of Europe, from the Greeks and Romans. In the second place, even amidst the forests of Germany, as has been frequently remarked, the germs of civil liberty—of that enlightened liberty which Britain enjoys—may be traced; and lastly, among the same people, evidently existed many institutions remarkably similar to the institutions of CHIVALRY, as has already been shewn under that article.

II. Before proceeding to a sketch of the principal revolutions of the Germanic empire, it may be proper to premise a very brief and rapid view of the more prominent and important points in the history of Germany before that empire was formed.

Historic sketch of them.

The invasion of Italy by the Cimbri and Teutones; their defeat by Marius, A. M. 3909; the invasion of Gaul by the borderers of the Rhine, under Arioristus, and their defeat by Julius Cæsar, A. M. 3950, are almost the only events of consequence in the history of Germany, before the Christian era, of which we have any certain account. When Cæsar had completed the conquest of Gaul, he divided it into the Celtic, the Aquitanic, and the Belgic provinces; in the last, all the German provinces on the left side of the Rhine were comprised. In the reign of Augustus, a further division took place, and the country lying between the Meuse, the Scheldt, and the Rhine, was separated from Belgic Gaul, and formed into a province, called Germania cis-Rhonanas. In A. M. 3995, the famous Arminius, at the head of the Cherusci, massacred three Roman legions under Varus, between the Lippe and the Ems. In the third century of the Christian æra, the German tribes formed different associations for their common defence against the Romans. Of these the most remarkable were the Saxons, comprising those who dwelt on each side of the Elbe; the Alemanni, formed by the nations between the Rhine, the Mayne, and the Lech; the Francici, by the nations between the Rhine, the Mayne, and the Weser, and the Thuringians, by the nations between the Mayne, the Danube, and the Hartz. Charlemagne was the first who united Germany under one sceptre. The name of Oriental France, may be traced in Franconia; the people of Hesse and Thuringia were incorporated by a similarity of religion and government. The Alemanni still continued the faithful confederates of the Francs. The hereditary dukes of Bavaria, having repeatedly revolted against the emperor, their power was shared among the counts of the empire. The north of Germany from the Rhine, and beyond the Elbe, was still hostile and pagan; but after a war of thirty-three years, the Saxons were subdued and converted. Beyond the Elbe, the Slavi occupied modern Prussia, Poland, and Bohemia; the first union of the last of these countries with the Germanic body, took place under Charlemagne. Soon after the reign of this monarch, his empire was divided; and one of his grandsons, Lewis the German, obtained for his share all Germany from the Rhine to the Oder, and the three cantons of Mentz, Spire, and Worms. These were called Francia Orientalis, and afterwards the kingdom of Germany. Till the reign of Charles the Bald, the Teutonic or German was the language of the court. In his time, the Romanic, afterwards called the French language, came into use. The three kingdoms were reunited in Charles the Fat; but when he was deposed by his subjects, they were again separated. From the confines of the kingdoms of France and Germany, two new kingdoms arose; viz. Lorraine and Burgundy; the former comprehended part of Ger-

Their associations.

Charlemagne.

Division of his kingdom.

many, viz. Alsace, the Palatinate, Treves, Cologne, Juliers, and Liege. Soon after the division of the empire of Charlemagne, the feudal system gained a consistency and firm footing, so that by degrees it overpowered the influence and authority of his descendants. In consequence of the weakness of the Carlovingian princes, the dukes and counts converted their hereditary possessions, which they parcelled out among their barons, and those among their vassals. The principal of these in Germany were the Dukes of Franconia, Saxony, Bavaria, Suabia, and Lorraine. These usurpations, joined to the incapacity of the Carlovingian princes, caused the house of Charlemagne to decline rapidly. In Germany, on the abdication of Charles the Fat, the people, from respect to the memory of Charlemagne, placed the crown on the head of Arnold, a natural son of Carloman, and after the decease of Arnold, on Louis, his son. On the death of Louis, they elected a duke of Franconia for their king, and then a Saxon line of princes.

...erors of ...ouse of ...ny, ...911— ...1024.

The Emperors of the house of Saxony reigned from A. D. 911, to A. D. 1024. They were Henry I. surnamed the Fowler; Otho I. surnamed the Great; Otho II. Otho III. and Henry II. During the period that the throne was filled by the Saxon Emperors, the limits of the empire were extended, chiefly by Otho the Great. A portion of Gaul, to the west of the Rhine, along the banks of the Meuse and the Moselle, was assigned to the Germans. Between the Rhine, the Rhone, and the Alps, the successors of Otho acquired a vain and doubtful supremacy over the kingdoms of Burgundy and Arles. In the north, the Slavonic nations of the Elbe and Oder were subdued. The marches of Brandenburg and Sleswic were colonized by Germans; and the King of Denmark, and the Dukes of Poland and Bohemia, became the tributary vassals of Otho the Great. The same monarch subdued the kingdom of Italy, delivered the pope, and fixed the imperial crown in the name and nation of Germany. From that era, A. D. 962, two maxims of public jurisprudence were introduced: 1. That the prince, who was elected in the German diet, acquired from that instant the kingdoms of Italy and Rome; and, 2d, That he could not legally assume the titles of Emperor and Augustus, till he had received the crown from the hands of the Pope.

...ripal ...at in ...many at ...eriod.

With respect to the principal states which composed Germany during the reign of the Saxon Emperors, a considerable portion of that part of Germany which lies on each side of the Mayne, was known by the various appellations of Nova Francia, Francia Orientalis, Francia Teutonica, Ostrofrancia, Austrasia, and Franconia. The space between this part of Germany and the Upper Elbe, called Saxonia, and Alemannia, was occupied by the Thuringians. At this period, the Saxons had left the Oder, and were spread from the Elbe to the Ems, reaching Francia and Thuringia on the south. The country between the Weser and the Meuse was called Frisia; that between the Rhine and the Meuse, Austrasia; the tract lying between the Rhine, the Necker, and the Lech, was divided between the Suevi and the Alemanni; and the country between the Lech, the Alps, and the Anisa, was called Boisaria, the modern Bavaria. On the east of this was Austria. Moravia was called Austria Maharensis; modern Bohemia was called Boheim.

Cities.

It has already been mentioned, that in the time of Tacitus, the Germans did not live even in villages; as, however, they spread themselves over the country on the west of the Rhine, they began to inhabit villages, and even to construct towns; so that at an early period, after the Triboci, Nemetes, and Vangiones, settled in the country between the Rhine and the Vosges, the cities of Strasburgh, Spire, Mentz, and Worms, are mentioned. Under the Francic sovereigns, cities were multiplied; and by Henry the Fowler, they were particularly encouraged by a singular institution. From the troops stationed in Germany, he chose every ninth soldier; the remaining eight were to sow and till the land, and to carry the produce to the ninth, whose business it was to build habitations for himself and his companions. By degrees, the lower order of the people united themselves to these soldiers; and the Emperor ordered the courts of justice, fairs, tournaments, &c. to be held in the cities they constructed. His example was followed in the other parts of Germany, so that in a short time it scarcely contained a district of any extent, which had not its city. To each of them exclusive privileges were granted; the most important of which were the *jus stapulæ* and the *jus geranii*; by the former, all commodities brought into them were exposed to public sale; by the latter, all commodities imported or exported, were to be weighed or measured by the public weights or measures of the city, for which it was entitled to a duty. At first, the chief magistrates were of noble birth; but by degrees, the chief offices were opened to the people at large. Thus, soon after the era of the Saxon Emperors, there were in almost every town three different classes,—nobles, citizens, and slaves; but, about the beginning of the 12th century, Henry V. enfranchised all slaves in cities who were artizans.

Emperors of the house of Franconia. A. D. 1027—A. D. 1137.

The emperors of the house of Franconia were called to the throne, after the Saxon emperors; they reigned from 1027 to 1137. They consisted of Conrad II. who conquered the kingdom of Burgundy; Henry III. who conquered the country between the Inn and the Lech, now called Lower Austria; Henry IV. and Henry V.; on the death of the last, Lothaire the Saxon was elected King of Germany. Under Henry III. the empire of Germany had its greatest extent. It comprehended Germany, Italy, Burgundy, and Lorraine. Poland, and other Slavonian districts, were tributary to it; and Denmark and Hungary acknowledged themselves its vassals. The Emperors of Germany at this period affected to consider all Christendom as forming a royal republic, of which the Emperor was chief. In consequence of this assumed supremacy, they claimed the exclusive right of creating kings; and the states of the empire proclaimed war against the Duke of Poland for having taken to himself the title of king, in 1077.

Decline of the empire.

Soon after reaching this point of power and grandeur, the empire began to decline, principally owing to the rapid extension of the feudal system. In every province, the subjects of the law were the vassals of a private chief; and the standard which he received from his sovereign, was often raised against him. The power of the Emperors was also curtailed by the increasing influence and possessions of the clergy; and the bishoprics in Germany became equal in extent and privileges, and superior in wealth and population, to most of the secular states. The emperors were gradually deprived of the privilege of filling up the ecclesiastical and secular benefices; and at length each sovereign was reduced to a recommendation, once in his reign, to a single prebend in each church. The secular governors could be degraded only by the sentence of their peers; the appointment of the son to the

Germany.

duchy or county of his father, which in the first age of the monarchy was solicited as a favour, was at length extorted as a right; and this right was claimed even by collateral or female branches.

Emperors of the house of Suabia, A. D. 1138 —A D. 1224.

The emperors of the house of Suabia succeeded to those of the house of Franconia, and held the empire from A. D. 1138, to A. D. 1254. They were Conrad III.; Frederic I. surnamed Barbarossa; Henry VI.; Philip; Otho IV.; Frederic II.; and Conrad IV. The principal events in the history of the latter princes of the Franconian line, and of all the princes of the Suabian line, were produced or influenced by the contests between the popes and the emperors; and the principal ground of these contests was the claim of the popes to the supreme dominion of every part of the Christian world, both in temporal and spiritual concerns.

Guelphs and Ghibelines.

This claim gave rise to the factions of the Guelphs and the Ghibelines; of which the former were attached to the popes, and the latter to the emperors. These two factions kept Germany and Italy in perpetual agitation during three centuries; and during this period, the imperial authority continued to decline.

Great interregnum, A. D. 1254 —A. D. 1272.

The next period, between 1254 and 1272, is generally called by the German writers, the Great Interregnum. During it, six princes claimed to be emperors. The interregnum was determined by the election of Rodolph, Count of Hapsburgh. From him till the ultimate accession of the house of Austria, the empire of Germany was held by the following emperors. Rodolph Count of Hapsburg, elected A. D. 1273. Adolph, Count of Nassau, elected A. D. 1292. Albert I. Archduke of Austria, elected A. D. 1298. Henry, Count of Luxemburg, elected A. D. 1308. Louis V. Duke of Bavaria, elected A. D. 1314. Charles, King of Bohemia, A. D. 1347. Winceslaus, King of Bohemia, A. D. 1378. Robert, Elector Palatine, A. D. 1400. Sigismond, King of Hungary, A. D. 1410. And Albert II. Duke of Austria, A. D. 1438. During the period between the last accession of the house of Hapsburg and the election of Charles V. the empire was possessed by the following emperors. Frederic III. elected A. D. 1440; Maximilian I. elected 1493; and Charles V. elected A. D. 1519.

Emperors between 1273 and A. D. 1519.

Boundaries at this period.

During this period, the boundaries of the Germanic empire, the form of its government, and the rise of its towns, particularly those which composed the Hanseatic league, are the chief subjects of consideration. Its boundaries were the Eyder and the sea on the north; the Scheldt, Meuse, the Saone, and the Rhone, on the west; the Alps and the Rhine on the south; and the Lech and Vistula on the east. In this great extent of country, the principal provinces were the duchy of Burgundy, comprising Savoy, the Lesser Burgundy, Provence, Dauphiny, and Switzerland: the duchy of Lorraine, which, besides Lorraine, contained Holland, Zealand, Brabant, Limburgh, Hainault, Flanders, Gueldres, and Luxemburgh. Friesland was attached to Lorraine, but was not governed either by a duke or a count. When the line of Suabian princes ceased, the ancient Alemannia and Franconia, in which their possessions chiefly lay, was divided into various principalities. At this period, Saxony was divided by the Weser into Eastern and Western. The former was sometimes called Saxony on the Elbe; the latter Saxony on the Weser. Misnia, Thuringia, and Hessia were usually comprised under Saxony. The Slavic territory, between the Oder and the Vistula, was occupied by the Margraves of Brandenburg, and the Dukes of Poland and Bohemia. To the last, Moravia, Silesia, and Lusatia were subject. Pomerania and Prussia were at this period in a very unsettled state. Bavaria still retained the name of Boisaria. To the east of it, a considerable tract was called *Marchia Orientalis*, or Oostrich; afterwards Austria.

Principal states.

Constitution.

The empire was always elective; but great alterations took place in the mode of election. In early periods, the emperor was chosen by the people at large: afterwards the nobility and principal officers of state possessed the privilege exclusively; by degrees, it was engrossed by the five great officers, the chancellor, the great marshal, the great chamberlain, the great butler, and the great master. At first they contented themselves with proposing a candidate to the general body of electors. Afterwards they confined the whole right of election to themselves. This mode was finally settled in the reign of Charles IV. by the celebrated constitution called the Golden Bull, which fixed the right of election in four spiritual and three temporal electors. These were, the King of Bohemia, the Duke of Saxony, the Margrave of Brandenburgh, the Count Palatine of the Rhine, and the three archbishops of Mentz, Treves, and Cologne. Subsequently, the Duke of Bavaria and the Duke of Brunswick Lunenburgh were added.

Electors.

States.

The multitude of princes, bishops, abbots, and male and female nobles, who, under various names, possessed sovereign rights, though all recognised the emperor as their feudal lord, were divided into the primitive states, or those which had always been held of the emperor, as the duchies of Saxony and Bavaria, the Palatinate, and several bishoprics; those which arose on the ruin of the Guelphic family, in consequence of the confiscation of the possessions of Henry the Lion; those which arose from the ruins of the Suabian family; and those which arose principally during the interregnum.

Diet.

But though the exclusive privilege of chusing the emperor was confined to the electors, they formed only one branch of the diet. The other two branches consisted of the princes, and of the free and imperial cities of Germany. In process of time, the college of princes and prelates purged themselves of a promiscuous multitude. They reduced to four representative votes the long series of independent counts, and totally excluded the nobles, 60,000 of whom had often appeared in the field of election.

Cities.

The cities of Germany, the origin and first state of which has been already noticed, insensibly became divided into the free cities, or those which held immediately of the emperor, and had a voice at the diet; the mixed cities, or those under the protection of some prince, which had no voice; and the municipal cities, entirely subject to the states.

Hanse towns.

The Hanse towns also arose during the same period. They were originally united for the support and encouragement of their commerce. Bremen and several sea-ports in Livonia first established the confederacy. At one time 80 towns were included in it. They were divided into four classes: the Vandallic, or the cities on the Baltic, between Hamburgh and Pomerania; over these Lubeck presided: the Rhinarian, or cities on the Rhine, at the head of which was Cologne: the Saxon, the cities in Saxony and Westphalia, over which Brunswick presided: and the Prussian, the cities in Prussia and Livonia, at the head of which was Dantzic. From the beginning of the 15th century, Lubec was regarded as the head of the whole confederacy. In the following century it declined; in the middle of the 17th, it was almost wholly confined to Hamburgh, Lubeck, and Bremen. Their political existence terminated in 1806.

Inst. of ele-

Another important event in this period of the history of Germany, is the division of the territories of the em-

Germany.

pire into circles. The first division of Germany was into the Upper and Lower, or southern and northern states. The line dividing them was supposed to be drawn easterly from the mouth of the Mayne. It was afterwards geographically divided into the states lying on the principal rivers, as the Danube, Rhine, &c. Maximilian the First divided it into ten circles, viz. Bavaria, Franconia, Suabia, Lower and Upper Saxony, Lower and Upper Rhine, Westphalia, Austria, and Burgundy; but the last, comprising High Burgundy or Franche Compté, and the 17 provinces of the Netherlands, was soon afterwards separated from the empire.

Complete establishment of the constitution, A. D. 1580.

During the same period, the diets which had been frequently held, were regularly and solemnly established, consisting, as has been already noticed, of three classes: the college of electors, of ecclesiastical and secular princes, and of imperial towns. This division was finally established at Frankfort in 1580. The three colleges deliberated separately. The agreement of them all, as well as the consent of the emperor, was necessary to form a resolution or law of the empire.

Imperial chamber and Aulic council.

Maximilian I. also established the imperial chamber and the Aulic council. The president of the former was appointed by the emperor; the assessors by the states. The Court Palatine, or Aulic Council, was established as a check on the imperial chamber. During the vacancy of the throne, its powers were suspended; but the imperial council acted under the vicars of the empire. There was no appeal from one to the other; the dernier resort was the diet. From the accession of the house of Austria to the imperial throne, the history of Germany may properly be sought for under the article Austria. It will be necessary here, however, to notice the leading events; *first*, from the division of the house of Hapsburg into its Spanish and German lines, till the final extinction of the latter in the house of Lorraine, or the period between 1558 and 1745; and, secondly, from the marriage of Maria Theresa, till the abdication by the emperor of Germany of the imperial government of the empire, and the formation of the confederation of the Rhine, or the period between 1745 and 1806.

War of thirty years, A. D. 1618—A. D. 1648.

The principal events in Germany during the first period, were the war of thirty years, which began in 1618 and ended in 1648; the war for the succession of Spain, which began in 1700 and ended in 1713; the war for the succession of Poland, which began 1733 and ended 1735; and the war for the succession of Austria, which began 1740 and ended 1748. The war of thirty years was principally owing to the religious disputes of the 16th century. At the diet of Augsburg, 1530, the Protestant princes of Germany delivered in their confession of faith, and afterwards formed the league of Smalkald against the Emperor. At the peace of Passau, the free exercise of the Lutheran religion was permitted. In consequence of the disputes regarding the succession to the duchies of Cleves and Juliers, the Protestant princes formed a confederacy, called the Evangelical Union, at the head of which was the Elector Palatine. To this the Catholics opposed the confederacy called the Catholic League, and placed at its head the Duke of Bavaria. From 1618, when open war began, till the peace of Westphalia in 1648, Germany was a scene of devastation. By this peace, the empire underwent considerable changes: the Swedes obtained Pomerania; the house of Brandenburg obtained Magdeburg, Minden, &c.; Alsace was conquered by France; and Lusatia ceded to Saxony. The war for the succession of Spain not producing any changes in the Germanic empire, need not be particularly noticed: the same remark applies to the war for the succession of Poland.

War on the decease of Charles VI. and seven years war, A. D. 1757—A. D. 1763.

In Charles VI. the male stock of the house of Hapsburg expired: in his grandson Joseph, the two lines of this family, after a separation of 1100 years, were reunited. On the decease of Charles VI. Maria Theresa, his only daughter, succeeded him. The first event of importance, after her accession, was the war of seven years. In consequence of the King of Prussia invading Saxony and Bohemia, the Aulic Council voted his conduct a breach of the public peace; and the Diet of the empire passed a decree to the same effect. This made it a war of that kind, which the publicists of Germany call a war of execution of the empire. The event of the war was, that a mutual oblivion and restitution took place. The next war was occasioned by the extinction of the house of Bavaria: it ended in the peace of Saxe-Teschen, by which the right of the Elector Palatine to the succession was allowed, with the exception of some districts of land between the Danube, the Inn, and the Salze, which were ceded to Austria.

Extinction of the house of Bavaria.

Consequences of the French revolution on the Germanic empire.

No event affecting the Germanic empire took place after this till the French revolution. By it the German states on the left of the Rhine were first overwhelmed: afterwards the power of Austria was reduced; Bavaria, Wurtemberg, and Saxony, raised to the rank of kingdoms, and their territories considerably increased, principally by the annexation of the smaller states. Shortly after the treaty of Presburg, most of the princes in the western and southern divisions of Germany separated themselves from the Germanic body, and formed themselves into a league under the protection of the Emperor of the French, under the title of the Confederated States of the Rhine. The contracting parties to this confederation were, the Emperor of the French on the one part, and, on the other, the Kings of Bavaria and Wurtemberg; the Elector Arch-Chancellor, and the Elector of Baden; the Duke of Berg, the Landgrave of Hesse Darmstadt, the Princes of Nassau, Weilbourg, Usingen, Hohenzollern Hechingen, Siegmaringen, Salm Salm, Salm Harberg, Isersbourg Bristein, Lichtenstein, the Duke of Aremberg, and the Count of Leyen. By the act of the confederation, all the laws of the empire were abrogated with respect to these states: their common interests were to be discussed in an assembly of the league at Frankfort, divided into two colleges of kings and princes: the members of the confederation to be independent of foreign powers, and not to enter into any kind of service except among themselves; the Emperor Napoleon to be protector of the alliance; all the princes, counts, &c. within the circle of the allied territory to be subject to the confederation; every continental war in which the Emperor of the French or the confederated states might be engaged, to be common to both; the contingents to be as follows: France 200,000 men; Bavaria 30,000; Wurtemberg 12,000; Baden 8000; Berg 5000; Darmstadt 4000; Nassau, Hohenzollern, and the others, 4000: other German princes were to be admitted into the alliance, when conducive to the common interest. See Confederation *of the Rhine*, vol. viii. p. 115, 116.

Confederation of the Rhine. 1806.

The emperor of Germany abdicates that title.

By a solemn act, dated at Vienna on the 6th of August 1806, the Emperor of Germany, after adverting to the consequences of the treaty of Presburg, and to the formation of the confederation of the states of the Rhine, absolved all his German provinces and states of the empire from their reciprocal duties towards the Germanic empire; and the electors, princes, and states, and all that belonged to the empire, from the duties

Germany.

by which they were united to him as their legal chief; at the same time abdicating the imperial government of the Germanic empire, renouncing the title of Emperor of Germany, and assuming that of Emperor of Austria.

Dissolution of the Confederation of the Rhine, A. D. 1814

The confederation of the Rhine was dissolved by the overthrow of Bonaparte, when the Emperor of Austria was solicited again to take the title, and exercise the privileges of Emperor of Germany: this, however, he declined. The internal regulation of the Germanic empire, and consequently every thing that relates to the constitution of the smaller states, and their mutual relation to one another, and to the more powerful princes, it is understood, has been left, by the Congress of Vienna, to a congress of German powers alone, to be assembled for that express purpose.

Statistics.

III. As the most important branches of the statistics of Germany naturally belong to the principal kingdoms which it contains, reference must be had to those kingdoms, under the articles AUSTRIA, BAVARIA, HANOVER, PRUSSIA, &c. for more full information on this point: here we must confine ourselves to an outline.

Boundaries of modern Germany.

We have already seen, that, in ancient times, the Rhine was reckoned the boundary between Germany and Gaul. During the usurpations of revolutionary France, that limit was renewed; but, on the restoration of the Bourbons, the boundaries of Germany, with very little exception or difference, were fixed as they had existed previously to the Revolution. The exception principally related to that corner of Germany in the vicinity of Liege, which was annexed to the new kingdom of the Netherlands. Germany may therefore still be considered as bounded on the west by France and the Netherlands. After the Rhine has reached the border of the Dutch provinces, an indistinct line between them and Germany runs northward to the mouth of the Ems; from which point the ocean takes up the northern boundary, only interrupted by the Danish peninsula, which commences beyond the duchy of Holstein. The German coast of the Baltic then succeeds, terminating with the extreme point of Pomerania. The eastern boundary is very indistinct, in consequence of the mixture of the Slavonian with the German tongue and manners, and the annexation of part of Poland to Prussia and Austria. Brandenburg, Silesia, Moravia, the Austrias, and Carniola, down to the Gulf of Venice, lie on the eastern boundary. The southern or Italian boundary, as far as the country of the Grisons, is formed by the Venetian states. The northern limit of Switzerland is the southern limit of Germany to the borders of France. It lies chiefly between the 46th and 54th degrees of north latitude; its greatest length is about 600 miles; its breadth rather more than 500. Its extent is variously reckoned, from 11,124 German square miles, (15 to a degree,) to 12,796; but, in the latter measurement, Silesia is included.

Climate and face of the country.

The climate is in general temperate, though the winter in the north is sometimes very long and severe. The air is everywhere salubrious, except in a few marshy places towards the North Sea. The northern part is mostly low: the first mountains that occur, on proceeding southwards, are the Hartz in Hanover; to the south-east of these are the Hesse mountains; towards the Rhine and Mayne there are other scattered ridges. That corner which lies between the upper part of the Rhine and Switzerland, comprising the Black Forest, is throughout a mountainous tract. On the east, the whole of Bohemia is surrounded with mountains, which branch on the east to Moravia, and communicate with the Carpathian mountains. To the south of the Danube are the mountains of Carinthia; and to the west of these the Tyrolese Alps.

Mountains and forests.

As might be expected from its extent, there is great variety of soil in Germany. The north-east is covered with sandy plains and heaths; in the north-west are swamps and marshes. Some of the interior and south-western districts possess a very fertile soil. In ancient times, Germany was covered with forests, of which there are only now detached remains; the most extensive is the Black Forest. Thuringia and the Hartz mountains abound in timber; and the passion for the chase has preserved or created many extensive woods in the middle and south.

Rivers.

Five hundred and twenty rivers are reckoned in Germany, sixty of which are navigable to a great length, and six, viz. the Danube, the Rhine, the Mayne, the Weser, the Elbe, and the Oder, rank amongst the noblest and largest in Europe. The Danube rises in the Black Forest; and receiving continual accessions on both banks, soon becomes a copious and navigable stream; it passes Vienna, and a short distance from that city becomes a Hungarian river: it terminates in the Black Sea. The Rhine has neither its source nor exit in Germany. It rises in Switzerland, and after passing Basle, flows for a considerable space, the boundary between Germany and France. From the western side of the former it receives numerous rivers, of which the Mayne and the Necker are the principal; it enters the sea below Rotterdam, affording a noble and highly useful inland navigation from Holland, quite to the borders of Switzerland. Of the rivers that enter the German ocean, the first on the west side is the Ems; next succeeds the Weser, which unites several streams of the north-west, and joins the sea below Bremen. The Elbe, rising on the confines of Bohemia and Silesia, augmented by many rivers from the centre of Germany, flows by Hamburg, and thence in a broad channel enters the sea on the west side of Holstein. The Oder, which derives it source from the foot of the Carpathian mountains, is the principal river that falls into the Baltic. In the duchy of Mecklenburg, there are several lakes. There are also some small lakes in Bavaria, Austria, Pomerania, and Brandenburg. The Boden sea, or lake of Constance, belongs partly to Germany and partly to Switzerland. There are upwards of 1000 mineral springs and baths, of which the most famous are Carlsbad in Bohemia; Toplitz in Austria; Seltzer in the upper Rhine; and Pyrmont in Westphalia. See the articles DANUBE and ELBE.

Vegetable productions.

There is a considerable variety in the vegetable productions of Germany; in general they are those of the northern and middle temperate regions. Besides corn of all kinds, flax of excellent quality, hemp, hops, tobaccco, madder, saffron, rape seed, rhubarb, &c. are grown; rice is cultivated in Moravia. The wine country begins about the junction of the Necker with the Rhine, and accompanies those rivers towards their rise.

Wines.

The most celebrated wines of Germany are those of the Rhine, especially about Manheim and Heidelberg, and in the district called the Rheinzan; here the lofty and romantic banks of the river are clothed with vineyards. The wine of Moselle ranks next; and after it a red wine called Pleiker, which is made near Mentz. Austria also affords wine, some of which is of excellent quality. Franconia, and particularly Bamberg, furnishes a great deal of liquorice; and the lower palatinate contains immense numbers of chesnut trees, and particularly fine walnut trees.

Horses.

The breed of horses, except in Mecklenburg, East Friesland, Oldenburg, Holstein, and some parts of Hanover and Wurtemberg, is very indifferent. The best breeds of oxen are in East Friesland, Oldenburg, and Holstein; but both they and the sheep are by no means sufficiently numerous; of the latter, the number is reckoned not to exceed 13 or 14 millions. The Merino breed has been introduced into Saxony upwards of a century, and now produces wool equal in quality to the finest Spanish; this breed is also naturalized in Prussia, but in general the sheep and wool of Germany are indifferent. The breed of hogs is much neglected; that of goats is encouraged in the mountainous districts. The forests are plentifully supplied with wild boars, which are reared to a large size. Westphalia is particularly noted for this species of game. Poultry is abundant. Some parts of Germany are remarkable for fine larks and thrushes of a delicious flavour. Others abound in singing birds, particularly Canary birds and goldfinches. Silk worms are reared in some of the southern districts. On the whole, agriculture is not in a very advanced state, except in Saxony, which, in every respect, is one of the finest parts of Germany. In the more mountainous parts, the lynx is still found; and in the Tyrolese Alps wolves are by no means uncommon. The only fisheries of Germany, with the exception of those carried on by the small towns on the Baltic and German Ocean, are those of the rivers, in some of which, besides the more common fish, the sturgeon is found.

Small particles of gold are found in the Rhine, the Danube, the Elbe, &c.; in most other mineral productions this country is very rich. The chain of hills between Saxony and Bohemia yields silver, copper, tin, lead, iron, cobalt, bismuth, &c.; most of these metals are also found in the Hartz mountains. Bavaria has mines of silver, copper, and lead, and is noted for its salt springs. There are also extensive salt works near Halle; and salt mines near Saltzburg. The iron of Carinthia and Stiria is particularly famous, as convertable to the finest steel. The quicksilver mines of Idria are also very productive, and of great fame. Besides the rarer and more valuable stones, Germany possesses large quarries of curious marble, and excellent mill and burr stones. In Misnia are found various sorts of fine earth, such as tripoli and porcelain earth, fullers' earth, &c. There are some coal mines, particularly in Westphalia, and abundance of peat mosses.

The manufactures are very various: pearl ashes and pitch are made in various parts. Linens are made in almost every part; but principally in Austria, Saxony, Lusatia, and Silesia; the cotton manufacture is establishing itself in Austria, Prussia, and Saxony. Woollen manufactures are spread throughout the empire, but with the exception of the cloths of Silesia, chiefly of the coarser kind. The silk manufacture was established in Brandenburg, by the refugees driven from France, at the time of the revocation of the edict of Nantz; silk is also manufactured in Austria and Saxony. There are many iron works at Nuremberg, and in Silesia, Saxony, and Holstein; here also are copper works. The porcelain of Saxony is still good, though not so famed as formerly.

The principal sea ports of Germany are Hamburg, Kiel, Lubeck, Wismar, Rostock, Stralsund, Stettin, Embden, and Bremen; its inland towns of great trade are Magdeburg, Leipsic, Naumburg, Francfort on the Mayne, Francfort on the Oder, Vienna, Augsburg, Nuremberg, Breslaw, and Ulm. The principal articles of exportation are timber, corn, fruit, wine, tobacco, madder, cobalt, smalts, potash, horses, oxen, salt and smoked meat, butter, cheese, wax, leather, wool, linen cloth to a very large amount, linen yarn, lace, lead, copper, brass, quicksilver, mirrors, glass, wooden toys, and trinkets. It imports corn, oxen, and horses, chiefly from Hungary, Poland, and Denmark; hogs from Hungary; butter from Ireland and Holland; all sorts of colonial produce, cotton stuffs, hardware, &c. It carries on a lucrative trade by means of the Danube, with European Turkey, whence it imports an immense quantity of raw cotton.

The Roman Catholic, Lutheran, and reformed religions, are established in Germany; but all other sects are tolerated. The German language is derived from the Gothic: it is strong, copious, abounding in compound words, but rough in the sound, and involved in the syntax: the purest dialect is that of Saxony; the least pure is spoken in the southern provinces. It has been much studied of late years, in the others parts of Europe. The literature of Germany, till lately, was more distinguished by erudition than by taste or genius; and even yet, the history of literature and statistics are more cultivated in Germany than elsewhere. There are upwards of 30 universities, some of which are of great repute; particularly those of Jena, Leipsic, Gottingen, &c. The most distinguished of its learned societies are at Vienna, Berlin, Gottingen, Manheim, &c.

Before the peace of Luneville in 1801, the population of Germany was rated at 27 millions; by the cession of the country situated on the left shore of the Rhine, it lost 3,700,000 inhabitants; but as most of that territory is restored, its present population may be reckoned at nearly 27 millions.

"The German people, from the earliest times, have borne a high character for bravery, and the masculine qualities of the mind They are in general frank and open, but inclined to be boastful and boisterous. They are indefatigable in their pursuits, and engage in them with a seriousness and sense of importance, which not unfrequently lead them to laborious trifling."

GERMINATION. See Botany.

GERONA, the *Gerunda* of the ancients, is a town of Spain, in the province of Catalonia, situated on both sides of the Ter, on the side and at the base of a steep mountain. It is encircled with good walls, flanked with fortifications, and is defended by two forts erected upon the mountain. Gerona is nearly of a triangular shape, and the houses are well built, though the streets are crowded and narrow. The principal public buildings are the cathedral and collegiate churches. The cathedral stands on the ridge of the mountain. It exhibits a magnificent front at the top of three grand terraces, adorned with granite ballustrades, and the ascent is by a flight of 86 steps, as broad as the whole extent of the church. The front, which is flanked with three hexagon towers, is ornamented with the Doric, Corinthian, and Composite orders. The interior is large and handsome, but the nave only is Gothic. The treasury of the cathedral was very rich before the revolution. The collegiate church of St Felix, formerly St Mary's, is built in the Gothic style, and has a body and two aisles, divided by pillars, with a large and fine casement in the middle. In front of the façade is an old and lofty tower.

In the Capuchin convent, there is a curious Arabian bath constructed in the most elegant style. It consists of columns standing on an octagonal stylobate, or low base, which surrounds a reservoir for water. The Benedictine nunnery of St Daniel is about a mile from Gerona. It is one of the principal nunneries in Catalonia of the order of St Benet, and those ladies only are admitted who can bring proofs of nobility.

The university of Gerona, founded in 1521 by Philip II. was abolished in 1715 by Philip V. After the suppression of the order of Jesuits, the means of public instruction were concentrated in one college, where there are 900 students, who are instructed in Latin grammar, rhetoric, philosophy, and theology. The library of the Jesuits, which is now open to the public, is extensive and well selected. Other three professors chairs are supported at the expence of the town. Schools for the gratuitous instruction of poor girls, and a boarding-school for young ladies, are kept by the community of Beguine nuns. This institution is owing to the generosity of the bishop Don Thomas de Lorenzana, who encouraged in his diocese, agriculture, manufactures, and all the useful arts. The civil and military administration of the town resides in a governor, a king's lieutenant, a mayor, a governor of the little castle of Mountjouy, an alcade major for the administration of justice, and a municipal body of twelve regidors, and a small garrison.

Very little trade is carried on in this town. It possesses a few looms for stockings, coarse cloths, and woollen and cotton stuffs, which have been established within the last thirty years.

Gerona is the see of a bishop suffragan of Tarragona. The diocese consists of 4 arch-deaconries, 470 parishes, 2 collegiate chapters, and 8 abbeys or priories. In the town there are five parishes, 9 convents for men and 3 for women, a nunnery of Beguines, a college, seminary, general hospital, and charitable asylums. Population about 14,000, a fourth of whom consisted before the revolution of priests, monks, nuns, scholars, and students. See Laborde's *View of Spain*, vol. i. p. 13, &c.

GERS, the name of one of the departments of France, is so called from the river of the same name by which it is traversed from north to south. It is bounded on the north by the departments of the Lot and Garonne, on the west by that of the Landes, on the south by those of the Higher and Lower Pyrenees, and on the east by that of the High Garonne. The soil of this department is far from being fertile. The western part of it is the best, and produces some wheat, and a considerable quantity of wines, some of which are esteemed. It has almost no manufactures, and its principal trade is in brandy. The forests occupy from 12,000 to 13,000 hectares, or about 25,000 acres, of which one half belongs to individuals, and the rest to the nation and the communes. The Adour also waters the department. The following are the principal towns:

	Inhabitants.
Auch	7696
Condom	6917
Lectoure	5453
Mirande	1558
Lombez	1443

The population of the department is 291,845; and its contributions in 1803, 2,660,310 francs.

GERSAU, or GHERSAU, is a village of Switzerland, situated on the lake of Waldstettes, at the foot of Righi, in an angle between the mountain of Gersau and the Rothe-Schouth. Its territory is only about one league broad and two leagues long, and it constitutes the smallest republic in the world. There is not a single horse in the republic; and, excepting a narrow path down the side of the steep mountain, the only way of arriving at the town is by water. Gersau forms part of the canton of Schweitz. It contains 1500 inhabitants, who are employed principally in spinning silk for the manufacturers at Basle.

GERTRUYDENBERG, is a fortified town of Holland, situated on the river Merwe, which forms a good harbour, and expands into a considerable lake, called Bies Bosch, across which there is a two hours passage to Dort. The town is remarkable, principally for the abundance of salmon, sturgeons, and shad, which are caught in the neighbourhood. It has sometimes happened, that 18,000 shads have been taken in one day. The town enjoys the staple right for this species of fish, and therefore its principal trade consists in salting and smoking them, and in sending them to the neighbouring towns. Distance from Dort ten miles south-east, from Breda seven north-east.

GESNER, or GESSNER, CONRAD, a learned Swiss, was born at Zurich in the year 1516. He received the rudiments of his education in his native city, and discovered an early genius for literature and science; but he experienced many serious difficulties and discouragements in the course of his zealous pursuit of knowledge. His father's circumstances were insufficient for his maintenance as a scholar; and he was in consequence about to discontinue his studies, when Ammien, professor of Latin and eloquence at Zurich, generously took young Gesner into his own house, and charged himself with the care of his education. The death of his father, however, again reduced him to great extremities; and his misfortunes were increased by his falling into a dropsical complaint. Having in some measure recovered his health, he determined to travel and seek his fortune; and after the termination of the troubles in Switzerland, the Academy of Zurich allowed him a pension, in order to enable him to make the tour of France. On his return, he accepted an invitation from the university of Zurich to take charge of a school; but having married, and finding his appointment inadequate to the support of a family, he resolved to study physic, and accordingly devoted all the time he could spare from the duties of his school to books of medicine. Being at length disgusted with his situation at Zurich, he removed to Basle, and employed himself in reading the works of the Greek physicians, until he was appointed Greek professor at Lausanne. Having now acquired the means of attending to his favourite pursuits, he was enabled to repair to Montpelier, where he studied anatomy and botany for some time, and then returned to Zurich to prosecute his profession as a physician. He was admitted to the degree of Doctor, and was soon afterwards appointed professor of philosophy; a situation which he held during the remaining twenty-four years of his life. In the year 1565, he was carried off by the plague.

Boerhaave emphatically styles Conrad Gesner *monstrum eruditionis*, "a prodigy of learning." Mr Coxe, in his Letters on Switzerland, justly observes, that "those who are conversant with the works of this great scholar and naturalist, cannot repress their wonder and admiration at the amplitude of his knowledge in every species of erudition, and the variety of his discoveries in natural history. Their wonder and admiration," says he, "are still farther augmented, when they consider the gross ignorance of the age which he helped to enlighten, and the scanty succours he possessed, to aid him in thus extending the bounds of knowledge; that he composed his works, and made those discoveries, which would have done honour to the most enlightened period, under the complicated evils of poverty, sickness, and domestic uneasiness." On account of the variety of his attainments, and the extent of his learning, he was distinguished by the name of the German Pliny.

His works are numerous; of these the principal are, 1. *An Universal Dictionary*, published at Zurich in 1545. 2. *A History of Animals*, in four volumes folio, Zurich, 1551. 3. *A Greek and Latin Lexicon*. 4. *Opera Botanica*, Nuremberg, folio. (z)

GESNER, or GESSNER, JOHN MATTHEW, an eminent German philologer, was born at Roth, a village in the territory of Anspach, on the 9th of April 1691. He was reduced to great poverty by the death of his father, at a very early age; but by the kindness of a relation, he was enabled to acquire the elements of learning at the public school of Anspach. In 1710, he repaired to the university of Jena, where he studied theology, and supported himself partly by occasional poems, until he obtained the patronage of Buddeus, by whose recommendation he was appointed, in 1715, to superintend the public school at Weimar; from whence he was removed to a similar situation at Anspach in 1728, and in 1730 to Leipsic. Having greatly distinguished himself as a profound philologer, he repaired to Gottingen, where, in 1734, he was appointed professor of humanity in the newly erected university, to which were added the offices of public librarian, and inspector of schools throughout the electorate of Hanover. In the year 1751, he was made director of the Royal Academy of Sciences at Gottingen; and in 1756, he received the honorary title of Aulic Counsellor. In every situation, he exhibited proofs of uncommon industry and erudition; he was zealous in promoting the interests and prosperity of the university, to which he was so great an ornament; and endeavoured to discharge his duties as a public teacher in a manner at once agreeable and useful. He died at Gottingen in the year 1761.

To this eminent scholar, we are indebted for some excellent editions of the classics, particularly Quintilian, Pliny, Claudian, and the poems of Orpheus, which last were published, after his death, by Hamberger. Besides these, his principal work is the *Thesaurus Latinæ Linguæ et eruditionis Romanæ*, Leipsic, 1747, 1748, in four volumes folio. The great value of this work is well known to every scholar. Gesner also published several learned memoirs in the Transactions of the Gottingen Academy of Sciences. (z)

GESNER, or GESSNER, SOLOMON, a celebrated German poet and landscape painter, was born at Zurich on the first of April 1730. In the early period of his youth he made very slow progress in his education, and was considered by his teachers as a pupil of very mean capacity. But this backwardness must be ascribed to the perverse method of instruction at that time in use, and not to any deficiency of intellect on the part of the pupil. During his school hours, instead of devoting his attention to the study of grammatical rules, he often employed himself in modelling figures of various kinds, groups of men and animals in wax, and thus discovered an early genius for the imitative arts. By some accident, a copy of Robinson Crusoe fell into his hands, and awakened a poetic fancy, which his preceptors endeavoured to stifle by every means in their power.

His parents, however, perceiving the education of their son advance so slowly, resolved to try a different method, and accordingly sent him to the country, to the Rev. Mr Vögeli, a gentleman who had acquired great reputation as a teacher. Here, under a milder system of discipline, Gesner made sufficient progress to enable him to read the Roman poets in the original, and the Greek writers in the Latin version. His intercourse with the son of his instructor, a passionate admirer of ancient literature, and a lover of the *belles lettres* in general, was likewise of great advantage to him. Through him he became acquainted with the works of the German poet Brockes, which he perused with avidity, and to which he was indebted for the developement of his poetical talents.

After a residence of about two years at Berg, he returned to his family, and resolved to follow his father's profession of a printer and bookseller. At Zurich he had an opportunity of increasing his knowledge and improving his genius, by cultivating the society of men distinguished for their talents and learning. In the year 1749, he was sent to an eminent bookseller at Berlin, in order to learn his business. But the mechanical occupations in which he was employed by his master were by no means suited to the taste of Gesner, who already began to feel the consciousness of his own abilities. He therefore quitted his employer, hired an apartment for himself, and resolved to devote himself to the study of landscape painting, which had long been his favourite pursuit. This hasty step excited the displeasure of his parents, who determined to make him feel his dependence, by withdrawing from him their support. A reconciliation, however, soon took place; and Gesner obtained their permission to remain at Berlin, with the liberty of following his own inclinations. Here he formed an acquaintance with several eminent literary characters, and was particularly intimate with Ramler, by whose advice he was induced to resolve his poetical compositions into harmonious prose, instead of verse, which presented many serious difficulties to an author who was not conversant with the more improved dialect of the German language.

After paying a visit to Hamburgh, Gesner returned to Zurich, and published, in succession, those pieces which have procured for him an extensive and well-merited reputation. In 1751, his *Song of a Swiss to his Mistress on her appearing in Armour*, was inserted in a periodical publication. His next essay was the piece entitled *Night*. In 1754, he published a larger poem, entitled *Daphnis*, which was suggested to him by Amiot's translation of Longus. These were followed by a volume of *Idyls*, in 1756; *the Death of Abel*, 1758; a collection of his poems, in four volumes, 1762, including *The First Navigator*, which was always a favourite production with the author, and the two dramatic pieces, *Evander* and *Erastus*. In 1772, he published a second volume of *Idyls*, with a letter on landscape painting, addressed to M. Füssli.

When about thirty years of age, Gesner married Mademoiselle Heidegger, a young lady endowed with rare accomplishments of mind and person. Finding, however, that the resources of his pen were inadequate to the support of a family, he resolved to apply more seriously than ever to his favourite art of landscape painting, in which he ultimately attained a very high degree of excellence. Indeed, his pictures have been by some esteemed superior to his poems. He died on the 11th of March, 1787, at his country seat in the forest of Sihl. A monument, on which Nature and Poetry are represented weeping over his urn, was erected to his memory by some of his fellow-citizens, on a charming spot in his favourite walk, near the confluence of the Sihl and the Limmat.

The works of Solomon Gesner are too well known to require any particular notice. His poetry is all of the sentimental kind; and he excels especially in the description of natural scenery. He is undoubtedly the first writer of pastorals in modern times; and it is not the least of his merits, that his productions uniformly breathe a spirit of purity highly favourable to innocence and virtue. In private life, he was modest, ingenuous, and amiable; and the cheerfulness and natural gaiety of his temper, combined with great goodness of heart, endeared him to a numerous circle of friends. (*z*)

GHAUTS is a name which properly signifies a pass through a range of lofty hills, but it has been extended to designate the mountainous chains which support the centrical table land in the south of India.

The *Eastern Ghauts* commence in N. Lat. 11° 20′ to the north of Caverey, and stretch nearly and almost uninterruptedly in a straight line to the banks of the Khrisna, in N. Lat. 16°, separating the two Carnatics, which are named the Carnatic Balaghaut, or above the Ghauts, and the Carnatic Payeenghaut, or below the Ghauts. The greatest height of this ridge, which is about the latitude of Madras, is nearly 3000 feet.

The *Western Ghauts*, or *Hills of Sukkien*, extend from Cape Comorin to the Tuptee, or Surat River, where they leave their southerly elevation, and bend eastward in a waving line parallel to the river, till they are lost among the hills near the river Boorhanpoor. With the exception of a single opening, 16 miles wide, which admits the Paniany, the Western Ghauts include 13 degrees of latitude. Their distance from the coast is commonly 40 miles, and seldom more than 70.

GHEE is the name of a kind of clarified butter, made from the milk of buffaloes. It may be preserved sweet for a considerable time, and forms a great article of commerce in various parts of India. It is generally put up in duppers or bottles made of hides, each containing from 10 to 40 gallons. In some parts of Bengal the price varies from 6 to 8 seers for a rupee.

GHENT, or *Gand* in French, *Gandavum* in Latin, is a town in the Netherlands, and formerly capital of Austrian Flanders. It is advantageously situated at the conflux of the rivers Scheldt, Lis, Moere, and Lieve, which intersect it in various directions, and divide the town into 26 small islands. The town is encircled with walls about 15 miles in circumference, comprehending numerous corn fields and gardens. Many of the houses are excellently built; some of the streets are broad and well paved, and the market places are spacious. In one of these is a statue erected to the Emperor Charles V. who was born in this city. The cathedral church is the principal edifice in Ghent. The pulpit, which was made by the celebrated Delvaux of Nivelles, has been particularly admired. The musical bells of the cathedral have been much noticed by strangers. The principal altars, the magnificent tombs of the bishops, and the subterraneous church, are well deserving of examination. Besides the cathedral, there are six churches and a collegiate church. The church of St Michael is admired on account of the boldness of the nave. There is a beautiful promenade along the canal, which is called *De la Coupure;* one of the sides is for foot passengers, and the other for carriages. The other public establishments are the library, the academy of painting, and the botanic garden, which is reckoned extremely beautiful.

Ghent communicates with Bruges, and afterwards with Ostend, by means of the canal which was begun in 1613, and with the western Scheldt by the Saas-de-Gand, by means of another canal. The principal articles of commerce in Ghent are French wines, grain, flax, hemp, and colza for the manufacture of oil. The manufacture of linen cloths is carried on to a great extent in this town and its neighbourhood. Twilts for beds, table linen, and lace, are also made here to a great extent. There are likewise manufactures of glue, woollen stuffs, cottons, soap, paper, vinegar, tobacco, hats, and stockings, besides refineries of sugar and salt. Population 58,000.

GHERIAH, or Corepatam, is a sea-port of Hindostan, in the county of Concan. The fort stands on a rocky promontory, about one mile long, and a quarter of a mile broad. This promontory is joined to the continent by a narrow neck of land, beyond which, where the ground expands, is a large open town. On the neck of land are docks where grabs are built and repaired. The river runs in a south-westerly direction, and washes the north side of the town, the neck of land, and the promontory. The point, which bounds the entrance on the south side, is high and broad, and is situated in 73° 25′ East Long. The fort consists of a double wall, with round towers; the inner wall being several feet higher than the outer one. The harbour is very good, without any bar, and has at its entrance a depth of from five to seven fathoms, and from three to four fathoms at low water. Vessels are here completely sheltered from every wind.

This town was formerly the capital of Angria the Pirate. In 1756 it was taken by the British fleet under Admiral Watson, who found in it 200 pieces of cannon, six brass mortars, great quantities of military and naval stores, and money and effects to the amount of £125,000. Angria's fleet was also destroyed, and the town was given up to the Mahrattas, in whose possession it has since continued. Latitude of Gheriah point 16° 31′ N. See Milburn's *Oriental Commerce*, vol. i.

GHILAN, or Kilan, the *Gela* of the ancients, is a province of Persia, which stretches along the south-west shore of the Caspian Sea, from Kizilagatch to beyond Rudizar. On the south and south-east it is bounded by Irak and Mazanderaun, on the north by Shirvan, and on the west by Azerbijan. It extends about 200 miles from north to south, and 150 from west to east. This province, which is one of the most beautiful and picturesque in Persia, is encircled with lofty and almost inaccessible mountains, and like Mazanderaun is intersected with forests and morasses. There are whole forests of oak, boxwood, mulberry, and walnut trees; and honey-suckles, flowers, sweet-briars, and roses, cover the vallies. The soil, which is excellent, affords hemp, hops, olives, rice, wheat, tobacco, and various kinds of fruit, such as lemons, oranges, peaches, and pomegranates. Grapes, though not of a good quality, are very plentiful; and, as in Georgia, the vines which grow wild on the mountains support themselves on the trunks and branches of trees.

The manufactures and silk of Ghilan have been reckoned the best in Persia. The cultivation of silk is the principal employment of the inhabitants, and constitutes the chief trade of the province. It is annually exported in great quantities to Astracan from Resht and Lankeroon. The finest kind is usually white, and is either sold to the Turks, or sent into the interior of Persia. The inferior kind, which is yellow, is exported to Russia.

The principal river in Ghilan is the Kizilozien, or Golden Stream. It is the Gozan of Scripture, and rises eight or nine miles to the north-west of Sennah in Kurdistan. After running along the north-west frontier of Irak, and passing under the Kufulan Koh, or Mountain of Tigers, it is joined a little to the east of Meanna, by the Karanku, which has its origin in the mountains of Sahund to the west of Meanna. Their united streams force a passage through the great range of Caucasan, and receives in their course the Shahrood. These collected currents traverse the province of Ghilan, under the name of the Sifud Rood, or white river, and throw themselves into the Caspian. The road from Hamadan to Resht is upon the edge of the deep chasm through which the river flows, and is described by Captain Sutherland as one of the grandest and most terrific scenes.

The principal town of Ghilan is Resht, on the Caspian. In rough weather, its harbour is less safe than that of Lankeroon in the district of Talish.

The inhabitants of Ghilan are said to have a language of their own, different from the Persian and Turkish. Ghilan was ceded by Persia to Russia in 1724, taken by Catherine in 1780, and restored to Persia in 1797. The nett revenue of the province is 149,490 tomarins, and 9058 dinars. See Kinneir's *Geographical Memoir*, p. 159, 160; and Morier's *Travels in Persia*, p. 288.

GHILJIE Country, is the name of a district of Afganistan, inhabited by the Ghiljie tribes. It forms a parallelogram about 180 miles long, and 85 broad. The climate is in general severer than that of England, and the summer not much hotter. The Ghiljies were formerly the most celebrated of the Afghans. About the commencement of the last century, they conquered all Persia, and defeated the Ottoman armies. A full account of these wars, and of the tribe itself, will be found in Hanway's *Travels*; Jones's *Histoire de Nadir Chah*; and Elphinstone's *Account of Cabul*, p. 433, &c.

GHIZNEE, Ghizne, or Ghizni, was formerly the capital of an extensive empire, extending from the Tigris to the Ganges, and from the Taxartes to the Persian Gulf. It is situated on a height, washed by a pretty large stream, and is encircled with stone walls. Beside several dark and narrow streets, the town contains three bazars, with high houses on each side, and a covered chaursoo. Among the few remains of the ancient grandeur of this city, are two lofty minarets, at some distance from each other, the least of which is above 100 feet high. "The tomb of the great Sultan Mahmood," says Mr Elphinstone, whose excellent account of Cabul contains all the information we have on this subject, "is also standing about three miles from the city. It is a spacious but not a magnificent building, covered with a cupola. The doors, which are very large, are of sandal wood, and are said to have been brought by the Sultan as a trophy from the famous temple of Somnaut in Guzerat, which he sacked in his last expedition to India. The tombstone is of white marble, on which are sculptured Arabic verses from the Koran, and at its head lies the plain but weighty mace, which is said to have been wielded by the monarch himself. It is of wood, with a head of metal so heavy that few men can use it. There are also some thrones or chairs, inlaid with mother-of-pearl, in the tomb, which are said to have belonged to Mahmood. The tombstone is under a canopy, and some Moollahs are still maintained, who incessantly read the Koran aloud over the grave. There are some other ruins of less note, among which are the tombs of Behlole Dauna, or Behlole the Wise, and that of Hukeem Saunauee, a poet still greatly esteemed in Persia; but nothing remains to shew the magnificence of the palaces of the Gaznavide kings, or of the mosques, baths, and caravanseras, which once adorned the capital of the East. Of all the antiquities of Ghiznee, the most useful is an embankment across a stream, which was built by Mahmood, and which, though damaged by the fury of the Ghoreé kings at the capture of Ghiznee, still supplies water to the fields and gardens round the town. The immediate environs of the city are inhabited by Taujiks and Hazaurehs." Ghiznee contains only about 1500 houses, besides the suburbs without the walls. East Long. 68° 58′, and North Lat. 33° 10′. See Elphinstone's *Account of Cabul*, p. 432. Lond. 1815.

GIANTS, is the name given to men whose stature greatly exceeds the ordinary size of the human race.

On surveying the field of nature, we sometimes discover aberrations from her usual course. Animals are seen of dimensions infinitely surpassing those which commonly belong to their kind; and vegetables of a bulk so remarkable, as to excite astonishment in the beholder. We are thence led to enquire, What secret principle is it that limits the expansion of animal and vegetable matter? How is it confined within definite boundaries, those which at once mark the identity of species by the most prominent analogies? We should find it difficult to solve these questions, and perhaps our knowledge of the vital and material economy of the two great kingdoms now alluded to, is still too imperfect for us to hazard conjectural explanations.

In most of the ancient histories of the world, we read of giants. They also find a place in many of those of modern date; and the name is so universally employed by poets and romancers, that nothing can be more familiar to our ears. Not only are individual giants repeatedly referred to, but the existence of whole nations of those who have viewed their fellow-men as a pigmy race, has been admitted as a fact not to be called into dispute. During a retrospect of many centuries, likewise, successive degradation in the stature and strength of mankind is maintained to have taken place, which, were it true, would scarcely allow our contemporaries to reach the knees of their ancestors, and bestow no more power upon them, than the others possessed in their fingers. Those, however, who are accustomed to reason from facts, who disregard conjecture, and are enabled to separate truth from fiction, feel inclined to question whether there ever was a race of giants, as generally understood by that name; and whether the race of mankind

Giants.

under the same latitude, has decreased in any respect since the days of our original parents.

Perhaps the discordant opinions on this subject are not so irreconcileable as at first sight may appear; and by carefully analysing all that has been recorded in history, we shall find that individuals of gigantic stature have existed at different æras; and that at the present day, there are one or two tribes of South Americans, whose size considerably surpasses the dimensions commonly allotted to mankind. But it is essential to beware of the exaggerations to which men have ever been prone; and not to allow our credulity to be imposed upon by what is utterly beyond belief, from whatever source the narrative shall be received.

Giants described in sacred writ.

In scripture it is related, at a period apparently contemporary with Noah, or immediately antecedent to the flood, "that the sons of God saw the daughters of men, that they were fair, and they took them wives of all which they chose." Further, "there were giants in the earth in those days, and also after that, when the sons of God came in unto the daughters of men: and they bare children to them, the same became mighty men which were of old, and men of renown." These passages, it is true, contain some obscurities; but we do not conceive that they warrant the conclusion which certain critics have deduced, of this gigantic race being the offspring of divinities and human females. At Hebron, in Judea, there was a celebrated tribe of giants, the sons of Anak; and the spies sent out by Moses to reconnoitre the country, seem to have made their report in these words: "And there we saw the giants, the sons of Anak, which come of the giants; and we were in our own sight as grashoppers, and so we were in their sight." Although only three individuals, Ahiman, Sheshai, and Talmai, are previously named as the children of Anak, it is elsewhere said, "it is a land which eateth up the inhabitants thereof, and all the people that are in it are men of great stature." Thus the context proves the correctness of the translation of this part of scripture; and that the appellation giants is not the proper name of a particular tribe, or nation, or tyrants, or evil doers, as commentators have inferred. Further, their history is continued, and Og, King of Bashan, in the same regions, is specifically described, somewhat later, as the last of the race; as also, "Bashan which was called the land of giants." This king was encountered and slain by Moses at the head of the Israelites, apparently at the gates of his own city; and it is said, "for only Og, King of Bashan, remained of the remnant of giants: behold his bedstead was a bedstead of iron: is it not in Rabbath of the children of Ammon? nine cubits was the length thereof, and four cubits the breadth of it, after the cubit of a man." This extraordinary bedstead, therefore, must have been between 14 and 16 feet long, and about 7 in breadth, according as the cubit is taken, at 18 or 20 inches. The next giant of whom we read in scripture was Goliath; but before leaving the gigantic king of Bashan, we may remark, that a spacious cavern is said to have been found near Jerusalem some thousand years after his death, containing a grave or tomb, with an inscription in Chaldaic, *Here lies the giant Og.* A tooth weighing four pounds and a quarter was found in the tomb, which, being sent from Constantinople, was offered to the emperor of Germany as a curiosity for 2000 rixdollars, in 1678. The emperor, however, being doubtful of the fact, ordered the tooth to be returned. The stature of Goliath must have been considerably inferior to that of Og; but his corporeal strength is undoubted, on considering his weapons and armour. Commentators conclude that six cubits and a span, described to be his height, make about eleven feet, though we should be inclined to reduce it to about ten at the utmost. He was a professed warrior, and a champion of the Philistines; "the staff of his spear was like a weaver's beam, and his spear's head weighed 600 shekels of iron." "He was armed with a coat of mail, and the weight of the coat was 5000 shekels of brass." No profane history is equally explicit as scripture regarding a distinct race of giants of extraordinary size; and we have united the passages to be found concerning them, previous to descending to a later date.

Gigantic remains.

The ancients considered persons whose stature exceeded seven feet as gigantic. Living giants have certainly been seen who were somewhat taller; but the existence of those who greatly surpassed it, or were double the height, has been inferred only from remains discovered in the earth, and not from the ocular testimony of credible witnesses. Were we to admit what has been reported on the subject, there would be no bounds to the dimensions of giants; the earth would seem unsuitable for them to tread upon. Thus Strabo speaks of the skeleton of a giant 60 cubits in length, found near a city in Africa now called Tangier; and without bestowing due reflection on the improbability of the fact, it is ascribed to Antæus, a reputed gigantic sovereign of Mauritania, whose very existence is still more problematical. The same observation will apply to another skeleton 46 cubits in length, alluded to by Pliny, which was exposed by the overthrow of a mountain in Crete by an earthquake. In the year 758, during the darker ages, we are told, that at a place called Totu in Bohemia, a skeleton was found whose head could scarcely be compassed by the arms of two men, and whose legs, which are said to have been kept a long time in the castle, were 26 feet long. Possibly this last measurement belongs to the entire skeleton rather than to a part of it. Simon Majolus relates, that in the year 1171, a skeleton 50 feet long was discovered in England in consequence of a breach made by a river; but we are not aware that his account, which is in these words, has any corroborative testimony. *Longe ante Fulgosi seculum, annis plus trecentis, anno scilicet* 1171, *in Anglia, illuvione fluminis relectæ sunt humani olim hominis ossa, adhuc ordine composita. Longitudo totius corporis inventa est longa ad pedes quinquaginta.* In the year 1516, the skeleton of a giant 30 feet high is reported to have been found near Mazarino in Sicily. The skull was as large as a hogshead, and each of the teeth weighed five ounces, which it may be remarked in passing, is not a tenth part as heavy as the reputed tooth of the gigantic king of Bashan. In the same island, other remains of a giant 30 feet high were discovered in 1548, and two years afterwards, those of a third, whose height attained 33 feet. Instead of these being entire skeletons, however, it is infinitely more probable that they were only detached fragments of bones, while conjecture enlarged the wanting parts to the size which is ascribed to the whole body.

Florus, the Roman historian, in narrating a battle between Marius and the Teutones, at the foot of the Alps, describes the king of that people as of wonderful stature. *Certe rex ipse Theutobochus, quaternos, senosque equos transire solitus, viz. unum quum fugerit, ascendit: proximoque in saltu comprehensus insigne spectaculum triumphi fuit, quippe vir proceritatis eximiæ super trophæa ipsa eminebat.* The first part of the sentence is obscure, but the historian in the rest apparently infers, that the stature of the captive king was such, that he could overlook the trophies exhibited at the triumph of the consul. In the year 1613, the French journals relate, that while some workmen were digging near the ruins of a castle in Dauphiny, in a field which had long bore the name of the Giant's Field, they discovered, at the depth of 18 feet, a brick sepulchre, 30 feet long, 12 feet wide, and eight deep, whereon was a grey stone, inscribed *Theutobochus Rex*. On opening the tomb, a skeleton appeared, 25½ feet long, 10 feet broad across the shoulders, and five feet deep from back to breast. Each of the teeth was the size of an ox's hoof, and the leg bones were four feet loug. These bones continued to be exhibited for some time as the identical remains of the Teutonic king mentioned by Florus, and carried under that name through Flanders into England. A convent of Dominicans at Valence, in Dauphiny, lately had part of a human leg bone, and articulation of the knee, found near the banks of the stream Morderi, which they affirmed belonged to a certain tyrannical giant, Bucant, 22 feet high. He lived on a mountain, and was slain by one of his own vassals, the Count de Chatillon; but to perpetuate his immense stature, the monks preserved a painting of him in Fresco. Rioland, a celebrated anatomist, is said to have written a specific account, in 1614, of the discovery of a tomb in the suburbs of St Germains at Paris, which contained the remains of Isoret, a giant 20 feet in height. But we have understood that the same physician called in question the identity of the bones as being of a human subject, which were exhibited for those of the Teutonic king. It is recorded, that in the course of digging a ditch at Rouen, near the Dominican convent, in the year 1519, a tomb was found, with a plate of copper inscribed: "In this tomb lies the noble and puissant lord, the Chevalier Ricon de Vallemont and his bones." The tomb contained a skeleton whose skull held a bushel of corn, and whose leg bone, about four feet long, reached up to the girdle of the tallest man in company. Platerus, a physician, declares, that at Lucerne he saw real human bones of a person who must have been 19 feet high; and it is calculated, that in the preceding instance, the Chevalier can have been scarce more than a foot shorter. A voyager to the Canary Islands speaks of the body of one of the ancient Guanches, in a cavern in the Peak of Teneriffe, as being 15 feet long, and having a head of enormous dimensions. Several navigators to the Straits of Magellan, both foreigners and Englishmen, affirm, that on examining graves at Port Desire, they found human skeletons ten or eleven feet in length, and on passing somewhat farther to the westward, as appears, other bones, in no respect inferior, were discovered. We shall say nothing of the giants referred to by Olaus Magnus, who, independent of men, says that a woman was found who had been killed by a wound in the head, clothed in a purple cloak, 50 cubits in length, and four in breadth between the shoulders: *Reperta est puella, in capite vulnerata, morta, induta chlamyde purpurea longitudinis cubitorum quinquaginta, latitudinis inter humeros quatuor.* But if we are to confide in history, here are examples of gigantic human remains, progressively decreasing from 60 cubits to 10 feet as the height of the living being. Whether the historians were competent judges of the fact they relate, is a different enquiry; few, however, will hesitate to reject the gigantic skeleton spoken of by Strabo, ascribed to Antæus; or that supposed to be the body of Orion, exposed by the dislocation of the Cretan mountain. The existence of enormous giants is conjectured from nothing but their remains, and it is extremely doubtful if there be authentic accounts of any living giant having been seen whose size exceeds the lowest term of the remains we have quoted.

The ancients acquaint us, that in the reign of Claudius, a giant named Galbara, 10 feet high, was brought to Rome from the coast of Africa. An instance is cited by Goropius, an author with whom we are otherwise unacquainted, of a female of equal stature. A certain Greek sophist, Proæresius, is said to have been nine feet in height. Julius Capitolinus affirms, that Maximinian the Roman emperor was eight feet and a half: there was a Swede, one of the life guards of Frederick the Great, of that size. M. Le Cat speaks of a giant exhibited at Rouen, measuring eight feet and some inches; and we believe some have been seen in this country, within the last 30 years, whose stature was not inferior. In Plott's *History of Staffordshire*, there is an instance of a man of seven feet and a half high, and another in Thoresby's account of Leeds, of seven feet five inches. Examples may be found elsewhere of several individuals seven feet in height, below which, after the opinion of the ancients, we may cease to consider men gigantic. A porter belonging to the Prince of Wales, commonly called Big Sam, though long esteemed of much larger stature, we believe proved to be only six feet ten inches. Entire families sometimes, though rarely, occur of six feet four, or six feet six inches high.

From all this we may conclude, that there may have possibly been seen some solitary instances of men who were ten feet in height; that those of eight feet are extremely uncommon, and that even six feet and a half far exceeds the height of men in Europe. Neither, as we shall afterwards explain, is there any reason to suppose that the human race has degenerated with the progress of time. But first let us say a few words on a subject which has excited much controversy, the existence of a nation of giants on the continent of South America.

Gigantic tribes still exist.

The earlier navigators towards the Straits of Magellan and the neighbouring coasts, soon remarked the extraordinary size of the natives repairing to the coast; and in the narrative of Magellan's own voyage, is an account of the first Patagonians, so called by the Portuguese in allusion to a long measure, who came on board a European vessel. The strangers were also visited by others displaying the same good nature, and those properties which still characterize the inhabitants of the coast; they were pleased with every thing they saw; the shackles with which Magellan prepared to make them prisoners, they took for play-things, and innocently allowed themselves to be fettered, and carried into captivity from a barbarous curiosity. Sir Richard Hawkins, and Nodal, a Spanish navigator, describe the natives of the coast as a head taller than Europeans, and of such stature that the crew of their vessels called them giants; and Sir Thomas Cavendish, speaking of those at Port Desire, says one of their feet measured eighteen inches long. The Spaniards also, who had formed settlements in South America, seem to have been acquainted with a tribe of large stature; and a woman, who had been many years in captivity, returned with an account of a whole army of giants. Still there was but a very imperfect knowledge of their history in Europe, until the public curiosity was roused by the narratives of the English circumnavigators, between the years 1760 and 1770; for the preceding notices of Turner, who said he had

Patagonians.

Giants. Patagonians.

seen a giant 12 feet high on the coast of Brazil, and of Knivet who had seen a youth 13 spans in height, attracted no attention. In the year 1764, Commodore Byron visited the coast of Patagonia, and, in describing the inhabitants as of gigantic stature, concluded from his own size, that they could not be less than six feet and a half, or seven feet high; but he did not measure any of them. This omission, however, was supplied by Capt. Carteret of the Swallow sloop of war, which reached Cape Virgin Mary near the eastern entrance of the Straits of Magellan in 1766. When he went ashore, 60 or 70 of the natives had assembled, and the number continually increasing, had augmented next morning to several hundreds of men, women and children. They were a fine race of people, their features large, with tolerably clear complexions and long black hair; and on measuring the size of many, Captain Carteret found it in general from six feet to six feet five inches high; some were six feet seven inches, but none taller. This proves the hazard of conjecture, for Mr Charles Clarke, who had accompanied Commodore Byron, concludes, that of about 500 people, there was hardly a man less than eight feet high, most of them considerably more, and some who certainly attained the height of nine feet, if not above it. The women also, he infers, were from seven and a half to eight feet. Except with regard to the height, the accounts of Captain Carteret and Mr Clarke coincide; but Captain Wallis further corroborates the words of the former. In the course of several interviews, he found by "measuring rods," that the tallest man among the Patagonians was 6 feet 7 inches high; that several were within an inch or two of that height, but the ordinary size was from 5 feet 10 inches to 6 feet. Both sexes were clothed in skins, and so much alike, that at first sight it was not easy to distinguish them. Their manners were mild and courteous; they had a ready apprehension, and were extremely intelligent. Many rode horses of the Spanish breed, fourteen or fifteen hands high; and it appeared their residence was inland, not on the coast. Mr Clarke seems aware, that the credibility of his relation might be called in question: Captain Carteret's was written very soon after the interview, and was accompanied with regrets, that the orders of his commanding officer were of such a description, as to preclude a more familiar intercourse with the Patagonians. We call them Patagonians, in coincidence with the name bestowed on them by their earlier visitors; but their proper appellation is Tehuels, or Tehuelhets,—as we learn from a missionary who resided many years in the country, and whose remarks will probably solve the difficulties which have been excited by the accounts of transient navigators. The Tehuelhets occupy a mountainous tract of South America, intersected by deep vallies, and wanting rivers of considerable size, bounded on the east by a vast desert, and on the north by a tribe called Chechehets. Their stature rarely exceeds seven feet in height, and often does not reach six feet. About forty or fifty years ago, they had a chief seven feet and some inches high, with whom the missionary Mr Falkner was well acquainted; but he affirms, that he never saw any Indian above an inch or two taller; that is, we conceive, seven feet and a half. The brother of this chief did not exceed six feet. They are a strong well made people, not so tawny as the other Indians, and some of their women as white as Spaniards: They are restless and nomadic, chiefly mounted on horseback, and always in motion. Another tribe, or, as some suppose, a different division of the same tribe, called Puelches, dwells on the western side of the continent, where bounded by the straits of Magellan on the south. They are very large, several being nearly seven feet six inches high. One branch of the tribe Huilliches, in the same vicinity, is denominated *Great* Huilliches, from their larger stature; and the Chechehets are tall and stout, like their neighbours the Tehuelhets, but speak a different dialect: and both acknowledge the Levuches, of whom we have no particulars, as their head. Most of those tribes are equestrian; but there is one called Yacanacunnees, or *foot-people*, because they always travel on foot, and have no horses in their country. Many concurring circumstances tend to prove, that the Patagonians of the older authors, and also of more recent navigators, are the various races of South Americans now described, though at this day greatly reduced from their former numbers. Larger stature, personal appearance, courteous disposition, a nomadic life, and a variety of peculiarities, are common to both. Thus it seems undoubted, that certain tribes of mankind exist on the South American continent, whose size considerably exceeds the common stature of mankind, that they might reasonably be esteemed giants when compared with their Portuguese or Spanish visitors, who probably were of very ordinary dimensions; but that the extreme height to which the tallest reach at present, does not exceed seven feet and a half. We read, that the ancient Germans, Gauls, and Caledonians, were men of great bulk and strength: *magna corpora et tantum ad impetum valida,*—as expressed by the historian of Agricola. Had these nations been preserved pure, and without intermixture, perhaps their stature might have been preserved also: Yet it is scarcely to be denied, that the stature, or at least the strength, of mankind, improves with civilization. The savages of no part of the New World, if we except the Patagonians, of whose powers we have never obtained a comparative view, are equally strong as the inhabitants of Europe; and it has been ascertained, that the natives of Great Britain are individually the strongest of all the human race hitherto known. The warmer climates, as well as those where extreme cold prevails, are equally unfavourable to strength and stature; and each seems to have a decided influence on the mind: It is within the temperate regions of the earth, that nature has endowed mankind with the most distinguished mental and personal energies.

Analo[gies] betwe[en] dwarfs [an]d giants.

From all that has hitherto been explained, the solitary instances of gigantic stature occurring in Europe, as well as uncommon diminution of the human size, ought to be assimilated to that species of monstrosity, where the aberrations of nature tend either to excess or defect. Symmetrical giants are seen, it is true, though very rarely, and also symmetrical dwarfs; but more generally there is some disordered organization in their persons, particularly in the head and extremities. These are small in giants in proportion to their other members; but the head of dwarfs is almost invariably very large. Giants are seldom endowed with physical power or mental energy: the period of life is, for the most part, abridged in dwarfs. Nature seems to languish in the preservation of both, but more conspicuously in regard to the former: They want strength, and are deficient in courage; nay, it is said, that on some extraordinary occasion, when several dwarfs and giants were assembled at Vienna, a quarrel ensued, and one of the dwarfs fought a giant to considerable advantage. Did we not view these beings as mere exceptions, the scale of disparity in the human stature would not be so limited as is wont to be supposed. The difference between a person of two feet four inches, said to be the shortest dwarf, and another of eight feet, whom we shall here esteem the tallest man, being five feet eight inches, is enormous. But, in Great Britain, the scale of size does not, at an average, range through five inches, nor probably in the rest of the world. That gigantic and pigmy stature is a simple accident, is proved from numerous facts. They are alike the children of ordinary parents; and their descendants, instead of resembling themselves, resemble their forefathers. Besides, all the other members of their own generation are usually of the common size. Nevertheless, with proper precautions, the human race, as that of other animated beings, may be improved; of which a notable instance is said to exist at Berlin, in the posterity of a very fine grenadier regiment formed by Frederic. Thus the stature of an entire tribe may be preserved, as in South America. In Europe, it is observed that men of the largest dimensions are generally of fair complexion, but that their muscles are soft, and their pulse slow and languid.

There are several reasons why mankind have been prone to believe in gigantic nations. First, among the Jews, from its being recorded in scripture; secondly, from the mythologies and fabulous histories of the Greeks and Romans; thirdly, from the discovery of enormous bones in the earth, belonging to no existing race of animals in the place where they were found. This last has been deemed one of the strongest confirmations; and unquestionably, without due consideration, it might stagger the most incredulous. Suetonius tells us, that in the time of Augustus huge bones were shewn as those of former races of men; and St Augustine reasons on the existence of giants before the deluge, from observing a tooth an hundred times exceeding the common size on the shores of Cilicia. At the present times, bones of immoderate dimensions are frequently dug out of the earth, which it has been reserved for modern anatomists to prove are those of extinct animals, instead of gigantic men. But it is not surprising, if, in the ages of ignorance, they were supposed to be such; and even now, osteology is so little understood by the vulgar, that few can tell, on the first discovery of a bone or a fragment of it, whether it has belonged to a man or an animal. Those enormous skulls or leg-bones, which would have created a race of giants sixteen or twenty feet high, have therefore been the relics of elephants, or of some of those extinct animals, whose dimensions surpassed those of any which at present inhabit the known world.

There is no evidence whatever, that the modern tribes of mankind have degenerated in size. The catacombs of ancient Egypt and Palestine; the cenotaph, if it be truly such, in the great pyramid; the tomb of Alexander the Great, are all calculated for bodies of ordinary dimensions. The truth is still more satisfactorily established from the mummies which are yet withdrawn from their subterranean receptacles in Egypt, and the caverns of the Canary Islands. In the most ancient sepulchres of Britain, those apparently anterior to the introduction of Christianity, no remains are discovered which indicate the larger stature of the inhabitants than our own. In every part of the world, domestic implements and personal ornaments, many centuries old, are obtained from tombs, from bogs and mosses, or those cities overwhelmed by volcanic eruptions, which would be ill adapted to a gigantic race of ancestors. (*c*)

GIANT's CAUSEWAY. To traditionary ignorance we may safely attribute a name, by which a basaltic portion of the coast of Antrim has been distinguished. Fin M'Coul, or, as he is classically denominated, Fion Mac Cumhal, desirous to punish the daring inroads of the Scots, resolved to

> " Bridge the ocean for the march of war."
> DRUMMOND.

And as all the heroes of his standing were either gods, demigods, or giants, we cannot be surprised, that an appearance bearing such close resemblance to artificial combination, should have been attributed to one or other of these agents.

The Giant's Causeway must not be limited to the particular mole or quay to which the traveller is conducted, when he approaches the coast from Bush Mills, the usual resting-place. It extends, as we have already observed under the article FAIRHEAD, throughout the whole of Bengorehead, from Port Moon on the east, to Port na Ganye on the west; a district of coast extending to more than a mile and a half in a direct line; and in every part of it, deeply indented with the most beautifully diversified bays.

Upon approaching the Causeway, the tourist is sure to be assailed by a host of ragged natives, whose attentions it is utterly impossible to get rid of: he must therefore quietly submit to take a few of them into his pay in the character of guides, in order to defend him from the importunities of the rest. Accompanied by these unwelcome guests, he is conducted down a steep path, which was formed at a great expence by the late Earl of Bristol, Bishop of Londonderry, to a natural mole which projects considerably into the sea; and here he is told, that this is the Giant's Causeway. The impression which generally follows is something like disappointment, so much has been heard, and consequently so much expected of the place. This feeling, however, is only of a momentary nature; for the mind has no sooner time to reflect on the admirable symmetry of an object with which nature seems purposely to have sported, in order to baffle the feeble intellect of mankind, than wonder and delight replace the apathetic feeling, which had nearly produced an ejaculation of discontent.

This mole or quay is entirely composed of basaltic columns: it is part of an immense bed, which here dips into the sea, and rises, as it is traced eastward, until it reaches a height of 200 feet above the level of the sea. These columns are arranged perpendicularly, and so accurately fitted into each other, that the point of a knife is not to be introduced between them, excepting where the seams have been opened by the action of the weather. This collection of columns extends from the base of the cliff into the sea about 725 feet, part of it at low water being still covered. It is divided into three parts, which are denominated the Great, the Middle, and the Little Causeway. These separations are occasioned by two parallel dykes, which traverse the columns in a northern direction; and to these perhaps the preservation of this mole is to be attributed; for although they are excavated, and worn down on the surface, still they remain firm at the base, and afford an immoveable support to the columns. These are of all shapes, from the triangular prism to

Giant's Causeway.

figures of nine sides. It is seldom that any among the multiplicity of forms which present themselves are very symmetrical, those of the pentagon and hexagon are most common; and they sometimes, though rarely, occur perfectly equilateral. In the highest part of the mole, the columns are from 25 to 30 feet in length, extremely straight and well proportioned: to this place the name of the Loom has been given. The prisms are wonderfully sharp in the angles, and present the very curious phenomenon of articulation throughout their whole extent. This articulation is not performed by a simple section of the column, but the joints are let into each other in the manner of the ball and socket, so that the angles of the under joint extend in the form of triangular projections, over those of the one above it. These projections, or spurs as they have been denominated, are easily detached; and in some places, particularly among the columns at the Organ a little east of the mole, where they are 45 feet in height, this mutilation renders the articulation particularly remarkable. The joints are from eight inches in length to a foot and a half, and sometimes even two feet; they are often longest towards the bottom. In diameter, the columns may average about 16 or 20 inches; they are wonderfully uniform in this respect; those of a triangular and square form are very rare, as well as those of nine sides.

The height of the cliff which overhangs this mole, is about 330 feet above the level of the sea, and varies from that to 400 feet, which is the elevation of Pleskin, one of the principal promontories towards the eastern extremity of this basaltic district. This portion of the coast is deeply indented; each little bay is denominated a port, and distinguished by its particular name, as Port Nofer, Port na Spania, &c. and along the whole coast the basaltic formation is beautifully exposed to view, in one of the most magnificent façades perhaps in the world. In some of the promontories, the ranges of columns placed over each other, and separated by amorphous trap, extend to the number of four or five. This is particularly the case in the great headland which bounds the east side of Port na Spania. At Port Pleskin, the visible ranges of columns are only two, but here they are magnificently displayed, and on a larger scale than in any other part of the causeway. The number of beds of trap are altogether about 16, partly very soft amygdaloid mixed with much zeolite, and partly irregular prismatic basalt. These are here and there interspersed with beds of bright red ochre; on one of which, at an elevation of about 200 feet from the sea, the first bed of columnar basalt rests, measuring about 44 feet in thickness. On this a bed of irregularly prismatic basalt lies, 54 feet thick; and on it another colonnade, still more magnificent than the first.

Pleskin is the highest elevation of this basaltic district; from it the beds all dip to right and left, and that which we have just mentioned, as resting on a surface of red ochre, 200 feet above the level of the sea, on the west, sinks below its surface at the mole, which in fact is merely a portion of it, and on the east it disappears in the middle of Port Moon. The view from the summit of Pleskin, is one of the most imposing that can be imagined; the series of headlands, which are seen in perspective from this point, form one of the grandest pictures of coast scenery, that it is possible to conceive.

The substance of the columnar basalt is extremely compact, of a dark iron grey colour, fine grained in the texture, and conchoidal in the fracture, with sharp-edged angular fragments. It is totally different from the substance of which Fairhead is composed; and perhaps we could not point out where the distinction between basalt and greenstone is better defined, than at Fairhead and the Giant's Causeway. The blocks or joints are extremely sonorous. Small pieces of calcedony, fine semi-opal, and even precious opal, have been found imbedded in it: it is occasionally cellular, and in some places presents the very singular phenomenon of containing fluid water; a circumstance which may be observed in the columnar basalt that occurs in a quarry not far from the summit of Pleskin. This fact has been urged by Dr Richardson as an incontestible proof of the impossibility of basalt being of igneous origin; but the theorists on that side of the question have no difficulty in accounting for it; we may remark, however, with regard to the value of the fact itself, that it cannot be of much consequence; for if pieces of the stone be removed for a time from the quarry, water will no longer be found in them, having made its escape; hence, if the stone be sufficiently porous to admit of the escape of the fluid, it cannot be denied that water may also be admitted through the same channel.

The Causeway has one considerable advantage over its rival Staffa, being much more accessible; it is distant about six miles from Colerain, between which and Belfast there is a regular mail-coach communication.

Trans.* 1808, vol. xcviii. p. 187. (S. N.)

Gibbon.

GIBBON, Edward, Esq. celebrated for the elegance and depth of his literary and historical works, was the first child of the marriage of Edward Gibbon, Esq. and Judith Porten. He was born at Putney in the county of Surry, on the 27th of April O. S. 1737. His maternal grandfather was Mr James Porten, a London merchant. By the father he was descended from John Gibbon, who is recorded to have been the *marmorius* or architect of Edward III. The strong and stately castle of Queensborough, which guarded the entrance of the Medway, was a monument of his skill, and obtained for him the reward of a hereditary toll on the passage from Sandwich to Stanar, in the isle of Thanet. The family was at that time possessed of lands in Kent, and the elder branches continued to possess them without much alteration till the present time. Our author, who was descended from a younger branch of the family, counts among his kindred several individuals of rank, learning, and political eminence. He was the only surviving member of a family, consisting of six sons and one daughter, all of whom, himself only excepted, were snatched away in infancy. In his Memoirs of himself, published by his friend Lord Sheffield, he makes use of the following tender expression of his feelings: "My five brothers, whose names may be found in the parish register of Putney, I shall not pretend to lament; but *from my childhood to the present hour,* I have deeply and sincerely regretted my sister, whose life was somewhat prolonged, and whom I remember to have seen an amiable infant." His own constitution was so extremely feeble even from his birth, that, anticipating his early loss, his father's prudence had the name of Edward repeated in the baptism of each of his sons, that this hereditary appellation might assuredly belong to the heir.

Gibbon.

It is strange to say, that such a succession of melancholy casualties did not wean the parents of this last hope of their family from the ceremonies and gaieties of life; and that the historian acknowledges, with grateful warmth, that even the maternal office was supplied by his aunt Mrs Catherine Porten, to whose gentle and unremitted assiduities he does not hesitate to ascribe the wonderful preservation of his life. His tender attachment, and his filial duty to this lady, place his character in a very amiable point of view. At the age of fifteen, "the mysterious energies" of his constitution began to display themselves, and from that time till within a few years of his death, he enjoyed an extraordinary and uninterrupted course of good health. In his nursery lessons, and at the day school at Putney, he shewed some quickness of apprehension, and such a readiness in arithmetical exercises, as leads him to suppose, that, had he persevered in such studies, he might have acquired eminence as a mathematician. At the age of seven, he was committed to the care of Mr Kirkby, a domestic tutor, who remained with him eighteen months, and taught him, among other things, the elements of the Latin language. Young Gibbon was sent in his ninth year to the grammar school of Kingston-upon-Thames, where he continued one among a crowd of boarders for two years, (with the exception of intervals occasioned by illness and vexations,) and from which he was removed home in consequence of the death of his mother. As his grandfather Mr Porten's house at Putney was near his father's, he again enjoyed the society and kindness of his beloved aunt; and having acquired some taste for reading poetry and romance while at Kingston, she encouraged his taste, and supplied him abundantly with books from her father's library. Some months having thus elapsed, Mr Gibbon, senior, finding himself inconsolable for the death of his wife, removed from Putney, where every object was associated with afflicting remembrances, to the rustic and retired family residence at Buriton, in Hampshire. Soon after, Mr Porten's affairs fell into disorder, so that he judged it prudent to abscond for a time. Mr Porten's unmarried daughter, Catherine, now found herself destitute, and partly with the design of being independent, but chiefly actuated by the motive of superintending her nephew's education, and watching over his health, she resolved to open a boarding house for Westminster school; and she and her young charge removed to her new house in College street, in January 1749. In the autumn of 1750, she accompanied him to Bath, on account of his bad health, where her own avocations compelled her to leave him under the care of a faithful domestic.

After various changes of place, and the complete establishment of his health, Gibbon was entered a gentleman commoner of Magdalen College, Oxford, in April 1752. At this ancient and far-famed seat of learning, he passed fourteen months, which, with bitterness of spirit, he declares to have been the most idle and unprofitable of his life. For this he does not blame himself, for he declares he had now a keen appetite for knowledge; but the relaxed discipline and customs of the university. He describes it as a place in which a young man may keep terms, spend money, and acquire bad habits, but totally unfit for stimulating genius to exertion, or promoting the attainment of knowledge and wisdom.

He declares that all the direct advantage which he received from Oxford was the reading of some of the comedies of Terence; and while he admits that some colleges may be better regulated than that to which he belonged, that many eminent men have been educated there, and that some practical improvements have been adopted since his time, he still insists on the necessity, at the same time that he admits the difficulty of a great reformation. He even complains that his moral conduct, and religious instruction, were completely neglected, and that, without a single exhortation or lesson, he was left, by the dim light of his catechism, to grope his way to the chapel and communion table. His sedentary habits, and infirm health in early life, had led him to indulge in desultory reading; and though his father was a man of the world, who cared little about religious controversy, yet his pious aunt had taken pains to instruct him, and had encouraged him to ask questions and propose objections, which she was not always well qualified to answer. At Oxford he read with avidity certain of the writings of Parsons the Jesuit, and of the learned and profound Bossuet, in defence of the doctrines of the Catholic faith, and having formed an intimacy with a young man of the same college to which he belonged, who had imbibed opinions favourable to the Church of Rome, he actually became a proselyte, and with the zeal of a martyr he went to a Catholic priest in London, renounced the Protestant faith, and was admitted into the pale of the Romish church.

He then wrote a long letter to his father, explanatory of his new profession, and the grounds of it. His father, equally indignant and amazed at the intelligence, somewhat imprudently spoke of his son's change of religion, and the gates of Magdalen College were thenceforth shut against him. This only added zeal to the faith of the young disciple, and his father, after much deliberation and sorrow, determined to exile him for some years from his native country, and to fix him at Lausanne in Switzerland, under the roof of Mr Pavilliard, a Calvinistic minister, in the hope that his errors would be corrected. Thither young Gibbon accordingly went, rejoicing that he was counted worthy to suffer for what he deemed the cause of truth. In his new situation, he enjoyed few of the comforts, and none of the luxuries to which he had been accustomed. His accommodation was mean, and the economy of the house by no means suited to the elegance of an English taste. Yet he soon became not merely reconciled to, but even pleased with his situation. The conversation, the books, but above all, the kindness and confidence of his amiable host, promoted his intellectual improvement, and his happiness. His mind too was amply gratified in its appetite for religious controversy; and Monsieur Pavilliard, who, in his letters to Mr Gibbon, senior, extols the progress of his pupil, informs him from time to time of the tenacity with which he held his opinions, and the obstinate perseverance with which he debated every point of his faith. At length the various articles of the Romish creed vanished like a dream, and after full conviction, he was a communicant on Christmas day 1754, in the Presbyterian church of Lausanne. As this forms a most important part of Mr Gibbon's life, and as it tends to throw light on the subsequent scepticism which too plainly marks his writings, we have dwelt more fully on it than we should otherwise have done. The following oracular sentence contains the only allusion which he himself makes to its influence on his opinions. "It was here that I suspended my religious inquiries, acquiescing with implicit belief in the tenets and mysteries which are adopted by the general consent of Catholics and Protestants."

The incident next in importance, which distinguishes Mr Gibbon's residence at Lausanne, was the honourable attachment which he formed for the accomplished Mademoiselle Susan Curchod, the daughter of an obscure Protestant clergyman in the neighbourhood. The lady favoured his addresses, but they were opposed by his father, on whom he found himself completely dependent, and to whose *veto* he submitted with a degree of apparent *sang froid,* not easy to be explained consistently with the professed warmth of his affection. This interesting female attained afterwards a melancholy eminence as the wife of Neckar. As the sensitive Rousseau speaks in terms of keen disapprobation of the conduct of Gibbon on this occasion, it is fair to state, that the latter afterwards renewed his intimacy with her as the wife of the celebrated ex-minister, and lived for many years on a footing of easy and affectionate familiarity with herself and her husband.

At length, after an absence of nearly five years, he was permitted to return to England about the beginning of summer 1758. In the interval, his father had formed a new connection by marriage, and our learned stranger was received with a degree of kindness which filled him with satisfaction. After two years passed in study or amusement, his father and he rashly offered their services in the Hampshire militia, in which they were appointed major and captain, and kept under arms and in constant service for nearly two years. During this time, young Gibbon, though deeply disappointed at the sacrifice he had made, and of which he had by no means anticipated the extent, endeavoured to acquire a knowledge both of the art of war and of British tactics, and acknowledges, with great honesty, that "the captain of the Hampshire militia has not been useless to the historian of the Roman empire!"

When at Lausanne, he meditated, and began, the composition of a small work, entitled *Essai sur l'Etude de la Literature,* which he finished in England, and published, with a dedication to his father, in 1761. This work was written in French, a language in which his daily habits of conversation and study when at Lausanne, had rendered him more adroit than in his vernacular tongue. His chief object in this *coup d'essai,* was to revive on the continent, and especially in France, the decaying taste for the languages and literature of Greece and Rome. This juvenile production was well received, both at home and abroad. After the peace of 1763, he again went to the continent, and on his way to his favourite Lausanne he visited Paris, where he remained for three months, and was introduced to the acquaintance of D'Alembert, Diderot, and many other of the literati of the day. Having passed through Dijon and Besançon, he arrived at Lausanne in May 1762, and, fascinated with the renewal of the scenes, studies, and associates of his early years, he remained there till the following spring. Having prepared himself, by extensive study, for a projected tour through Italy, he set out in April 1764, and going by Parma and Florence, proceeded through Sienna to Rome, on entering which renowned city he was almost overwhelmed with emotions of enthusiasm. It was at Rome, on the 15th of October, that, as he sat musing amidst the ruins of the capital, while the bare-footed friars were singing vespers in the Temple of Jupiter, that, as he informs us, he conceived the idea of writing the Decline and Fall of the Roman Empire! He proceeded south to Naples, revisited Rome and Paris, and arrived at his father's house in June 1765. Every spring he attended the monthly meeting of the militia, and was promoted to the rank of lieutenant-colonel commandant. Wearied with the details of this service, he resigned his command in 1770. An annual visit at Buriton, from his much-loved friend M. Deyverdun of Lausanne, formed the most agreeable enjoyment of his life during this period; and, with the aid and encouragement of that learned and elegant scholar, he proceeded some length in preparing a history of the rise and progress of liberty and independence in his adopted country, Switzerland. The great difficulty of procuring materials, and his ignorance of the German language, induced him to desist from the completion of this interesting design. In 1767 and 1768, he in his turn materially assisted M. Deyverdun in the publication of a work intended to be annual, entitled, *Memoires Literaires de la Grande Bretagne.* This work, of which the third volume was nearly ready, was discontinued, in consequence of Mr Deyverdun agreeing to accompany on his travels as tutor, a young friend of Mr Gibbon's. The next publication of Mr Gibbon, is an able and spirited, but most severe answer to that chapter in Warburton's "Divine Legation of Moses," which represents the sixth book of the Æneid as containing a veiled account of the initiation of Æneas, in the character of a lawgiver, into the Eleusinian mysteries. This essay was published in English anonymously early in 1770; and the author, with great ingenuity, shews, that the sixth book is not an allegory, but a fable founded on the popular belief, and that there is not a shadow of probability in the hypothesis of Warburton. The Bishop and his friends remained silent under this attack, and the voice of the learned pronounced that Gibbon was master of the field.

The grand project of "the History of the Decline and Fall of the Roman Empire," which had been formed in the interesting circumstances already alluded to, was ever present to the mind of the author, though its execution was for some time delayed; and the embarrassment of his father's affairs, as well as the decline of his health, prevented Mr Gibbon from pursuing his studies with his usual ardour. In November 1770 his father died, and during the two succeeding years, the arrangement of his affairs occupied much of his time and attention. Finding himself at length comfortably settled in a house in London, furnished with a valuable library, and having long prepared for the task, he entered seriously on the composition of his great work; and when he published the first volume in quarto, his success was so great, that the first impression was exhausted in a few days, and a second and third edition were speedily called for. Letters of compliments flowed in upon him from various quarters. These were speedily succeeded by the strictures, attacks, and confutations of those who were offended with his 15th and 16th chapters, which contain an unfair and insidious account of the rise and progress of Christianity. The principal assailants were Dr Watson, now Bishop of Landaff, Taylor of Norwich, Mr Milner of Hull, Lord Hales, Mr Davies of Oxford, and Dr Priestley. That he was much stung by these publications, he does not attempt to deny. But the only one of them which he answered from the press was the pamphlet of Mr Davies, because, as Mr Gibbon alleges, he had attacked not so much the *faith* as the *fidelity* of the historian. This answer is entitled, *A Vindication of some Passages in the 15th and 16th Chapters of the History,* &c. and if he does not shew great candour in his defence, the praise of ingenuity and learning will not be denied to him. After the lapse of a con-

Gibbon.

siderable interval, the second and third volumes were published. The three last volumes, chiefly composed at Lausanne, were printed in England, and published in May 1788.

In 1774, Mr Gibbon was returned as a member of parliament from the borough of Leskeard, and was a uniform but silent supporter of administration during the American war. Timidity, he says, was fortified by pride, and even the success of his pen discouraged the trial of his voice. He held his seat during eight sessions, and seems to have enjoyed the confidence, and occasionally assisted the councils, of the administration. Through the favour of Lord North, of whom Gibbon always speaks with high respect and esteem, he was appointed one of the lords commissioners of trade and plantations, and had thus a clear addition to his income of between L. 700 and L. 800 a year. The board was abolished in the following session by a small majority of votes in the House of Commons, but was soon afterwards revived. Mr Gibbon held the place for three years, that is, till the board was abolished by Mr Burke's bill. Mr Gibbon having got into next parliament through Lord North's influence, for Lymington, tells us, that he uniformly supported the famous coalition between that minister and Mr Fox *from a principle of gratitude.* This confession, to be sure, though hardly becoming the dignity of a historian, or the morality of a philosopher and patriot, who may be expected to act in a public cause, not from private feeling, but from conviction, does yet sound as a weakness leaning to virtue's side; but most unfortunately for his reputation, *even as a friend,* he adds: "My vote was counted in the day of battle, *but I was overlooked in the division of the spoil.* There were many claimants more deserving and more *importunate* than myself." A more unblushing and more unvarnished acknowledgment of venality we do not recollect to have seen; and we must confess that it lessens Mr Gibbon, in our moral estimate, to a degree that is painful to contemplate. One wonders that the man who had the meanness thus to act, had the candour to acknowledge such meanness in a memoir designed for the public eye. But, in truth, with all the extent of his learning, and all the force of his genius, he does not appear to have discovered the unworthiness of thus betraying the interests of his country for a private end.

The attachment of Mr Gibbon to Lausanne, and his friendship for Mr Deyverdun, who was now residing at his delightful villa there, induced him to form the romantic design of settling at that place, and living as an inmate with his friend. This wish, no importunities of his friends at home could prevent him from accomplishing; and accordingly he realized his project in 1783. His friendship with Mr Deyverdun continued uninterrupted till the death of that respectable man, which happened in 1789. Mr Gibbon often lamented this event in language that shews how deeply he estimated his loss; but by an arrangement with the heir, he continued to reside in the house till 1793, when the horrors of the French Revolution, and the domestic affliction of his friend Lord Sheffield, induced him to return to England. He was looked up to while at Lausanne with respect and admiration, and his house was the centre of learning and hospitality. The preference which he shewed to that little *paradise,* as he used to call it, made the inhabitants regard him as a father; and the regrets that followed his departure are a most honourable tribute to his name. He arrived at the house of Lord Sheffield in London about the beginning of June, and spent the summer and autumn chiefly at Sheffield Place, where he seemed to enjoy good health, and where his conversation was the delight of all who heard it. For several years he had been subject to occasional attacks of gout. Towards the close of this autumn he was attacked with a dropsical tumour, the formation of which he had too long concealed. After submitting to several operations, after each of which he anticipated a complete recovery, inflammation came on, and he expired in London on the 16th of January 1794, in the 57th year of his age. We understand that the friendship of Lord Sheffield induced him to erect a handsome monument to his memory.

That Mr Gibbon possessed, in an eminent degree, many of the qualities which constitute a good historian, will readily be admitted, even by those who most disapprove of some of his sentiments. Extensive, varied, and profound learning, unwearied perseverance, great coolness of judgment, belonged to him in a high degree; and though his own diffidence leads him to disclaim a place beside our two great Scottish historians, Robertson and Hume, we apprehend that he is not much inferior to either. He has ably supplied a most important desideratum in historical knowledge, and has filled up the chasm which divided ancient from modern history. Though the history of his early life cannot excuse, it leads us, in some degree, to extenuate the disingenuousness with which he appears to be chargeable in discussing the nature and propagation of Christianity; and the able answers which have appeared, have, we hope, effectually counteracted the baneful effects of his misconceptions or misrepresentations. GIBRALTAR.

Gibraltar.

Gibraltar, the *Mons Calpe* of the Romans, is a celebrated promontory in Andalusia, the most southern province of Spain, stretching into the Mediterranean towards the opposite promontory of Ceuta on the Barbary coast. It is situated in Lat. 36° 6′ 30″ North, and Long. 5° 19′ 31″ East, from the meridian of Greenwich.

Situation.

General description.

The mountain of Gibraltar is of an oblong form; its summit consists of a sharp craggy ridge, running in a direction nearly from north to south. The line of this ridge is undulated, being somewhat higher at the two extremities than in the centre. The whole rock is about seven miles in circumference, and forms a promontory about three miles in length. Its breadth varies with the indentations of the shore; but it no where exceeds three quarters of a mile. It is joined to the continent by a low sandy isthmus, the greatest elevation of which, above the level of the sea, does not exceed ten feet; and its breadth, at the base of the rock, is about 900 yards; but it grows considerably broader towards the country. This isthmus, with the mountain and the opposite coast of Spain, forms the Bay of Gibraltar, which is nearly eight miles and a half long, and upwards of five miles broad. The most elevated point of the promontory, towards the south, which is the summit of the Sugar Loaf, stands 1439 feet; the Rock Mortar, the highest point towards the

Gibraltar.

north, 1350; and the Signal House, which is nearly the central point between these two, 1276 feet above the level of the sea. The western side of the mountain presents a gradual slope, interspersed with abrupt precipices. The northern front, facing the Spanish lines, is perfectly perpendicular, with the exception of a narrow passage of flat ground towards the north-west, which leads to the isthmus. The eastern side consists, in a great measure, of a range of precipices; but about a third of its perpendicular height is covered by a bank of sand, which rises from the Mediterranean in a rapid acclivity. The southern extremity of the mountain falls, in a rapid slope, from the summit of the Sugar Loaf into a rocky flat, of considerable extent, called Windmill Hill. This flat is bounded by a range of precipices, at the southern base of which there is a second rocky flat, of similar form and extent, and surrounded also by a precipice, the southern extremity of which is washed by the sea, and forms Europa Point.

History.

This promontory has become famous, in modern times, for the site of a fortress, which nature and art have conspired to render the strongest in Europe, perhaps in the world. The Bay of Gibraltar affords so commodious a harbour for shipping, and the promontory itself seems so completely formed by nature for commanding the narrow entrance into the Mediterranean from the ocean, that a town of considerable strength probably stood somewhere in this bay from the earliest times. Indeed, ruins of great antiquity are still distinguishable at the bottom of the bay, on the banks of the Guadaranque, about four miles north-west from Gibraltar, which are supposed to be the remains of the ancient city of Carteia, or Heraclea. But the mountain itself does not appear to have been an object of particular attention in early times; and the present town and fortress are indebted for their name and existence to the Moorish invaders of the peninsula.

The Saracens, under the conduct of Tarif, invade Spain,

About the commencement of the eighth century, Count Julian, a nobleman of great wealth and influence, whose daughter had been violated by Roderick, the last of the Gothic monarchs of Spain, determined to revenge the dishonour done to his family; and having secretly retired into Africa, acquainted Mousa, the Saracen governor of the western provinces, with the distracted state of the kingdom, and promised to assist him in an attempt to dethrone the Gothic monarch. Mousa communicated the proposal to his sovereign, the Caliph Al Walid Ebn Abdalmalic, who resolved to try the practicability of the project; and accordingly a small detachment, consisting of 100 horse, and 400 foot, was embarked in the year 711, under the command of Tarif Ebn Zarca, who landed near the present town of Algeziras, and finding the country almost defenceless, ravaged the neighbouring towns, and returned laden with spoils. In the following year an army of 12,000 Saracens was assembled for the invasion of Spain, and Tarif was again appointed to the chief command. He landed on the isthmus between Mons Calpe and the continent; and having determined to establish a port on the coast, by means of which he might secure a communication with Africa, and at the same time cover his retreat, in case he should be unfortunate in his future operations; he preferred the strong natural situation of Mons Calpe, and gave orders to erect a castle on the face of the hill, which the Saracens now called, in compliment to their general, *Gibel-Tarif*, or the mountain of Tarif; whence the modern name of Gibraltar. From an inscription discovered over the principal gate of this once magnificent pile, the period of its completion is ascertained to be about the year 725. Having left a garrison at Gibraltar, Tarif marched into the country, and seized upon several of the towns in the neighbourhood. In the mean time, King Roderick, having received intelligence of his approach, assembled a numerous army to oppose his progress. A battle was fought near Xeres, in Andalusia; and after a long and sanguinary contest, victory declared in favour of the Saracens, and left them in possession of the whole kingdom.

and founds Gibraltar. A. D. 725.

Gibraltar taken by Ferdinand King of Castile.

From this period the Moors continued masters of Gibraltar, until the beginning of the 14th century, when it was wrested from them by the victorious arms of Ferdinand, King of Castile. In the year 1333, Abomelique, son of the Emperor of Fez, was dispatched with assistance to the Moorish King of Granada, and landing at Algeziras, immediately laid siege to Gibraltar. Alonzo XI. who was then upon the throne of Castile, was prevented from marching to its relief by a rebellion in his kingdom, and by the approach of Mahomet, King of Granada, towards his frontiers. The fortress was attacked with great judgment and bravery, and defended, with equal obstinacy, by the governor, Vasco Perez de Meyra, who was compelled, however, to surrender, after a five months siege. Having quelled the rebellion, and obliged Mahomet to retire, Alonzo had advanced within a short distance of Gibraltar, when he was informed of the capitulation. Having resolved, however, to attempt its recovery, before the Moors could victual and repair it, he encamped before the town five days after it had surrendered. But after several serious attacks had been made upon the castle, Mahomet, King of Granada, having joined Abomelique's forces, their combined army encamped in the rear of the Spaniards, extending across the isthmus from the bay to the Mediterranean. Being thus placed in an extremely critical situation, Alonzo was at length obliged to listen to an accommodation, in consequence of which he was permitted to retire unmolested. In the beginning of the year 1349, Alonzo again encamped before this important fortress; and, in the course of several months, the castle was almost reduced to capitulate, when a pestilential disorder carried off a great number of the besiegers, and, among the rest, Alonzo himself, who died, much lamented, on the 26th of March 1350. The Spaniards immediately afterwards raised the siege. The descendants of Abomelique continued in quiet possession of Gibraltar till 1410, when it was seized and retained by Jusaf III. King of Granada. In 1435, Henry de Guzman, Count de Niebla, lost his life in an unsuccessful attack upon Gibraltar. In 1462, a great part of the garrison having been withdrawn, to assist one of the parties in a civil war which broke out in Granada, a Spanish army was collected from the neighbouring garrisons, and Gibraltar was besieged. The inhabitants defended it with great resolution; but the besiegers having been reinforced, the garrison surrendered to John de Guzman, Duke of Medina Sidonia, son of the unfortunate Count de Niebla; and thus was this important fortress finally wrested from the Mahometans, after they had possessed it during 748 years. This conquest was so acceptable to Henry IV. of Castile and Leon, that he added it to his royal titles, and gave it for arms, *gules*, a castle, *proper*, with a key pendant to the gate, *or;* which arms have ever since been continued. In the year 1540, Gibraltar was surprised and pillaged by Piali Hamet, one of Barbarossa's captains. During the reign of the Emperor Charles V. the fortifications of the town were modernised and augmented by Daniel Speckel, a Ger-

man engineer; after which the garrison was thought to be impregnable.

Gibraltar taken from the Spaniards by the English, under Sir George Rooke, 1704.

From that period there is a chasm in the history of Gibraltar down to the year 1704, when this fortress was wrested from the dominion of Spain by the English, under Sir George Rooke. Sir George had been sent into the Mediterranean with a strong fleet, in the spring of that year, to the assistance of Charles, Archduke of Austria; but not having been able to succeed in any enterprise of importance, it was at length resolved, in a council of war, to make a sudden and vigorous attempt upon Gibraltar. The fleet arrived in the bay on the 21st of July; and 1800 English and Dutch, commanded by the Prince of Hesse d'Armstadt, were landed on the isthmus. The governor having refused to surrender upon being summoned, the cannonade was commenced with such vivacity and effect, that, in five or six hours, the enemy were driven from their guns, especially from the New-mole head. The armed boats were then dispatched to take possession of that fortification; but some pinnaces having pushed ashore before the rest came up, the Spaniards sprung a mine, which blew up the works, and killed a number of men. The assailants however advanced, and took a small bastion half way between the mole and the town; upon which the governor, being again summoned, thought proper to capitulate; and, on the 24th, the Prince of Hesse took possession of the gates.

Besieged by the Spaniards and French, 1705.

The capture of Gibraltar by the English could not fail to excite considerable alarm in the courts of Madrid and Versailles; and its recovery being considered as of the last consequence to the cause, the Marquis de Villadarias, a grandee of Spain, was ordered to besiege it. On the 11th of October, the Marquis opened his trenches against the town; and on the night of the 29th he had resolved to attack the place by sea and land, at five different points, had it not been most opportunely reinforced and supplied, on that very day, by the fleet under Sir John Leake. Nevertheless, the Spaniards still entertained hopes of taking the fortress, and formed the desperate design of surprising the garrison, although the British admiral was before the town. On the 31st of October, 500 volunteers took the sacrament never to return till they had taken Gibraltar. Fortune at first favoured the enterprise, and they succeeded in scaling Charles the Fifth's wall, and surprised and put to death the guard at Middle Hill; but having been at length discovered, they were vigorously attacked by a strong detachment of grenadiers, and the whole party were either killed or made prisoners. In the beginning of December, the garrison received the long-expected succours; and the Spanish general being also reinforced with a considerable body of infantry, on the 11th of January 1705, made an attack with 60 grenadiers on the works at the extremity of the King's Lines; but two officers and several others being killed, the rest retreated. The attack, however, was renewed on the following day, by 500 or 600 grenadiers, French and Walons, supported by 1000 Spaniards, under Lieutenant General Tuy. Their disposition was to storm a breach which had been made in the Round Tower, at the extremity of the King's Lines, and another in the intrenchment on the hill. The detachment for the upper breach mounted the rock at dead of night, and concealed themselves in the clefts. At day-break, they advanced to the point of the intrenchment, and compelled the party who defended it to retreat. At the same time the Round Tower was stormed by 300 men, in spite of a vigorous defence. But the garrison being at length alarmed, the assailants were charged with such bravery, that they were repulsed; and the Tower was retaken after it had been in their possession upwards of an hour. The Marquis de Villadarias was soon afterwards superseded by the Marshal Tessé, a French general; but the place was now so well supplied, that the Marshal withdrew his troops from the trenches, and converted the siege into a blockade; drawing an intrenchment across the isthmus to prevent the garrison from ravaging the country. The Prince of Hesse remained in the place while the batteries were repaired. He also made some additions to the fortifications, and left the garrison much stronger than it was before the siege. Major General Ramos, who had been present during the siege, was then appointed governor. He was succeeded by Colonel Roger Elliot; during whose government, in the month of April 1706, Gibraltar was made a free port, by a special order from her Majesty Queen Anne.

The siege turned into a blockade.

Gibraltar made a free port by Queen Anne, 1706.

The Spaniards form a secret design of surprising Gibraltar; but are obliged to abandon it, 1720.

In the year 1720, the Spaniards formed a secret design of surprising Gibraltar, under the pretence of relieving Ceuta, then besieged by the Moors. A formidable force was accordingly assembled in Gibraltar Bay, under the command of the Marquis de Leda; but the British ministry had timely notice of these proceedings; and such precautions were taken, that the Spaniards were obliged to abandon the project. From that period, Gibraltar remained unmolested, till the latter end of the year 1726, when the Spaniards, having assembled an army in the neighbourhood of Algeziras, encamped on the 20th of January 1727, on the plain below St Roque, and began to erect a battery on the beach to protect their camp. The fortress had undergone considerable alterations since the siege in 1705. Several new works had been constructed on the heights above the lines, which were distinguished by the name of Willis's batteries; the Prince's lines were also extended to the extremity of the rock; and an inundation was formed out of the morass in front of the grand battery. The Count de Las Torres commanded the Spanish forces, amounting to near 20,000 men; and soon after his camp was formed, he advanced within reach of the garrison. The British military and naval commanders, having no instructions, were for some time at a loss how to act; but the Spaniards having, at length, sufficiently discovered their hostile intentions, the lieutenant-governor withdrew the out-guard, and on the afternoon of the 11th of February, opened the old mole, and Willis's batteries, on the enemy's workmen. The enemy, however, still persisted in carrying on their works; and on the morning of the 22d, the Count opened on the garrison, with 17 pieces of cannon, besides mortars. On the 3d of March he opened a new battery of 22 guns on the old mole and town; and on the 8th another of 15 guns, bearing also upon the old mole, which, it seems, proved a troublesome battery to the western flank of their approaches. On the 21st of April, Lord Portmore, the governor, arrived with reinforcements to the garrison. On the 26th the Count opened a new battery against Willis's, and the extremity of the Prince's lines. Their batteries now mounted 60 pieces of cannon, besides mortars. The firing continued on both sides, until the evening of the 12th of June, when dispatches arrived with a copy of the preliminaries of a general peace, upon which all hostilities ceased.

Gibraltar besieged by the Spaniards, 1727.

Hostilities terminated by the preliminaries of peace.

Overtures had been made by his Majesty George I. to restore Gibraltar to Spain, if the parliament would consent to the restitution; but the measure being strongly opposed, was relinquished by the minister. In

Gibraltar.

Spanish lines erected, 1730.

1730, Lieutenant General Sabine was governor of Gibraltar. During his government, the Spaniards erected the forts and lines across the isthmus, about a mile from the garrison, which effectually prevent any communication with the country, and are of considerable advantage in case of a siege.

Famous siege of Gibraltar by the Spaniards and French, 1779—1783.

Although the Spaniards had been defeated in three different attempts to recover Gibraltar, they still continued to look upon that fortress with a jealous eye, and seemed only to wait for a favourable opportunity of wresting it, if possible, from the dominion of Great Britain. No such opportunity, however, occurred, until the war in which England was engaged with her American colonies. France having espoused the cause of our Transatlantic enemies, the court of Madrid thought proper to come forward with an offer of mediation, upon terms to which the belligerent powers could not accede. The refusal of Great Britain was followed by a declaration of war on the part of Spain. It was obvious that this war was undertaken principally with a view to the recovery of Gibraltar; and accordingly a contest ensued for the possession of that celebrated fortress, which will be ever memorable in the military annals of this country.

Preparations for the attack and defence, June, 1779.

At this period, General Elliott was governor of Gibraltar, Lieutenant-General Boyd lieutenant governor, and the garrison consisted of 5382 men. On the 21st of June 1779, the communication between Spain and the garrison was closed, by an order from Madrid. In the mean time, preparations had been privately made for the defence of the place, as soon as intelligence was received of the probability of a war; and when the first hostile indications of the Spaniards were perceived, the northern guards were reinforced, land port barriers were shut, and an artillery officer was ordered to Willis's batteries, to observe the movements of the enemy, and protect the Devil's-tower guard. In short, every precaution was taken to insure the safety of the garrison. In the month of July, the Spaniards formed a camp on the plain below St Roque, which was daily reinforced with additional regiments of cavalry and infantry; and large parties were constantly employed in landing ordnance and military stores at Point Mala.

The Spaniards form a camp at St Roque, July.

The garrison erect new batteries.

The garrison, in the mean time, were not less active. The works at Willis's were put in the best repair, and new batteries erected on the heights of the north front. A new battery was also begun in the navy-yard, as a resource, in case the enemy's operations should make it necessary to lay up the ships. In the month of August, the enemy were enabled to enforce a strict blockade; their army was now in force before the place; their squadron under Admiral Barcelo, who commanded in the Bay, could prevent succours from being thrown in by neutral vessels; whilst their grand fleet, united with that of France, would be superior to any which Great Britain could equip. The plan, therefore, seemed to be, to reduce Gibraltar by famine; and the place, indeed, might have been in imminent danger, had not the garrison fortunately received a supply of provisions, &c. in the preceding month of April. On the 27th, a fascine-work was observed to be begun upon the glacis north of Fort St Philip, which afterwards proved to be a mortar-battery. The enemy's camp was now considerably increased. It consisted of two lines, (independent of the Catalonians, who were separately encamped,) extending from Point Mala in an oblique direction into the country, towards the Queen of Spain's Chair. In the beginning of September, their workmen in the lines were busily employed in filling up with sand the north part of the ditch of Fort St Philip, completing the mortar-battery before mentioned, and raising the crest of the glacis of their lines in different places. From the noise often heard during the night, and the number of lights seen, it was conjectured that they worked without intermission. These operations of the enemy now began to engage the attention of the garrison; and the governor did not think it prudent to allow them to proceed any longer with impunity. A council of war was accordingly summoned on the 11th, to confer upon the measures proper to be pursued; and on the morning of the 12th, the artillery officers were ordered to the batteries on the heights, the Devil's-tower guard was withdrawn, and the governor opened on the enemy from Green's lodge, (a battery constructed since the blockade commenced,) Willis's and Queen Charlotte's batteries. This fire disconcerted the enemy; their advanced guards were in a short time compelled to retire, the workmen assembled in the lines were obliged to disperse, and the cavalry galloped off towards the camp. For some hours afterwards, scarcely was there an individual to be seen within the range of the guns of the garrison. The firing was continued on the subsequent days, as circumstances directed. The enemy, however, appeared to bear our fire very patiently in their lines; their parties continued working on the mortar-batteries, and a *boyau*, or covered-way, was begun, to make a safe communication from the lines to their camp. In the beginning of October, the enemy's army, according to the intelligence received by the garrison, consisted of sixteen battalions of infantry, and twelve squadrons of horse; which, if the regiments were complete, would amount to about 14,000 men. The whole were under the command of Lieut. Gen. Don Martin Alvarez de Sota Mayor.

The enemy enforce a strict blockade by sea and land, August.

They strengthen their lines, and erect new batteries, Sept. 1779.

The governor opens his fire upon the enemy's lines.

A gun mounted on the summit of the northern front, and called the Rock-gun, October.

The great command which the garrison had over the enemy's operations from the Green's lodge battery, induced the engineers to mount still higher, and endeavour to erect a battery on the summit of the northern front. A place was, therefore, levelled, and a road for wheeled carriages begun at Middle-hill. On the 12th of October, the platform on the summit of the rock was completed; and the gun being mounted, the enemy's forts were, on the following day, saluted with a few rounds of shot and shells. This gun was mounted on a traversing carriage, and was distinguished by the name of the Rock-gun. On the evening of the 19th, the enemy's working parties were uncommonly busy; and on the following morning at day-break, the garrison were surprised on observing 35 embrasures opened in their lines, forming three batteries; two of fourteen guns each bore on our lines and Willis's, and one of seven apparently for the town and Waterport. They were cut through the parapet of their glacis, and situated between the barrier of the lines and Fort St Philip. The governor ordered the artillery to direct their fire on these works, and on the seven-gun battery in particular, where the enemy had a party finishing what was left imperfect in the night. Our workmen now became extremely diligent; new communications and works were raised in the lines; and on the 27th, guns were carried up, to be in readiness for a new battery to be erected below the Rock-gun. Nothing remarkable occurred during the months of November and December. Both parties were occupied in improving and augmenting their works. The garrison, however, now began to be greatly distressed for want of provisions; not only bread, but every article necessary to the support of life, was procured with difficulty, and only to be purchased at exorbitant prices. This distress was considerably re-

The garrison distressed for want of provisions;

lieved in the month of January, when Sir George Rodney arrived in the bay with a convoy, after having defeated the Spanish fleet under Langara. At the same time, the garrison was reinforced by the second battalion of the 73d regiment. After the departure of Sir George Rodney with the fleet, in the month of February 1780, the Spaniards resumed the blockade with the same vigilance as before. No other event of importance occurred until the month of June, when the enemy made an unsuccessful attempt to destroy our vessels in the bay by means of fire-ships, which was defeated by the skill and intrepidity of the seamen. This attempt, however, induced the governor to direct particular attention towards that quarter of the garrison. Batteries for heavy metal were made on the rock above Parson's lodge, at Rosia; and orders were given to clear the new mole of shipping, that the ordnance might have more liberty to play. On the morning of the 1st of October. it was observed that the enemy had raised an *epaulement*, about six or seven hundred yards in advance of their lines. It was about thirty yards in extent, and was erected near the windmill, or tower, on the neutral ground, about 1100 yards distant from our grand battery. The garrison were at a loss to conceive what could induce the enemy to act in a manner so contrary to the usual mode of approaching a besieged place, by erecting a work so distant, and which had no connection with their established lines. But it now appeared evident, that they had determined on a more serious attack, in case the second blockade should prove unsuccessful. On the night of the 21st, the enemy threw sand in the front of their *epaulement*, to cover it from our fire; and on the 26th, they lengthened it to the west about thirty yards. The night of the 28th, they erected two large traverses in the rear for magazines. From the compact appearance of this new work, which was distinguished by the name of the Mill battery, the garrison concluded that it was intended for a mortar battery. On the night of the 17th of November, two *places d'armes* for musketry were thrown up on the flanks of the Mill battery; the parapets formed semicircles adjoining the battery, but afterwards extended, in an oblique direction, towards the lines. On the night of the 23d, the enemy began an approach from the lines to this battery, which they completed during the month of December. On the 12th of April 1781, the garrison, who for some time had been greatly in want of provisions and necessaries, was relieved by the arrival of the fleet under Admiral Darby. As soon as the van of the convoy had come to an anchor off the new mole and Rosia bay, the enemy opened a smart fire from all the batteries which bore upon the garrison. The fire was returned by the latter; and the bombardment was continued during the 13th and 14th. On the 15th and following days, it was continued with greater vivacity on the part of the enemy; but the batteries of the garrison discontinued their fire, and the guns at Willis's were drawn behind the merlons, to secure them against the enemy's shot. On the 16th, 18th, and 19th, the enemy's gun-boats attacked the shipping in the bay; but were obliged to retire, after doing some mischief. At this time, the batteries at Willis's exhibited a very disorderly and ruinous appearance; the merlons were considerably damaged, and some of the cannon dismounted and injured. The engineers and workmen were therefore employed in repairing them. The remainder of the month of April was remarkable for excessive rains, attended with most dreadful thunder and lightning, which, in addition to the fire from the enemy, had an awful and tremendous effect during the night. The bombardment continued warm and well supported, but apparently without any particular object on the part of the besiegers. In the month of May, their fire became more regular, and amounted, upon an average, to 1500 rounds in the twenty-four hours. Their cannonade was directed principally against our upper batteries. On the 23d, the gun and mortar boats renewed their attack upon the camp, with more dreadful effect than upon any former occasion; seven individuals within the garrison were killed, and twelve or thirteen wounded. The boats continued to repeat their vexatious visits during the month of June, and kept the garrison in a constant state of alarm, as experience had proved their destructive effects. The governor, therefore, resolved to retaliate, by endeavouring to annoy the enemy's camp from the old mole head, and this experiment was found to succeed. At the same time, some brigs were ordered to be cut down and converted into *prames*, which were to be moored between the new mole and Ragged Staff, at such a distance from the works as to be easily protected, and yet far enough out to keep their boats at a respectful distance.

e garrison again relieved by Admiral Darby, April 12th 81.

The enemy's gun and mortar boats make an attack upon the camp, May 23d, 1781.

The governor retaliates from the old mole head.

In the month of November, the besiegers had advanced so far in completing their approaches, and their batteries exhibited so perfect and formidable an appearance, that the governor thought the time was now come to strike a blow, which should frustrate all their views, by destroying these stupendous works, which had cost them such immense labour and expence. Having procured the necessary information from deserters, this important design, which had not been previously communicated to the garrison, was put in execution on the night of the 26th. A strong detachment was formed into three columns, and tools for demolishing the works delivered to the workmen. The destination of the columns having been made known to the different officers, and the necessary orders given, the detachment began its march, about a quarter before three in the morning of the 27th. The enemy, thus taken by surprise, and assailed with irresistible ardour, gave way on every side, and precipitately abandoned the works. The business was completed by the exertions of the workmen and artillery. The batteries were soon in a state for the fire-faggots to operate; and the flames spread with astonishing rapidity. In the course of an hour, the object of the *sortie* was fully effected; and trains having been laid to the magazines, the troops were drawn off. Not the smallest effort was made by the enemy to save their works, or avenge their destruction. Scarcely had the rear of the detachment got within the garrison, when the principal magazine blew up with a tremendous explosion; throwing up vast pieces of timber, which, falling into the flames, added to the general conflagration. This important object was accomplished with little loss on the part of the garrison. For some time the enemy did not think proper to take any measures towards extinguishing the flames; on the 30th their batteries continued burning in five different places; and when they ceased to smoke, the works seemed to be completely destroyed, nothing but heaps of sand remaining. In the beginning of December, they seemed as if suddenly roused from their reverie; upwards of a thousand men were at work, making fascines, &c. From these operations the garrison concluded that they were resolved to restore their works, when sufficient materials were prepared. For some months the enemy continued to repair their works, but apparently only for defence. In the month

The garrison make a sortie, and destroy the enemy's advanced works, Nov. 27th.

Gibraltar.

The besiegers resolve to attack the garrison from the sea, by means of floating batteries. May 1782.

of May 1782, it was discovered that the besiegers had a new plan of operations in view. On the 14th several of the large ships at Algeziras struck their yards and top-masts, and a great number of men appeared on board them; which circumstances led to the belief, that they were intended to be fitted up as *floating batteries*, for a grand attack to be made upon the garrison from the sea; and this opinion was confirmed in the afternoon, by their beginning to cut down the poops of two of them. The garrison, on the other hand, made various dispositions to repel this meditated attack. The works at Waterport were strengthened; an additional number of grates for heating shot were distributed along the line-wall; and the navy lowered their yards and top-masts, to be in readiness to act on shore at a moment's notice. In the month of June, the army of the besiegers was reinforced by a strong body of French troops; and the Duke de Crillon assumed the command of the whole. The Duke had recently returned from the conquest of Fort St Philip, in Minorca, and brought with him M. d'Arçon, a famous French engineer, who had projected the plan of attacking Gibraltar with battering-ships, constructed upon such principles, that they were considered as equally impregnable and incombustible. In the beginning of August, the enemy completed the first parallel of their approaches. On the 15th the Count d'Artois arrived in the camp of the combined army, to serve as a volunteer at the siege.

Dispositions made by the garrison to repel the attack.

The Duke de Crillon assumes the command of the besieging army. June.

The Count d'Artois arrives in the enemy's camp.

The advanced batteries of the besiegers again destroyed, by means of red-hot shot. Sept.

The enemy's works, on the land side, were now rapidly advancing to perfection; but being still in an unfinished state, and not sufficiently protected, it was judged proper to make another attempt to destroy them. Lieut. Gen Boyd, the lieutenant governor, recommended the immediate use of red-hot shot against the land-batteries; and General Elliott acquiesced in the proposal. Accordingly, on the morning of the 8th of September, a brisk fire was opened from all the northern batteries which bore upon the western part of the parallel, and was supported through the day with great vivacity. The effect of the red-hot shot and carcasses exceeded the most sanguine expectations. In a few hours, the Mahon battery, with the two-gun battery on its flank, and great part of the adjoining parallel, were on fire; and the flames, notwithstanding the enemy's exertions to extinguish them, burnt so rapidly, that the whole of their works were consumed before night. The St Carlos's and St Martin's batteries were likewise so much deranged, that the enemy were obliged to take down the greater part.

The combined fleets of France and Spain arrive in the bay. 12th Sept.

On the 12th, the combined fleets of France and Spain arrived in the Bay from the westward; and every thing now seemed to indicate the approach of the grand attack. The garrison of Gibraltar, at this time, scarcely consisted of more than 7000 effective men. The accumulated forces of the besiegers, on the other hand, assumed the most formidable and imposing attitude. There were assembled in the bay 47 sail of the line; ten battering ships, deemed perfect in design, and esteemed invincible, carrying 212 guns; innumerable frigates, xebeques, bomb-ketches, cutters, gun and mortar boats, and smaller craft, for disembarking men. On the land side were most stupendous batteries and works, mounting 200 pieces of heavy ordnance, and protected by an army of nearly 40,000 men, commanded by a victorious and active general, and animated by the immediate presence of two princes of the royal blood of France. About seven o'clock in the morning of the 13th, the battering-ships got under way, and stood to the southward, to clear the men of war; then *wore* to the north, and a little past nine, bore down in admirable order for their several stations, taking their places successively to the right and left of the admiral, who was moored in a two-decker about 900 yards off the King's bastion. They were permitted to chuse their distance without molestation; but as soon as the first ship dropped her anchors, the fire from the garrison commenced. The cannonade then became tremendous; which may be easily conceived, when it is considered that 400 pieces of the heaviest artillery were playing at the same moment. While the battering-ships attacked the garrison from the sea, the besieged were at the same time warmly annoyed by the flanking and reverse fire of the enemy's land-batteries on the isthmus. The latter, however, they totally disregarded, directing their undivided attention to the battering-ships. For some hours, the attack and defence were so equally well supported, as scarcely to exhibit any appearance of superiority on either side. The red-hot shot began to be used about twelve o'clock, but did not become general till between one and two. Incessant showers of hot balls, carcasses, and shells of every species, were now poured upon the enemy from all quarters; and as the masts of several of the ships were shot away, and the rigging of all in great disorder, the garrison began to entertain hopes of a speedy and favourable result. Smoke was observed to issue from the upper part of the flag-ship, which seemed to increase, notwithstanding the constant application of water; and the admiral's second was perceived to be in the same condition. Confusion was now apparent on board several of the vessels; in the course of the evening their cannonade gradually abated, and about seven or eight, it almost totally ceased. As the evening advanced, signals of distress were made to their friends on shore, and several boats were seen to row round the disabled ships. At this period, our artillery caused dreadful havoc among them. A little before midnight, a wreck floated in, upon which were 12 men, who alone escaped, out of threescore who were on board their launch. About an hour after midnight, one of the battering ships was completely in flames; and by two o'clock, she appeared as one continued blaze from stem to stern. Another to the southward was also on fire; and between three and four o'clock, other six indicated the efficacy of red-hot shot. The sea now presented a spectacle of horror; men crying from amidst the flames for pity and assistance; others, on board those ships where the fire had made little progress, imploring relief with the most expressive gestures and signs of despair; while several, equally exposed to the dangers of the opposite element, trusted themselves on various pieces of the wreck, in hopes of reaching the shore. Brigadier Curtis, with the marine brigade, humanely exerted himself in endeavouring to save as many as possible of these wretches; and he succeeded in bringing off about 350, many of whom were severely, and some of them dreadfully wounded. Meanwhile the flames reached the magazine of one of the battering-ships to the northward, which blew up about five o'clock with a terrible explosion. In a quarter of an hour afterwards, another in the centre of the line met with a similar fate. Of all these formidable floating-batteries, upon which the enemy had rested their most confident hopes of success, not one escaped destruction; and on the 14th of September, the patient and intrepid garrison had the satisfaction of contemplating one of the most signal and complete defensive victories on record.

Grand attack made by the battering ships. 13th Sept.

They are entirely destroyed by red-hot shot from the garrison.

Gibraltar.

Gibraltar relieved by Lord Howe, Oct. 1782.

The remainder of this celebrated siege presents few incidents of moment. About the middle of October, the garrison was relieved by Lord Howe, in the face of the greatly superior combined fleets of France and Spain. In the beginning of the month of February 1783, intelligence arrived of the signature of the preliminaries of a general peace; and thus terminated an enterprise, upon which the resources of France and Spain were lavishly but fruitlessly expended; an enterprise towards which the eyes of all Europe had long been directed in anxious expectation; and which, in its glorious result, threw additional lustre on the military character of Great Britain.

The siege raised on receiving accounts of the signature of preliminaries of peace, Feb. 1783.

Since the period of this memorable siege, no serious attempt has been made upon Gibraltar; nor is it likely, considering the greatly improved state of the defensive works, that any future attack will be attended with the slightest probability of success.

Description of the town and fortifications.

In an account of Gibraltar, a brief description of the town and fortifications will be thought necessary. The town is situated at the foot of the north-west face of the hill, and is irregularly fortified. It communicates with the isthmus by a long narrow causeway, (serving as a dam to an inundation,) which is defended by a curtain, with two bastions, mounting 26 pieces of cannon, a dry ditch, covered way, and glacis, well mined. These are strongly flanked by the King's, Queen's, and Prince's lines; works cut in the rock with immense labour, and scarped to be almost inaccessible. Above the lines are the batteries at Willis's, and others at different heights, until they crown the summit of the rock. These elevated batteries mount between 50 and 60 pieces of heavy ordnance, and entirely command the isthmus below. The Old mole, to the west of the Grand battery, forms also a very formidable flank, and with the lines, a cross fire on the causeway and neutral ground. This battery has been found so great an annoyance to the besiegers, that, by way of distinction, it has long been known by the appellation of the *Devil's tongue*. From the Grand battery, along the sea line, looking towards the bay, the town is defended by the North, Montague's, Prince of Orange's, King's, and South bastions. King's bastion is a very complete piece of fortification, commanding the bay from New to Old mole heads. It mounts twelve 32 pounders, and four ten-inch howitzers in front, ten guns and howitzers on its flanks, and has casemates for 800 men, with kitchens and ovens for cooking. Montague's is much smaller, mounting only 12 pieces of cannon, with a casemate for 200 men, communicating with the Old mole. In 1782, a cavalier, for two guns, was erected upon this bastion; and another work of a similar nature, for five guns, on the north bastion of the Grand battery. From the south bastion a curtain extends up the face of the hill, and terminates, at an inaccessible precipice, the works of the town. In this curtain is the south-port gate, before which and the south bastion is a dry ditch, with a covered-way and glacis. At the east end, above the gate, is a large flat bastion, connected with the curtain, and mounting 13 guns, bearing on the bay, &c. This work is covered by a demi-bastion, that joins the precipice. Above the precipice, an old Moorish wall is continued to the ridge of the rock; in the front of which a curtain with loop-holes and redans, built in the reign of Charles V. and called after his name, extends to the top, effectually cutting off all communication in that quarter. From the south bastion, a line-wall is continued along the beach to the New mole, where there is an irregular fort, mounting 26 guns. This line-wall is divided by a small bastion of eight guns, with a retired work in the rear, called the Prince of Wales's lines. Near the south bastion is a quay or wharf, called Ragged Staff, where the supplies for the garrison are usually landed. The communication to it is by spiral wooden stairs, and a draw-bridge opening into the covert-way; in front of which is a small work of masonry, mounting two guns. At the New mole head is a circular battery for heavy metal, joined to the mole fort by a strong wall, fraised; having a banquet for musketry, with two embrasures opening towards the bay. From the New mole fort to the north end of Rosia bay, a parapet is continued, and batteries erected, as situations dictate. The works at Rosia are strong, and act as flanks to each other; they are close along the beach, which is low, and have a retired battery of eight guns in the rear. From the south point of Rosia bay, the rock continues to ascend, by Parson's Lodge, to Camp-guard, and Buena Vista. In this direction, a line-wall is raised, with cannon at different distances. At Buena Vista there are several guns *en barbet*, which have great command; and the hill towards Europa, is slightly fortified. The rock then descends, by the Devil's Bowling-green, to Little Bay. At this post, which is entirely surrounded with precipices, there is a barbet battery, flanking the works to the New mole; from thence the rock continues steep for a considerable distance, when the line-wall and batteries recommence, and extend irregularly to Europa Point, the southern extremity of the garrison. A few batteries at Europa advance, and a post at the Cave-guard, terminate the works. But this part of the garrison is greatly strengthened, by the retired and inaccessible lines of Windmill-hill, which are situated within musket-shot of the sea, and have great command in that quarter.

Alterations and improvements since the siege.

Considerable alterations have taken place in the town and fortifications, since the celebrated siege. The town, indeed, was entirely destroyed at that period by the enemy's fire; but it has been since completely rebuilt, and greatly enlarged. The actual number of inhabitants, exclusive of the military, amounts to about 12,000. The British settlers constitute but a small proportion of this population, which is principally composed of Jews, Genoese, Spaniards, and Moors. The strength of the garrison generally consists of five regiments of infantry, six companies of artillery, and two companies of military artificers; in all about 4500 men. The fortifications have recently undergone great improvements. The Waterport front has been entirely rebuilt, and greatly strengthened, and carried farther out into the bay. The inundation at Landport has been carried close into the body of the rock by two deep ditches, so as to render the approach to the garrison from the land side completely inaccessible, except by the narrow causeway between the bay and the inundation. The upper batteries at Willis's have been entirely rebuilt and greatly improved, and a new magazine erected there. Extensive subterraneous galleries have been cut in the rock, with numerous embrasures in them, bearing on the isthmus and the causeway leading to the garrison. These batteries present a most formidable flanking fire, which it would never be in the power of a besieging army to silence. A new line of defence has also been erected at Europa Point, at the southern part of the rock, to guard against any attempts of an enemy to land in that direction. At Rosia Bay, immense naval storehouses have been built; and a tank has been sunk there, which is capable of containing water sufficient for twenty sail of the line for six months. A new pier

Gibraltar.

is also in the course of being erected there, extending nearly three hundred yards into the sea; which, when completed, will afford perfect shelter to four sail of the line, besides double that number of transports. The Spanish lines and forts, erected on the neutral ground, about a mile from the garrison, and which afforded great advantages to a besieging army, were blown up and completely destroyed by the British, on the 14th of February 1810, on the approach of a French force towards that quarter. The guns and stores were previously brought into Gibraltar. It is to be hoped that the British government will never consent to the restoration of these works.

Spanish lines and forts destroyed. 14th Feb. 1810.

Among the most remarkable buildings at Gibraltar, the remains of the old Moorish castle are the most conspicuous. It was erected by the Moors on their first invasion of Spain, and still retains the traces of its former magnificence. This antique structure is situated on the north-west side of the hill, and originally consisted of a triple wall, the outer inclosure descending to the water's edge; but the lower parts have been long since removed, and the grand battery and Waterport erected on their ruins. The walls, at present standing, form an oblong square, at the upper angle of which is the principal tower, where the governor or alcaide resided. A Moorish mosque still exists within the walls, in a state of entire preservation, having been used as one of the grand powder-magazines during the siege; and there is also a neat Morisque court, and a reservoir for water. The other principal buildings are the Convent, or governor's quarters; the lieutenant-governor's house, a modern structure; * the admiralty house, or naval provision store-house, † formerly a monastery of white friars; the soldiers' barracks, victualling-office, store-house, south barracks, and the navy hospital.

Remarkable buildings.

Mineralogical structure of the mountain.

The principal mass of the mountain of Gibraltar, consists of a grey, dense, calcareous rock, by mineralogists called primary marble; the different beds or strata of which may be examined, with great accuracy, in the north front, where there is a complete vertical section, of upwards of 1300 feet of the rock. The strata are from 20 to 50 feet in thickness, running nearly from east to west, and having a dip in that direction at an angle of about 35 degrees. This species of rock, when it occupies large districts, is always found to be cavernous. At Gibraltar, the caves are many, and some of great extent. The most remarkable is St Michael's cave, situated upon the southern part of the mountain, about 1000 feet above the level of the sea. The mouth is only five feet wide; but on descending a slope of earth, it widens considerably, leading to a spacious hall, incrusted with spar, and apparently supported in the centre by a large massy stalactitical pillar. To this succeeds a long series of caves of difficult access. The fossil bones which are found, of various sizes, in the rock of Gibraltar, have frequently attracted the attention of naturalists. It was formerly supposed that these bones existed in a petrified state, and were enclosed in the solid calcareous rock; but Colonel Imrie, who examined them with great attention, is of opinion that they have been swept, by heavy rains, at different periods, into the situations where they are now found, and having remained, for a long series of years, exposed to the permeating action of water, have become enveloped in, and cemented by, the calcareous matter which it deposits. And in confirmation of this opinion, he observes, that the appearance of these bones indicates calcination rather than petrifaction.

Caves.

Fossil bones.

Climate.

The climate of Gibraltar is temperate and salubrious, during the greater part of the year. From the circumstance of its being surrounded on three sides by the sea, the summers are generally cooler, and the winters milder, than on either of the neighbouring continents. Snow falls seldom, and ice is a rarity. Violent showers of hail, however, are not uncommon during the winter. Heavy rains, high winds, and most tremendous thunder, with dreadfully vivid lightning, are the usual attendants on December and January. The summer months are extremely warm; but the heat is frequently alleviated by a constant refreshing westerly breeze from the sea, which, from its invigorating and agreeable coolness, is emphatically called the *Doctor*. During an easterly wind, or a *Levanter* as it is called, the top of the rock is commonly covered with a heavy dense vapour, through which the sun is seldom visible. At such periods, the effects of the climate are peculiarly severe upon persons of delicate constitutions, particularly such as are subject to pulmonary or rheumatic complaints. Consumptions generally prove fatal.

Animals.

The summit of the mountain is inhabited by a large species of ape; an animal not to be found in any other part of Spain, and which is therefore thought to have been originally imported from Barbary by the Moors. Red-legged partridges are often found in coveys; woodcocks and teal are sometimes, though rarely, seen; and wild rabbits are caught about Europa and Windmill hill. Musquitoes are exceedingly troublesome towards the close of summer; and locusts are sometimes found. The scorpion, centipede, and other venomous reptiles, abound amongst the rocks and old buildings; and the harmless green lizard and snake are frequently caught by the soldiers, who draw their teeth, and treat them with fondness. The mountain of Gibraltar presents an interesting field to the botanist; as it connects, in some measure, the Flora of Africa with that of Europe. Colonel James, in his elaborate history of Gibraltar, enumerates no less than 300 different herbs, which are to be found on various parts of the rock

Botanical productions.

Trade and revenue.

The trade of Gibraltar is very considerable; that port being the great *depot* from which the neighbouring countries are supplied with British manufactures. During the last war, between four and five thousand square rigged vessels arrived there upon an average yearly. The imports from Great Britain, in some years, exceeded three millions sterling, being more than the whole of the exports to the West Indies. The expences of Sicily and Malta, and the money for the pay and maintenance of the British army in Spain and Portugal, were chiefly defrayed by bills drawn on the British government, and discounted by the merchants at Gibraltar; to the amount, it is believed, in some years, of 11 millions of dollars annually. The public revenues arise from the ground-rent of houses, the duties on wine and spirits sold in taverns, the licence-duties on wine-houses and taverns, and the auction duties; amounting, altogether, to about £35,000 sterling per annum.

Authors.

See Colonel James's *History of the Herculean Straits;* Colonel Drinkwater's *History of the Siege of Gibraltar*; *Annual Register*, vol. xxv. for 1782; Colonel Imrie's *Mineralogical Description of Gibraltar*, in the 4th volume of the *Transactions of the Royal Society of Edinburgh*.—For the information relative to the present

* This building was destroyed during the siege, and is still in ruins, having never been rebuilt.

† It has been since sold, and the provisions removed to the new stores at Rosia.

Gilbert.

state of Gibraltar, the writer of this article is indebted to the liberality of Colonel Wright, Commandant of the Artillery at Leith Fort, whose professional talents, and opportunities of observation, during a long residence in the garrison, render his communications on this subject peculiarly valuable. (z)

GILBERT, or Gilberd, William, an eminent philosopher and physician, was born at Colchester, in the year 1540, and was the son of the recorder of that town. After having attended the two English universities, he set out upon his travels, and graduated at some of the foreign universities. Upon his return to England, he settled in London in 1573, was admitted a member of the College of Physicians, and practised medicine with great success and reputation. His fame became so great, that he was appointed first physician to Queen Elizabeth, who generously allowed him a pension for the purpose of carrying on his philosophical experiments. He retained his pension and his office after the accession of James I. but he did not long enjoy the patronage of the new sovereign. He died on the 20th November 1603, in the 63d year of his age, and was interred at Colchester, where a handsome monument was erected to his memory by his brothers. His library, minerals, globes, and mathematical instruments, were left to the College of Physicians. His picture is placed in the gallery over the schools at Oxford. He appears to have been a man of tall stature, and cheerful disposition,

The reputation of Gilbert is founded on his work entitled, *De Magnete, magneticisque corporibus, et de Magno Magnete Tellure, Physiologia novo, plurimis et argumentis et experimentis demonstrata.* It appeared in London in 1600, in folio, and was afterwards reprinted in Germany. The following analysis of this admirable work has been given by our countryman, Dr Robison, and is too valuable to admit of abridgment.

"In the introduction, he recounts all the knowledge of the ancients on the subject, and their supine inattention to what was so entirely in their hands, and the impossibility of ever adding to the stock of useful knowledge, so long as men imagined themselves to be philosophising, while they were only repeating a few cant words, and the unmeaning phrases of the Aristotelian school. It is curious to remark the almost perfect sameness of Dr Gilbert's sentiments and language with those of Lord Bacon. They both charge, in a peremptory manner, all those who pretend to inform others, to give over their dialectic labours, which are nothing but ringing changes on a few trite truths, and many unfounded conjectures, and immediately to betake themselves to experiment. He has pursued this method on the subject of magnetism, with wonderful ardour, and with equal genius and success; for Dr Gilbert was possessed both of great ingenuity, and a mind fitted for general views of things. The work contains a prodigious number and variety of observations and experiments, collected with sagacity from the writings of others, and instituted by himself with considerable expence and labour. It would indeed be a miracle if all Dr Gilbert's general inferences were just, or all his experiments accurate. It was untrodden ground. But, on the whole, this performance contains more real information, than any writing of the age in which he lived, and is scarcely exceeded by any that has appeared since. We may hold it with justice as the first fruits of the Baconian or experimental philosophy.

This work of Dr Gilbert's relates chiefly to the loadstone, and what we call magnets; that is, pieces of steel which have acquired properties similar to those of the loadstone. But he extends the term *magnetism*, and the epithet *magnetic*, to all bodies which are affected by loadstones and magnets, in a manner similar to that in which they affect each other. In the course of his investigation, indeed, he finds that these bodies are only such as contain iron in some state or other; and in proving this limitation, he mentions a great variety of phenomena which have a considerable resemblance to those which he allows to be magnetical, namely, those which he called *electrical*, because they were produced in the same way that amber is made to attract and repel light bodies. He marks, with care, the distinctions between these and the characteristic phenomena of magnets. He seems to have known, that all bodies may be rendered electrical, while ferrugineous substances alone can be made magnetical. It is not saying too much of this work of Dr Gilbert's, to affirm, that it contains almost every thing that we know about magnetism. His unwearied diligence in searching every writing on the subject, and in getting information from navigators, and his incessant occupation in experiments, have left very few facts unknown to him. We meet with many things in the writings of posterior enquirers, some of them of high reputation, and of the present day, which are published and received as notable discoveries, but are contained in the rich collection of Dr Gilbert. We by no means ascribe all this to mean plagiarism, although we know traders in experimental knowledge who are not free from this charge. We ascribe it to the general indolence of mankind, who do not take the trouble of consulting originals, where things are mixed with others which they do not want, or treated in a way, and with a painful minuteness, which are no longer in fashion.

Gilbert, Gilding.

Dr Gilbert's book, although one of those which does the highest honour to our country, is less known in Britain than on the continent. Indeed, we know but of two British editions of it, which are both in Latin; and we have seen five editions published in Germany and Holland, before 1628.

We earnestly recommend it to the perusal of the curious reader. He will, (besides the philosophy), find more facts in it than in the two large folios of Scarella." *

Besides this work, there appeared a posthumous publication of Gilbert's, entitled, *De Mundo nostro sublunari Philosophia nova*, Amst. 1651, 4to. It was printed from two MSS. in the library of Sir William Boswell, and consists of an attempt to establish a new system of natural philosophy upon the ruins of the Aristotelian system. It was edited by the learned Gruter. Dr Gilbert invented two very ingenious instruments for ascertaining the latitudes of places without the aid of celestial observations. See Magnetism.

GILDING, is the art of ornamenting various articles, by covering them with a superficial coat of gold, to obtain the brilliant appearance of that valuable metal.

For some purposes the appearance is not the only object; for, in situations where wood or metal work is much exposed to the weather, gilding forms a more durable protection from decay than any kind of paint or varnish, as the gold, if well put on, is equally impenetrable to the sun, rain, wind, or frost.

Gilding is an art with which the ancients were acquainted, although they had not discovered the means of extending the leaves of gold to such a surprising de- Ancient gilding.

* See Robison's *System of Mechanical Philosophy*, vol. iv. Art. Magnetism.

gree as is done at present. From the information of Pliny we learn, that their thickest leaves were called *bracteæ prænestinæ*, because a statue of Fortune at Prænestina was gilded therewith. An ounce of gold formed 750 of these leaves, each being 4 fingers or 3 inches square: this is 9 square inches in each leaf, or 47 square feet very nearly for the whole ounce. The Romans employed thinner leaves, which they called *bracteæ questoriæ*. From the great malleability of gold, the moderns have discovered means by which it can be reduced to such extremely thin leaves, that, notwithstanding its high specific gravity, a given weight of gold can be made to cover a greater surface than any other metal. An experiment by M. Reaumur shewed the superficies of a grain troy weight of gold leaf to be 42 square inches and three-tenths. This is at the rate of 141 square feet per ounce, and the thickness of such a leaf has been estimated at the $\frac{1}{207355}$th part of an inch. Mr Boyle found that a grain might be spread to 50 square inches and seven-tenths. This gives 169 square feet for the ounce; and, by the same mode of estimation, the thickness would be only the $\frac{1}{248532}$d part of an inch. Gold is not at all liable, like other metals, to tarnish or oxidate by the action of the air or damp; and therefore this thin covering is very durable. It is not susceptible of any other decay or waste, than from those causes which produce friction or abrasion of the gilded surface.

Superficies of a grain of gold leaf.

Three kinds of gilding.

Gilding is performed either upon metals, or upon wood, leather, parchment, or paper; but three distinct methods are employed; the first called wash or water gilding, in which the gold is spread whilst reduced to a fluid state by solution in mercury; 2d, Leaf gilding, either burnished or in oil, is performed by cementing thin leaves of gold upon the work, either by size or by oil; 3d, Japanners gilding, in which gold dust or powder is used instead of leaves.

By amalgam.

Wash or water gilding.—The method of gilding by a solution of gold is only applied to metals. The gold is first dissolved or reduced to the consistency of a semifluid, by amalgamation with mercury. In this state, by the assistance of an acid, it can be spread or washed evenly upon every part of the surface of the article to be gilded; the mercury is afterwards evaporated by heat, and leaves a covering of pure gold, the thickness of which is inconceivably small, although forming a most perfect surface. By this method, brass ornaments, watch-cases, buttons, and jewellery of all descriptions, are made to represent gold. The latter branch of the art is carried to such a high degree of perfection, that the deception can only be detected by the weight of the article, by cutting into it, or by some chemical test.

Its applications.

A mixture of copper and brass is the metal most commonly employed for this kind of gilding: pure copper does not readily receive the mercury amalgamated with the gold; and, being of a soft and rather porous nature, requires more gold to produce an equally brilliant covering. About one-seventh part of brass, being mixed with the copper, renders it harder, and makes the gold spread very readily: brass itself will receive a very fine surface of gilding. The endeavour of the workman is, to make such a mixture of brass and copper as will produce nearly the same colour as the gilding is intended to have; for a great variety of shades in the colour of the gold can be produced by a subsequent process, after it has been laid on; but it requires less trouble to give the gilding the same colour as the metal which is beneath, than to make a different shade.

Proper metals for wash gilding.

In effect, the gold adheres to the metal by forming a very superficial amalgamation or alloy therewith; hence the gold will partake of the colour of the metal. A second coat of gilding laid on will have a greater appearance of pure gold, and will have a more durable brilliancy than an equal quantity of gold spread upon the metal at one process.

Silver takes a fine surface of gold, and of a yellow colour, unless it is gilt twice over, and coloured afterwards.

Iron and steel will not take the amalgam, as the mercury has no affinity for these metals.

Tin, zinc, lead, or other of the baser metals, are never gilded by amalgam: they would deteriorate the gold too much, nor would they bear a sufficient heat.

To amalgamate the gold for wash gilding, a small quantity is put into a crucible, or an iron ladle, with about six times its weight of mercury. The ladle or crucible should be rubbed on the inside with whitening, to prevent any waste; and being put upon a charcoal fire, and gently heated, the mercury will soon dissolve the gold. To assist the solution, it should be stirred with an iron wire. The heat should not be sufficient to evaporate the mercury, at least not until the solution of the gold is nearly effected; the heat may then be increased for a moment, till a vapour is seen to rise from the crucible. The amalgam being made, is thrown out into water, where a small portion of mercury will be seen to separate itself. This contains very little if any gold; but the real amalgam forms a small lump of paste, of nearly the same consistence with butter; but it will be observed to have particles of mercury intermixed with it. To remove these, the amalgam is twisted up in a piece of fine wash leather, and gently pressed with the finger and thumb: the mercury will pass through the pores of the leather, and leave the amalgam fit for use. In this state it is the colour of silver, without any appearance of gold, and does not contain more than twice the weight of mercury to that of the gold. The mercury which has passed through the leather, should be reserved for making future amalgam, as it will probably contain a small proportion of the gold.

Amalgam of gold and mercury.

Some workmen vary this process by heating the gold to redness, and heating the mercury to the point of evaporation; then, throwing the hot gold into the mercury, the amalgam is quickly effected. We do not know any difference of effect which should give the preference to either of these processes.

It is essential that both the gold and the mercury should be pure. The mercury of commerce is almost always adulterated with lead, which is very prejudicial to the gilding. It should be separated by distilling the mercury in an iron retort, with a gentle heat: this will leave the lead in the retort; or the mercury may be revived from cinnabar in a very pure state. Nothing can be gained by employing gold of an inferior quality, as it will always require a greater proportion to produce the same covering, and the brilliancy will be much impaired.

Material should be pure.

It has been recommended to grind the amalgam on a marble stone, or in a glass mortar, and to wash it continually with a solution of common salt in water. This will carry away a blackish colour, occasioned by the oxide of the mercury; and the washing is to be continued till it ceases to colour the salt and water. We have never met with any artist who practises this washing; for if the gold and mercury are pure, and the amalgam is not overheated, so as to oxidate the mercury, it will be unnecessary.

ilding.

Cleaning of metal,

The first circumstance to be attended to in wash-gilding, is to make the surface of the metal perfectly free from all scurf, tarnish, or oxidation; for the covering of gold upon the metal unites therewith by a kind of amalgamation, and forms a superficial alloy, which would be discoloured by the smallest coat of tarnish.

ickle.

The cleaning is performed by pickling the metal, in a solution of aquafortis and water: the strength of the solution is immaterial, except with respect to the time that the metal must remain in it. A quantity of acid, equal to one-fourth of the water, will clean the metal in a few minutes; but if weaker, is equally effective in a longer time: and if the article is accidentally left in the pickle for a long time, it will not be injured. For cheap and coarse articles, a strong solution of sal nixon, or sal ammoniac, is employed; and to render it more active, the metal is heated and plunged into it: this raises a black or brown oxide over the whole surface. It is then dipped in the pickle of aquafortis, which throws off a slight scale from the surface, and renders the metal clean at once; and it is put into clean water, to prevent the farther action of the acid from producing a tarnish before the gilding is performed.

Acid.

ratch-ush.

For the best work, the aquafortis pickle is used cold, and the cleaning is performed by the friction of a scratch-brush, formed of fine brass wire instead of hairs. The brush is sometimes made of a circular form, and mounted on a spindle, turned rapidly by the motion of a foot-wheel and treddle, in the manner of a lathe, whilst the work is presented to the brush. But for delicate work, such as the wheels and other parts of watches, a very delicate hand brush is used; and here it must be noted, that when the steel arbors of the wheels, or any other part of steel, are attached to the work, it must not be dipped into the pickle, but the pickle should be made stronger, and only the scratch-brush dipped into it, before the work is brushed with it. The steel must be frequently dipped into clear water during the brushing, to prevent the action of any acid which may touch it.

ckening metal.

To spread the amalgam perfectly upon the surface of the article which is to be gilt, an acid, called the quickening, is used. This is made of aquafortis, (nitrous acid) with a small quantity of mercury dissolved in it, so as to give it a milky whiteness. The article being dipped into this, attracts a coat of the solution of mercury, over the whole surface, in an instant; and with this preparation, the amalgam is applied with the pencil. This is a piece of flattened copper wire, fixed in a handle: it is occasionally dipped into the quickening, then touching the amalgam with it, it will take up a small quantity, which is rubbed upon the work, and spreads or flows in an instant over all the parts which have been touched by the quickening. The action of the quickening appears to arise from the greater affinity of the nitrous acid for copper than for the mercury; in consequence of which, the acid takes to the copper the instant it is applied upon it, and leaves the mercury precipitated upon the surface. This coating of mercury facilitates the spreading of the amalgam when it is applied, although it may be spread without it, by merely dipping the pencil into the aquafortis, then into the amalgam, and afterwards applying it upon the surface of the work. This is the method employed for delicate works, particularly where there are any parts of steel. Another method of applying the amalgam, is to mix it up in a cup or jar, with mercury and aquafortis, to the consistency of thin cream. Into this the articles are dipped, and become at once perfectly coated with the amalgam. We have seen this method used by a button manufacturer, and it succeeded very well, with scarcely any trouble; but it is only applicable on a large scale, for this amalgam will not keep long, because the acid turns the mercury black, by an oxide which will not pass off in the drying. They can only mix up, in this way, as much amalgam as they intend to use in a very short time. Without acid, the amalgam will keep any length of time.

lication ie amal-

Gilding.

Drying off stove.

The next step in the operation is the *drying off*, or evaporating the mercury. For this a small charcoal stove or oven is used: it is merely a square opening, surrounded by brick on every side, except the front, and a flue proceeds from the top. It is made of a size proportioned to that of the work intended to be dried in it. As it is not intended that the draught of air shall be rapid, the stove may be placed in the lower part of a chimney, which is open all round the stove, so as to admit part of the current of air to ascend into the chimney without passing through the fire; and the charcoal being laid upon a small stone hearth, without any grate, it does not burn away very rapidly. The front of the chimney should be closed by a window-sash, which draws up and down, leaving just room enough beneath for the gilder to put his arms and hands into the chimney, while he sees his work in the stove through the glass, which prevents his inhaling the pernicious vapour of the mercury. A drawing of an apparatus of this kind is represented in Fig. 9. of Plate CVII. Button, Manufacture, with an additional apparatus to condense and preserve the mercury dissipated by the evaporation. The gilder is generally seated before this stove, and holds the work in a pair of iron pincers, over the burning charcoal, till he sees it change colour from the white silvery appearance produced by the amalgam, to a gold colour, which gradually comes on as the mercury passes off.

Operation of drying off.

At the first application of the heat, before it is sufficient to make the mercury evaporate, the amalgam will be seen to grow more fluid, and flow as it were upon the surface. In this state it is liable to collect more to one part of the work than others, probably because the heat is not equal in all parts, but renders the amalgam more fluid in some places than in others.

Spreading the gold by a brush.

To counteract the effect of this tendency, a brush of soft hog's hair is frequently drawn over the work, to spread the amalgam perfectly equal over the whole surface. This is a part of the process which requires much attention from the workman; for if he does not spread it well, the parts where the mercury accumulates will form whitish spots when dry; and these spots will afterwards tarnish, and at length turn black, having very little of the gold laid upon them. A great deal depends upon the heat being very equally and regularly applied, until the mercury begins to dry off, and the amalgam becomes fixed. The common gilder's stove is very ill calculated to attain this equality of heat. If the work has any cavities or hollow parts, into which the amalgam is liable to be accumulated by the brush, it must be dislodged by shaking the work. The hair of the brush must be very soft and pointed, by rubbing it upon a piece of pumice-stone; and where there is any extent of surface to be gilt, the brush must be drawn in one direction, because it leaves a sort of grain, which will have a disagreeable appearance if it is not laid straight.

Gilding pan,

It is usual for the gilder to have a small iron pan, into which he puts a few of the pieces he intends to

Gilding.

gild, and places it upon the fire; and he takes them one by one with the tongs, out of this pan, to brush them, and then returns them to heat, whilst he brushes others: at last, to finish the operation, he holds them in the tongs over the hottest part of the charcoal; this completes the evaporation of the mercury, and leaves the gold of a dull yellow, or gold colour. Small articles of which there are a great number of the same size, such as buttons, rings of watch chains, &c. are put all together into an iron frying pan to heat, and when the mercury begins to flow, they are all together thrown out into a cap, in which they are shaken up, and well stirred about with a painter's brush. This operation effects the spreading of the gold with very little trouble. It should be repeated several times, and the heat brought on very gradually, which the pan admits of doing more conveniently than any other means. As the heat continues to increase, the mercury begins to evaporate, and soon leaves the amalgam, or rather the gold, fixed upon the surface. The work being now dried off, presents only a dull scarfy appearance; but being brushed by a few strokes of the scratch-brush, it assumes a polished surface. The brushing is done with small beer or ale grounds, which however contribute nothing more to the operation than to soften the strokes of the brush, and prevent the work having any appearance of scratches. If a thicker coat of gilding is required, the operation is repeated once or twice, and every time the colour will approach nearer to that of fine gold. The scratch-brush must be applied to clean the work between each gilding.

Gilding cap.

Colouring the gilding by heat,

The simplest mode of heightening the colour, is to hold the work over the charcoal of a small stove, similar to the gilders stove, and heat it till the colour increases. During the heating, if any spots appear of a different colour, they are touched with a stick dipped in aquafortis, which restores them. It is then thrown into a weak solution of aquafortis and water, which will discover any spots where the coating of gold is deficient. This method is supposed to act by making a perfect dissipation of the mercury; but we think it rather operates to produce a farther alloy or amalgamation of the gold with the metal upon which it is spread. The work being again polished with the scratch-brush, is finished unless a very high polish is required: it must be produced by burnishing with a blood-stone, using water to prevent the gold being rubbed off.

or gilder's wax,

When a higher colour is required, the work is covered with a composition called gilding wax; and being held over the fire till the wax smokes, and is on the point of inflaming, it is then suddenly cooled in water, and the scarf of the wax is cleared off by the scratch-brush and beer.

Gilding wax is compounded of bees wax and red chalk in equal quantities, with French verdigris and alum or green vitriol, which are added in small portions. The use of the wax seems to be only to flow, and carry the other ingredients to every part of the surface, and to determine the proper degree of heat to be applied. There is another preparation of sal ammoniac, nitre, green vitriol, and verdigris, in equal parts, which they use after the wax is cleared off, and they desire to produce a very high colour. It is spread over the work in a state of paste, to which it is mixed by urine, and heated till it smokes in the same manner as the wax. This composition may be used instead of the gilding wax; or, by repeating the application of the gilding wax two or three times, it will produce the same colour, which is a deep and brilliant copper colour, but very superficial, and wears off long before the gilding is worn away.

or saline preparation.

Dead colour.

Dead yellow is a preparation of gilding which presents a frosted surface, without any polish, and of a beautiful yellow colour. It is produced by a saline preparation like that above, but some yellow colouring matter is employed instead of the green verdegris. When the work is heated with this upon it, it is thrown into aquafortis and water, and the ebullition which this occasions produces the dead colour.

Improved stove for drying off.

The operation of drying off, as formerly practised, was very prejudicial to the health of the workman, who always inhaled the fumes of the mercury. The application of a glass front to the chimney in which the stove is placed, has obviated this inconvenience; but still the stove is not judiciously constructed with a view of producing a gradually increasing heat. A considerable improvement might be made by employing an iron box, or oven, set in brick-work, over a close fire, and surrounded by flues, in the same manner as a boiler. It should be open in front, and have two or three shelves within it. The whole stove should be inclosed within a chimney, with a glass window in front, and a sufficient draft up the chimney window to carry off all the fumes. In using this stove, the work should at first be laid on the top of the box, where it will be gradually warmed; then the workman removing it to the upper shelf, it would become more heated, and fit for brushing. When this is done, he should place it on the second shelf, which would produce a greater heat. Being again brushed, and afterwards placed on the bottom of the box or stove, the heat would be sufficient to complete the drying off.

Gilding iron.

Iron or steel, may be ornamented by wash-gilding, if the surface is first covered with copper, by dipping the iron into a strong solution of blue vitriol, (sulphate of copper.) Upon this the amalgam can be applied; but such gilding presents a very indifferent colour, and is not durable.

By burnishing.

Another method is, to spread a thin plate of gold upon the steel, then heating them both, and burnishing the gold down, it will adhere, but so slightly as to have but little durability; and the heat must be so considerable, that it frequently injures the temper of the steel.

By ether and gold.

In the Philosophical Magazine, vol. ii. a new mode of gilding steel is described, as being the same by which the Sohlinger sabres are ornamented. A solution of gold in nitro-muriatic acid, (*aqua regia*,) being poured into about twice as much ether, the latter will float upon the surface of the acid; but if shaken together, the gold will be taken up from the acid by the ether; which may then be separated, by pouring the mixture into a long glass funnel with the tube stopped, and when it is completely at rest, the tube being opened, will run off the acid; and being again stopped, will leave the ether, with gold in solution.

This solution of gold being spread upon the surface to be gilt, the ether evaporates and leaves the gold, which, however, does not adhere very strongly, but may be fixed, by heating the steel moderately, and burnishing the gilding down.

Leaf gilding.

Leaf Gilding.—It is so called, because the gold is laminated, by the operation of gold beating, into very thin leaves, which are cemented upon the article to be gilded, by gum, size, white of an egg, or drying oil. Leaf gilding can be applied on metals as well as wood; or, with an appropriate cement, it may be laid on any substance which presents a surface sufficiently even, and

Of two kinds.

free from pores. It is distinguished into burnished gilding and oil gilding. In the former, the leaves being cemented upon the work by gum or size, admit of being burnished or polished. This is sometimes called water gilding, because the size or gum is mixed up with water; but as this term is also applied to the wash gilding by mercury, it should be avoided, as tending to confusion. Oil gilding, is that in which the leaves are stuck on by fat or drying oil. The advantage is that it will bear the weather, but, on the other hand, it will not admit of being burnished.

Size. *Burnished Gilding.*—When this is laid upon wood, the surface must be prepared for it by a thin coating of size whitening, to fill up the pores, and make a closer ground for the gold leaf. The size used to mix up the whitening, is made from cuttings of parchment, or of glovers' leather. These must be gently boiled in water for several hours, till the water extracts sufficient size to form a jelly when it cools. This size is strained through a flannel to clear it from the cuttings, and fine powder of whiting is added, being stirred up with the size until it forms a coarse paint whilst hot, but will congeal into a very close solid substance when cold. With this composition when heated, the surface of the wood is coated or primed over several times, spreading it evenly with a painter's brush, and carefully laying it into all the hollows or cavities of the work where it is carved. Each coat should be suffered to dry perfectly before another is applied, and the last must be rendered as smooth and even as possible. For this purpose, it is brushed over with water before it is quite dry, and any lumps removed at the same time the whole surface is rendered closer. When perfectly dry, the priming of whitening must be examined to fill up the cavities, and the carved parts must be cut or scraped sharp with a knife, and polished up in parts with a Dutch rush. After this, the parts where the gilding is intended to receive a burnish, must be rubbed gently with a rag wetted with water. This produces a surface, which has a polish when dry.

The gilding size which is to cement the gold leaf, is now applied hot with a brush over all the parts intended to be gilt. This is made of the same size as before mentioned; but instead of the whitening, a mixture of bole ammoniac and tallow is ground together upon a marble slab; and, in order to render the mixture more easy, a little soap suds is put upon the slab. The size of parchment before mentioned, being diluted by double its quantity of warm water, this composition is added till it becomes as thick as cream. Some artists add black lead to the bole, at the rate of one-sixteenth of black lead; and instead of tallow, they use a mixture of equal parts of olive oil and bees-wax. Others add colouring matter, such as vermilion and fine yellow; but these are quite useless, if they intend to cover the work completely with gold. The gilding size is laid on in a thin coat, which is repeated when the first is dry, and sometimes a third time, which prepares the work for the application of the gold leaf.

The gold leaf is kept in small books, the leaves of which are rubbed with red chalk. To take up the leaves, and particularly the small pieces, the gilder has a small pair of tweezers made of two slips of cane, united together at one end by glue, so that they will spring open; but the ends, which are to take up the leaves, are cut extremely thin, though left sufficiently broad to take up the leaves by the corners without breaking them. The gilder is also provided with a cushion, upon which he spreads out the leaves when it is necessary to cut them to any particular size. The cushion is made of leather, stuffed with tow or wool upon a square board, which has a projecting handle to hold it by. To divide the leaves, a common pallet knife is used. The article upon which the gold is to be applied is placed in an inclined position, and the size is wetted by a camel hair pencil. This wetting renders the size sufficiently adhesive to cement the leaves, which are removed from the book, by sliding them upon the paper of the book with a squirrel's tail, until the edge of the leaf overhangs the edge of the paper. This overhanging edge is applied upon the sized work, and fastened down, by touching it with a piece of soft carded cotton wrapped up in a piece of fine linen. The gilder then withdraws the paper upon which the leaf lies, and thus spreads the gold upon the surface. This drawing away the paper from beneath the leaf extends the leaf in every direction, and lays it flat upon the work. If any folds or wrinkles appear, the gilder blows on the leaf, to press it against the paper, and cause a very slight adhesion, though sufficient to draw the leaf straight without tearing, which would not be practicable if it was pressed upon the paper by any other means than a current of air. This part of the operation requires much dexterity; and if the workman breaks a leaf, it must be taken up with the tweezers, which, indeed, are frequently requisite to place the leaves straight. It is very difficult to place a broken leaf sufficiently exact upon the size that no joint shall appear. The gilder endeavours to lay the leaf, by first fastening the top of it, or that edge which is most distant from him; then he withdraws the book downwards, and for this reason he begins the work at the top. In some cases the right or left hand side of the leaf must be first stuck on, and then the book must be withdrawn sidewise, to the left or right. The gold leaf being by these means spread on the work, is first pressed close by blowing upon it, and afterwards by dabbing it with a squirrel's tail, or with a ball of very soft cotton wrapped in a fine linen rag. The gilder does not wet a greater extent of the size than he can cover with gold before it becomes too dry; but if this happens, he wets it again, and thus procceeds until the whole is covered. The leaves are overlapped, to ensure that every part shall be covered; but, of course, the overlay is as little as the workman can make it.

Application of the leaves.

Any small spots which remain uncovered from deficient corners of the leaves, or other causes, are covered with pieces cut by the knife upon the cushion. The gilder reserves for this use those leafs which are broken in attempting to lay them on: They are removed from the book with the pincers. and laid upon the cushion. The pincers are likewise used to apply these pieces upon the work; but if they are very small, they may be taken upon the cotton dabber, when rendered damp by breathing upon it. These repairs should be performed as the defects occur, before the size becomes dry; but, if any escape, the size in the defective places must be carefully wetted by a camel hair pencil, the surrounding gold being preserved from the water. When all the work is covered, and sufficiently dry, it is brushed over with a large and soft hogs' hair brush, which takes off the loose gold; it is then minutely examined, and defects removed, by painting them over with shell gold mixed with gum-water. But for common work a colour resembling gold is used: it is composed of vermilion and yellow ochre, or red lead and Dutch pink, ground up with the white of an egg or isinglass size.

Burnishing. The gold remains only to be burnished by rubbing

Gilding.

it over with an agate fixed in a handle, or a dog's tooth. It is requisite to attend to the state of dryness of the work before burnishing: for if the size is not sufficiently dry, the gold rubs off or scratches; and if too dry, it is tedious to raise a fine surface, because the size becomes hardened with those small irregularities, which prevent the surface of the gold from presenting a polished surface.

Gilding in oil.

Gilding in oil.—This is used for work which is exposed to the weather, and is therefore performed on wood, lead, or other metals, and sometimes on stone.

Ground of paint.

The ground must be laid of oil paint instead of size, and whitening as for burnishing gilding. White lead is a very proper colour for the first coat; then a second coat of yellow ochre and vermilion mixed up with drying oil. This has a colour which will render any slight defects in the gold less apparent. If great nicety is required, the last coat of paint, when dry, should be rubbed smooth with pumice stone. In general this is neglected, because oil gilding is in almost all cases intended to be viewed at a distance.

Preparation of oil size.

The surface, thus prepared, is ready to receive the fat oil size, by which the gold leaves are to be cemented upon it. This is prepared from linseed oil, exposed to the weather in a large flat pan, which is filled five or six inches deep with water, and the oil is poured upon the water about an inch deep. It should be placed where it will receive the action of the sun and rain for five or six weeks in summer. This will cause the oil to become thick like treacle, and some impurities will descend into the water. The oil is then to be taken off the water, well separated from it, and poured into a long phial, which is to be heated until the oil becomes perfectly fluid, by the settlement of the foul parts to the bottom. The clear oil size is then to be poured off, and strained through flannel. To render the oil fit for use, it is ground to a thin paint with yellow ochre. A coat of this paint or size is brushed over the surface which is to be gilt, but if found too thick to work well, it must be mixed up with drying oil.

Sizing the work.

Great care must be taken to cover every part, and to render this very certain, a second coat may be spread over the first, after it is dry. The gold leaves are applied upon this second size, when it is in such a state of dryness, that, on touching it with the finger, it feels strongly adhesive, but at the same time does not come off upon the finger.

Gilding.

The gold is applied by the same means as before described for burnished gilding, and after becoming dry is brushed over to remove the superfluous gold. If this operation produces any spots, they must be retouched with the size, and fragments of gold applied where it is requisite.

Leaf gilding on paper, &c.

Leaf Gilding, on paper or vellum.—This is extremely simple, as the surface requires no other preparation

By gum size.

than a wash of dilute gum water, or isinglass size. Upon this the leaves of gold are laid, when it is in a certain state of dryness, which must be known by practice: if it has become only a little too dry, it may be sufficiently damped by breathing on it. When the surface is covered with gold, it can be burnished with an agate, or dog's tooth.

Gilt letters.

Gilt Letters.—If it be required to gild manuscript writing, a strong size must be used for writing, instead of ink: it is made of gum ammoniac dissolved in

Writing size.

water previously impregnated with a little gum arabic, and some juice of garlick: this forms a fluid of a milky colour, which will flow very readily from a pen, or it can be laid on according to any design by a camel-hair pencil: it may be suffered to dry, and then, by breathing upon the paper, the size will be softened sufficiently to receive the gold, which is applied in leaves in the same manner as for any other kind of gilding. The superfluous gold being removed by a brush, the writing is found covered, in its finest strokes, with gold which may be burnished. Gold letters for shop fronts, &c. are painted in oil size, by the process of gilding in oil.

Printi[ng]

Printing in gold may be performed by beating up the white of eggs to a proper consistence, to mix with vermilion, and make a thick ink; with this the paper or vellum must be printed, and the gold applied in leaves, as before directed.

Gildi[ng let]ters b[y] gold.

A different method is sometimes employed to ornament paper with gilt letters. This is to use printing ink, composed of strong gum water; and the letters, after being printed with this, are sprinkled over with very fine powder of crystal or glass, so as to form when dry, a kind of sand or glass paper upon the form of letters. To gild these parts, it is only requisite to rub them over with a piece of solid gold, and the sharp angles of the crystal will cut off sufficient gold to gild the writing, which will be very brilliant from the reflexions of the crystal. It has been recommended to employ stamps for the printing, in which the letter shall be engraved or sunk, instead of being raised as in printing types. The sunk parts of these letters are to be filled up with an ink composed of gum, or whites of eggs, and the raised surface being kept clean, the stamps when applied upon the paper and pressed, will leave the mixture upon the paper in the form of the letters, engraved upon the face of the stamp, and considerably raised. The gilding is performed when the mixture is dry, by rubbing it with a piece of gold as before directed.

Gold on bo[oks].

Book-binders imprint gold letters on the backs of books, without any size, by means of brass types, which are cut the same as printing types; these are made hot in a charcoal fire, and are pressed upon the place where the letters are to be, over which a leaf of gold has been previously spread. The heat and pressure causes the gold to adhere to the leather, where the type was applied, but the gold brushes off from the other parts. Scrolls and all kinds of ornaments are impressed in the same manner; but when a length of bordering is required, the impression is engraved on the surface of a small roller, which is used hot, in the same manner as the types.

Gilt e[dges of] paper.

In order to gild the edges of the leaves of books, or writing paper, they must be strongly screwed in a press, after being cut as smooth as possible, and the edges sized with isinglass glue, mixed up with spirits of wine. The gold should be laid on when the size arrives at a proper degree of dryness.

The French workmen employ a ground of bole ammoniac, mixed up with powdered sugarcandy, by means of white of eggs. This is laid very thinly upon the edges, after isinglass size or gum has been applied. when the ground is dry, it is rubbed smooth with a wet rag, and this moistens it sufficiently to take the gold.

Japann[ers'] gildin[g].

Japanners' Gilding.—Gilding with gold powder is only used where the appearance of frosted gold is desired. The powder is sprinkled upon the article after the cement has been laid on. This method is not so durable as leaf-gilding, that is, it requires a greater proportion of gold to form an equally effectual covering by this means; for this reason it is generally covered with a coat of varnish, and is hence called *japanners' gilding.*

To reduce the gold to powder, two different means ilding.

reparation the pow- r by aqua gia,

may be employed; one by precipitation, and the other by grinding. For the first, any quantity of pure gold is put into a glass containing about eight times its weight of aqua regia, (nitro-muriatic acid). The gold will more readily dissolve, if it is either beat out into thin plates, or divided into small grains, by pouring it into water when melted. A gentle heat being applied, will facilitate the progress, and by occasionally stirring it with a glass rod, the gold will be wholly taken up. A solution of sulphate of iron or green vitriol, in about eight times its weight of water, is made at the same time, and if it leaves any sediment, it must be separated and rendered clear.

d sul- ate of in,

To precipitate the gold in a state of powder, a small quantity of the solution of sulphate of iron is poured into the glass containing the solution of gold, and a red powder immediately falls to the bottom from the nitro-muriatic acid, leaving the gold to unite with the iron of the vitriol, for which it has a greater affinity The fluid must be now poured off, and leaves the bright gold powder at the bottom of the glass, which is then to be filled with clean water, and the powder stirred up to wash it from any remains of acid. It will soon settle again, and the water must be poured off to leave the powder as dry as possible. The remaining water is evaporated, by exposing the powder in the air upon a piece of glass.

by mer- ry,

Another method of producing gold powder, is to form an amalgam of gold with mercury, by the same process as described for wash-gilding, namely, heating the gold to redness, and throwing it into mercury, heated nearly to its point of evaporation. The gold forms an amalgam with the mercury, and after being separated from the superfluous mercury, by passing through a piece of leather, the amalgam is put in a crucible or a glass, and exposed to a sufficient heat to evaporate the mercury, and this leaves the gold in a fine yellow powder. For this method, the mercury must be quite pure, and free from any admixture of lead, otherwise the powder will be found in lumps, and discoloured.

by grind- i.

Gold may be mechanically reduced to a powder by grinding leaves of gold with a muller upon a marble stone, and working it up with fine clear honey. The fragments brushed off by the leaf-gilders will answer this purpose, and the grinding must be continued until the gold forms a perfect yellow paste with the honey. This paste being thrown into water, the honey is taken up by it, and the gold settles in a fine powder. It must be repeatedly washed till the honey is quite separated, and then the powder is dried. This does not produce so brilliant a powder as the former means, because the particles of gold are bruised, and rendered dull by the action of the muller and stone.

Japanners'

The cement or size used for japanners' gilding is composed of linseed oil and gum. The oil is boiled, and whilst upon the fire, pieces of gun anime being put in, will be dissolved. The proportion of gum should be about one-fourth (by weight) of the oil; the mixture is boiled till it is reduced to the consistence of tar, and then strained through a cloth. When wanted for use, it must be ground with vermilion, adding as much oil of turpentine as will make it work with a brush. Some gilders add to the above composition asphaltum, red lead, and umber. These ingredients are pounded and mixed with the gum, before it is put into the oil. Such additions give the size a good colour, which is more necessary in gilding with powder than for leaf gilding, because the size appears in innumerable small specks, which will diminish the lustre of the gold unless the size is of a brilliant colour.

Gilding.

Operation.

The operation of gilding with powder, is nothing more than to paint the work over with the size, mixed up with oil of turpentine; and when the size is so far dried that it feels adhesive without coming off when touched with the finger, the gold powder is applied, by dipping a piece of soft wash leather into it, and daubing it upon the work. When the work is small, it is best to strew the powder upon it, and shake off the superfluous gold.

Gilding upon porcelain or glass.

by gold powder.

Gilding upon Porcelain or Glass.—The gold is reduced to a fine powder by any of the means described under japanners' gilding, and mixed with borax, adding as much gum water as will make it work with the pencil, with which it is to be laid upon the porcelain or glass; it must then be subjected to a sufficient heat to make the enamel soft, to which the borax contributes very much. This fixes the gold, and it can afterwards be burnished; or leaf-gold may be laid on with gum water, and fixed by burning. Borax is sometimes mixed with the gum.

or leaf-gold.

To gild upon glass without burning, a cement or size may be made of amber, melted in drying oil, and boiled to a strong consistence. It must be tempered for working with the pencil by oil of turpentine, and laid on the glass or porcelain, and the gold leaf spread over it. When perfectly dry, it will bear a careful burnishing, and is durable.

False or imitative gilding.

Dutch leaf

varnished.

False or Imitative Gilding.—Wash gilding cannot be imitated; it must, as we have before mentioned, be of pure gold. Leaf gilding may be done in Dutch leaf, which is made of copper covered with gold upon its surface, by the wash gilding process, and afterwards beat out in the same manner as the gold; but the leaves are much thicker, because there is little inducement to reduce them so far, and they are more easily laid on. When first done, this work has all the appearance of true gold, but soon tarnishes by the air, and any dampness will produce spots in it; if secured by a transparent varnish, it preserves its beauty as long as the varnish lasts, and in this case becomes a very good substitute. The proper varnishes are made of mastic sandarac, white resin, or copal, these alone being sufficiently white and transparent.

Silver or tin foil.

Silver leaf and tin-foil are made to represent gold, by covering them with a varnish or lacker of white resin, gum-sandarac, aloes, and red lead, mixed up and boiled with linseed oil. See *Gilding on Leather.*

False gilding upon leather.

For hangings.

False Gilding upon Leather. This is an art which was formerly practised very extensively for the hangings of apartments. At present it is scarcely known, but some very fine specimens which remain perfect, after being in use for a century, shew that it is a most durable kind of furniture for rich apartments. In the French *Collections des Arts et des Metiers*, the following account of this art is given. "The leather of calf skin is preferable to any other; the skins are softened in water, then beaten on a stone, and curried out to their greatest extent whilst wet; when dry they are cut square, and all reduced to the same size; after which, if any skins are defective, they are pieced with the fragments, which are joined by glue; the edges of the joints being pared away so as to make no increase of thickness. The grain side of the leather is now rubbed over with a piece of size, whilst in a state of jelly; and before this size dries, leaves of silver are laid on in the manner before described of the gold leaves for burnished gilding. When

Sizing the leather.

Silvering.

Gilding, Gilolo.

covered with silver, the skins are dried till they are in a proper state for burnishing, which is done by a large flint fixed in the middle of a wooden handle: the workman holds it with both hands, and forcibly rubs upon the silver till it becomes brilliantly burnished. The appearance of gold is now given to the silvered surface, by covering it with a yellow varnish or lacker, which is composed of white resin four pounds and a half, common resin the same quantity, gum sandarac two pounds and a half, and aloes two pounds. These ingredients are melted together in an earthen vessel, and after being well mixed by stirring, seven pints of linseed oil are poured in, and when the composition is sufficiently boiled to make a perfect union, and to have the consistence of syrup, half an ounce of red lead is added, and the liquor is passed through a flannel bag.

Burnishing.

Varnish.

To apply this varnish, the silvered skins are spread out upon a board, and fastened down by nails: These are exposed in the sun, and when thus warmed, the white of an egg is spread over the silver. After this is dry, the workman lays on the varnish, by spreading it with his hands till he covers the whole. The varnish will dry in the sun in a few hours, and is very durable. When the gold is desired to be laid according to any design, the varnish is printed upon the surface of the skin by a wooden block and a rolling press. By this means only the printed parts will appear to be gilt, the others remaining in silver as a ground, and are frequently painted in oil colours.

Printing.

False gilding for picture frames and other similar ornaments, may be performed with silver laid on in the manner described for burnished gilding, and the above varnish laid on after it is burnished: as the varnish preserves it, tin-foil answers almost as well, except that it will not bear too fine a burnish.

By tin-foil.

False Gold Powder, is made by melting tin, and pouring into it about half as much mercury. The amalgam thus produced must be pounded and mixed up with sal ammoniac and sulphur, each in weight about half the tin. The composition being calcined in a matrass, will form a bright-gold coloured powder, which answers very well for japanners, but will not keep its colour unless it is covered by a varnish. For farther particulars relative to this art, see *Handmaid to the Arts*; Lewis's *Commercium Philosophico Technicum*; and the *Circle of Mechanical Arts*. (J. F.)

False gold powder.

GILOLO, or Halmahera, one of the Spice Islands, is a large and singularly shaped island, which divides the Indian Ocean from the great South Sea to the east. It is composed of four peninsulas, separated from each other by deep bays. The equator passes through the island, and a meridian 126° east of Greenwich. Its average breadth is about 30 miles, and its length 220. The western side of the island is nearly straight, and the peninsulas extend towards the east.

The principal towns in the island, are Ossa, Maba, Patany and Weda; but they are little known, as they are seldom visited by Europeans. There is a fine watering place on the south side of the Bay of Ossa, where vessels may procure water and refreshments; and on some of the islands excellent timber for spars may be obtained.

Gilolo is naturally fertile. It abounds with bullocks, buffaloes, goats, deers, and wild hogs. The latter frequent the places where the sago trees have been cut, and get very fat upon the remains of it. The inhabitants subsist chiefly on the sago tree. It is a long tube of hard wood, about two inches in diameter, containing a pulp mixed with longitudinal fibres. The sago flower is procured from this pith, and large quantities of it may be obtained here at a very reasonable rate.

Gilsland.

The inhabitants carry on a considerable trade in their proas with Amboyna and the adjacent islands. They import cutlery, scarlet cloth, china ware, gold lace, iron in bars, opium, piece goods, and steel; and for these they exchange mats, nutmegs, mace, cloves, beech de mer, birds nests, pearl shells, seed pearl, and tortoise shell.

The Dutch were formerly masters of this island, but it is now in the possession of independent rajahs. See Forest's *Voyage*; Hamilton's *East India Gazetteer*; and Milburn's *Oriental Commerce*.

GILSLAND, is a watering-place in Cumberland, much resorted to in the summer season, chiefly on account of its sulphureous mineral waters. It is situated on a steep bank of the river Irthing, about two miles north of the road leading from Carlisle to Newcastle, and is about eighteen miles distant from the former place. The water issues out of a thin bed of argillaceous shiver, reposing on a stratum of indurated argil, through a small leaden pipe, at the rate of about two gallons and a half per minute. It exhales a strong sulphureous odour, which may often be distinctly perceived at the distance of forty or fifty yards. When first drawn from the spring, it is transparent and colourless, but becomes turbid on exposure to the air, and gradually loses its fœtid smell. As the properties of these waters were till late years but little known, Dr Garnet, formerly professor of natural philosophy and chemistry in the Royal Institution, undertook a series of experiments, of which the following were the principal results: A solution of acetite of lead, dropped into the water, produced a very copious brown precipitate, which afterwards changed to black. A similar change was produced in it by nitrate of silver. An infusion of litmus was converted into a red. Polished plates of silver or lead, immersed in the water, soon became tarnished, and lost their metallic lustre. Muriate of barytes, oxalic acid, and tincture of galls, produced no apparent change. When the gaseous products were expelled by boiling for about ten minutes, acetate of lead and nitrate of silver produced a white precipitate, but muriate of barytes and oxalic acid no effect. A wine gallon of this water evaporated slowly, yielded four grains of muriate of soda. From these experiments it is evident, that this water is impregnated with sulphuretted hydrogen, and carbonic acid gas in combination with muriate of soda. In respect of chemical composition, therefore, it has a striking resemblance to the sulphureous waters of Moffat. Besides these saline and gaseous ingredients, the Gilsland waters, like those of Buxton and Harrowgate, contain a considerable portion of nitrogen or azotic gas. A wine gallon, English measure, of the Gilsland waters, yielded four grains of solid matter, and twenty-five cubic inches of elastic fluids, viz.

Of muriate of soda four grains.

Of sulphuretted hydrogen gas	17	cubic inches.
Of azotic or nitrogen gas . .	4	
Of carbonic acid gas	4	
	25	

Gilsland has been long celebrated in the northern counties of England as a place of fashionable resort, and for the efficacy of its suphureous waters in the cure of certain nervous and bilious complaints, in diseases of the digestive organs, dyspræda, hypochondriasis, and also in scrofulous affections. Taken internally, in doses of from half a pint to two or three quarts (English measure) in the morning, it generally acts very powerfully as a diuretic, increases the cuticular discharge, and, from the moderate stimulus of the carbonic acid, increases the appetite, and promotes digestion. But these waters often produce a degree of constipation which ought to be carefully obviated, otherwise a disagreeable giddiness and head-ache comes on. Externally applied in the form of warm bath, it has been employed with considerable advantage in herpetic eruptions; and particularly in those morbid derangements of the dermoid texture, psoriasis, and lepra, which are referred by Dr Willan to the order Squamæ, in his admirable treatise on cutaneous diseases. Locally applied, it is also used to remove contractions and pains in the joints from strains or hard glandular tumours, and is a valuable remedy in chronic rheumatism. Though the sulphureous water is resorted to and chiefly drank at Gilsland, there is a fine chalybeate situated on a moor, at no great distance from the former spring. The water sparkles when poured into a glass, has a strong styptic taste, and deposits a copious yellow sediment. A wine gallon of this chalybeate, according to Dr Garnet, contains

Of iron	$2\frac{1}{2}$	grains.
Of muriate of soda	3	
Of carbonic acid	14	cubic inches.
Of azotic gas	5	

From this analysis, it would appear that this mineral water, if properly administered, might prove a useful remedy in all cases where chalybeates are indicated. (J. S.)

GINGEE, is a town and fortress in the Carnatic, and the capital of a district of the same name.

The fort is situated on a stupendous and almost impregnable rock, and has always been considered by the natives of India as the strongest in the Carnatic. The climate is very unhealthy; and the French are stated to have lost 1200 troops during the 10 years in which it was in their possession, although they never kept more than 100 Europeans. It is situated 82 miles south-west from Madras, and 37 north-west from Pondicherry. East Long. 79° 34′, and North Lat. 12° 15′.

GINGER, is the root of a plant which grows spontaneously in the East and West Indies, and in China. It flowers about August or September, and fades about the end of the year. When the stalks are withered, the roots are dug up, commonly in January and February, and are picked, cleansed, and gradually scalded in boiling water. They are then dried by exposure to the sun, and form what is called *black ginger*. White ginger is the very same root, but in order to produce it, the roots are not scalded, but are picked, scraped, separately washed, and dried very carefully. Ginger is generally sold in knotty, branched, and flattish pieces, and is of a pale colour and fibrous texture, when stripped of the outer bark. It should generally be chosen in large roots, new, and not easily broken; its colour should be of a light brownish green, and it should be resinous within, and of a pungent aromatic taste. The dark, soft, and fibrous kind, should be rejected. Sometimes it is imported green from Bengal. Preserved ginger is brought from the West Indies and China, but the former is preferred. It is brought home in large and somewhat transparent pieces, of a bright yellow colour. The jars which contain it should be carefully sealed up.

The following Table contains the quantities of ginger imported and sold by the East India Company, from 1804 to 1808. Sixteen cwt. of dry and 20 cwt. of green ginger are allowed to the ton. The permanent duty is 14s. 6d. per cwt. and the war duty, 4s. 10d.

Years.	March Sale.		Sept. Sale.		Total.		Average per cwt.

See Lewis's *Materia Medica*, and Milburn's *Oriental Commerce*.

GINGOULPH, St, is a large village of Switzerland, situated on the extreme frontier of the Lower Vallais, upon the lake of Geneva, and at the foot of a rugged mountain, from whose summits, called the *Dents d'Oche*, about 5655 feet high, the environs of Geneva can be distinctly seen at the distance of ten leagues. The village is divided into two parts by a torrent, which issues from the valley of Oche, and forms the boundary between Savoy and the Vallais. The road from Evian to St Gingoulph, was formerly only a foot path, but the French government cut a magnificent road out of the rock, which has been open to all sorts of carriages since the 6th of December 1805. The lime of St Gingoulph is esteemed the best in this part of Switzerland. See Ebel's *Manuel du Voyageur en Suisse*.

GINSENG, is the name of a root which constitutes one of the principal medicines of the Chinese and Tartars. It grows chiefly in Chinese Tartary, and also in several parts of North America, from which it is sent to China. This trade to China was carried on by the French in 1750, and subsequently by the English; but since the Americans established their independence, they have carried it direct to China. The American root seldom exceeds the size of the little finger. It is frequently forked, and is of a horny texture, and a yellowish-white colour. The large roots, which are sound, fresh-coloured, and not very tough, are those which should be chosen for the Chinese market. In the year 1709, the Emperor of China sent an army of 10,000 Tartars in search of this root, on condition that each soldier should give him two catties of the best, and sell the rest for its weight in silver. By this means the Emperor gained 20,000 catties in one year.

GIORNICO, called *Irnis* by the Germans, is a town of Switzerland, situated on the Tesino, at the mouth of the Lower Levantine valley. It stands 1098 feet above the level of the sea, and 462 above that of the Lake Maggiore. The village, which is divided into two parts by the Tesino, is encircled with superb chesnut trees, some of which are more than thirty feet in circumference. Near the bridge are the remains of an old castle, which is supposed to have belonged to the ancient Gauls; and in the east are the ruins of a tower built in 940. This town is celebrated by the battle which 600 of the Swiss confederates, under Henry Troger, gained over 15,000 of the Milanese, under Borelli, in 1478. More than 1500 of the Milanese were killed, and most of their cannon, horses, and mules taken. Several of the cannon were kept at Giornico till 1798.

GIPSIES. See GYPSIES.

GIRGENTI, or AGRIGENTI, is a town of Sicily, Gironde || Gizah.

built on the spot which was formerly occupied by the citadel of Agrigentum. It is situated on a mountain on the river St Blaise, at the distance of about three miles from the sea. The streets, on account of their steepness, are impassable both for carriages and mules. The harbour of Girgenti is liable to be filled up by the south-east and north-west winds. The erection of two piers having failed to remedy this evil, the harbour is constantly clearing by galley slaves. The great magazines of the Caricatoria are large excavations in the solid rock, in which great quantities of corn are preserved without the least injury. There is constantly in these magazines 80,000 salmes of grain, a salme being that which is sufficient for the annual nourishment of one man. The magazines belong to the king, who is accountable for the corn lodged in the caverns. The proprietors pay a small sum for store-house rent. Foreign merchants come to Girgenti to purchase the surplus grain, when a sufficient quantity has been reserved for the home consumption. See AGRIGENTUM; and CIVIL ARCHITECTURE, p. 601, 602. (*j*)

GIRONDE, is a department in the south of France, bounded on the north by that of the Lower Charente, on the west by the sea, on the south by the department of the Landes, on the east by that of the Lot and Garonne, and by Dordogne. Its superficial extent is about 11,270 square kilometers, or 571 square leagues. It is watered by the rivers Dordogne and Garonne, and the Gironde, which is formed of the other two when united near Bec-d'Ambez, where they form a vast bason, or rather an arm of the sea, capable of receiving the largest ships. This department has more a commercial than an agricultural character. The districts of Blaye, Libourne, and Bazas, are very fertile in corn, while that of Bourdeaux produces the finest wines, of which 100,000 tons are annually exported, independently of what is consumed in France. One of the cantons of Esparse, near the sea, produces the celebrated wines of Medac. The best red wines are those of the Bordelais, Haut-Brion, and St Emelion; and the best white wines those of Sauterne, Langon, and Barzac. The other productions of the province are, brandy, wood, cork, turpentine, cattle, and fish. The following are the principal towns:

	Population.
Bourdeaux	112,844
Libourne	8,076
Bazas	4,215
La Reole	3,808
Blaye	3,580
Lespare	800

The forests occupy 100,000 hectares, or about 200,000 acres, of which three-fourths belong to individuals. The contributions in the year 1802 were 5,835,053 francs. Population 519,685.

GIRVAN. See AYRSHIRE.

GIZAH, DJEZA, GIZE, or JIZA, is a town of Egypt which stretches along the west bank of the Nile, and is supposed by Dr Shaw to occupy the site of the ancient Memphis. It is surrounded with walls of great extent, about ten feet high and three feet thick. They have only one gate, and six half moons, and are intended to resist the attacks of cavalry. Ismael Bey, who fortified the town, built a palace in the southern quarter of the city. There is here a cannon foundery established by Murad Bey, and a manufacture of sal ammoniac. Splendid country houses, with gardens, are built to the north-east of the city. The ground under the calcareous mountains, to the east, is filled with tombs. The town is surrounded with numerous date trees, which give it a fine appearance at a distance, when intermixed with the lofty turrets of the mosques. Gizah is the nearest town to the principal pyramids, which are called the Pyramids of Gizah. They are distant only about three leagues from the town. See Brown's *Travels in Africa*; Savary's *Letters*; and Sonini's *Travels in Egypt*. See also EGYPT and PYRAMID.

Glacier

GLACIERS, *Gletscher* in German, is a name given to extensive fields of ice and indurated snow, which occur in elevated mountainous districts, but particularly in the Alps of Switzerland and Savoy.

Position of the glaciers.

In all elevated countries, where the mountains rise above the line of perpetual congelation, their summits and flanks are covered with eternal snow. The snow which falls on these lofty regions at different seasons of the year, continues nearly in its original state, being converted into a substance of an intermediate character between snow and ice. On the sides of the mountainous declivities, there is more ice than on the summits; but still these fields of indurated, or of half-congealed snow, are by no means entitled to the name of glaciers, although they have been very improperly called the Upper Glaciers by an intelligent traveller.

The real glaciers are those accumulations of ice and snow which occupy the high vallies between individual mountains, generally far below the line of perpetual congelation, and extend themselves into the cultivated vallies which border upon the great chain. These glaciers are commonly encircled with lofty mountains; they stretch from north to south, and very few have an easterly or a westerly direction.

Description of a glacier.

The general character of a glacier depends upon the nature and state of the valley in which it lies. When the sides of the valley are smooth, and its inclination small, there is little variety in the appearance of the glacier. It presents a tolerably smooth surface, and is intersected with few rents or ravines. When the sides of the valley are rough and unequal, and its general inclination considerable, the surface is divided by deep chasms, and covered with numerous elevations, sometimes 50 or 100 feet high. If the declivity is more than 30° or 40°, the large cliffs and masses of ice are forced against each other with great violence, and are accumulated in the most varied and singular forms. These general remarks will be better understood from a particular description of the two celebrated glaciers of De Boisson and De Bois, in the valley of Chamouni, as they were seen by the writer of this article in the autumn of 1814.

Description of the Glacier de Boisson.

After crossing the Arve, above Servoz, by the wooden bridge of St Pelissier, and ascending a steep and rugged road, the sides of which are everywhere marked by the scoops and rents which Sir James Hall has observed on the whinstone and sandstone rocks in Scotland, we approach the village of Chavanon, and obtain a fine view of the different peaks of Montblanc. The village of Les Ouches is seen in front, and the Glacier de Boisson distinctly appears on the flank of Montblanc, stretching its frozen masses into the plain. We now leave the road, and after a little more than half an hour's walk through a fine meadow, and a gloomy forest of lofty pines, we reach the glacier. Its lower extremity and its lofty sides rise into high peaks and pyramids of ice, resembling regular crystals, and having their hollows and crevices of a bright azure blue, which forms a fine contrast with the broken sunbeams diverging in every direction from the numerous surfaces by

Glaciers.

which they are reflected. On ascending the hill, we reach the plateau or surface of the glacier, which does not present any thing remarkable. Its gently undulating surface is crossed with numerous chasms, and covered with enormuos masses of granite, which are gradually transported to a lower level, and accumulate in the plain below, forming what is called the *moraines des glaciers.* The Glacier de Boisson is bounded on the east side by lofty pines, many of which are crushed to pieces by the irresistible pressure of the walls of ice; and the ground in the neighbourhood is torn up, as if great convulsions were constantly accompanying the fall and descent of the icy cliffs. A few hundred yards only intervene between this region of sterility and desolation, and the rich and cultivated fields in the valley.

Glacier de Bois.

The Glacier de Bois has quite a different character from that of Boisson; and though it does not rise into such singular and varied shapes, yet its vast extent and its remarkable situation, and perhaps the difficulty of reaching it, render it a still more interesting object to the traveller. In order to examine this glacier, we left Chamouni about half past one o'clock upon mules; and after ascending a steep and rugged declivity, through a wood of firs, we reached, in 52 minutes, that part of the ascent where it was necessary to exchange our mules for long poles pointed with iron. The footpath crosses a deep ravine cut out by an avalanche; and at the end of other 43 minutes, we obtained a splendid view of the Aveyron, rushing out with great fury from below its icy covering, and throwing itself over a lofty precipice. At the end of two hours from our setting out, we reached the summit of Montanvert, which is 5724 feet above the level of the sea, and 2568 above that of the valley.

After resting half an hour in the temple erected for the accommodation of travellers, by M. Felix Desportes, the French resident at Geneva, we descended the hill till we reached the Mer de Glace. At first sight, this immense field of ice, about 6 miles long and 1½ wide, has the same appearance as if a tumultuous and highly agitated sea had been suddenly frozen; but upon examining it more narrowly, we found it intersected with numerous chasms and ravines, some of which are 100 feet deep. On the sides of these crevices the ice is most perfect, and has a fine blue colour; while on the surface, which is granular and porous, the congelation appears to have been less complete. By the assistance of our long poles we entered upon the Mer de Glace, and from our recollection of Saussure's description of the hazards which attend such a journey, we were not a little surprised at the apparent absence of all danger. The assistance of the guide was sometimes necessary to cross the yawning chasms; but in other respects, we experienced no difficulty. We passed a huge block of granite about 24 feet high, resting on the ice, and in the act of gradually descending to the valley; and we were now considerably advanced upon the glacier. Hitherto we had attended only to the objects below our feet, and were quite unaware of the magnificent situation in which we were placed. The whole of this frozen sea is surrounded with bare and lofty mountains. On the north-east, the red aiguille of Dreux rises like a huge obelisk to the height of 5832 feet above Montanvert, occasionally displaying its strongly illuminated summit from among masses of clouds that rolled about its base. On the south-west appeared the black peak of Charmoz; and on the south-east, where the glacier divides itself into two branches, called the Glacier of Lechaud, and the Glacier of Tacul, we discover the aiguilles of Lechaud, and the Great and Little Jorasse, the lofty peaks of the Giant and of Tacul. The black desolation which presented itself on every side; the dreary and unbroken silence which reigned around, and the sublimity and novelty with which every object was marked, gave to the present scene a peculiarly impressive character, of which it is impossible to form the least conception. The sound of the waters rushing below, at the depth of 80 or 100 feet, which is the general height of the glacier, and the crashing noise of large stones loosened by the melting of the ice and tumbling into the chasms, begin to remind the traveller that his situation is not without danger. A similar but louder noise arises during winter from the formation of the chasms, which sometimes shakes the whole mass with a noise like thunder, and which is the general harbinger of a change of weather. In many places there is something like a vertical stratification in the icy masses, stretching in the direction of the valley, and the surface of the ice has an appearance as if intersected by veins. Towards the edge of the Mer de Glace, the ice is covered with pounded granite, and huge masses of this rock mark the boundary between the glacier and the mountain. In those places where the ice is covered with sand, it appears completely black, like the darkest cairngorms, while in other places the perfect ice is green. Upon breaking this apparently black ice, however, we found it quite transparent, and remarkably pure and hard.

Mouth of the Aveyron.

We now descended Montanvert by another road, in order to see the extremity of the glacier, where it delivers the waters of the Aveyron. The whole of the glacier is supported on a granite base, which terminates towards the plain in a lofty precipice. The Aveyron formerly issued from below the glacier, through a frozen vault, where the rock had very little height; but it now discharges itself at a much higher point, producing a waterfall of great height and impetuosity. Sometimes it issues with dreadful force, and then abates, and over those parts of the rock where no water flows, huge masses of ice are constantly precipitating themselves, with a noise like that of the loudest artillery.

In ascending the valley, for the purpose of crossing the Col de Balme, we saw also the glaciers of Argentiere and Trient, which do not merit any particular description. The glacier of Argentiere lies at the foot of the lofty aiguille of the same name. It is covered at its extremity with blocks of granite, and almost blackened by a profusion of granite sand.

Subterraneous glacier of Beaume.

There is another species of glacier of a very interesting nature, but essentially different from those which we have described. One of them is in France near Beaume, and the other in the Carpathian mountains of Hungary. The first of these glaciers is near the village of Beaume, in a deep cave. The mouth of the cave is 45 feet wide, and after reaching by a long descent a hall 100 feet high, a ladder of about 40 feet long conducts to the glacier. About the beginning of the last century it was completely filled with ice, which was renewed every summer. The water, which descended on all sides from the surface, formed huge pyramids of solid ice, partly hanging from the rock, and partly shooting up from below. In winter, this cavern, which is 700 or 800 feet below ground, was filled with smoking water. The ground above it was formerly covered with huge trees, which kept off the sun's rays; but in 1724, a country-house having been erected on the place, the trees were cut, and the ice carried away for the use of the proprietor. The entrance of the cavern was covered up with a wall, and the ice has not formed so rapidly since that time. The glacier and cavern of Tselitz is in a very lofty rock in the Carpathian mountains. Its mouth is large, its width is 26 fathoms, and it penetrates to a depth of 50 fathoms, advancing still farther by a rough and winding passage. When the snow, which clothes the mountain in winter, begins to melt in spring, it filters through the rocks, and falls in drops, which are instantly frozen, and which form pyramids of ice both in the roof and on the floor of the cavern. The cavern is thus lined with ice, sparkling like the most brilliant crystals. M. Bel informs us, that six hundred carts would not be able to carry off this ice in a week. At the approach of autumn the ice begins to melt; and at the beginning of winter the air is mild, the earth dry, and not a vestige of ice is to be seen.

Subterraneous glacier of Tselitz.

Origin and formation of the glaciers.

It was long the opinion of the vulgar, and even of some intelligent writers, that the glaciers increased from below; and M. Altmann was the first who maintained their true origin, although he erroneously supposed that the pyramids of ice rose from the glacier itself. In order to explain the origin of glaciers, let us suppose that all the lofty mountains and peaks which surround the Glacier de Bois have been covered with snow during winter. At the approach of spring, the snow at low altitudes, and at the place where the glacier itself exists, is completely melted by the influence of the sun and the rains. At a greater altitude, varying with the latitude of the place, and with local circumstances, the snow is only partly melted, and having, therefore, imbibed a great quantity of water, it is frozen into a mass of imperfect ice during the succeeding winter. A fresh fall of snow covers these frozen spaces, and is in its turn converted into imperfect ice. In this way, the ice is accumulated during every succeeding winter, till the equilibrium of the mass is destroyed, either by its own magnitude, or by other causes, and the whole is precipitated in the form of an avalanche into the valley below. The snow which falls in still higher regions, lies in tranquillity on the level summits, or the hollow cavities of the mountain; but that which falls upon the declivities is easily loosened by any sudden thaw, and falling down, it adds either to the accumulated ice below, or passes directly to the bed of the glacier. The ice thus collected from the surrounding heights, will experience particular changes in its new situation. It is now subject to the action of the sun and the rain, which will wear down the high and angular masses into pyramidal and other shapes; and the water will fall down the chasms, and give a particular transparency to their sides. At the lower extremity of the glacier towards the plain, the greatest changes will take place. The fall of the exterior masses will be followed by the advance of those behind them, and a movement will thus be propagated throughout the whole glacier.

Progressive descent of the glaciers.

From these causes, the glaciers will progressively descend to the plains below; and the rapidity of their motion will depend upon the inclination of the bed on which they rest, and on the magnitude and velocity of the reinforcements which they receive from fresh avalanches. The stream which flows from the extremity of the glacier, forms in general a vault of ice above, which gradually widens as the ice melts, and when it can no longer sustain the superincumbent mass, it is crushed by its own weight, and gives place to the masses behind it. This progressive motion of the glaciers, is rendered visible by the variation in the position of large stones on the surface, or of trees frozen in the ice. In the glacier of Chamouni, the progressive motion has been observed to be 14 feet in the year; and on those of Grindelwald, 150 feet in six years, or 25 feet in the year.

On the increase or diminution of the glaciers.

It has been a question keenly agitated among naturalists, whether the glaciers are in a state of increase or diminution, and each party has succeeded in proving the truth of his opinion. We may necessarily infer, therefore, that they sometimes increase and sometimes diminish. The lower extremity which projects into the plain, sometimes continues to diminish for a series of years, as the quantity which is annually dissolved is not replaced by the superjacent masses. At other times, when they are copiously supplied by fresh avalanches, they advance more rapidly than they dissolve, and therefore encroach upon the cultivated plains. Their augmentation commonly takes place in spring, and when they have made great inroads upon the lower ground, they are generally found to diminish for some years afterwards.

On the heaps of stones on the surface and at the foot of the glaciers.

We have already had occasion to mention both the masses of granite rock, which lie upon the surface of the glacier, and the heaps of enormous stones, called the *Moraine*, or *Murren*, which are accumulated at its lower extremity. These stones sometimes are totally different from those in the valley where they now lie, and must have been detached from rocks often six or eight leagues distant. These stones are frequently accumulated in separate mounds like hillocks or graves, and arranged in parallel lines of a considerable height and width. These are generally called Gouffrelynes, and appear on a great scale in the glacier of Rosboden on the Simplon. Sometimes a large regular pyramid of ice is seen, with a huge stone upon its summit. The heaps of stones which we have mentioned, contain in general specimens of the rocks in the higher regions of the mountains.

On the texture of the ice of the glaciers.

It has been already stated, that the glaciers are composed of different kinds of ice. Some of it is granulated and imperfectly frozen, other parts have a transparent green colour, as in the chasms and crevices, while that which is near the heaps of gravel, is of a bluish black colour. The only exception to the generality of this remark occurs in the glacier of Rosboden, the whole of which consists of ice, hard, firm, and compact, and of a blackish blue colour.

Vaults of ice.

The vaults of ice are always formed at the exit of the little stream which runs below the glacier. In winter, all these openings are closed up by ice, but the heat of spring speedily dissolves it, and vaults sometimes 100 feet long, and 50 or 60 wide, are formed. The figure and magnitude of these suffer constant changes. That of the Aveyron, once so much admired, is no longer in existence.

On the number and extent of the glaciers.

In the extensive alpine chain from Montblanc to the borders of the Tyrol, there are no fewer than 400 glaciers, the greater part of which are six or seven leagues long, by one half or three quarters of a league wide, and from 100 to 600 feet thick. A very few of these are so small as a league in length. M. Ebel has calculated, as nearly as can be done, their general extent, and has found that those between Switzerland and Montblanc, and on the frontiers of the Tyrol, would form a single glacier of 130 square leagues.

For farther information on this subject, we must refer the reader to the article Alps, where he will find an account of the glacier of Furca, the glacier of the Aar, and the glaciers of Grindelwald and Lauterbrunnen. See also Grouner's *Histoire Naturelle des Glaciers de Suissè*, translated by Keralio; Saussure *Voyages* diators, Iorgan-hire. *dans les Alpes*; Ebel's *Manuel du Voyageur en Suisse*; Lambert's *Voyage Pittoresque en Suisse*.

GLADIATORS is the name given to persons usually slaves, or condemned criminals, who were brought out to fight one another for the amusement of the Roman people. See ROME.

GLAMORGANSHIRE, a maritime county in South Wales, is bounded on the north by Caermarthenshire and Brecknockshire; on the south by Merionethshire; on the east by Monmouthshire, from which it is separated by the river Rumsey; and on the south and west by the Bristol Channel. The greater part of its sea-coast swells into a semicircular sweep; but the west extremity is formed into a narrow beak, between the open channel and an arm running round the coast of Caermarthen. The county measures from east to west 48 miles; from north to south, at the broadest part, 26 miles: its circumference is 125 miles. It contains 822 square miles, or 526,680 acres. There is in it one city, Landaff; one county town, Cardiff; ten hundreds, viz. Caerfilly, Cowbridge, Dinas Powis, Kibber, Langwelack, Miskin, Neath, Newcastle, Ogmore, and Swansea; eight market towns, and 118 parishes. It returns two members to parliament, one for the county, and one for Cardiff, and is in the province of Canterbury; three parts of it are in the diocese of Landaff, the remaining part in the diocese of St David's. There are in it two deaneries, Landaff and Cowbridge; and it pays one part of the land-tax. The north part of the county is very mountainous and barren; thinly inhabited, and serving chiefly for the feeding of cattle and sheep. In this part various rivers take their rise, which run to the south through vales, gradually enlarging; thus forming a middle district tolerably adapted for cultivation, and at last terminating in the great level or vale of Glamorgan. This is a tract extending along the sea-coast to the distance of eight or ten miles inland, the most fertile part in Wales, rich in corn and pasture, and well furnished with coals, lead, iron, and limestone: it is open, but not a dead flat: it has an undulated surface, on a dry substratum of limestone. The land is inclosed with good hedges, mostly hawthorn. To the north and north-east, the vale is well sheltered by mountains. To the south, it has the dry, rocky shores of the Bristol channel, without any fens. Another district of Glamorganshire deserving particular notice, is what is termed Gowerland: it is a tract of country bounded by the Neath and Loughor rivers. Its circuit is between 40 and 50 miles; in point of landscape, it is inferior to most other parts of the county; but the origin and habits of the people, and its antiquities and curiosities, render it highly worthy of attentive examination. It abounds in many places with deep pits. The east side is remarkably fruitful and well cultivated. The south-west is inhabited by the successors of a colony of Flemings, probably planted there at the same period that the Flemings were settled in Pembrokeshire. They do not understand the Welsh language; but are distinguished by their dialect and provincial dress, and rarely intermarry with the Welsh. They wear what is called a *whittle*, made of fine wool, dyed scarlet, nearly a yard square, with a fringe at bottom. This garment is thrown across the shoulders, and fastened with a pin or broach; anciently it was fastened with the prickle of the black thorn, which is still used by some of the old women.

The climate of the higher parts of Glamorganshire is of course rather severe; but in the lower districts it is uncommonly mild, so that myrtles, magnolias, and other tender exotics, grow luxuriantly in the open air.

Rivers. The principal rivers are the Lower Taafe, which rises in the mountains that separate Glamorganshire from Brecknockshire, and traversing a wild district towards the south, falls into the Bay of Glamorgan, near Swansea. The Neath, a much more considerable river than the former, rises in the same mountains, more to the eastward; descending from these with great rapidity, it forms a deep valley, through which it flows to the south-west to Neath, where it meets the tide; and after several windings in the marsh below that town, falls into the Bay of Swansea. The Avon, the Ogmore, and the Ewenny, are three small rivers which cross the vale of Glamorgan, each falling successively into Glamorgan Bay. The Taafe rises within the limits of Brecknockshire, considerably to the eastward of the source of the Neath; soon after passing Merthyr Tydvil, it precipitates itself into the deep abyss of a vale, forcing its way with great fury between mountains and woods, till, not far from Caerfilly, it is crossed by the wonderful structure of the Pont-y-Pryd—a stone bridge of a single arch, supposed one of the widest, constructed of masonry, in the world: this bridge springs from rock to rock, with indescribable lightness and beauty. Several miles lower, the Taafe emerges into a spacious and well-inhabited plain, in which Landaff and Cardiff are situated: flowing through their bridges, it meets the tide, and traverses a broad marsh to fall into the sea, opposite to the high rock of Pennarth.

Woods. The level and more cultivated parts of Glamorganshire are rather destitute of wood; but its eastern and western extremities are well wooded. The magnificently clothed hills of Margam, Bagland, Briton Ferry, and the vale of Neath, unite the beauties of cultivation with the luxuriance of forest scenery. The wood, which rises immediately from the church of Margam, covers the breast of a mountain 800 feet in height, and more than a mile in circumference; the value of the oak timber has been estimated at L. 60,000.

Agriculture. The agriculture of this county presents little that is interesting; it is behind many other counties in Wales, although the vale of Glamorgan offers many facilities to the husbandman. It is naturally fertile, and lime is every where to be found in abundance, and with ease. On the mountains, a breed of sheep, somewhat similar to those on the Cotswold hills, is kept. The cattle of this county, which resemble those of Normandy, are in high repute for draught.

Mineral productions. But it is its mineral productions, and its manufactures depending upon them, which distinguish and enrich Glamorganshire. It abounds in limestone, iron, and coal. With respect to that most extensive bed of limestone, of which nearly the whole of Glamorganshire forms only a part, it commences with the eastern extremity of the county, and, taking a direction due west, runs in a straight line to Swansea Bay, appearing again in Gowerland, and, having passed under Caermarthen Bay, is seen to occupy the greatest part of the south and west of Pembrokeshire. The neighbourhood of Merthyr Tydvil abounds with excellent coal, iron ore, mill-stones, and limestone rocks. Excellent flag-stone for paving, and a very good kind of slate, are found in this neighbourhood, and, indeed, throughout the mountainous district of Glamorgan. On the left of the road about Pentyrch are very extensive coaleries, and abundance of iron ore. In some respects this county is interesting to the geologist. On the top

Glamorganshire.

of Curn Bryn, one of the highest mountains in South Wales, is a huge cromlech, consisting principally of an immense stone of lapis molaris. The lake of Config is esteemed a singular geological curiosity. The water is contained in a depression of an irregular form, in the midst of sands; and, though lying within a very short distance of the sea at flood tides, invariably retains its freshness pure and untainted. At a short distance from Newton Noltage is the well mentioned by Camden, which ebbs and flows reversely with the tide of the sea. The only mineral spring in the county of Glamorgan is at Swansea. This spring has an acid, styptic taste, like alum, though the predominant salt in it is the sulphate of iron. It turns blue with vinegar, but will not curdle with milk.

Manufactures.

The principal manufactures of iron, copper, &c. are at Swansea, Merthyr Tydvil, and Neath. In 1720, Swansea was noted for the manufacture of straw hats; in 1730, the first copper work was established, on the east side of the river; since that period they have gradually increased, as well as the iron works, to an extent equalled in few parts of the kingdom. Lead is also smelted here. The copper is brought from Anglesey, Cornwall, and Devon. Merthyr Tydvil was a very inconsiderable village till 1755, when the iron and coal mines in its vicinity first attracted attention; and a Mr Bacon obtained the lease of a district abounding in them, eight miles long and four wide, for £200 per annum. About 10 years ago, about 190 tons of iron were, on an average, sent weekly, from one person's works only, to Cardiff. The number of smelting houses is sixteen. About the year 1800, an overshot wheel was constructed, upwards of 50 feet in diameter, and six in breadth; the gudgeons, on which it turns, are supposed to be the largest in the kingdom. The quantity of iron sent from Penydarran works by the canal, averages annually about 7000 tons; the Dowlas works produce annually about 5000 tons; and the Plymouth works about 4000 tons. In the neighbourhood of Neath are very extensive works for the manufacture of iron and copper. Two immense blast furnaces produce 30 tons of pig-iron every week. A copper foundery, and manufactory on a very extensive plan, is carried on near the village of Margam, the works of which consume 70 tons of coal daily. The tin works of Melin Gryffyd, four miles to the north of Cardiff, are, perhaps, the largest in the kingdom; producing not less than 13,000 boxes of tin plates, each containing 225 plates, in one year.

Canals.

The internal commerce and manufactures of this county are much facilitated by its canals. The canal for the carriage of the coal to the Neath river, was the first work of the kind attempted in Wales. There is a bog of two miles, between the colliery and the river, the spongy nature of which, for some time, baffled the skill of the engineers. The length of the canal is little more than three miles; it was executed entirely at the expence of a private individual. The canal from Merthyr Tydvil to Cardiff was completed in 1798; it is navigable for barges of 100 tons. In some places it skirts precipitous mountains, at the height of 300 feet above the river Taafe, which it accompanies. The space it passes is 26 miles; in which there are 40 locks, and as many bridges. The new iron rail-way runs nearly by its side. The fall of the canal is nearly 600 feet. The head of the Swansea canal in Brecknockshire is 372 feet above the level of the Tawy at Swansea bar; there are 36 locks upon it in the space of 16 miles, and several aqueducts.

Glamorganshire ‖ Glaris.

Antiquities.

As connected with the antiquities of this county, the ancient buildings, called Church-houses, may be mentioned. There are at least fifty of them still remaining in this district. Their origin and use are not accurately known; but most probably they were the halls in which the courts of legislation and of justice were held for the respective petty lordships of the great lordship of Glamorgan, every one of whom exercised *jura regalia*. The Roman stations, forts, and camps in this county, are generally understood to be at Cardiff, Caerfilly, and Caera. The great Roman road runs over Newton Down, through Kenfig, Margam, Aberavon, and Neath. But the most celebrated monument of antiquity is Caerfilly castle, now in ruins, said to have been the largest in the kingdom, next to that of Windsor. The wall of the celebrated leaning tower of this castle is still between 70 and 80 feet high, and of a prodigious thickness. It hangs 11½ feet out of the perpendicular.

Customs.

It is a very common practice in this county to plant the graves with flowers, or with sweet-scented herbs. No person ever plucks them up; but a relation or a friend will gather a little, and wear it in remembrance of the deceased. When a young couple are to be married, their way to church is strewed with sweet-scented flowers and evergreens. About two miles from Cowbridge is a place famous for the meeting of the Welsh bards: it took place annually on the 28th of May, under the immemorial patronage of the Hensolt family, at whose expence they were entertained. The last meeting was held in 1720; and in consequence of the death of Richard Jenkins, the last of the family, it was discontinued.

Bards.

In the time of the Romans, Glamorganshire was inhabited by the Silures: it was, in succeeding ages, an independent principality, which was overrun and divided by some of William's Norman nobles in the year 1088.

Population.

By the population returns, there were, in 1811, 8217 families in this county, principally employed in agriculture, and 7915 in manufactures, &c. (W. S.)

GLANDS. See Physiology.

GLANDERS. See Veterinary Medicine.

GLARIS, or Glarus, is a town of Switzerland, and the chief place of a canton of the same name. The town is very gloomily situated upon the river Linth, and is large and populous. The town-house is a good building, and contains, in one of the antichambers, the huge horns of the Bouquetin, an animal which was destroyed in the canton about the end of the 16th century, and also a bear which was killed in the Alps in 1716. There is here a good public library, founded by a society in 1758. India stuffs and drabs are manufactured at Glaris; and there are mills in which is prepared the famous green cheese, known by the name of Schabzigher. There is an agreeable promenade to Enneda, a thriving little town, inhabited by about 150 families. The inhabitants of Glaris are principally merchants, who wander through the whole of Europe, from Lisbon to Moscow.

GLARIS, Canton of, is one of the Swiss cantons, extending about 15 leagues in length and 7 in breadth. It contains 21¼ square geographical miles, only two of which are arable. This canton consists of a great valley, and three lateral vallies enclosed on all sides except the north-east by lofty mountains, rising to the height of from 5000 to 11037 feet. The vallies of this canton are watered by the Linth, the Sernft, and the Lontsch; and its principal lakes are those of Wallenstadt and

Glaris.

Clonthal, and some smaller ones among the mountains. Some corn and grapes, and much fruit, are raised in the canton. In summer, about 7000 or 8000 cattle are pastured on the mountains; but, in winter, they do not exceed 4000 or 5000. The milk is principally employed in making butter and the celebrated Schabzigher cheese, which is exported in great quantities. The blue melilot, one of its principal ingredients, is carefully cultivated by the inhabitants. Goats are so numerous, that every commune has about 300 or 400. Since the year 1802, the Merino sheep have been introduced, and the wool of the country has been thus ameliorated. The inhabitants are distinguished by habits of active industry. England was supplied with writing slates from the valley of Sernft, till the opening of the Caernarvonshire quarries. At the beginning of the 18th century, a manufactory for linen cloth was established. The spinning of cotton was introduced in 1714, and from 1755 to 1760 muslins were fabricated. Since that time, India stuffs, pocket handkerchiefs, stockings, and muslin shawls, have been manufactured. Paper is also made in the canton, and muslin embroidered. The climate is very mild in the vallies. The spring is early, and strawberries are ripe in the middle of April, and cherries about the end of May. In 1803, the population of the canton was 24,000.

GLASGOW,

Glasgow.

GLASGOW is a great commercial and manufacturing city of Lanarkshire in Scotland, situated on the north bank of the river Clyde, in West Long. 4° 15′ 51″, and North Lat. 55° 52′ 10″.*

There is no authentic record by which the origin of the city can be ascertained. Its name, in the Gaelic language, signifies a *grey smith*. It has since been inferred, that a person of this description, eminent in his profession, had taken up his residence in the place, and that, in compliment to him, it had received this name.

[Bi]shopric of [Gl]asgow [fo]unded in [56]0.

In the year 560, it is said, a bishopric was founded here by St Mungo, or Kentigern, and to this circumstance the origin of the place has been attributed; it being probable that the sanctity of the residence of this holy man, and the observance of miracles which would in all probability take place, would naturally draw those to the spot who were religiously inclined.

From this period, and for the space of more than 500 years, history has declined to record any thing worthy of notice respecting this place. Prior to 1100, it would appear, the Bishop's Church was a mean building, chiefly constructed of timber, and had gone into decay.

[Ca]thedral [b]uilt in [11]23.

In the year 1123, John Achaius, nominated bishop by David I. finished and decorated a considerable part of the present cathedral, and solemnly consecrated it in presence of the king, who immediately bestowed on the church the lands of Perdeye, now Partic, &c. This prelate divided the diocese into two archdeaneries of Glasgow and Tiviotdale, established the offices of dean, sub-dean, chancellor, treasurer, sacrist, chanter, and successor, and settled a prebendary on each of them, out of the donations he received from the king.

In 1174, Joceline, abbot of Melrose, was elected bishop of Glasgow, and made an addition to the cathedral, which had been so far carried on by John Achaius. He also procured a charter from William, King of Scotland, surnamed the Lion, in 1180, erecting Glasgow into a royal burgh, and likewise a charter to hold a fair for eight days annually.

[Gl]asgow [er]ected into [r]oyal [bu]rgh.

In 1387, during the time that Matthew Glendoning was bishop, the great spire of the cathedral, which had hitherto been formed of timber, was consumed by lightning. In 1408, his successor, William Lauder, built the great tower of stone as far as the first battlement: he also laid the foundation of the vestry of the cathedral. The great tower of the Episcopal palace was founded about the year 1437, and carried on by the exertions of Bishop Cameron.

[Spi]re of the [ca]thedral [des]troyed by [lig]htning, [13]87.

In 1450, Bishop Turnbull obtained from King James II. a charter, erecting the town and the patrimonies of the bishopric into a regality. He also procured a bull from Pope Nicholas V. for erecting a university within the city, which he endowed, and on which he bestowed many privileges.

Erected a regality, and the university founded.

The establishment of this seat of literature contributed, more than any thing that had formerly been done, towards the enlargement of the town, which, before this period, was so inconsiderable as not to contain more than 1500 inhabitants. In the year 1488, the bishopric of Glasgow was erected by act of Parliament into a metropolitan see, and the temporalities and liberties of the church were after this confirmed by a charter of James VI.

Inhabitants reside near the cathedral.

Prior to the year 1400, it would appear that the inhabitants chiefly resided in the vicinity of the cathedral, and in that part of the High Street which is bounded by the cathedral and the convent of the Black Friars, (now the College Church.) On the establishment of the university, the number of buildings gradually increased downwards to where the Cross now is, and from thence eastwards on the Gallowsgate (now Gallowgate.) Some time after this period, the citizens founded a collegiate church in the Trongate, which they dedicated to the Blessed Virgin; and this circumstance naturally induced the citizens to continue their buildings as far west as this place of worship, which now bears the name of the Tron Church. It then became necessary for the inhabitants to form the Saltmarket Street, so as to procure an easy approach to the Clyde. As many of the citizens supported themselves by fishing in the river, they were incorporated into a society; and in order that they might be at hand to prosecute their business, they built a considerable part of the Fishersgate Street, which has since gone under the name of Bridgegate Street.

Inferiority of Glasgow in 1556.

Notwithstanding this apparent extension, Glasgow at this time held but an inferior rank among the towns of Scotland; for it appears that, even in 1556, at Queen Mary's taxation, it held only the eleventh place. This inferiority has been attempted to be explained in various ways; among others it has been remarked, that in proportion as the reformed religion preponderated, the money which had been expended in the town by the bishop, and the other dignitaries of the church, would be directed into other channels; and as the early reformers undervalued human learning, if they did not entirely despise it, the influence of the college was for a time suspended; it may be also remarked, that Glasgow suffered severely during the civil wars, and afterwards experienced the miseries of famine and pestilence. In 1652 a great fire

* This is the position of the New Glasgow Observatory, as determined by the observations of Mr Cross. ED.

Glasgow.

Great fire in 1652.

broke out, which destroyed a considerable number of the houses in the Saltmarket, Trongate, and High Streets, which at that time were formed of timber. By this calamity, the habitations of nearly one thousand families were completely destroyed, and their fortunes nearly ruined; so that they were under the necessity of applying to other towns for relief. Notwithstanding these discouraging circumstances, we find that Glasgow had so far recovered from her disasters, that in 1695, at the assessment of the burghs, she was rated as the second in Scotland in point of wealth.

From the year 1450, when the town and the patrimony of the bishops were incorporated, down to the Reformation, the bishops, or certain lay lords in their right, nominated the magistrates. Although the parliament, in 1633, declared the burgh to be royal, with freedom of election, we find it afterwards disturbed by Cromwell and the Privy Council.

Glasgow declared free by William and Mary.

In 1690, the town was again declared free by a charter of William and Mary, which was confirmed by an act of Parliament in the same year, to the effect that the town council should have power to elect their own magistrates, as fully and freely in all respects as the city of Edinburgh, or any other royal burgh within the kingdom. This freedom of election has continued ever since.

Glasgow sea port.

Prior to the union between England and Scotland, the river was not in a state to bring up vessels of burthen to the city; the magistrates, therefore, purchased eleven acres of ground near the village of Newark, to enable them to form a sea-port town. In 1710, we find that wharfs, docks, and storehouses, had been erected, a bailie appointed, and the town, which was now called Port-Glasgow, formed into a separate parish, with right of patronage.

Armorial bearing.

The armorial bearing of the city is on a field parti. p. fess. argent and gules, an oak tree surmounted with a bird in chief, a salmon with a gold stoned ring in its mouth in base, and on a branch on the sinister side, a bell languid or, all proper. The motto, "Let Glasgow flourish." In former times, "through the preaching of the word," was added to the motto.

Situation of the town.

The situation of this city commands the attention of strangers: It lies on the north bank of the Clyde, is bounded on the west by the village of Anderston, on the east by the Calton and Bridgeton, on the north by the Barony or Landward Parish, and on the south by the river.

Climate.

The air, though generally healthy, is somewhat moist. The average of rain which has fallen for 30 years previous to 1790, is 29 $\frac{65}{100}$ inches. The greatest quantity in any year during that period was in 1775, which was 43 $\frac{9}{10}$ inches, and the least, which was in the year 1788, was 19 $\frac{43}{100}$ inches.

The following Table shews the quantity of rain that fell at the Macfarlane observatory from 1810 to 1814, as measured by an excellent rain-gage by Crichton of Glasgow:

	Inches.		Inches.		Inches.
1810	25.132	1812	22. 81	1814	19.522
1811	27.801	1813	18.368		

In 1712, the river was swoln to a height never before remembered. On the 12th March 1782, it rose 18 inches higher than in 1712, so that boats were floated in the streets of the under part of the town.

The soil around the city being very various, is so improven by an abundant supply of manure, as to produce heavy crops of every description. Coal, freestone, whinstone, and clay of excellent quality, are to be found in almost every direction.

The greater part of the buildings are erected on ground having a gentle ascent from the river; the ancient part of the town being separated from the more modern by a considerable acclivity, commencing near the College. The public park, or green, on the banks of the river, adjoining the south-east side of the town, contains upwards of 108 acres of grass, and 3 miles 6 furlongs and 12 poles of gravel walks. This park is of great use to the inhabitants, and contributes much to the general appearance of this part of the town.

The length and breadth of the city is ascertained by two main streets, which cross each other nearly at right angles. The principal street running nearly east and west, bears the several names of Westergate, Argyle Street, Trongate, and Gallowgate, and is one mile and a half, one furlong, fifteen poles, and two yards long; 83 feet broad at King Street, and 77 feet at Queen Street. The street which runs south and north takes the names of the Saltmarket, High Street, Kirk Street, and Castle Street, and is three-fourths of a mile thirty-four poles and three yards long; 54 feet wide at Bell Street, and 47 feet at George's Street. The greater part of the streets are 60 feet wide; the average width is between 56 and 57 feet. They are all causewayed with very durable whin-stones, and skirted with hewn stone pavements of various breadths, conformable to the police act. Common sewers, large enough to admit persons to clean them, extending four miles seven furlongs and ten poles, are formed in the streets.

Common sewers.

Of the three squares in the city, St Andrew's, St Enoch's, and St George's, the latter is the most spacious: the centre of it is reserved for an equestrian statue of his Majesty. Public buildings, and the tenements fronting streets, are built with hewn stone, and covered with slates. The greater part of the private buildings, particularly in the ancient part of the town, are built in what is called flats; by which two or more families are accommodated under the same roof. In the more modern part, however, the tenements are so formed, that one family possesses the whole.

Building ground, r disposed

The building ground here is not disposed of by the lineal foot of front, as is the case in the other great towns in the island; it is sold or feued by square measure. A yard of nine square feet will bring from one to eighteen guineas, according to the situation. The general rate of ground, however, for dwelling houses fronting a street, not in a very centrical situation for business, is from two to four guineas per yard.

Since the erection of the village of Glasgow into a burgh, in 1180, its constitution has undergone several alterations. In 1268, it appears that the town was governed by a provost and bailies, and that the corporation was duly organised. In 1636, a royal charter was obtained, appointing a water-bailie, and empowering him to exercise a maritime, civil, and criminal jurisdiction, from the bridge to the Clough, at the mouth of the river, 26 miles below the town.

Office o water b first appointed 163(.

By the constitution of the burgh, three distinct bodies are recognised, viz. the magistrates and town council, and the merchants and trades houses. The set, or constitution, having undergone some slight alterations by the convention of royal burghs in 1801, is now declared to be as follows: The affairs of the burgh shall be governed by a provost, and three bailies of the merchant rank, and two bailies of the trades rank; twelve councillors of the merchant, and eleven of the trades rank; a master of works, who must be of the merchant rank; and a treasurer of the merchant and trades rank alternately. These two officers are councillors *ex officio*. The offices of the Gorbals bailie, and the bailie and depute bailie of the river, do not add to the number of

Set or c stitution the bur

councillors, and, like the treasurer, are chosen from each of the ranks alternately. The dean of guild and convener of the trades' house, are councillors *ex officio* during the first year they are in office, after which they must be elected ordinary councillors. The lord provost (who from courtesy is stiled honourable) and the five bailies are charged with the executive, while the magistrates and council conduct the other public affairs of the community.

The provost, two senior merchant bailies, the senior trades bailie, the dean of guild, and the convener, are justices of the peace for the county; the junior merchant and trades bailies exercise similar powers within the burgh. In 1720, the lord provost first began to wear a velvet court dress; and in 1767, the provost and bailies, magistrates, dean of guild, and convener, first began to wear gold chains; the bailies of the river and barony of Gorbals have also latterly worn gold chains. It is to be regretted, that the funds of this respectable corporation are not in a situation to warrant its managers to appropriate a sum to support the dignity of the chief magistrate, without affecting the progress of public improvements, which have been carried on for a number of years past with a spirit which does honour to the managers of the city. This burgh, of itself, does not return any representative to Parliament. The magistrates and council of the burghs of Glasgow, Rutherglen, Dumbarton, and Renfrew, elect one member among them: In the event of equality, each burgh takes the casting vote in rotation. Although the population of either of these conjoined burghs do not exceed one-fortieth part of Glasgow, they are equal in their political franchises.

[agistrates ...st began ... wear gold ...ains in ...67.]

The revenue of the burgh arises from various sources, but chiefly from what is called the common good. The following may be considered as the most productive, viz. an impost of two pennies Scots on the Scots pint of all ale or beer, brewed or sold within the city. This impost, which was first laid on in 1693, extended only over the burgh, has since been made to comprehend the barony of Gorbals, and the town of Port Glasgow. (For the history of these, see LANARKSHIRE and PORT *Glasgow.*) Ladles and multers, these are certain dues paid on grain, meal, and fruit, &c. brought into the burgh; dues on cattle killed within the burgh; dues from the public washing house and tron; rents of markets, church seats, houses, mills, and mill lands, burgess entries, feus of land, and ground annuals, &c. amounting in whole in the year ending 31st December 1813, to £13,604, 11s. 8d. The following may be considered as the particulars of the expenditure, viz. burgh assessment, criminal prosecutions, alimenting criminal prisoners, general expence of the prison and bridewell, expence of church and civil establishment, ministers stipends and officers salaries, police establishment, repairs of heritable property, and general improvements; the amount of all which, for some years past, has exceeded the revenue. This excess may be accounted for, by the extension of public improvements of late years, which have necessarily required an anticipation of the funds.

[...venue ...d expen...ure of the ...rgh.]

Exclusive of the above, which may be considered as the revenue and expenditure *proper* of the community, the magistrates and council are entrusted, in whole or in part, with the administration of the following funds, the particulars being elsewhere narrated:

[...er trusts ...mitted ...the ma...rates ...council.]

Navigation of the river Clyde;
Assessment for the maintenance of the poor;
Statute labour conversion fund;
Pontage of the bridges; and
Police establishment.

It appears from ancient records, that those persons who bought and sold merchandise of any description in this burgh, considered themselves as a distinct class of citizens from those who manufactured the articles, and the claim of precedence often gave rise to dissensions among the burgesses. In the year 1604, when both parties became anxious for an amicable adjustment of their political differences, they submitted their claims to the final decision of Sir George Elphinstone, who was then Provost, and to two of the ministers of the city. The arbiters, to use their own words, declare, that after great pains, long travailing, and mature deliberation, they, on the 6th of February 1605, pronounced their decreet, containing fifty-four articles, which is the letter of guildry. This decreet was immediately confirmed by the magistrates and council, and in 1612 by an act of parliament, and has been, after a few slight alterations, acted upon ever since. By the letter of guildry, the Dean of Guild is president of his house, and from courtesy is stiled Lord Dean of Guild. He takes precedence of the convener of the trades house in all places, and of the provost and bailies at every meeting of his house.

[Merchants and trades ranks.]

The merchants' house consists of all the merchant burgesses who have matriculated, that is, who have paid a fee, now fixed at ten guineas, to the funds of the house. These members, however, have only the privilege of attending one meeting in the course of the year, and of electing 24 members of the Dean of Guild's council, which is made up as follows: the Dean names 12 members, who may be either foreign or home traders; he then puts the whole of the remanent members into 24 lists or leets, whereof 12 must be foreign, and 12 home traders. The qualified members, at the meeting, elect one person from each leet, who, together with the dean, the provost, three merchant bailies, the collector, and the 12 persons nominated by the dean, compose the council, to whom the administration of the whole affairs of the house is entrusted throughout the year. The funds of this public body arise chiefly from rents, feus, ground annuals, interest, matriculation, and burgess entry money, donations, and mortifications.

[Merchants' house.]

The convener is president of the trades house, and takes precedence of the trades bailies, at all meetings of the house. The members consist of the present and late convener, two trades bailies, the present and late collector, the present and late deacons of the 14 incorporations, and 26 assistants, nominated as follows: the deacons of the hammermen, tailors, cordiners, and maltmen, nominate four of the members of their incorporation; the weavers two; the bakers, skinners, wrights, coopers, fleshers, masons, gardeners, and barbers, one each; the dyers do not nominate any. These members constitute the trades house, and to them its whole civil and political concerns are entrusted.

[Trades' house.]

The affairs of finance are placed under the exclusive management of the convener and deacons, and extraordinary members of the house; the latter are the trades bailies, collector, and members who have passed the chair, or have been at any time in the magistracy. The funds of this public body, like the merchants house, arise chiefly from rents, ground annuals, and feus from the lands of trades-town, interest, burgess entries, donations and mortifications.

A circuit court of justiciary, (anciently termed justice in Ayre,) is held here in the months of April and September yearly, wherein all criminal cases, high treason excepted, are tried by a jury of 15 persons. The jurisdiction of the circuit extends over the counties of Lanark, Renfrew, and Dumbarton. It has been custo-

[Court of justiciary.]

Glasgow.

mary for two of the judges to be on this circuit attended by the sheriffs of the three counties, and the Lord Provost and magistrates of the burgh. Formerly it was necessary for the jury to retire from the court, and make up a written verdict. In 1814, an act of parliament was passed, empowering juries, when they were unanimous as to the verdict, to return it, *viva voce*, without leaving the box. Forty-five jurymen are summoned on each circuit, whereof 25 are from Lanarkshire, and 10 from each of the other two counties. This court also gives judgment in appeals from inferior courts, in civil matters, where the sum at issue is not under £15. An elegant hall, or court room, was fitted up in the public offices in 1810, for the accommodation of this court, which contains more than 300 persons.

Sheriff's court.

The sheriff's court has jurisdiction in civil as well as in criminal matters within the county. The civil court, for ordinary procedure, is held every Wednesday, at eleven o'clock, in the circuit court room, during the sitting of the court of session; and during the vacancy, the court is held at such intervals as the judge may think expedient. In cases of a summary nature, there is access to him every lawful day. All crimes competent to be tried before the sheriff, which infer capital or corporeal punishment, or banishment from the county, must be tried by a jury of 15 persons; the forms of the justiciary court being strictly adhered to, with this difference, that, in all cases, the objections to witnesses and other steps of procedure must be taken down in writing. No capital sentence can be inflicted in less than 40 days after the passing of the sentence, nor corporeal punishment in less than 12 days. The sentence of this court, whether of a civil or criminal nature, are, like other inferior courts, subject to the revisal of the supreme courts.

Commissarial court.

The commissariat court was formerly the bishop's court. The jurisdiction of the commissariat of Glasgow, Hamilton, and Campsie, is very extensive, comprehending a great part of the counties of Lanark, Renfrew, Stirling, Dumbarton, and Air. It takes cognizance of all testamentary affairs, and matters of scandal. Civil actions for debt may also be tried in it, to the extent of 40 pounds Scots. The term of this court is similar to the sheriff's, and is held in the same hall on Thursdays at 11 o'clock; in former times, it was held in the consistory house, adjoining the cathedral.

Town court.

The town court is the principal civil court of the burgh. It seems to have been instituted about the same time that the burgh was erected. The provost and bailies are the judges. The procedure is conducted in writing, by procurators, under the superintendance of a legal assessor, who is a member of the faculty of advocates. In ordinary cases, the court is held in the burgh-hall every Friday at 11 o'clock during the session, and at least once a month during the vacation of the Court of Session; but in cases which require extraordinary dispatch, the court is open every lawful day. Its jurisdiction is limited to the burgh, and is competent to decide questions of personal obligation to pay or perform to any extent; no claim, however, can be enforced in this court, unless it exceeds 30s. The court is also competent to judge in questions of property, pledge, hypothec and retension, of exclusive privilege of count and reckoning, service of heirs, &c.

Inferior civil court.

The inferior civil court, commonly called the conscience court, from the matters at issue being often left to the oath of parties, was instituted for the determination of small civil claims, not below five, nor exceeding forty shillings. Each of the magistrates, in rotation, officiates as judge; an assessor attends, to give legal advice, if it should be found necessary, and to minute the verbal debate, procurators not being admitted. This court is held in the hall of the town court every Monday at 11 o'clock.

Daily court.

The daily court is held every lawful day at two o'clock, in the burgh court hall. The bailies officiate in rotation, without the assistance of assessors; the procedure is not taken down in writing, no claim being competent above ten shillings.

Criminal court of the burgh.

In the criminal court of the burgh, as is the case in the principal civil court, the magistrates officiate as judges; the procedure is conducted in writing, under the superintendance of legal assessors; and is held every lawful day in the police office at 10 o'clock, and thereafter in the clerk's chamber at 12 o'clock. This court grants warrants for the arrest and commitment of offenders of every description, so that they may be brought to trial either in the supreme court of justiciary, or in this court. In particular, it takes cognisance of those inferior offences, which, by the law of Scotland, do not require a trial by jury; to the effect of inflicting punishment by fine, banishment from the burgh, exposure to public contempt, imprisonment in jail, solitary confinement in bridewell, subjection to hard labour, or even to the effect of inflicting a slight corporeal punishment.

Dean of guild court.

The dean of guild court takes cognisance of all matters within the burgh, wherein the heritable rights of the citizens are involved. It consists of the dean of guild, who is president, four members from the trades-house, and four from the merchants-house, chosen annually, who are termed the Dean of Guild's Brethren. This court determines in all matters of dispute between conterminous proprietors, encroachments on the streets, insufficiency of buildings, and the adjustment of weights and measures, &c. The procedure is conducted in writing by procurators, under the superintendance of a legal assessor. This court is held on Thursdays at 11 o'clock in the burgh-hall. The trades rank, conformable to ancient usage, sits on the right of the president.

Justice of peace court.

The judges in this court are those gentlemen in the commission of the peace, who act for the under ward of Lanarkshire; the jurisdiction being confined to that district. The court meets in the circuit court hall, on the first Monday of every month, at 11 o'clock A. M. two justices forming a quorum. They decide in all matters of debt, which do not exceed five pounds; and determine on fines and penalties to any amount that may have been incurred in consequence of illegal traffic, infringement on the game laws, &c. in determining disputes between master and servant, whether as to aliment or rate of wages. Procurators are not admitted in this court, nor is the procedure taken down in writing.

Public buildings for the purposes of religion.

The Cathedral or High Church, is perhaps the most splendid edifice, and entire specimen of our ancient architecture, that is in Scotland. It was founded, as has been before mentioned, in the year 1123, by John Achaius, Bishop of Glasgow, and was dedicated to St Mungo, or Kentigern, during the reign of David I.

Cathedral.

This venerable pile is placed on the west bank of the Molindinar Burn, on an elevated part of the north quarter of the town, declining considerably to the eastward; and is seen at a very great distance in almost every direction, the floor of the choir being 104 feet above the level of the river at the foot of Saltmarket street, at low water mark.

Although we have not been able to ascertain the name

Cathedral.
