LIST OF CONTRIBUTORS.

- SAMUEL W. ABBOTT, M. D., BOSTON, MASS.
Secretary of the Massachusetts State Board of Health.
- JOHN J. ABEL, M. D., BALTIMORE, MD.
Professor of Pharmacology, Johns Hopkins Medical School, Baltimore, Md.
- J. MONTGOMERY BALDY, M. D., PHILADELPHIA, PA.
Professor of Gynecology, Philadelphia Polyclinic; Surgeon to the Gynecean Hospital, Philadelphia.
- CHARLES H. BURNETT, M. D., PHILADELPHIA, PA.
Clinical Professor of Otolaryngology, Woman's Medical College; Emeritus Professor of Diseases of the Ear, Philadelphia Polyclinic.
- ARCHIBALD CHURCH, M. D., CHICAGO, ILL.
Professor of Mental Diseases and Medical Jurisprudence, Northwestern University Medical School, Chicago, Ill.
- J. CHALMERS D'ACOSTA, M. D., PHILADELPHIA, PA.
Clinical Professor of Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital.
- W. A. NEWMAN DORLAND, M. D., PHILADELPHIA, PA.
Assistant Demonstrator of Obstetrics, University of Pennsylvania; Consulting Obstetrician to the Southeastern Dispensary, Philadelphia.
- LOUIS A. DUHRING, M. D., PHILADELPHIA, PA.
Professor of Diseases of the Skin, University of Pennsylvania, Philadelphia.
- VIRGIL P. GIBNEY, M. D., NEW YORK CITY.
Clinical Professor of Orthopedic Surgery, College of Physicians and Surgeons, New York City.
- HOMER W. GIBNEY, M. D., NEW YORK CITY.
Clinical Assistant in Orthopedic Surgery, Vanderbilt Clinic, College of Physicians and Surgeons, New York City.
- HENRY A. GRIFFIN, M. D., NEW YORK CITY.
Assistant Physician to the Roosevelt Hospital, Out-Patient Department, New York City.
- JOHN GUITÉRAS, M. D., PHILADELPHIA, PA.
Professor of General Pathology and Morbid Anatomy, University of Pennsylvania, Philadelphia.
- C. A. HAMANN, M. D., CLEVELAND, OHIO.
Professor of Anatomy, Western Reserve University, Cleveland, Ohio.

- HOWARD F. HANSELL, M. D., PHILADELPHIA, PA.
Professor of Diseases of the Eye, Philadelphia Polyclinic; Clinical Professor of Ophthalmology, Jefferson Medical College, Philadelphia.
- BARTON COOKE HIRST, M. D., PHILADELPHIA, PA.
Professor of Obstetrics, University of Pennsylvania, Philadelphia.
- E. FLETCHER INGALS, M. D., CHICAGO, ILL.
Professor of Laryngology and Diseases of the Chest, Rush Medical College, Chicago, Ill.
- WYATT JOHNSTON, M. D., MONTREAL, CAN.
Assistant Professor of Public Health and Lecturer on Medico-Legal Pathology, McGill University, Montreal, Canada.
- W. W. KEEN, M. D., PHILADELPHIA, PA.
Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia.
- HENRY G. OHLS, M. D., CHICAGO, ILL.
- WILLIAM PEPPER, M. D., PHILADELPHIA, PA.
Professor of the Theory and Practice of Medicine and of Clinical Medicine, University of Pennsylvania, Philadelphia.
- WENDELL REBER, M. D., PHILADELPHIA, PA.
Ophthalmic Surgeon to the Franklin Dispensary and to the Methodist Episcopal Orphanage, Philadelphia.
- DAVID RIESMAN, M. D., PHILADELPHIA, PA.
Adjunct Professor of Clinical Medicine and Therapeutics, Philadelphia Polyclinic; Demonstrator of Pathologic Histology, University of Pennsylvania, Philadelphia.
- LOUIS STARR, M. D., PHILADELPHIA, PA.
Late Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania; Late Physician to the Children's Hospital, Philadelphia.
- ALFRED STENGEL, M. D., PHILADELPHIA, PA.
Physician to the Philadelphia Hospital; Professor of Clinical Medicine, Woman's Medical College; Physician to the Children's Hospital; late Pathologist to the German Hospital, Philadelphia.
- G. N. STEWART, M. D., CLEVELAND, OHIO.
Professor of Physiology and Histology, Western Reserve University, Cleveland Ohio.
- J. R. TILLINGHAST, JR., M. D.,
Assistant Physician to the Roosevelt Hospital, Out-Patient Department, New York City.
- THOMPSON S. WESTCOTT, M. D., PHILADELPHIA, PA.
Instructor in Diseases of Children, University of Pennsylvania; Visiting Physician to the Methodist Episcopal Hospital, Philadelphia.

P R E F A C E .

THE largely increased demand for the 1897 *Year-Book* leaves no doubt as to the usefulness of our work and of appreciation on the part of the profession; these facts have increased the endeavor of all concerned in the preparation of the volume for 1898 to bring it more nearly to our ideal of perfection. With the growing clearness of conception, on the part of the editors, of the exact nature of the professional need there has been a corresponding recognition of the necessity of keeping the epitomization within the limits allotted to previous issues. The vast and increasing literature has this year rendered the task of the editors of especial difficulty; but we believe it has been more thoroughly carried out than ever before, despite the protests of most of the editors that any possible sins of omission must be charged to "insufficient space," and not to neglect.

Several changes in the editorial staff have been caused by reasons that seem almost inevitable in a profession as active as ours. Among these I regret to chronicle the resignation of Professor Leffmann. The growing importance of the subjects heretofore so ably edited by him has warranted the creation of three departments, of which three distinguished specialists have kindly consented to take charge. These are: 1. That of Physiologic Chemistry, by Prof. John J. Abel, of Johns Hopkins Hospital; 2. That of Public Hygiene and Preventive Medicine, by Dr. Samuel W. Abbott, Secretary of the Massachusetts State Board of Health; 3. That of Legal Medicine, by Dr. Wyatt Johnston, of Montreal, Canada.

To these gentlemen especially, and to all the other editors, who, without exception, have labored so loyally, I wish to acknowledge my heartiest appreciation of many courtesies and sacrifices.

GEORGE M. GOULD.

GENERAL MEDICINE.

BY WILLIAM PEPPER, M. D., AND ALFRED STENGEL, M. D.,

OF PHILADELPHIA.

General Summary of the Year's Work.—The most important contribution to the progress of internal medicine is the serum-test for typhoid fever, the Widal test as it is now commonly designated. The reaction which is the fundamental basis of this test was first recognized by Pfeiffer, but was applied to the uses of the practical physician by Widal. Grünbaum almost at the same time, and apparently independently, described the same method, though his contribution lacked the definiteness and finish of that of Widal. Details regarding this method will be given in the appropriate place, but it is fitting to refer here to some of the general bearings of the subject. In previous volumes of the *Year-Book* we have had occasion to deplore the lack of a distinctive test by which typhoid fever might be recognized and differentiated from other febrile affections. This need was particularly emphasized in the discussion of Elsner's method last year. At that time Widal's communication had just appeared, and its value remained to be determined. In the year which has elapsed investigators in every part of the world have tested its value, and, with remarkable consonance, declare it a diagnostic method of the very greatest importance. It is true that dissenting voices have been heard, but these, for the most part, represent no considerable authority or following. A careful and scientific analysis shows that in thousands of cases of typhoid fever, in which the diagnosis was established beyond peradventure, the test, when applied in an approved manner, has seldom failed. In almost equally numerous cases of other diseases the test has rarely resulted positively. Many reported cases must be excluded from such an analysis. In the case of certain typhoid with negative results it has often happened that the proportion of blood-serum to culture has been incorrect, that the cultures were unreliable, or that the test was not repeated at suitable times. In the case of positive results in other diseases it has happened that previous attacks of typhoid fever have not been excluded, that the nonexistence of typhoid infection at the time has not been satisfactorily determined, or that the proportion of serum to culture was so great that even a normal serum might have given a more or less definite reaction. With regard to the positive exclusion of typhoid infection, it is of interest and great importance to note that several cases have been studied in which typhoid fever did not exist (that is, the local intestinal lesions and the typical symptoms), and yet the bacillus was present in the spleen and other organs. This is of interest in connection with the rare cases of general typhoid septicemia, and especially important in its bearing upon reported instances of positive Widal reactions in the absence of typhoid fever (as determined by course, symptoms, and lesions). For our own part, we have become so thoroughly convinced of the value of the test that we should hesitate to diagnose typhoid fever in any case in which repeated examinations, made in

approved fashion, failed to reveal agglutination. If further experience shows these views to be well founded, the possibility will be afforded of distinguishing typhoid fever from a number of doubtful diseases having some resemblance to it. The certain determination of the nature of these has hitherto proved difficult, because fatal cases have not been admitted as instances (typhoid lesions having been discovered in some of these), and the nonfatal cases could not be surely distinguished from typhoid fever. The same method of diagnosis has been extended to cholera, diphtheria, plague, glanders, pyocyanous infection, and other conditions, and there are no doubt still greater possibilities to be discovered.

In the domain of treatment we note the further advances of serum-therapeutics. The brilliant discovery of the plague bacillus by Kitasato has been followed by the extensive investigations of Yersin and others of the serum-treatment, and the results justify great hopefulness. The same may be said of cholera-vaccination. In the case of tuberculosis there is little certainty, notwithstanding the favorable reports of the followers of Maragliano, of Paquin, and of Koch. The untimely publication of Koch's original method, and the unfortunate element of commercialism manifest in the whole matter of preparation of serum, have begotten a proper feeling of conservatism and doubt.

The physiologic chemist continues as an active factor in medical progress. Despite much careful investigation, however, the pathology and therapeutics of gout have not been materially advanced during the year. In the case of other diseases in which abnormal metabolic processes are concerned many details have been studied, and some cleared up, but no striking progress can be recorded.

INFECTIOUS DISEASES.

TYPHOID FEVER.

Although the larger part of the literature upon this disease during the past year has been devoted to the investigation of the Widal reaction, numerous other papers of considerable importance have been published.

Remlinger and Schneider,¹ having become convinced that it was possible by using in conjunction the method of Elsner, the reaction of Widal, and inoculation-tests upon immune animals, to diagnose positively the presence of the typhoid bacillus, undertook a series of experiments to determine whether it existed in nature **outside the human body**. Their results were quite unexpected. In 37 specimens of water drawn from various sources (sewers, springs, and rivers) they were able to recognize its existence 9 times. Of these specimens only 2 came from regions where an epidemic of typhoid fever existed. In 13 specimens of dust and earth they found it 7 times—once from the dust of a room where typhoid fever had not existed for a long time. The bacteria obtained from 3 of these specimens were pathogenic for animals; 10 patients not suffering from typhoid fever were also examined, and in 5 cases organisms were found in the feces, 1 being a case of leukemia of febrile type with intermittent diarrhea. Of these 5 specimens, 4 were pathogenic for guinea-pigs, and their pathogenic action was prevented by previous injection of antityphoid serum. In view of the ubiquity of the typhoid bacillus the authors ask if it be not possible for infection to be greatly favored by the presence of other microorganisms.

Etiology.—Boyer² finds that in Beyrouth the local epidemics of typhoid fever are closely related to the **rainfall**; this is explained by the fact that the

¹ Ann. de l'Inst. Pasteur, Jan. 25, 1897.

² Lyon méd., No. 46, 1896.

water washes the typhoid bacillus from the ground into the canals, causing infection in all regions through which they pass. From the ground he believes the bacillus is occasionally **transmitted** to the inhabitants **through the air**, but most commonly by the water. [Although favorably considered also by the following writer, the possibility of transmission through the air is more than doubtful.] Wolff¹ reports an epidemic of typhoid fever occurring upon Neuhoof Island. As the possibility of infection by water and milk was excluded, it was decided that the cause must reside in an open sewer, and was probably distributed by the atmosphere. Henrot² reports an epidemic of typhoid fever that attacked only members of a dragoon regiment, numbering 1200 men, that lived in garrison with 4000 other soldiers in a town of 30,000 inhabitants. The only cause of infection that could be found was the **dust** of a field upon which human manure had been used, and which had recently been ploughed. [In this and the following article infection from water contaminated by the soil is at least as likely as transmission by the dry dust.] Gibert,³ having been called to investigate the causation of endemic typhoid fever in Havre, found that the water-supply was quite pure, and was therefore inclined to find the source of infection in the **soil** upon which the city was built. He was more inclined to believe this on discovering that in the part of the city built upon pebbly soil there were few cases of typhoid, while in the section, inhabited chiefly by the rich, that was built upon a less hygienic foundation many cases occurred.

Achille Hauser⁴ believes that typhoid fever by **direct contagion** is not so uncommon as is generally supposed; he also believes that it may be transmitted by a third person who does not acquire the infection. He therefore lays down the following rules for the management of typhoid-fever patients: a special nursing-personnel which should itself be immune to the disease and isolated from other patients; the isolation of the typhoid patients; and the frequent and careful disinfection of all the objects that are used by or for them. [The author does not sufficiently establish his contention regarding contagion. Of course, this term is a relative one, and he may apply it to the transmission of the disease by close personal contact in which the germs may somehow reach the alimentary tract of the second person.]

Chantemesse⁵ alludes to the danger of infection with typhoid fever through **oysters**. He cites particularly an instance in which 14 persons in 6 families became affected. The other members of these families who did not eat the oysters remained healthy; 8 of the patients had mild symptoms (pain in the stomach, vomiting, diarrhea, loss of appetite, and tympany) for 2 or 3 days; 4 younger members, who had eaten only a little, had severe symptoms of the same general character, with dejections of dysenteric appearance; 2 others of 20 and 21 years had severe typhoid fever, and 1 died. The illness was not one of simple poisoning, such as occurs after consumption of ordinary shellfish. Finally, the author was able to show by direct experiment that typhoid germs become incorporated in the body of oysters when the latter are placed in infected water. [This subject has been discussed in previous numbers of the *Year-Book*, and the truth seems quite well established.]

Symptomatology.—M. A. Bunce⁶ reports 2 cases of typhoid fever in which the **onset** was marked by symptoms **resembling influenza**. Among these were the usual languor, drowsiness, muscular soreness, pain in the eyeballs, coryza, and cough. The patients were at first treated as cases of

¹ Berlin. klin. Woch., No. 39, 1896.

⁵ Gaz. des Hôpitaux, No. 64, 1896.

⁶ Phila. Polyclinic, Aug. 15, 1896.

influenza, but the persistence of the symptoms later made the diagnosis clear. [We have seen a number of instances during the past year in which the difficulty of diagnosis between these diseases at the onset was quite considerable. In two cases very marked coryza and conjunctivitis, with injection of the conjunctival blood-vessels and fine contraction of the pupils, gave a striking resemblance to influenza. Both of these patients had epistaxis, but, as a rule, we have found this more copious when it occurs in influenza than when it occurs in typhoid fever.]

Wallace Beatty¹ reports a case of typhoid fever commencing suddenly with nausea and pain in the back, followed by rapid development of profound **jaundice**. Death occurred on the 6th day. At the autopsy a large spleen and enlarged mesenteric glands were found. The intestines were free from lesions. Typhoid bacilli were found in the spleen. [The typhoid bacillus does not always give rise to a characteristic clinical or pathologic picture.]

A. G. Nicholls² discusses the question of **hemorrhagic typhoid fever**, and particularly the hemorrhagic eruptions. These are especially frequent about the joints. The spots are usually small, but large suffusions may occur. Referring to the more serious hemorrhagic manifestations, he mentions hemoptysis, hematemesis, and severe hemorrhages from the bowels. The tendency to hemorrhage is probably due to the action of the typhoid bacillus in conjunction with pyogenic microorganisms, and to the coincidence of general cachexia. He has observed 2 cases, 1 of which showed a staphylococcus in the abscesses; the other, the microorganism of hemorrhagic septicemia in the organs. Altogether, the author refers to 4 cases of his own, in which the hemorrhagic diathesis developed on the 13th, 28th, 36th, and 40th day of the typhoid fever, respectively. Three of the patients recovered.

J. Comby³ calls attention to the fact that more or less extensive **desquamation of the skin**, occurring in small branny particles or in large flakes, is frequently met with at the time of defervescence in typhoid fever of childhood. It begins at the neck and spreads over the body, but the hands and feet are unaffected. The sudamina usually occur previous to this, and both the latter and desquamation may be met with in defervescence of other febrile diseases. They are favorable in prognostic significance. [We have repeatedly observed desquamation of marked character in patients who had been treated by cold bathing or frequently sponged.]

E. McD. Cosgrave⁴ reports 5 cases in which **scarlet fever and typhoid fever** were coincident. All had the symptoms of enteric fever and of scarlatina, with general desquamation. In all, the incubation-stages were concurrent, the scarlatinal infection being secondary to the typhoidal infection, so that the two diseases started almost at the same time. It was interesting that neither disease apparently aggravated the other; indeed, the typhoid fever appeared to have a mitigating effect on the scarlatina. In the discussion, Dr. Moore referred to the fact that desquamation may occur in typhoid fever, and stated also that he has seen certain papules on the skin in scarlatina very closely resembling the spots of typhoid fever. [In examining this paper we cannot feel certain that the cases are free from all reasonable doubt as to diagnosis.]

Kühnau⁵ records a case of typhoid infection in which the clinical history was that of a **septicopyemia**. The diagnosis of typhoid was supported by a gradual onset and the discovery of rosolæ and hypolenkocytosis. Bacilli were obtained from the lymphatic glands and from the spleen that had the

⁴ Brit. Med. Jour., Jan. 16, 1897.

⁵ Berlin. klin. Woch., No. 30, 1896.

characteristics of Eberth's bacillus. The author states that there are two possibilities: first, that the infection occurred from the endometrium, from which the virus entered the circulation, or, second, that the infection occurred from the intestinal tract, with absence of local lesions. [It seems to us that the typhoid nature of this case admits of considerable question. The occurrence of ascending infection of the urinary tract was highly suggestive of the bacillus coli communis, and the difficulties of distinguishing this organism from the typhoid bacillus are well known. The clinical facts upon which the author bases his diagnosis are most uncertain; roseolæ occur in other conditions or accidentally at times, while gradual onset and reduction of the leucocytes are by no means distinctive.]

Complications.—Dieulafoy¹ discusses **perforative peritonitis** in typhoid fever. This occurs during the height of the disease or during a relapse. It may occur in mild as well as severe cases, and the most constant and significant sign is sudden fall of temperature, although this does not always indicate this accident, as some cases terminate by crisis and hemorrhage is similarly accompanied by rapid decline. In the latter, however, the fever rises quickly again. Peritonitis from perforation usually lasts from 3 days to a week, and deceptive remissions may occur. In rare cases protective adhesions form and recovery ensues. When peritonitis is due to propagation of the infectious process through the ulcerated but not perforated intestines, there may be a lesion in the vermiform appendix. The symptoms are the same as those of other typhoid perforation. The term paratyphoid peritonitis may be applied to cases in which there is a sudden rise of the temperature due to late perforation resulting from a remnant of the typhoid lesion in the appendix. When the occurrence of perforation has been established operation holds out some hope of success. Lerboullet² reports several cases of typhoid fever in which perforation was accompanied by increase in the temperature. A case of unusual interest, though not entirely unique, is the following: Heagler³ reports a case of typhoid fever that occurred in a woman suffering from **ventral hernia**. Perforation of the ileum contained in the hernial sac occurred, and also pierced the epidermis, giving rise to a fecal fistula. This gradually increased in size until it formed an opening 6 by 2 cm. The nutrition of the patient was profoundly depressed; she became greatly emaciated, but subsequently there was some improvement and she ultimately recovered. E. B. Steel⁴ reports a case of supposed enteric fever complicated by perforation, peritonitis, and perityphlitic abscess. The onset was sudden, with severe abdominal pain and the signs of peritonitis. Later collapse occurred, and subsequently well-defined typhoid spots appeared. Finally, a local mass developed in the right iliac fossa. It was regarded as a perityphlitic abscess, and was drained. [The author reports this as a case of typhoid fever with perforation, but we must confess that the history is far from satisfactory. It seems to us rather an instance of appendicitis. The presence of spots and the history, upon which the author lays great stress, are insufficient for the purpose of making a positive diagnosis.]

J. B. Herrick⁵ reports a case of typhoid fever occurring after an attempt to produce abortion that was supposed, at first, to be septic in nature. Death occurred as a result of hemorrhage, and at the autopsy, besides the lesions of typhoid fever which were confirmed by bacteriologic examination, an **extra-uterine pregnancy** was discovered.

⁴ Brit. Med. Jour., Jan. 2, 1897.

⁵ Med. News, Oct. 17, 1896.

[The more general application of bacteriologic methods is bearing fruit in the way of showing the frequency of secondary and mixed infections in typhoid fever. No useful rules for treatment or prevention can as yet be formulated.] Nicholls¹ reports a case of typhoid fever with **septic infection**. The rarity of the condition is manifest from the absence of reported cases even in extensive statistics, although a number of cases of general septicemia have been reported in which the typhoid germ and some other germ or germs were found in the various organs, or in which a simple secondary infection had occurred in the course of typhoid. The latter is more often the case. These cases run an atypical course, and are usually marked by great prostration, stupor, at times low delirium, subsultus, lividity, high fever, chills, and local septic processes. These symptoms, while they are at times met with in uncomplicated cases, are exceptional when the bath-treatment is used. His own case, a man of 30, had been ill 6 weeks before admission with vague prodromes of typhoid. When admitted his temperature was 104.8°, the skin was slightly livid, his tongue was swollen, and the pulse was dicrotic. The cyanosis increased and a membranous patch developed on the soft palate; the cultures from this showed micrococcus tetragonus and a few short bacilli not resembling the diphtheria bacillus. Bronchopneumonia developed and the patient died. Cultures from the blood during life showed a mixture of the streptococci, staphylococci, and 2 bacilli, 1 conforming to the tests for the typhoid bacillus. At the autopsy cultures were made from all the viscera, and these confirmed the examinations of the blood.

A. Schmidt² reports a case of typhoid fever which was followed by the development of **suppuration** beneath the diaphragm. When the abscess was opened by an operation 3 liters of clear brown liquid pus were evacuated, containing a pure culture of typhoid bacillus. The origin of the lesion was either an abscess of the spleen or a suppurated mesenteric gland. He also reports another case in which, after a severe colitis, particularly affecting the transverse and descending colon, a left-sided pleural empyema developed, which contained only the bacterium coli communis. He adopts the explanation of Cürschmann, that the organisms find their way into the pleura along the retro-peritoneal space. H. B. Anderson³ reports a case of suppurative **cholecystitis following typhoid fever**. A man of 67 was attacked suddenly with chill, fever, diarrhea, and pains in the abdomen. He recovered somewhat, but recurrence of similar symptoms followed. Malarial plasmodia could not be detected and the spleen was little enlarged. The right side of the abdomen was tense and very tender, so that the edge of the liver could not be felt. The history gave no indication of previous occurrence of gall-stone or jaundice. A probable diagnosis of abscess of the liver following some form of intestinal lesion was made. The patient died in coma. The autopsy showed an acute peritonitis due to rupture of the gall-bladder. The solitary follicles of the intestine were swollen, and there was ulceration of several of Peyer's patches in the lower part of the ileum. The cystic duct was obstructed by a gall-stone and there were a perforating ulcer and dilatation of the gall-bladder. Typhoid bacilli were obtained from the peritoneal liquid. The author concludes, therefore, that the original disease was typhoid fever. [The diagnosis in this case is not entirely free from doubt. The following case is, however, more satisfactory:] A. L. Mason⁴ reports a case of typhoid fever in which, toward the end of the third week, there was pain in the right hypochondrium, followed by development of a tumor in this region. There was partial collapse, and a diagnosis of suppurative distention of the gall-bladder was made. This was tapped, and several ounces of sero-

¹ Montreal Med. Jour., Aug., 1896.

² Deutsch. med. Woch., No. 32, 1896.

³ Med. News, Aug. 8, 1896.

⁴ Boston M. and S. Jour., May 13, 1897.

purulent fluid withdrawn that was found to contain the typhoid bacillus. The patient recovered. Fernet¹ reports a case of typhoid fever in a patient suffering from intermittent hydronephrosis. Toward the end of the disease a fluctuating tumor developed in the abdomen, and this was punctured and found to be a **pyonephrosis**, the pus containing a pure culture of typhoid bacilli. As a result of the operation peritonitis developed, and this was apparently due to infection with bacterium coli. During the course of the pyonephrosis there was no pyrexia.

Widal² describes a case in which an **exostosis** appeared on the posterior part of the 9th rib, and grew to the size of an egg, beginning on the 27th day of a case of severe typhoid fever. The mass was bony-hard and appeared quickly, but disappeared just as quickly with the improvement in the general condition, and by the 41st day there was no visible swelling. The skin over the seat of the tumor remained slightly discolored for a long time. [The appearance and disappearance of swellings of this character are sometimes remarkable. In a recent case under our care appeared on the outer side of the left humerus, and suppuration seemed inevitable. Unexpectedly resolution occurred, complete disappearance of the mass, which had reached the size of a small lemon, speedily following.] Tuffier and Widal³ report a case of periostitis following 16 months after a mild attack of typhoid. Both tibiæ were affected, and an abscess occurred in the left. This was incised, but no typhoid bacilli could be detected in the pus. The authors ascribe this to the death of the organisms having occurred, such as is known to take place at times in post-pneumonic abscesses. Bruni⁴ reports a case of **osteomyelitis** in which typhoid bacilli were found, occurring six years after the patient had had typhoid. The patient, aged 36, had chronic afebrile osteomyelitis involving the left tibia and resembling that met with in tuberculosis. The bacteriologic study showed typhoid bacilli.

Salles and Borjon⁵ describe a case of **orchitis** in the course of typhoid fever. The case is of special interest from the fact that the epididymis and the body of the testicle, as well, were involved. The tunica vaginalis at the same time was the seat of exudation, this being rather common in cases occurring in typhoid orchitis. The typhoid bacilli were found on the 6th and on the 17th days in some of the serum that had been removed.

Bresler⁶ reports a case of **thrombosis** of the vena cava inferior which occurred in a patient who had had typhoid fever 17 months previously. The swelling of the abdominal veins became quite marked, and the upward current of blood was easily demonstrated. As this dilatation was only moderate, and there had been very slight edema of the feet, the author was inclined to the belief that the occlusion was only partial. [This complication is infrequent. Its termination in abscess of the liver was referred to in the last *Year-Book*.] Etienne⁷ reports the case of a young man of 18 who on the 51st day of an attack of typhoid fever went into a state of collapse and died 3 days later. At the autopsy a thrombus was found in the coronal vein.

C. S. Bull⁸ describes the following **ocular complications** of typhoid fever: conjunctivitis, which may be catarrhal or phlyctenular and combined with keratitis, loss of accommodation, and dilatation of the pupil from paresis of the ciliary muscle, retinal hemorrhage, paralysis of the external muscles, neuroretinitis, and inflammations of the uveal tract.

M. L. Griffin¹ reports a case of enormous **enlargement of the spleen**, following typhoid fever and progressing for 15 years. Upon the administration of arsenic the organ returned to its normal size in the course of 2 months. [It is, of course, very doubtful whether the typhoid bacillus was responsible for this condition.]

Diagnosis.—[Our knowledge of the reaction that takes place between the blood-serum of an infection and the infecting microorganism is based upon the work that has been done by many investigators during the past years. Pfeiffer pointed out the peculiar reaction, which bears his name, that occurs when the microbe is injected into the body of an immune animal. Further investigation proved that a similar reaction took place outside of the body, in the test-tube, with serum from the immune animal. Others found that the reaction occurred also with the blood of convalescents, and even of cases in the acute stages of the infection. Its great practical value in the diagnosis of typhoid fever was discovered by Widal; and, although Grünbaum in Vienna at the same time and independently published similar results, the investigations of the former have been much more useful.]

The **Widal reaction** is manifested on adding to a fresh bouillon-culture of typhoid bacillus a small amount of the serum; after a certain time (8–16 hours) the turbidity of the medium disappears. The liquid becomes clear, and the microbes settle to the bottom of the tube as a flocculent deposit. The cause of this, as witnessed under the microscope, is due to a complete loss of the natural motility and an agglutination of the bacilli—a clumping into more or less large masses.

This method of Widal gives such brilliant promise that the more cumbersome bacteriologic methods have received little attention during the year. Clinicians in many quarters incline to make the diagnosis too readily. This tendency is especially marked among some of those who report remarkable results for new “cures.” It is hoped that the serum-test will prove a reliable indication, if for no other reason than to serve as a check to reckless laudation of methods of treatment based upon speedy cure of doubtful cases.]

Widal² reports the examination of the serum of 6 cases of typhoid on the 7th, 12th, 15th, 16th, 19th, and 21st days of the disease. All gave **characteristic immobilization and agglutination**. With a sterilized syringe a small quantity of blood was withdrawn from the median cephalic vein, and a few drops of the serum thus obtained added to a fresh bouillon-culture of the typhoid bacillus in the proportion of 1 : 10 or 1 : 15. After 24 hours in the incubator the cloudiness had mostly disappeared and the microbes had sunk to the bottom of the tube in flocculent masses. The serum of cases other than typhoid did not have this action. The coli bacilli behaved in the same way toward 2 cases that had had typhoid; but in cases of other diseases they retained their motility and remained free. Achard³ reports 6 cases, 3 positive and 3 negative. Of these latter, 2 were of doubtful diagnosis, and the course of the disease disproved typhoid; the third was some febrile gastric trouble. Of the 3 positive cases, the first was examined on the 8th day after a relapse; the second was a typical case of typhoid; and the third was a patient with fever and diarrhea, but no stupor nor adynamia. Splenic puncture gave a culture of the bacillus typhosus. Lemoine⁴ studied an epidemic of “*typhoidette*” and gastric disturbance: 3 cases of the former gave positive serum-reactions; 7 cases of the latter gave 6 negative results. The one positive reaction was in a case simulating, in some respects, typhoid, which was ren-

¹ Dublin Jour. Med. Sci., Apr., 1897.

² Sem. méd., p. 259, 1896.

⁴ Bull. de la Soc. méd. des Hôp., July 24, 1896.

dered probable by the course of the disease. Siredey¹ gives a case of typhoid of 31st day, with positive reaction. The patient had fetid diarrhea and a scarlatiniform erythema, and the disease ran a rather abnormal course. Lemoine² reports a case of acute tuberculosis in whose stools a bacillus identical with Eberth's bacillus that gave a reaction with typhoid serum was found by Elsner's method. The serum of this patient gave no reaction with the typhoid bacillus. It is interesting to note that this patient had had typhoid fever 17 years before. Widal³ reports 14 positive cases. In 4 it existed on the 8th day; in 1 it appeared on the 5th; in 1, absent on the 6th day, it appeared on the 7th; 11 cases of gastric disturbances were without result, and the clinical history confirmed this. 1 case for a while was suspicious, but a bacteriologic examination of the spleen gave a culture of staphylococcus. In another very light case the reaction was positive. In association with Sicard he found that the reaction sometimes occurred in the urine, but that this was a very inconstant phenomenon. Chantemesse⁴ examined many febrile cases with negative results. In every one of 11 cases of typhoid there was a positive reaction (9th day to convalescence). The serum of these had no effect on the bacillus coli communis.

Achard and Bensaud⁵ observed **agglutination in the milk** of typhoids. A case of 15 days with a 2 months' child had all the typical signs of typhoid, with positive reaction. The milk gave a good reaction with 1:10 dilution. The milk of 6 nursing-women with other diseases gave no reaction; 2 of these had had typhoid 16 and 15 years before. A slight alkalization or acidification produced no alteration in the reaction. A temperature of 60° C. did not alter it; one of 100° diminished it; and one of 120° for 15 minutes destroyed it. Filtration through a Chamberlain bougie caused its disappearance. The case with which milk is decomposed makes its use undesirable for the clinical application of the test. Widal and Sicard⁶ found that the serum dried on different substances retained a certain amount of its agglutinative action. The best reaction was obtained from that dried on small pieces of **sponge**; 3 cases of typhoid gave a positive result with such serum—1 case at the height of the disease and 2 during the decline. A person who had had typhoid 7 years previously still gave a positive result. Other cases remained negative. The serum obtained from vesicles also gave a distinct reaction.

Widal⁷ says the serum of **coli-infection** differs in no way from that of other diseases. Hypothetically, the serum of typhoids whose intestinal lesions have permitted a secondary infection from the intestinal tract may show some reaction with the bacillus coli communis. But this does not affect the specificity of the typhoid-serum reaction. Vedel⁸ reports a case of typhoid of 28 days' duration, whose serum gave the reaction. It had also a slight action on a fresh culture of coli communis. Another case, apparently typhoid, gave a negative result. These tests were confirmed by the clinical course. In the second case defervescence took place on the 10th day. Haus-halter,⁹ among many positive results, reports that the serum of a newborn child of a typhoid mother with positive reaction was negative.

Dieulafoy¹⁰ reports that Widal and Sicard have shown that the **fibrinogen and seroglobulin** of the blood when separated retain the whole of the agglutinative substances. The same is true of other fluids of the body, pericardial and peritoneal, edematous and vesicular. In milk the casein is the active principle.

¹⁰ Bull. de l'Acad. de Méd., 346, 1896.

A. S. Grünbaum¹ says that, "although anticipating matters, it may be stated that hitherto it is only in cases of enteric fever that the serum shows a distinct agglutinative action within 30 minutes **when diluted** 16 times." Owing to the rarity of typhoid fever in Vienna, he is able to report only 8 cases, in all of which a positive reaction was obtained—2 with a dilution of 1:25; 4 with 1:64; 1 with 1:100; and 1 with 1:128. The blood taken from the ear or finger into a V-shaped capillary tube and centrifugated, is broken at the junction of the serum and corpuscles, and the drop or so of serum blown out. A number of tests were made with dilutions of 1:4 and 1:8, and positive results were obtained in many cases of diseases other than typhoid fever, and in healthy persons.

Achard and Bensaude² claim that the agglutinative power does not reside in the leukocytes. Plasma obtained from blood by addition of extract of leeches and centrifugating gave a reaction in no way less complete than plasma containing many leukocytes. Leukocytes separated by filtration through cotton, though living and capable of phagocytosis, had no effect on a culture of typhoid bacillus. This power, then, exists in the **plasma**. It can be dialyzed. It also exists in milk, tears, hydatid-cyst liquid, saliva, gastric juice, and bile.

Pugliesi³ reports 44 observations of Widal's reaction. In the author's cases the serum was obtained from **blisters**, although in a small number the reaction was confirmed by serum drawn directly from the blood. In the most typical cases the reaction was noticed in from 5 to 6 hours; sometimes, however, not until 48 hours had elapsed. In 16 cases of typhoid the result was positive in 13, while in 11 cases of other diseases the reaction was negative in 8 and uncertain in 3. He details 6 cases in which the diagnosis was doubtful; in 4 of these the reaction was positive and in 2 negative: 1 of these was believed to be puerperal fever, but at the autopsy typhoid lesions were found. Widal's reaction was positive. On the other hand, a case diagnosed as typhoid fever gave no reaction, and post mortem there was no evidence of typhoid.

Widal and Sicard⁴ think that in general the reaction is less intense in **mild cases** and in convalescence, but that this is not absolute.

Achard⁵ found that serum that had lost its agglutinative action on the 16th day of **defervescence** differed in nothing, as regards its immunizing power, from the same serum during the febrile stage. He also noticed an increase of the reaction after relapses. Widal⁶ found that the agglutinative action generally decreased after defervescence, but completely disappeared in only 2 cases of 16 on the 18th and 24th days of fever. It existed in 3 cases who had had typhoid 6 months, 3 years, and 7 years previously. During the febrile period the reaction may vary from 1:60 to 1:80, while in the convalescent stage it drops to 1:20, 1:10, or even lower. It thus appears to be greatest during infection, and to diminish at the beginning of immunity; it is therefore a phenomenon of infection, not of immunity.

Cutin⁷ reports 2 cases of typhoid fever: 1 was followed after convalescence by rise of temperature and subsequent development of a phlegmon on the right arm, containing staphylococcus pyogenes aureus. The **pus** itself gave the typical reaction of Widal. The second case developed a phlegmon on the anterior surface of the thigh, giving the same cultures and having the same effect upon the typhoid bacillus.

⁷ Gaz. de Méd. de Paris, Oct. 15, 1896.

Haushalter¹ reports 15 cases of typhoid fever with positive reaction; in 2 cases, however, it was incomplete. Of 8 cases of gastric disturbance, 5 gave a positive reaction; 4 cases of bronchopneumonia were negative.

Thirolaix² found that with 1:10 dilution the reaction began in 10–20 minutes on the 4–13th day of disease. Once it was negative on the 3d day, and appeared on the 5th. 28 cases of other diseases were negative. In 3 cases of typhoid it persisted for 3, 6, and 8 months. The prognosis does not depend upon the intensity of the reaction.

Villiez and Battle³ say that in 6 undoubted cases of typhoid the reaction was positive. In 3 of malaria from Madagascar a constant positive reaction occurred in 1 [possibly typhomalaria(?)]. Some cases of simple gastric catarrh gave positive results, and these convalesced slowly; others were negative, and these convalesced rapidly. [The careless manner in which the term **simple gastric catarrh** is employed by some French writers is exceedingly confusing.]

R. Breuer⁴ gives a very interesting review of the subject. In his cases he makes use of the second method of Widal. In 43 cases, the diagnosis of which was verified by the course of the disease, and in 3 cases by section, there were marked and undoubted positive reactions: 27 nontyphoids were examined, and 22 gave completely negative results. In some there was a slight agglutination, shown macroscopically by a dust-like cloudiness of the bouillon, without flocculent deposit. The same occurred in 3 cases of short febrile attacks which somewhat simulated typhoid, but which were finally diagnosed as cases of autointoxication. 9 convalescents were tested at periods of from 5 days to 3 months after recovery. In 2 only was the result negative. No relation was observed between the severity of the attack and the intensity of the reaction.

Achard and Bensaude⁵ report 2 cases—1 of suppurative arthritis, and the other of paratyphoid, a case with characteristic typhoid symptoms excepting roseolæ and splenic enlargement. The urine gave cultures of the bacillus paratyphosus. No typhoid bacilli were found in spleen or stools. These **paratyphoid** bacilli were akin to the typhoid microbe, but were a different species: they fermented glucose and maltose, but not lactose and saccharose. Inoculations on cultures of Eberth's bacillus acted like the bacillus coli communis. Typhoid serum agglutinated 12 of 14 specimens of bacillus paratyphosus. Paratyphoid serum may agglutinate under some conditions the bacillus typhosus. The serum on the 21st day agglutinated both the bacillus typhosus and paratyphosus. The reaction persisted until the 53d day with the paratyphoid bacillus, but with only 3 out of 13 specimens of the typhoid.

Widal and Sicard⁶ claim that the reaction can definitely differentiate the bacilli of typhoid and of **psittacosis**. In dilutions of 1:10 the reaction occurs in both, but the masses of bacilli of psittacosis are smaller and more crowded. In dilutions of 1:20, 1:30, 1:40, there arrives a moment when the bacillus psittacosis no longer reacts. With fresh cultures the difference is most marked with 1:40–1:60, both in test-tube and microscopically. Grüber obtained agglutination with bacillus entericus, but only in concentrated solutions; with dilute solutions there was a distinct difference. They noticed a variation in some of the specimens according to their virulence, transplantation, medium, age, etc.

E. B. Block⁷ gives the results in 20 cases of typhoid tested in Dr. Oser's

⁷ Bull. Johns Hopkins Hosp., Nov. and Dec., 1896.

wards. The dilution was 1:16, and the reaction was complete in only 11 cases. In 6 it was partial. In 3 it was but slight, and these were very mild cases. Grünbaum's method for collecting the serum was used. The dry method was employed in 17 cases, with marked reaction in 9.

Ménétrier¹ observed a case of typhoid complicated with pleurisy in which the **pleural effusion** did not give the reaction on the 35th day. At the same date the serum was not examined, but on the 8th day it had given a decided reaction. Achard² has found many times a positive reaction with pleural effusions, but has found it wanting in the **pericardial fluid**.

Wyatt Johnston and D. D. McTaggart³ have contributed papers upon the diagnostic value of the **serum-reaction in typhoid fever**, using the drop-method described by Johnston. The blood is received in drops upon sterilized paper; these drops are afterward treated with distilled water, and the reaction tested with the solution so obtained. The blood used had usually been sent to them from a distance. The reaction occurred usually in a few minutes, but sometimes 3 or 4 or even 24 hours were required. It was best obtained with fresh, active cultures. The following are the results in 143 cases: positive results on first examination, 118, of which the reaction was complete in 112 and partial in 6, 3 of these being about the 3d day. The reaction was doubtful on the first examination in 5 cases, 4 of which were examined about the 6th day. Negative results were as follows: decisively negative, 14 cases; all were proved afterward to be other diseases; doubtfully negative, 3 cases; these were mild cases of typhoid first examined during convalescence; 2 cases with clinical history of typhoid in which no reexamination was made, and the primary examination was negative; 1 case of severe fever of typhoid type in which Widal's method and the dry method (3 times) gave negative results. This makes the total negative results in cases of possible typhoid 6 in 143 cases. The authors have also studied the serum of dry blood in experimental cholera and found that it gave positive results. They were able to demonstrate that the blood of guinea-pigs after a single intraperitoneal injection becomes positive in action. They substantiate the statement of Bordet that the blood of horses produces clumping.

Stern⁴ has examined the blood in typhoid-fever patients with regard to leucocytosis and the presence of the typhoid bacilli. Considerable quantities of blood should be used, as the number of bacilli present is always small. The author has also investigated Widal's serum-test in 16 cases. He has taken blood from the finger-tip and added it to a bouillon-suspension of the typhoid bacillus, and then separated the red corpuscles by the centrifugal machine. The exact quantitative estimation of the effective substance in the blood cannot be made by this method. The earliest time that he obtained successful results was the 9th day of the disease, and he invariably obtained negative results in other diseases, excepting in 1 case of otitis, where there was a slight but distinct reaction obtained after 1 hour. The patient had never had typhoid fever. It is necessary, the author states, to determine the proportion of serum to culture that is powerless to give a reaction with blood-serum of other cases than those of typhoid fever. This proportion he found in his cases was 1 to 100, and even 1 to 200; Widal gives it as 1 to 60. The negative result in the early stages of typhoid fever must not be forgotten, and repeated testing of suspicious cases should be practised.

¹ Bull. de la Soc. méd. des Hôp., Dec. 4, 1896.

³ Brit. Med. Jour., Dec. 5, 1896; N. Y. Med. Jour., Oct. 31, 1896.

⁴ Centralbl. f. innere Med., Dec. 5, 1896.

² *Ibid.*

C. L. Greene¹ gives a further report of cases tested: 16 cases of typhoid reacted positively, and 19 cases of diseases other than typhoid were negative. He uses both the dried blood and the serum methods. He also observes that the diagnosis may be made by the naked eye, a fact which might sometimes be of service. Thiercelin and Lenoble² report a case of fever lasting 4 weeks that reacted during this period; on the 4th day of normal temperature there was a reaction in 3 minutes in 1:10. A relapse occurred 5 days after this and lasted 10 days; 20 days afterward no reaction occurred even in 2 hours.

Widal and Sicard³ found the reaction in the **pleural fluid** of 3 cases, although it may be wanting in large effusions. This is not due to the presence of the bacillus, for pus containing bacilli may give a very active reaction. The fact may be due to the rapidity of the formation of the effusion in some way. **Tears** give the test in 1:10 and 1:5; but with artificial lacrimation due to ammonia the reaction does not occur.

Thoinot and Cavasse⁴ report a case of mild typhoid or typhus levisimus. The reaction until the period of defervescence was always negative. After 7 days of apyrexia, during which the spleen remained enlarged, a **relapse** occurred of 15 days' duration, with classical symptoms. 2 days after defervescence the reaction by culture-method gave positive result; none, however, by the extemporaneous method. A second relapse took place 1 month later. On the 8th day the reaction was slow, but positive; by culture in only 48 hours. 1 day after defervescence the reaction occurred in 10 minutes. The serum from vesicles also gave positive results.

Thiercelin and Lenoble⁵ record a case of typhoid in which blood and milk reacted, but the spontaneous **sweat** did not.

Widal and Sicard⁶ discuss the **limits of the agglutinative action** of the serum of typhoid-fever patients, and state that it usually occurs on the first day of the infection. Its disappearance may occur as early as the 18th day after convalescence. In the cases that they observed, the disappearance usually took place at the end of a year; although immunity still exists at this time. However, in 22 cases that had had typhoid fever at varying times up to 26 years before the examination the agglutinating reaction was observed 6 times; three of these showing it very markedly in dilutions of 1 to 10; one had been well for 3 years, another for 7 years, and the third for 9 years. In other cases it required a larger proportion to obtain this result. They insist again that serum presenting this agglutinating action is not necessarily bactericidal, as they have been able to maintain cultures in it for 2 months without destroying their vitality. They believe, however, that this reaction is one of defence on the part of the organism, especially during the period of infection.

Charrin⁷ holds that the Widal reaction is a **defensive action**;—in other words, that it is the beginning of an immunity.

Charrier and Apert⁸ report 5 cases of typhoid with positive results. They also report the examination of the tissue of an embryo—from a mother in the third week of typhoid fever. They found that there was total absence of agglutinating action in the tissues of the fetal organism, and that in the placenta this property was present with a dilution of 1 to 15. They conclude that **the placenta** acts as a sort of filter and retains in the maternal organism not only the agglutinating substance, but probably also the toxins, whose dis-

¹ Med. Rec., Dec. 5, 1896. ² Compt. rend. de la Soc. de Biol., No. 32, Dec. 11, 1896.

⁴ Ibid.

⁵ Compt. rend. de la Soc. de Biol., No. 33, Dec. 19, 1896.

⁶ Ibid.

⁷ Ibid.

⁸ Ibid., Jan. 1, 1897.

charge into the fetal circulation would doubtless cause the development of the agglutinating property. [We have knowledge of a case, not yet published, that occurred in the service of one of our colleges, in which the Widal test was positive for the infant blood. Moreover, positive demonstrations have been made of the transmission of typhoid bacilli through the placenta to the fetal circulation.]

Jez¹ reports a case in which reaction by the cultural method took place in 24 hours; by the microscopic in 15 minutes. A control-test was negative. The patient, a woman of 23 years, gave no history of typhoid. The test was made on the 13th day of the disease. The postmortem showed a basilar **tuberculous leptomeningitis**. [It is worth noting that no cultures from the organs were made for typhoid bacilli.]

Fränkel² hastened to confirm **Widal's method** as soon as published, and by great good fortune was enabled to study two epidemics, using in every case the three methods—the culture, the hanging-drop, and the test-tube. He believes that the microscopic investigations of the hanging drop give the most delicate, the most accurate, and the most rapid diagnosis of typhoid fever that could be desired. In a large number of investigations he obtained no reaction in only a few cases; they were either doubtful or in persons that had been convalescent for 5 weeks or more. In the latter class of cases he also found some whose blood gave a positive reaction. He also investigated a number of cases that were probably suffering from infection with the bacterium coli communis, and in all cases the result was negative, nor did cultures of the bacterium coli communis ever show the reaction in serum from typhoid fever. He naturally speaks highly of the trustworthiness of Widal's method, and simply raises the question whether the rapidity with which the reaction takes place and its completeness bear any relation to the severity of the infection. In conclusion, he triumphs over those "independent" and "cautious" investigators who have hitherto doubted the specific nature of the bacillus of Eberth.

Pfuhl³ has employed Widal's method of serum-diagnosis for typhoid fever in a number of cases, and found that it occurred in all cases of typhoid fever, and in no others, excepting in one of so-called gastric fever, which he looks upon as a case of mild typhoid. He suggests as a **simplification of the method** the mixture of 1 drop of blood with 10 drops of water; 1 drop of this then being mixed with 1 drop of bouillon-culture and examined in the hanging drop.

Jemma⁴ agrees that promptness and character of the reaction depend upon the **intensity of the infection**. Jemma's experiments show that the reaction is greatest during the period when the bactericidal power of the blood-serum is greatest—at the febrile acme. Also, the quantity of serum used is less in this stage. Widal and Sicard show that the agglutinative effect and bactericidal power are in part related. Dienlafoy, Widal, and Sicard claim that it is not the serumalbumin, but the serumglobulin and fibrinogen to which the action is due. Devoto isolated the globulin with a saturated solution of ammonium sulfate, and dried the filtrate at low temperatures. When dried at 55° C. it lost its bactericidal property, but the ordinary room-temperature did not destroy this. Under this condition the test occurred with especial rapidity on the addition of the globulin. The same property exists in the urine, milk, tears, and all exudates. Widal and Sicard hold that the reaction is a phenomenon of infection, while others (Maragliano) ascribe it to immuniza-

¹ Wien. med. Woch., Mar., 1897.

⁴ Centrallbl. f. innere Med., Jan. 23, 1897.

tion. Jemma says that a temperature of 37° for 24–96 hours has no detrimental effect; also that 40° for 18–50 hours, 55° for 40 minutes, and 60° for 20 minutes diminishes, and 70° for 10 minutes destroys, the agglutinative action completely. It withstands the ordinary temperatures of 12° – 15° for 40 days.

Pick¹ gives a **brief resume of the literature** to date. A series of cases were tested to find the most practical method. Venesection proved not to be a good routine practice. He then used blood from the sterilized finger, drawn into a small glass tube. The coagulum was removed and $\frac{1}{2}$ – $\frac{3}{4}$ c.c. of pure serum obtained. Mixing 1 part of this with 10 parts of 24–48 hours' bouillon-culture, examination was made under the microscope in hanging drop. He also used the dried blood. Among 20 healthy persons and those with febrile diseases he never found a positive reaction. Sometimes there was a slight agglutination, but the masses never increased in size and the bacilli retained their motility. 20 cases of typically typhoid course and symptoms gave positive reactions. In 16 on the 3d to 21st day of the disease the reaction was immediate; in 4 it occurred in 10–30 minutes; in 12 cases the culture-test was complete in 8–16 hours; in 3, with less than 1 : 20 of serum, it was incomplete. The earliest period at which the reaction appears was on the 3d day. In 4 cases on the 5th day a dilution of 1 : 80 was sufficient; in 2 it took place, but only after 10 minutes; and in 1 a dilution of 1 : 5 was necessary; 1 case gave slow (30 minutes) reaction with 1 : 5 on the 6th day, and a slight one on the following day with 1 : 10. Another gave on the 7th day none; on the 9th day a slight one; and on the 11th an immediate and typical reaction; 12 suspicious and doubtful cases were examined; 3 gave immediate positive reactions, and the course of the disease confirmed the results; 9 were negative. Of these, 3 proved to be pneumonia; 2 tuberculosis and sepsis; 1 meningitis. In 1 the reaction was negative with 1 : 10 and 1 : 4 from the 6th day on by repeated tests, and only on the 34th day with 1 : 2 was there a reaction; 2 cases are worth details. A girl, aged 19, had been sick for a week; there were pain in the head and neck and a temperature of 39.5° . The condition resembled typhoid, but the serum-test was negative. Later symptoms of meningitis developed. A woman, aged 23, had been ill for 16 days with a temperature of 39.3° C., bronchitis and constipation; she had no tumor of the spleen and no roseolæ. The test was markedly positive on the 21st day of the disease. A general low typhoid developed and she died on the 24th day. The section showed no typhoid intestinal lesions, no splenic enlargement. Cultures gave the bacillus typhosus. Blood from the veins and extract of the lymph-glands gave positive reactions. Extract from the lungs and muscles gave only a slight reaction, that from the spleen none at all. Blood after the action of alcohol was negative. He also examined the blood of persons who had had the disease previously. 3 cases after $1\frac{1}{2}$ years and one after 9 days gave an incomplete reaction; 2 after 12–16 years gave none; 1 after 14 days gave a complete reaction. Tests with the cultural method in the 12 negative cases gave the same results as with the microscopic examination. The dry method gave identical results, but he notes two objections—the masking of the reaction due to the coloring, and the difficulty of determining the exact quantity of serum used.

A. E. Wright and D. Semple,² in the course of their experiments on the effect of **typhoid vaccine**, tested the blood of their patients for the Widal reaction. The vaccine used was sterilized cultures. In 17 healthy persons that had been injected the reaction appeared almost immediately with 1 : 10 dilution

¹ Wien. klin. Woch., No. 4, 1897.

² Brit. Med. Jour., Jan. 30, 1897.

of the serum. The maximum reaction, however, did not develop until a much longer period—2 to 5 weeks—and sometimes even only after repeated injections of the vaccine.

Mesnil de Rochemont¹ reports 2 cases in which an **early diagnosis** of typhoid fever was made. One on the 2d day from the initial chill gave a reaction, microscopically, with a 1 : 10 and, macroscopically, with 1 : 100 dilution. The other on the second day was positive with 1 : 10 and 1 : 40 dilutions. The diagnosis was in both cases confirmed by the subsequent course of the disease. 3 cases of typhoid complicating other diseases gave positive results by the microscopic method with 1 : 10, 1 : 40, and 1 : 40 dilutions; by the macroscopic, 1 : 30, 1 : 40, and 1 : 60 dilutions. Another case, which always was negative by the macroscopic culture-method, gave a positive reaction with 1 : 10 dilution under the microscope, and proved at the autopsy to be purulent meningitis and follicular enteritis. The author concludes that with high dilutions a positive reaction renders the diagnosis absolutely certain.

A. H. Appel and F. J. Thornbury² never observed any effect on the **bacillus coli communis**, even with serum that reacted strongly with the typhoid bacillus. With the **bacillus pyocyaneus** they obtained a slight reaction with typhoid serum, but were unable to find any other organisms, pathogenic or saprophytic, that were at all affected by it. Fifty cases of typhoid fever were tested upon attenuated cultures, and more or less typical reactions obtained. With virulent cultures cases which were convalescent for a number of years under the same conditions gave constant negative results; 25 persons in health or suffering from diseases other than typhoid were examined with varying results.

Courmont³ reports the results of examination of **7 cases of typhoid**. In 4 a mixture made of 1 : 10 of body-juices and culture, the heart's blood and pericardial, pleural, and peritoneal serous fluids gave distinct positive reactions. The liver and spleen gave very feeble ones; in 1 case the latter was negative. The other 3 cases were examined by exact dosage, and it was found that the blood gave the strongest reaction, whilst that of the splenic pulp was always very weak; in other words, those organs in which the bacillus was localized contained little or no agglutinin, whilst the abnormal presence of the bacillus in any situation caused its disappearance. Menetrier⁴ found a pleural fluid containing bacilli that did not agglutinate. Other germs have no such effect. Pleural effusions due to pneumococcus and to tubercle-bacillus gave the reaction in cases of typhoid fever.

Stern⁵ points out certain **sources of error** in the manipulation of the test. There are sera of nontyphoids which, when used in the dilution originally recommended by Widal, give a distinct reaction. He agrees with Grüber that even normal serum will agglutinate when used with equal parts of culture. In practice he obtains the limit of reaction for the particular culture that he uses. A young culture is necessary, from 8–12 hours old. He also recommends the microscopic method. The cultural reaction, he claims, does not depend wholly upon the agglutination, but “upon the energy of the growth of the culture, the quality of the medium, and, with low dilutions, the bactericidal power of the blood-serum.” He fixes the time-limit of observation at 2 hours. In 20 of 70 nontyphoid cases there was a reaction after 2 hours with a 1 : 10 dilution; in 5 with 1 : 20; in 2 with 1 : 30; and in none with 1 : 40. Of 50 cases in which there was no reaction with 1 : 10 dilution, some reacted with 1 : 5; others did not even with equal parts of serum and culture. He reports a

⁴ Bull. de la Soc. méd. des Hôp., xii., June, 1897.

⁵ Berlin. klin. Woch., No. 11, 1897.

case which, at the beginning of the 9th week, reacted with 1 : 1000. A relapse occurred a few days after and a reaction could be obtained with 1 : 5000. This, he thinks, speaks against the theory that agglutination bears a relation to immunity. Stern can find no relation between the strength of the agglutination and the severity of the attack : the test is of no value in prognosis. He also calls attention to the fact that the reaction may not appear until the disease is advanced to the 2d, 3d, or even 4th week. Also, that it lasts for months, even years, after convalescence. The following case is of interest : of a family of 8, the parents and 3 children were attacked with typhoid and taken to the hospital. The seroreaction was present in all. 2 of the children remaining at home also had symptoms of light typhoid, with positive reactions. The sixth child was never in the least unwell, but his blood showed a reaction with 1 : 50. Stern considers the possibility of an individual immune to typhoid becoming infected and revealing the specific reaction without showing any symptoms.

Scheffer¹ reports 21 cases of typhoid with positive reactions. The reappearance of the agglutination so markedly during the relapses seems to him to confirm Widal's idea that it is a phenomenon of infection rather than one of immunity. Two positive cases are given in some detail. In both the clinical signs of typhoid were slightly marked. In the first the eruption, which quickly disappeared, was the only diagnostic sign. There was no tumor of the spleen, no typical fever, and no intestinal symptoms. In the second case the spots were also wanting, and the case reminded one of tuberculosis of the peritoneum. H. M. Biggs and Wm. H. Park² report their experience in the laboratories of the New York Board of Health. As the most practical method the dried blood is used. A test is made with virulent culture of typhoid bacillus. If a reaction takes place with a dilution of 1 : 10, then a higher dilution is employed. In all, 200 cases were examined. In 140 in which the final diagnosis was typhoid, there was a reaction in 100. In 57 in which the final diagnosis was other than typhoid there were 57 negative results ; 3 doubtful cases, which were not regarded as typhoid by the clinical observers, gave positive reactions. They observed clumping and immobilization in other than typhoid bacilli, even when high dilutions were used. They claim that a positive diagnosis may be made in 50% of cases, and a probable one in half the remaining.

Mossé and Dannie³ report the case of a woman that had typhoid fever in the 8th month of pregnancy. At delivery the blood and colostrum of the mother and blood taken from the placenta and the child gave immediate positive reactions, and the reaction was still found in the **child's blood** 33 days later. The placenta was normal, and a bacteriologic examination was negative.

Siegert⁴ regards the Widal reaction as of great value in the diagnosis of the often **abnormal typhoid fever of children**. He gives as examples the cases of 2 brothers, 9½ and 10½ years old. The first came to the hospital with the diagnosis of perityphlitis. He had high remittent fever, small, frequent pulse, constipation, enlarged inguinal glands, and none of the usual typhoid symptoms. Tuberculosis of the mesenteric glands was thought of. The history of the case inclined to typhoid fever. The other brother was more like typhoid ; he had roseola and meningeal symptoms. Widal's reaction with 1 : 25 and 1 : 100 dilution cleared up the diagnosis. The similarity of the cases, and the fact that the first case gave the Widal reaction 6 weeks after recovery, made it probable that it also was one of typhoid fever.

⁴ Münch. med. Woch., No. 10, p. 250, 1897.

Guinon and Meunier,¹ *apropos of* certain positive results obtained with the Widal reaction in **tuberculosis**, report a case of acute tuberculosis associated with typhoid fever in a boy aged 8. He had fever (39°–39.2° C.) and characteristic physical signs. Six days after admission the temperature began to rise by oscillations to 40°, where it remained for 10 days. The symptoms corresponded to a pulmonic exacerbation. There were no intestinal signs of typhoid, nor diarrhea. The temperature fell somewhat, and this was followed by frequent, slightly yellow half-formed stools. After 12 days of fever a few roseolæ appeared. There was some splenic enlargement. The diagnosis of typhoid fever was made, and Widal's test gave positive results on the 11th and 17th days of the infection. Defervescence was followed 16 days later by a relapse terminating in death. The postmortem showed tuberculosis of the liver, intestines, mesenteric glands, kidneys, pleura, lungs, spleen. The tubercle-bacillus was present. Cultures from the spleen, pleura, and lungs demonstrated the presence also of the bacillus typhosus. In answer to M. Rendu, who expressed doubt as to the absolute diagnostic signification of the presence of typhoid bacillus after death, the author gives his reasons for believing the case to be one of typhoid fever. The roseolæ, the splenic tumor, the temperature-curve point to such a diagnosis. The age of the patient explains the absence of any typhoid intestinal lesions. [The Widal test and the presence of typhoid bacilli in the spleen are certainly significant. M. Widal also supports this view, and records a similar case of his own.]

J. B. Thomas, Jr.,² examined 28 cases of typhoid, with 4 negative results. These last were tested on the 6th, 7th, and 9th days respectively. It is probable that in these the reaction had not yet developed. In 8 cases the clinical diagnosis at the time of the test was doubtful, but the course of the disease confirmed the reaction. Of 29 diseases other than typhoid, 5 gave the reaction (phthisis, rheumatism, malaria, and 2 old typhoids of 3 and 6 years). He uses the dried blood. A drop of water is added to this, the mixture transferred to a cover-glass, and a drop of typhoid emulsion added to it. It is examined during 2 hours and at the end of 24. [It is seen that the dilution used must have been too low. This criticism is further warranted by his results with the colon-bacillus.] Eleven typhoids and 11 nontyphoids were tested with this microbe with positive results—in all 22 cases. [This certainly throws some doubt on the positive results of the reaction obtained in the nontyphoid cases with the bacillus typhi.] Gruber³ reports 36 cases, 34 typhoids and 2 of other diseases. With a dilution of 1 : 1 of serum 25 examinations gave 3 negative results. Two were not typhoid fever, and the other a very light case, the temperature of which rose only to 38.9° C., and which was examined on the 11th day. With 1 : 32 dilution he found 12 negative results, 2 being nontyphoids. The period of examination was from the 5th day to the 5th week. The serum was diluted with distilled water and the time of observation was $\frac{1}{2}$ to 1 hour. He concludes that the reaction is a most useful aid to our diagnosis, but that it is not in any way absolute. [It is worth noting that the 1 : 1 dilution he uses is too low, and that the negative cases might have reacted to one less than 1 : 32.]

C. A. Elsberg⁴ used the dried blood, employing an approximately definite dilution of 1 : 8 by means of measured wire loop. Clumping and cessation of all motility should take place in 15 minutes for a complete and positive test. With this dilution he never found any agglutination with normal serum ; 3

¹ Bull. de la Soc. méd. des Hôp. de Paris, No. 13, Apr. 2, 1897.

² Med. News, Apr. 3, 1897.

³ Münch. med. Woch., Nos. 17 and 18, 1897.

⁴ Med. Rec., Apr. 10, 1897.

specimens of the typhoid bacillus were used, 2 of low virulence, and these he found to give the best results; 262 examinations of 36 cases of typhoid were made. The reaction appeared on the 4th day in 1; on the 5th in 2; on the 7-12th days in 20; on the 12-14th in 8; on the 14-17th in 2; and on the 24th, 27th, and 32d in 3. Out of 148 cases of other diseases but 1 gave the reaction. This case was considered one of biliary calculus. Splenic cultures were negative. At one time it was thought that there might have been a mild typhoid before admission to the hospital, but this was eliminated. The author concludes that the reaction is in no sense absolute, but that it is of value in doubtful and irregular cases.

Wyatt Johnston¹ states that he was the first to suggest the use of **water as a diluting-fluid** for the dried blood of typhoid cases that was to be submitted to the Widal method. He also declares that attenuated cultures react less delicately than those that are virulent.

H. M. Bracken² reports his results in 47 cases examined for the Minnesota State Board. In 28 the clinical diagnosis was that of typhoid: of the 19 not typhoid, none gave the reaction. Of the typhoids, 3 did not react: 2 of these results the author blames on poor technic in collecting the serum. The 3d case had been classed as an aborted or cured typhoid by the attending physician. The diagnosis, judged from the history of the case, was undoubtedly wrong. The earliest date at which the reaction was obtained was the 4th day. The dry serum was used.

Kuhnau³ points out the importance of using as nearly as possible the same **concentration of bacilli**. He calculates that there are 120 millions of microbes in 1 c.c. of an emulsion made from a fresh agar-culture; 50 specimens of normal serum gave the reaction with low dilutions (11 with 1:3; 8 with 1:10-1:20; 4 with 1:30; 3 with 1:35; and 1 with 1:50). With 4 cases of typhoid fever the reaction occurred respectively with 1:30, 1:30, 1:40, and 1:100. With 11 more cases the same result obtained. Coli bacilli were affected by both normal and typhoid sera only in strong solution—1:5-1:10. His experiments also seem to show that the reaction with non-virulent cultures is nearly double that with virulent ones.

J. L. Miller⁴ reports 43 cases examined by the culture-method. Of these, 15 typhoids gave the complete reaction within 20 minutes; 20 sera from healthy persons and 8 from cases of acute disease failed to give any reaction. Thirty more cases were examined by the dry method. The dried blood was dissolved in water, and to it was added a drop of the bouillon-culture. No attempt was made at accurate dilution: 3 typhoids gave the reaction; 22 nontyphoids were negative; and 5 gave a more or less complete reaction. Further, 63 cases were examined with a dilution of 1:10 by removing the blood in a hematocrit-tube and adding a definite quantity to the bouillon-culture. Of 13 typhoids, 10 gave a complete reaction, 2 a partial, and 1 was negative. This last was a mild case; 42 nontyphoids were negative, 3 doubtful, 3 slight, and 2 typical.

Commont⁵ reports the results of the Widal test in 240 cases. He used the rapid method, with blood taken from the finger-tip, the same specimen of typhoid bacillus from a sugar-containing medium, and a 1:10 dilution; 169 cases were examined during the febrile period. The reaction was present before the 6th day in 13; from the 7th to 8th days in 10; 9th to 15th in 73; 16th to the defervescence in 41. In 7 cases only did the reaction, which was absent at first, appear at a subsequent examination. The reaction was positive,

⁵ *Compt. rend. de la Soc. de Biol.*, No. 19, June 4, 1897, p. 528.

then, in 167 cases. In 2 only was it negative. In 1 of these splenic puncture gave negative cultures; in the other the symptoms were by no means those of typical typhoid. Of 72 convalescents, 58 were examined during the first 6 months. Twenty-three gave positive results during the 1st month; 11 during the 2d; and 2 during the 3d, 4th, and 6th months. The rest were negative. Fourteen other cases were examined at periods of at least 1 year after convalescence: 2 were positive (1 and 2 years); 7 were negative (1-25 years); 5 gave a slight reaction (1-10 years). In 71 cases of disease other than typhoid (mumps, scarlatina, grippe, erysipelas, diphtheria, pneumonia, dysentery, pleurisy, meningitis, etc.) the reaction was absent in all but 1. In 7 there was formation of very small clumps with incomplete immobilization. In 1 case (scarlatina) there were typical clumping and nearly complete immobilization, which disappeared upon convalescence.

Wyatt Johnston¹ calls attention to the necessity of **accurate technic**. Among other things, he points to the importance of the alkalinity of the culture employed. A slightly acid medium may give no clumping, but slight alkalization may cause this phenomenon. He recently found spontaneous clumping in his cultures, which upon investigation, proved to be due to excessive alkalinity of the bouillon. He also calls attention to the personal equation. What one would call a reaction another would regard as incomplete. He looks upon the coincident occurrence of the gradual cessation of motion and clumping as characteristic. One without the other is a pseudo or partial reaction. He has never seen a typical reaction in a case in which there was not strong ground for believing it was typhoid.

Finally, we cannot do better than to quote in abstract **the last article**² by **Widal**, in which he very thoroughly reviews the whole subject. The method originally employed by Widal was to add either to a fresh bouillon-culture or to one 24-48 hours old a certain proportion of serum (1:10). A more simple procedure, and one that does not require any venous puncture, is to collect the blood in a glass tube of small caliber, which can be sent to a bacteriologist for examination. In a watch-glass 1 drop of the serum is added to 10 or more drops of fresh bouillon-culture, and the mixture examined under the microscope; or the blood may be added directly without waiting for the separation of the serum. In this way, too, a measurement of the agglutinative action may be made; and this should never be omitted, especially in doubtful cases. As was shown in a previous article by Widal, a good reaction can be obtained by the use of dried blood. This was put to practical use by Johnston and McTaggart (*q. v.*), and has since been employed almost universally. Bordet found that the reaction took place with cholera-serum and vibriones that had been killed by chloroform. Widal has also showed that typhoid bacilli destroyed by heat or by anti-septics remain capable of producing agglutination. From a practical point of view formol seems to be the most useful agent for this purpose. The **phenomenon of agglutination** is, then, not a vital reaction, but rather a passive one on the part of the protoplasm of the microbe. Although the blood contains the largest amount of the agglutinating material, it is not confined to this fluid. It has been found in the urine, the serous fluid of blisters, of the pericardial, pleural, and peritoneal cavities, milk, the bile, liquid of the seminal vesicles, the aqueous humor, tears, pleural exudates, and to a less extent in the spleen, liver, mesenteric glands. In other words, it is found in almost all of the fluids of the body, even in those which do not contain leukocytes. Outside of the body at least, experiments show that the

¹ Jour. Am. Med. Assoc., July 17, 1897.

² Ann. de l'Inst. Pasteur, No. 5, May, 1897.

leukocytes do not secrete agglutinin. Filtration through a porcelain filter diminishes the amount of the agglutinative substance in urine and in milk; and Widal and Sicard have shown the same to be true of the serum and other body-fluids. Filtration retains most of the albuminoid bodies. Fluids that are poor in these, such as the saliva and the cerebro-spinal fluids, are poor in agglutinating properties. Addition of 15 per cent. of sodium chlorid precipitates the fibrinogen, which has strong agglutinative action. Further precipitation by saturation with magnesium sulfate gives the globulins, which also contain much of the agglutinin. The authors never obtained the reaction with a liquid rendered nonalbuminoid by dialysis, nor were they able to separate albuminoid substances that did not give a reaction. **The agglutinating substance** has a great resistance. Serums have been kept for months. Impurities do not destroy the reaction. Relative high temperatures (50° C.) have no effect; only at 60° is there some diminution, and 80° destroys the action. Even direct sunlight does not affect it (Achard). These agglutinative are not identical with the bactericidal substances: often the pure serum from a typhoid patient, which possesses high agglutinative power, has no effect on the vitality of the bacillus. Neither has it any attenuating action. The bactericidal, attenuating, immunizing, and agglutinative properties of sera, although generally present at the same time, because they are derived from the same cause, are, however, mutually independent.

Examination of 26 different varieties of bacilli showed but faint and unimportant differences in agglutinative power. This result is somewhat different from that of some other investigators.

As to the **time of appearance of the reaction**, it is generally on the 7th day; it may, however, appear much earlier or much later. They have seen it on the 5th day. Its precocity bears no relation to the intensity of the infection. Injection of agglutinative serum into another animal produces agglutinative serum in it. As in immunity, this passively acquired agglutination is very transient. By repeated inoculations they obtained a serum which possessed the reaction to a high degree—an ass's blood that reacted in 1:43,000 dilution. The agglutinative property is generally lost during the first weeks of convalescence. The possibility of this gives us further proof that it is a reaction of infection (?). It may, however, last for years. It may occur in cases of typhoid without fever or other typhoid symptoms.

We quote at some length, in regard to the **specificity of the reaction**, the opinion of the author: "When, under the influence of an infection, the serum of an animal agglutinates the infecting microbe, this agglutinating action thus acquired, or exaggerated if absent a few days before, is specific for that microbe, in the rigorous acceptation of the term." If such serum is added to microbes which belong to the same family group, there is also a reaction, but to a less degree and proportionate one might say to the degree of relationship. "Again, passing from theory to practice, the bacteriologist in employing the reaction for purposes of diagnosis must recognize that this action is not limited to the infecting microbe—that it can occur, but in different degree with related species."

The following **technic** is proposed. Small glass pipets are prepared which give drops of equal size. With these the serum- and bouillon-cultures of the bacillus are mixed in the required proportions. A preliminary examination is made with a dilution of 1:10. If a reaction occurs, further dilutions of 1:50 and 1:100 are taken. If 1:50 does not give the reaction, then the serum is diluted 1:40, 1:30, etc.; or if it is negative only with 1:100, then 1:60, 1:70, 1:80, etc. In this way even higher dilutions may be made

until the limit of reaction is obtained. The time that a specimen should be observed is given at two hours.

Widal, in following out these methods, examined some 500 cases. Among these were 162 cases of typhoid, in which he obtained universally positive reactions. In no case of the whole 500 did he make an error in the diagnosis.

The **conclusions** the author draws are as follows:

1. The agglutinative action is a phenomenon of infection. It makes its appearance during the first days of the disease, but may be retarded or even (rarely, however) absent.

2. It is not a vital reaction of the microbes.

3. A negative reaction furnishes a probability against the diagnosis of typhoid fever, but it is only a probability. This is especially the case when the test is made during the early days of the disease: the examination should always be repeated during the following days.

4. A positive reaction, obtained by following the rules laid down, should be considered as a sign of certitude of typhoid fever.

[From the foregoing it may be seen that the test of agglutination and loss of motility of the microbe of typhoid fever occasioned by the addition of a certain quantity of the serum of a typhoid patient is a most important addition to our means of diagnosis. The most important articles have been given in abstract. It is impossible to quote all of the cases that have been reported. About 4000 typhoids and nontyphoids have been examined, with successful results in 96%. To eliminate as far as possible the negative results a most careful technic must be acquired. Lack of this is a most frequent source of error. A reaction with a 1:10 dilution does not indicate typhoid fever, and the absolute limit of the reaction must be obtained by repeated dilutions. The value of pseudoagglutinations and of partial reactions must be appreciated, and must not be mistaken for the complete positive reaction. The lack of a careful clinical diagnosis is possibly the cause of the low percentage of positive reactions obtained by workers in the various boards of health. Typhoid infection must be absolutely eliminated by a bacteriologic examination, even when at the autopsy there are no gross lesions of typhoid present. The importance of this is manifested in the cases described by Pick, by Guinon and Meunier, and by Du Mesnil de Rochemont. Those of the last named lose their value as evidence when we consider that no bacteriologic examination is reported as having been made. The presence of typhoid fever may be masked by other pathologic conditions, especially by tuberculosis. The absence or retarded appearance of the reaction during the first days, or even weeks, of the disease should be remembered, and that a previous attack of typhoid may cause a reaction that can lead one into error. If the rules as laid down by Widal be carefully followed, those contradictory results which even now are exceptional will be reduced to a minimum.]

[The following experiments, although made with the **cholera microbe**, bear such a close relation to the Widal reaction that it has been thought best to mention them at this place:]

Taurelli Salimbeni¹ criticises Gruber's assertion that the destruction of microbes *in vitro* or in the body of actively or passively immune animals is produced by the combined action of the alexins and agglutinin—that the agglutinin modifies the cell-membrane and permits the penetration of the alexins. Pfeiffer, and also Bordet, hold that this is entirely hypothetical, and that there is no alteration of the agglutinated microbes toward stains or in the fresh state. They used the serum of an immune horse, of which $\frac{1}{2}$ mg. will

¹ Ann. de l'Inst. Pasteur, Mar. 3, 1897.

protect a guinea-pig against a surely fatal dose of virulent cholera vibrio: $\frac{1}{20}$ mg. of this will give a reaction *in vitro* in 1 hour with $\frac{1}{10}$ of a 24-hour culture of the vibrio diluted in 1 c.c. physiologic salt solution. With the same emulsion $\frac{1}{50}$ mg. reacts in 24 hours. If 5 minutes after the subcutaneous injection of the culture into a guinea-pig a drop is removed and examined, there is seen a certain amount of immobilization, but no agglutination; but in the course of 2-6 minutes the reaction takes place *in vitro*. Examination of the exudate withdrawn 15-20 minutes after inoculation shows no pre-existent agglutination. They therefore hold that the phenomenon of agglutination does not occur in the subcutaneous tissue of horses and goats immunized against the cholera vibrio. Guinea-pigs were injected with immunizing serum, and 12 hours after with more than a fatal dose of cholera culture. Peritoneal lymph and blood of this animal gave the characteristic reaction *in vitro*. Immediate examination of the peritoneal fluid 2 minutes after injection showed most of the microbes immobile, but free and isolated, agglutination occurring under the microscope in 2-3 minutes at most. After 10-15 minutes in the peritoneum the vibriones are seen to be granulated (Pfeiffer's phenomenon), but retain their form and are perfectly free. The agglutination becomes slower in proportion as the Pfeiffer's granulations increase. After a time the exudate contains but a few masses of granules and some rare leukocytes. On sacrificing the animal it is easy to determine a coagulation of the exudate, which contains the microbes and is deposited upon the peritoneum. The phenomenon of agglutination does not occur when the microbes are injected subcutaneously or intraperitoneally into actively or passively immune animals. Agglutination, at least of the cholera vibrio, is a phenomenon that is produced exclusively outside of the organism.

[A definite reply to the above hypothesis put forth by Grüber is at present impossible. For Border's idea that the reaction is purely physical, there is not sufficient proof. Grüber's assertion, on the other hand, is at variance with certain morphologic and biologic considerations.]

The following table has been collated from the preceding abstracts and a number of other tables. No attempt has been made to eliminate doubtful results, nor does it contain all of the great number of cases that have found their way into the literature of the past year. It includes, however, many results that we look upon as erroneous, due either to ignorance of the diagnosis or to imperfect technic. Yet, in spite of these defects, it demonstrates very conclusively the great diagnostic value of the reaction:

Table of Results of the Widal Test.¹

Reactions in typhoid cases in	95.5%			
No reactions in nontyphoid cases in	98.4 "			
Correct results in	96.5 "			

Jez³ divides the diseases in which **Ehrlich's diazo-reaction** occurs into 3 groups—those in which it occurs constantly, those in which it occurs occa-

¹ "Typhomalaria."

² Two were convalescents.

³ Wien. klin. Woch., Dec. 19, 1896.

sionally, and those in which it has never been obtained. According to his experience, the 1st group contains only typhoid fever and military tuberculosis; the 2d, especially pneumonia and pulmonary tuberculosis; and the last, acute articular rheumatism, malaria, epidemic cerebro-spinal meningitis, erysipelas, and perityphlitis. The test, therefore, has a negative diagnostic value. The author claims that it is also an aid to the prognosis. If found on the 1st, 2d, or 3d days, or if it disappears by the end of the 2d or 3d week, the prognosis is favorable. If constant to the end of the 4th week, it is more uncertain and relapse likely. The sudden disappearance of the reaction should lead to the suspicion of some complication, as pneumonia. He holds that it depends upon the presence of a toxin. Courmont¹ performed a number of experiments by the **method of Elsner** in order to determine its value for detecting the presence of the typhoid bacillus in the feces, and found that, although the differences in growth were very distinct in this culture-media, nevertheless they were not absolute, and often disappeared, particularly in cultures from typhoid patients, where the bacillus coli frequently assumes a typhoid aspect. In 9 cases of typhoid fever the bacillus of typhoid was only isolated twice. In 11 cases suffering from other diseases it was not found at all.

P. H. Smith² has investigated the occurrence of **typhoid bacilli in the urine** in cases of typhoid fever. He examined 7 cases, making 61 observations in all. His method was to implant small and large quantities of urine, obtained aseptically, upon the surface of gelatin plates. The suspicious colonies were examined by all of the ordinary methods and also by certain special tests: (1) The cilia-test; (2) The serum-test; (3) The power of forming slight acidity in milk after 24 hours. These examinations showed typhoid bacilli at some period of the disease in 3 out of 7 cases, sometimes in enormous quantities. The bacilli were never found in the 1st or 2d week (17 observations), appearing first in the 3d week or later. In 1 case they persisted until 22 days after the temperature had become normal.

Treatment.—The search for a specific **antitoxic treatment** is still pursued with vigor, though, it must be confessed, the results are unsatisfactory. Brilliant successes have been reported only to be followed by failures with the same plan. T. M. Pope³ reports 4 cases in which antitoxic serum was used in the treatment of typhoid fever. In 2 cases the fever steadily declined after the injection, but the decline was gradual, and possibly the disease was scarcely shortened. The symptoms, however, during the 3d week were much less serious than is customary. In 2 of the cases there was an urticarial rash. E. B. Steel⁴ reports a case of typhoid fever which, on the 5th day after the development of the disease, was injected with 10 c.c. of antityphoid serum. In the next 2 days there was considerable improvement; nevertheless 10 c.c. of serum were again injected, and this was repeated twice. On the 15th day of the disease the temperature was normal in the morning and evening, after which improvement steadily progressed toward an uninterrupted recovery. The diagnosis was confirmed by the Widal test. P. R. Cooper⁵ reports a case of typhoid fever of exceedingly severe type, which on the 32d day was considered hopeless, and therefore injected with antityphoid serum procured from Burroughs Welcome & Co. The following morning the temperature was only 98.8°. The patient, however, began to hicough, and was apparently in a desperate condition, when renewed injections of serum were given, with immediate and permanent improvement.

Pollak¹ reports the results of experiments upon 18 cases of typhoid fever into which the **blood-serum** of patients convalescent from the disease was injected in quantities of from 2 to 45 c.c. In 3 very mild cases favorable action was noticed, and the fever disappeared permanently after numerous injections; but, as a rule, there was sudden rise of temperature immediately after the injection and no subsequent improvement. In 1 case, indeed, collapse occurred after this post-injection hyperpyrexia. In nearly all cases leukocytosis developed in the course of the treatment.

Weispecker² reports the result of the treatment of typhoid fever, scarlet fever, and pneumonia, with the serum of patients convalescent from these diseases; 2 cases of typhoid fever showed rapid reduction of temperature and disappearance of all the characteristic symptoms. Cure seemed to be complete within 48 hours, although in the first case the injection was made upon the 9th day, and in the second on the 8th day.

Pfeiffer and Kolle³ injected 3 persons with an attenuated culture of typhoid bacillus. Within 2 or 3 hours after the injections the subjects had chills, dizziness, malaise, and pain in the site of the punctures. In the evening the temperature reached $38\frac{1}{2}^{\circ}\text{C}$. All the disagreeable symptoms rapidly subsided, and 11 days later the blood contained specific bactericidal substances that had not been found in it previously. The authors believe that this method is practically applicable for the **immunization** of large numbers of persons, such as troops, or the inhabitants of neighborhoods where the disease has become epidemic.

C. H. Richmond⁴ reports 9 cases of typhoid fever treated with **salol**, the average duration being $12\frac{1}{2}$ days.

[The **purgative** treatment appears to be diminishing in popularity, but a few advocates are still found.] W. B. Thistle⁵ advocates the treatment of typhoid fever with **calomel** and **salines**, believing that it sweeps the intestines clear of bacilli and counteracts the augmentation of toxins in the body. T. B. Heimstreet⁶ recommends the protiodid of **mercury** in $\frac{1}{2}$ gr. pills for typhoid fever, and reports a case that he was able to abort by this treatment. J. E. Woodbridge⁷ reports 4 cases of typhoid fever treated according to **the Woodbridge method** in the Bellevue Hospital, all of which were apparently aborted.

The Cold-water Treatment.—Robin⁸ has investigated the respiratory exchange taking place in health and in typhoid fever. These studies show that the processes of oxidation are decidedly reduced during the course of this disease, the reduction depending upon the severity of the case. He then investigated the effect of cold baths upon the oxidation, and found that there was a distinct increase in the exchange of gases and in the whole process. This was commensurate with the reduction brought about in the temperature, and he found that when the latter was not reduced the beneficial effect of the bath upon the chemical processes was also wanting. He holds, therefore, that the occurrence or nonoccurrence of decline of temperature may be taken as a standard by which the usefulness or uselessness of bathing may be measured. The beneficial effects of bathing, he believes, are due to this increase of oxidation, whereby the toxic products of the tissue-destruction are reduced to harmless excrementory bodies. This effect is accomplished by the intermediation of the nervous system. [Clinicians have long been aware that the bath-treatment

⁸ Bull. de l'Acad. de Méd., Oct. 27, 1897.

exercises a powerful effect upon the process of respiration.] Thornley¹ gives the statistics of the cases of typhoid fever admitted to the Presbyterian Hospital of New York during the 1st and 2d weeks of the disease: 47 were treated with tub-baths, 25 by sponge-baths, 58 by sponge-baths and tub-baths, and 14 without baths: the latter were very mild cases. Of the 1st group, 4.1% died and 37.5% suffered from complications or relapses; for the 2d group the figures were 11.5% and 34.6%; and for the 3d group, all prolonged and severe cases, 13.7% and 55.1%. T. E. Hare² reports the results of Brand's treatment in the Brisbane Hospital. From 1882-86, 1828 cases were treated expectantly, with 14.8% mortality; from 1887-96, 1902 cases were treated by baths, with 7.5% mortality. Careful examination of the causes of death shows that the percentage due to perforation and hemorrhage was little, if at all, affected by the new treatment; but the deaths from other causes were reduced from 9.07% to 3.4%. The most beneficial effects were exhibited in the female wards, where the mortality diminished from 16.02% to 5.6%.

G. E. Armstrong³ contributes a paper upon **operative interference in typhoid perforation**. The author estimates that about 1 or 2% of typhoid cases are complicated by perforation, and about 6% of the mortality of the disease is due to this cause. The majority of the cases occur between the ages of 10 and 40, and more in the male than in the female sex. Regarding the recognition of the condition, the author points out that the symptoms are often obscure, though it is generally held that they are characteristic. Too much reliance should not be placed upon the disappearance of the liver-dulness, though the lessening in the dulness previously determined is significant. The symptoms somewhat resemble those of acute appendicitis, but are, as a rule, less marked. The temperature is usually lowered, but soon rises. In some cases symptoms are almost wholly absent. The author has collected 30 cases treated by operation, including some doubtful ones; there were 6 recoveries. Excluding the doubtful cases, there were 23 operations and 4 recoveries. He feels that the operations are less successful than these figures would indicate, as it is probable that many unsuccessful cases have not been published, while most of the successful ones are recorded. Five cases have recovered after incision and evacuation of local collections of pus, and 1 after aspiration of a collection of pus and gas in the cecal region. The author includes in these statistics 6 from the Montreal General Hospital, 3 of which were operated upon by himself. None of these recovered. He further refers to a case, not included in his series, the result of which was still undetermined. The perforation occurred on the 13th day in a severe case of typhoid. Pain and collapse were not marked, but there was some vomiting. Operation was performed 18 hours after the first symptoms; the perforation was found 6 inches above the ileocecal valve, and was readily closed. The patient 20 days after the operation was in good condition, passing firm stools, sleeping well, and taking nourishment freely. The abdomen was soft and painless, and the outlook favorable. Lerboulet⁴ believes that in cases of perforation, occurring in the course of typhoid fever, laparotomy still offers some hopes, providing the pulse is strong and not too frequent.

A. G. Barrs⁵ describes 2 cases of typhoid fever in which the use of a **freer diet** than is ordinarily permitted was followed by prompt improvement. In the 1st case the patient had been ill 8 weeks, and the temperature remained a little

¹ Med. News, Mar. 13, 1897.

³ Brit. Med. Jour., Dec. 5, 1896.

⁴ Bull. de l'Acad. de Méd., 1896, No. 43.

⁵ Brit. Med. Jour., Jan. 16, 1897.

above the normal in the evenings, falling to normal in the morning. Any attempt to get the patient out of bed was followed by temperature disturbance. In the 2d case there were great weakness and diarrhea, and the patient was at about the 22d day of the disease when a freer diet was administered. There was some tendency to decline of temperature at the time, and this continued without intermission. Reasoning from these cases, the author argues for a freer diet throughout the disease, and states that of 28 cases under his own care fed in this way only 1 died, but relapse occurred in 2. [We have seen a number of instances in which persistence of the temperature during convalescence has occurred, and in which a more liberal diet has been advantageous. This is particularly true of cases in which the general vitality has been reduced, and in which the gastrointestinal tract has not suffered greatly. In these cases the temperature apparently remains elevated from weakness, impoverished blood, and other causes, more than from the persistence of local lesions. The term "bed fever" has sometimes been given to these cases. It is scarcely justifiable, however, to conclude from instances of this kind that a more liberal diet is proper throughout the course of typhoid fever.]

H. L. Williams¹ has constructed a frame with a pulley arrangement and a swinging **hammock**, to be used for **lifting typhoid patients** from the bed and lowering them into the tub-bath. The frame is so constructed that it readily rolls over the bed, and then, carrying the patient, it may be rolled over the tub. [We have seen this frame in actual service, and have found, as the author claims, that two nurses are enabled by this means to administer the bath with practically no exertion.]

Infections Resembling Typhoid Fever.—R. S. Woodson² reports 2 cases of febrile disease of doubtful nature occurring during the heated period in soldiers stationed in Texas. The 1st case, a man of muscular development and gouty diathesis, exercised violently at baseball during intensely hot weather, and was much exhausted; on the following day he had general muscular soreness and fever. His temperature was 103°; his skin was dry, bowels constipated, and the urine loaded with uric acid. The disease dragged on with irregular febrile movement for 2 months, during which period the subjective sensations were excellent. There was very little emaciation. The 2d case, a man of similar physique and gouty diathesis, after playing baseball on a very hot day was very much exhausted and suffered with symptoms similar to those of the above. The temperature steadily declined, and reached the normal in about 8 days. The author regards these cases as being instances of a thermic fever in which the gouty diathesis of the patients also plays a part. He suggests the term "febris autointoxica." [It seems difficult to determine positively from the report what the nature of these cases was. It may have been typhoid in the 1st, and even in the 2d, despite the atypical symptoms. The author inveighs against the usual readiness with which continued fevers are classed as typhoid or malarial when the nature of the cases is obscure; but in his own cases the former of these diseases is not positively excluded.]

Guirand³ reports an epidemic that occurred in Lauragnais that resembled typhoid fever, but was peculiar in the fact that only 2 persons died out of 68 attacked, and that very frequently the symptoms of cerebrospinal meningitis were also present. As all the inhabitants obtained their water from a common reservoir situated in a depression in the village, the author made careful bacteriologic examination, but was unable to find the bacillus of Eberth. On the other hand, he discovered the coli bacillus in abundance, and also a strepto-

¹ Univ. Med. Mag., Sept., 1896.

² Jour. Am. Med. Assoc., Mar. 20, 1897.

³ Compt. rend. de la Soc. de Biol., Feb. 19, 1897.

coccus. This was moderately virulent, killing mice but not rabbits. In addition he also obtained a diplococcus somewhat resembling the pneumococcus of Talamon-Fränkcl, but differing from it in its cultural peculiarities. He believes that the peculiar character of the epidemic was due to the presence of the streptococcus.

INFLUENZA.

Lindenthal¹ reports 8 cases of **sporadic influenza** with autopsies, in all of which the diagnosis was confirmed by bacteriologic examination. From these he concludes that influenza may occur in periods when no epidemic exists, and then in no way differs from the ordinary epidemic form; also that the influenza bacillus is capable of giving rise to fibrous or serous, or even hemorrhagic, exudate in the lungs, which may become purulent—that when the sinuses communicating with the nose are inflamed it is nearly always a result of infection with the influenza bacillus.

Fränkel² reports some **complications and sequelæ** following influenza that he observed in an epidemic. These consisted of arrhythmia, which occurred especially during convalescence, and was either associated with tachycardia or bradycardia; arterial thrombosis, of which he observed 3 cases, 1 involving the right axillary artery, 1 the right iliac, and 1 the right central artery of the retina; and angina pectoris, which occurred in a few cases.

Batz³ also discusses the **cardiac complications** of influenza, as well as cardiac influenza, the distinction between these being that the former includes peri-, endo-, and myocarditis as distinct complications, and the latter a series of changes in the heart-action due to nervous disturbances. The cardiac rhythm is altered and the pauses become equal. The beats become accelerated, and the sounds resemble each other, so that the condition known as embryocardia is developed. Intermittence and bradycardia may occur, or, on the other hand, a high grade of tachycardia. Cardiac weakness and syncope may be noted, but angina due to influenza is of special importance. The latter resembles closely angina pectoris, and indeed is probably induced by the same conditions. The paroxysms are variable in duration, but usually last for some time. The author ascribes the variability of the cardiac conditions to the affection, in different cases, of different nervous structures (sympathetic, intracardiac ganglia, or the vagi). They may even have a bulbar origin.

Kamen⁴ reports 3 cases of influenza. The first had a temperature very like that of relapsing fever, a peculiar symptom being a stiffness of the neck during each febrile period. The second suffered from severe pains in the head, but also recovered. The third presented similar symptoms, and at death a purulent leptomeningitis was found. In all 3 the diagnosis was confirmed bacteriologically.

Reverdin⁵ reports a case of **multiple abscesses** after grippe. The patient, a young man of 18, had a large abscess beneath the left breast some weeks after the attack. Subsequently others appeared on the left arm and in the left gluteal region. For weeks he had suffered with pain in the right lumbar region and obstinate constipation, but no abscess was formed. Cultures developed only the streptococcus pyogenes.

G. V. I. Brown,⁶ a practitioner of dentistry, urges **care of the mouth** in grippe. He refers to cases in which examination showed unhealthy conditions of the oral mucous membrane and the necks of the teeth, and ascribed the continuation of sore throat, bronchitis, etc., to this cause.

⁴ Wien. klin. Woch., May 22, 1897.

⁵ Revue méd. de la Suisse romaine, No. 8, 1896.

⁶ Jour. Am. Med. Assoc., Jan. 9, 1897.

Delius and Kolle¹ have carried on a number of experiments with the influenza bacillus in order to decide whether it is possible to produce **immunity** either active or passive, or to obtain an efficient antitoxin. They conclude that a specific substance is to be found only in bodies of the microorganisms, and that neither active nor passive immunity can be produced, all their experiments having been absolutely negative. They admit, however, that it is not impossible that a brief period of immunity exists after convalescence from an attack.

CHOLERA.

E. H. Hankin² reports a **curious epidemic** of cholera that broke out in an officers' mess in Central India. Rigid antisepsis was employed in the kitchen, and it was difficult to ascertain the source of the infection, but it was finally traced to a chocolate pudding that had been infected either by a muslin-strainer or a dish-cloth used to carry the vessels containing boiled water, both of which had been washed in a stream in which cholera bacilli were found. F. Smith³ reports an epidemic of cholera that broke out in Penang, and was apparently due to the **aerial transmission** of the germs from the patients in the quarantine station to others that were detained with them. [The effort to exclude transmission in other ways was not sufficiently rigorous.]

Sonsino⁴ has noticed the frequency with which **intestinal lesions**, either dysenteric or parasitic, are found in persons that have died of cholera in Egypt.

Engel⁵ has criticised the statement of Baehelein's in regard to the diagnostic value of **chrysoïdin** in the recognition of cholera. He finds that although it produces agglomeration in vibrio cultures, the vibrio of Asiatic cholera is by no means the most sensitive, and that it is most efficient in those cultures that, through prolonged growth upon artificial media, have lost their virulence.

Treatment.—Kolle⁶ carried out 3 series of experiments upon **immunization** against cholera. In the first Haffkine's method was employed; that is, a definite quantity of sterilized culture was injected; 5 days later a small dose and in 5 days more a larger dose of the living virulent culture. The second series was made with 1 injection of a freshly prepared sterilized culture, and the third with a sterile culture that had been kept 4 weeks. The results were essentially the same by all methods. The effects of the injection were swelling and pain at the site, sensitiveness of the neighboring lymph-glands, chills, fever, malaise, and anorexia. The reaction was complete in 3 days; the immunity appeared at the end of the 5th day, and reached its maximum at the end of the 20th day. It then decreased gradually, but was still quite marked at the end of the year. Kolle concludes that it is possible to prepare effective sterile cultures in large quantities at laboratories, and the protective results of the inoculation can be counted upon as lasting for a year after inoculation. He believes that he has furnished convincing proof of the effectiveness of Haffkine's method, and warmly recommends it wherever cholera is endemic or in communities that must necessarily remain isolated and exposed; as, for example, on shipboard.

A. Powell⁷ summarizes the results of all of Haffkine's observations in **cholera-inoculations**. He concludes that the largest dose hitherto used

¹ Zeit. f. Hyg. u. Inf'kr., Apr. 13, 1897.

³ Lancet, Jan. 30, 1897.

⁵ Centralbl. f. Bakt. u. Parasit. u. Infek., Jan. 30, 1897.

⁶ Deutsch. med. Woch., Jan. 1, 1897.

² Brit. Med. Jour., Dec. 26, 1896.

⁴ Ibid., July 18, 1896.

⁷ Lancet, July, 1896.

does not confer complete immunity, but it is quite marked if there is considerable febrile reaction, and insignificant if not.

Nakagawa¹ reports the results of the treatment of cholera with the anti-cholera **serum of Kitasato**. In 270 cases the total mortality was 51.1%. Of these, 163 were treated with the serum, with a mortality of only 33%. The cases were nearly all mild.

Chanvin² believes that it is impossible to secure **antisepsis in the intestinal canal**. The object of the treatment, therefore, in choleraic diseases should be to render the intestinal contents as unfavorable a culture-media for the growth of the organism as possible. This he obtains by the administration of small doses of bichlorid of mercury and a special mixture of his own, of which the essential ingredients are HCl, pepsin, and tincture of opium. He reports 23 cases treated in this manner, in some of which the vibrio of Koch had been found, without a single unfavorable result.

THE BUBONIC PLAGUE.

[The bubonic plague has been the subject, during the past year, of considerable careful scientific investigation. Viegas, Cantlie, Lowson, and the German Plague Commission have studied the epidemic at Bombay and discriminated various clinical forms; Ogata, that at Formosa, particularly from a bacteriologic standpoint. The most important advance, however, is the introduction of successful serum-therapy, for which the whole credit should undoubtedly be given to Yersin. Haffkine has experimented with preventive inoculations according to the methods he has employed for cholera, but it is as yet too early to criticise his results. Finally, it appears that Widal's method of serum-diagnosis may be applied to this disease with as much accuracy as in typhoid fever.]

Epidemics and General Considerations.—A. G. Viegas³ discusses the outbreak of bubonic plague in **Bombay**, which he was the first to report. He does not believe that it was imported from Hong-Kong, either along with sugar and dates, by infected clothes, or by live or dead plague-stricken rats. Neither can the grain be accused, as nothing whatever suspicious was found in the granaries, and dead rats were found at least as frequently in other places. As all classes of inhabitants have been affected, it cannot be said to be due to a vegetable diet or any particular racial characteristic. Viegas' own opinion is that the disease is due to, or at least favored by, the accumulation of sewerage filth. He believes that the plague-bacillus, like that of tetanus, is widely spread, and that its virulence is subject to great alterations, under favorable conditions reaching a point that renders an epidemic possible. The chief predisposing causes are a warm climate, poverty, and youth. Sex does not seem to exert any particular influence. He does not believe that the contagium frequently enters through the skin, only 5 out of the 79 cases he examined showing lacerations of any form. Personally, he thinks that it is most frequently introduced through the respiratory tract, and occasionally he has been able to trace transmission by direct contact. In the 2 cases in which the period of incubation could be determined it was exactly 5 days. He recognizes 3 varieties of the disease, the *pestis minor*, the *pestis major*, and the *pestis siderans*. Generally, the patient has only 1 bubo, but occasionally there are 2. The commonest seat is in the groin, although quite a number occur in the axillary region. He lays great stress upon the physiognomy of the disease, which he

¹ Brit. Med. Jour., July, 1896.

² Revue de Méd., July 10, 1896.

³ Indian Med. Rec., Mar. 1, 1897.

describes as that of a person who has been taking hypnotics for persistent insomnia without obtaining any sleep. The eyes are red and injected, and slightly retracted. The face generally is of a bluish-yellow hue. The pulse and respiration are both rapid. In 4 cases there were petechiæ. The nervous system was usually affected between the 4th and 6th days, but there were no paralyses. Insomnia occurred occasionally, often associated with drowsiness, and coma usually developed in the later stages. Some cases had quiet delirium. The prognosis is most unfavorable, the mortality among the native patients being from 95 to 99% in the early part of the epidemic, and falling to 85% toward the end. Treatment is symptomatic, the important thing being to place the patient in favorable hygienic conditions and to commence stimulation as soon as possible. Hypnotics are of no use in combating the insomnia.

B. F. Willoughby¹ describes the epidemic of plague that commenced in Bombay on the 23d of September, 1896. He holds that it was much more severe than reported, as the European as well as the native physicians frequently, at the request of relatives, ascribed death to some other cause, usually remittent fever. Thus in December the death-rate from malaria is officially stated to have been 50 per day—an utterly incredible number. He criticises rather severely the utter lack of method employed by the authorities. He believes that the disease is endemic, the interepidemic periods being always characterized by the existence of an attenuated form called *pestis minor*. [The term "*pestis minor*" is indefinite, although well established, and apparently includes a number of totally dissimilar conditions.]

Ogata² reports the results of his investigation of the plague that occurred in Formosa in Oct., 1896. He first calls attention to the difference between the bacillus of Kitasato and the bacillus of Yersin: the 1st is found in the blood, colors by Gram's method, is motile, encapsulated, appears as irregular grayish-white colonies, and forms chains. The 2d occurs rarely in the blood, but always in the swollen lymph-glands, decolorizes by Gram's method, is not motile, forms white colonies with iridescent edges, and forms chains in bouillon-cultures. Altogether, Ogata examined 27 cases. Blood from the finger-tip, 19 to 65 days after the disease, failed to give any cultures of the bacilli, but killed mice, from whose tissues the bacilli were obtained in pure culture. In acute cases bacilli could be found in the blood both microscopically and in culture. Curiously enough, he also found in the blood of these acute cases a second microorganism resembling morphologically the pneumococcus of Fränkel, but not pathogenic for mice. In the blood of 2 cases examined post mortem the bacillus subtilis and the staphylococcus aureus were also found. In the urine and bile of 2 bodies examined after death plague-bacilli were found in great numbers. In all the cases these bacilli resembled in all respects those described by Yersin; he also examined several rats that had died of the disease, and found in their tissues pure cultures of the same organism. A very interesting observation was the fact that bouillon, in which fleas obtained from these rats had been crushed, was capable of killing mice, and from their tissues the plague-bacillus was obtained. In conclusion, he reports his results with antiseptics, to which, even in dilute solutions, the bacillus of the plague is extremely susceptible. He advises destruction of all rats and hogs that seem to be suffering from the disease, and the disinfection of all objects that come in contact with the invalids. [Two facts deserve particular attention in this valuable paper: first, the existence in the blood of convalescent and immune patients of virulent bacilli; and second, the role that suctorial insects play in

¹ Am. Jour. Med. Sci., Mar. 27, 1897.

² Centralbl. f. Bakt. Parasit. u. Infek., June 24, 1897.

the distribution of the disease—a role apparently not confined to plague and filariasis.]

J. Cantlie¹ suggests that the term *malignant polyadenitis* would be more appropriate for plague. He then discusses **the varieties and spread of the plague.** Of the former he recognizes 3—fulminant, typical, and pestis minor. The latter is the form of disease that sometimes precedes or follows severe epidemics. This disease, as he has observed it, consists of a slowly developing, nonvenereal bubo, attended by general weakness, anemia, and fever. There are, however, 2 other varieties—the idiopathic enlargement of one or more glands in the necks of children, associated with fever and without sore throat or swelling of the parotid, but undoubtedly infectious; and the form that prevailed in Hong-Kong in 1893-94, in which cases of fever of typhomalarial type frequently presented a general enlargement of the lymphatic glands in the 3d or 4th week, lasting for 10 days and then subsiding. He calls this condition benign polyadenitis, and holds that it may coexist or not with malignant polyadenitis. That it is sometimes of the same nature seems to be proved by the occasional discovery of the plague-bacillus. The animals most likely to be affected are rats, and they always suffer from the disease when it is epidemic among the human race, but do not die when only pestis minor exists. The fulminant and ordinary types may undergo sudden transformation from one into the other. In regard to the contagiousness of the disease, he finds that Europeans exposed to the most concentrated forms of poison are usually unaffected. The disease is not extremely contagious, as persons attending plague-patients under favorable sanitary conditions usually escape. Ordinarily, the disease is communicated by dust from the dwellings which plague-patients have inhabited. The plague spreads slowly. It is endemic in a definite area of Asia, with its chief source in Mesopotamia and adjacent countries. The length of the incubation-period is very doubtful. It seems probable that the patients may be affected with pestis minor, and that the bacilli subsequently become more virulent and give rise to the true form of plague.

J. A. Lowson² recognizes **3 varieties of plague**—pestis minor, pestis major, and pestis ambulans. The first includes those cases of bubonic disease which precede an outbreak of plague proper; they are of very mild character and usually disappear in a short time. He believes that these cases are exceedingly rare, the majority being venereal in character, although some cases have been described in which the bacillus was found. Pestis ambulans is again a mild form, which occurs after the main epidemic has subsided. As in the others, a great variety of diseases may be included under this definition, 1 case of filariasis being recorded. In regard to the way in which the infection leaves the body, he recognizes 4 channels: from the pus of a suppurating bubo; by the feces; by the saliva; and occasionally, if there are renal lesions, by the urine. He is quite convinced that the bacilli are not exhaled by the breath and are not carried by the atmosphere. Infection may take place by inoculation, inspiration, or introduction into the alimentary tract. He records 3 interesting cases of the first method—1, Professor Aoyama, who scratched himself twice while performing a postmortem; another, Dr. Ishigami, Kitasato's assistant, who had inoculated himself in the same way; and the third, a woman with an open sore upon the foot, who suffered from mixed infection with plague and streptococcus.

The Plague Commission of the Imperial Academy for Sciences of Vienna,³

¹ Lancet, Jan. 2, 1897.

² Ibid., Feb. 15, 1897.

³ Wien. klin. Woch., May 20, 1897.

in a preliminary report, gave the following results of their investigations of the bubonic plague at Bombay: They recognize three varieties: first, the septicemic-hemorrhagic form, characterized by the development of hemorrhagic buboes, in the neighborhood of which there is often extensive edema, and the presence of hemorrhages in the various organs; second, the septicemic-pyemic form, characterized by numerous metastases into the internal organs, particularly the lungs, liver, and kidneys; and third, a primary plague-pneumonia which appears as a confluent lobular pneumonia of characteristic appearance and usually without swelling of the lymphatic apparatus. The contagion usually enters through the skin, although the exact point of introduction can only occasionally be discovered. It may, however, get into the system either through the tonsils or the lungs. They have never been able to recognize a case where it entered from the gastrointestinal tract. The clinical course is that of an exceedingly severe infectious disease, and often the enormous buboes add a peculiar and characteristic appearance. Death may occur during the first 24 hours. The pulse and respiration are both greatly increased, and the former usually becomes soft and feeble. Consciousness is sometimes preserved until death; in other cases there is wild delirium. The fever is usually intermittent. Of points that aid in diagnosis, they call attention to the invariable absence of herpes and the rarity of cutaneous petechiæ. The spleen is swollen and soft, and the urine contains small quantities of nuclealbumin. In 2 cases neuritis was observed as a sequel of the disease. They regard the bacillus of Yersin and Kitasato as the specific cause of the disease, and were able to obtain cultures of it in many cases from the blood. When it could be recognized microscopically in the latter element the prognosis was exceedingly grave. Mixed infection is frequent, among the organisms found being the streptococcus, diplococcus pneumoniae, and the staphylococcus. The disease is communicated either by direct contact with other patients or by contact with infected lower animals, or by contact with objects that have conveyed the poison from other persons. They reserve their opinion upon the value of serum-therapy. Drugs have been useless. Prophylactic measures, however, particularly the isolation of all cases, should be rigidly enforced.

The German Plague Commission (communication from Bombay, Mar. 19, 1897)¹ has been able, as a result of a careful examination of about 100 cases, to determine the various **routes by which the plague enters the body.** In the great majority of cases this is unquestionably through small wounds in the skin; the organisms often entering by several of these at the same time, giving rise to those curious symptom-complexes in which primary glandular swellings occur simultaneously in various parts of the body. So long as the glands are not penetrated by the bacillus general septicemic symptoms do not arise. When suppuration takes place in the glands it ordinarily produces rapid destruction of the microorganisms, but in very light cases resolution may occur. When, however, the glandular filter has been passed an almost invariably fatal septicemia develops and plague-bacilli are found in the blood and internal organs. It seems not likely that the contagion is transmitted by suctorial parasites; at any rate, the mosquito does not seem to be guilty. The second mode of entrance is through the respiratory tract, giving rise to pneumonic areas in the lungs, where the organism is found either as a pure culture or mixed with diplococci or streptococci. This form is not only of itself usually fatal, but it is also extremely dangerous for all in the neighborhood of the patient, as the sputa contain numbers of virulent bacilli. It does not appear that infection ever takes place by the digestive tract. In 2 cases, how-

¹ Deutsch. med. Woch., Apr. 22, 1897.

ever, it appeared that a primary infection took place through the tonsils, leading to a rapid general infection. The diagnosis of the disease cannot be made invariably by microscopical examination of the blood. Cultures develop with sufficient rapidity to be characteristic in 48 hours. It is probably dangerous to puncture a bubo in order to get material for these cultures, as by this procedure bacilli may be introduced into the general blood-current. A method that promises greater accuracy is that which corresponds exactly to Widal's reaction for typhoid fever. It can be employed in exactly the same way and gives identical results. The commission refrain, on account of insufficient clinical observation, from expressing opinion upon either Haffkine's prophylactic inoculations or Yersin's curative injections of antitoxic serum.

The German Plague Commission¹ as a result of their further observations and studies recognize the following **varieties of plague**: the bubonic form; the pustular form, in which the primary lesion appears to be a carbuncle situated in the skin (in both of these varieties the swollen glands may undergo resolution or suppuration, with or without development of general septicæmia); the true septicæmic form, commencing with high fever, delirium, and collapse; and the pneumonic form, commencing with chill, rapidly increasing dulness in one or more lobes of the lung, and serous, white, or rusty sputum, to be distinguished from croupous pneumonia by the extreme prostration and a considerably enlarged spleen. Besides these, there is a milder form with fever lasting a day and swelling of one or more glands. Among the peculiar complications they mention an inflammation of the cornea, which usually leads to iridocyclitis or even complete suppuration of the eye, and the appearance of a pustular eruption, with sometimes the formation of multiple abscesses. The prognosis they regard as unfavorable. The septicæmic form is invariably fatal; the pneumonic form in the great majority of cases, for even after apparent crisis death may occur from vasomotor paralysis, cachexia, or septicæmia; but, on the other hand, patients apparently moribund or even dead may recover. The treatment is purely symptomatic. Among the pathologic lesions they mention the number of bacilli found in the lungs in the pneumonic form, and the presence of necrotic foci in the liver, and packing of the lymphatic tissues with bacilli in the septicæmic form. The organism is very easily destroyed.

Patrick Manson² states that the bubonic plague occurs in the lower animals; assumes two forms, benign and malignant; is caused by microorganisms, the virulence of which is susceptible to great modification; and can be both prevented and cured by practical serum-therapy.

Drasche³ calls attention to the fact that the present type of bubonic plague differs from those types that are recorded in history by the fact that it shows no tendency to become endemic.

Waters,⁴ in discussing the **etiology** of the plague, rejects the theory that it is distributed by insects or rodents. He believes that its development is favored by a certain emanation from fermenting grain, particularly the different varieties of millet, because the disease was only found among persons using this substance. Europeans using wheat and Asiatics using rice escaped completely; and, furthermore, whitewashing the granaries produced an immediate and notable diminution in the number of cases. In regard to the prophylaxis he suggests whitewashing of the native houses and the interdiction of the importation and the consumption of old or long-buried millet-grain. [These conclusions are very sweeping in character, and it seems doubtful whether they will be sustained by further observations.]

¹ Deutsch. med. Woch., May 6, 1897.

³ Wien. klin. Woch., Mar. 13, 1897.

² Practitioner, Jan., 1897.

⁴ Indian Med. Rec., Feb. 15, 1897.

S. Flexner¹ gives a *résumé* of the plague literature, and calls attention to the fact that streptococci and staphylococci, as well as the specific bacillus, are frequently found in the glands.

W. Wyman² reports some experiments with **disinfectants** upon the plague-bacillus. Formaldehyd in solutions of less than 1:1000 is not effective. The most effective antiseptics appear to be corrosive sublimate and trikresol (1% solution).

L. F. Child³ reports a case of plague in which the only lesions found were patches of **bronchopneumonia** in the lungs. The lymphatic glands were not enlarged. The peculiar symptoms of this condition are the great prostration, out of all proportion to the amount of pulmonary tissue involved, and the yellow serous expectoration.

Zaboltony⁴ has investigated the **agglutinating action** of the serum of patients suffering from the plague, and finds that it only commences to be manifest toward the end of the 2d week; becomes more distinct and is at its maximum during the 4th week. It is most marked in the grave cases and disappears after death.

Treatment.—Yersin⁵ reports the result of his experiments with the **serum-therapy** of bubonic plague. The immunizing serum was obtained by injecting a horse subcutaneously with minute portions of a virulent culture. Each injection was followed by a very powerful reaction, and the fever reached 41.5° C.; the horse became feeble, trembled, refused to eat, and emaciated rapidly, but ultimately, when completely immunized, recovered its normal health. With the serum obtained from this horse it was possible to prevent infection in mice inoculated with virulent culture: 0.1 c.c. sufficed to produce immunity if injected 12 hours before the inoculation; if, however, the mouse had been already inoculated, from 1 to 1.5 c.c. of serum were required to obtain a certain cure. Yersin returned to Indo-China in 1895, organized a Pasteur institute, and set about immunizing a number of horses. This required some time, but finally he obtained a supply of serum properly prepared, which was further increased by an invoice from Paris. He immediately departed for Canton, where, after some difficulty, he obtained permission to treat a young Chinaman, 18 years old, whose case was considered hopeless: 3 injections of 10 c.c. each were made at 5, 6, and 9 in the afternoon, and the next morning the patient seemed to be almost well. The temperature had fallen, lassitude and other serious symptoms had disappeared, and the swollen glands in the groin were no longer painful. Two other patients were treated with the serum at Canton after Yersin's departure, with equally good results. At Amoy he was able to make an extensive trial of the serum in the charity hospital, and so great was his success that the Chinese themselves called upon him to treat them. Altogether, 23 cases were treated. Of these, 6 were injected on the 1st day of the disease with from 20 to 30 c.c. of serum; cure occurred within 12 to 24 hours without suppuration of the buboes; 6 were injected on the 2d day with from 30 to 50 c.c. of serum; cure occurred in 3 or 4 days without suppuration; 4 were injected on the 3d day with from 40 to 60 c.c. of serum; all recovered, but fever usually persisted for a day or two; and in 2 cases there was suppuration of the buboes; 3 were injected on the 4th day with from 20 to 50 c.c. of serum; all recovered within 6 days; suppuration occurred in 1 case; 4 were injected on the 5th day with from 60 to 90 c.c.; 2 died, and they were apparently moribund when the injection was made; the

⁵ Ann. de l'Inst. Pasteur, Jan. 25, 1897.

other 2 recovered. Altogether, 26 cases were treated and 2 died—a mortality of 7.6%. The average mortality is rarely less than 80%. Yersin, although he admits that the number of cases is too small to enable him to make positive conclusions, feels sure that the rapid convalescence of the patients, so unlike the convalescence from plague, indicates that, in some way, the serum exercises a specific action. Not only had the serum that he used been kept a long time, but it is probable that none of the horses had reached the maximum degree of immunity. The only disagreeable result was a certain amount of pain at the site of injection. In view of its high protective action in the lower animals he believes that the serum should be used in the course of epidemics to protect those not yet affected. In the discussion of the nature of plague he recalls the fact that in an epidemic rats seem to be the first affected, then the larger domestic animals, and finally human beings. He therefore suspected that the microorganisms existed in the soil, and, indeed, was able to find in the earth of affected localities a bacillus similar to that of the plague, though not as virulent as that taken from the buboes.

Money Shewan¹ reports some experiments that he helped to perform at the Pasteur Institute for the purpose of producing **an antiplague serum**. The cultures were sterilized by exposure for 1 hour to 58° C., and then injected into rabbits and guinea-pigs. If only enough were employed to make the animals temporarily sick, it was found that they had acquired immunity, although this did not appear until the reaction had ceased; the serum of these animals would protect other animals against the subcutaneous inoculation of virulent cultures.

C. B. Fitzpatrick² first inoculated a horse with virulent cultures of the plague-bacillus, and then, after apparent immunity had been attained, used its serum to prevent or cure **experimental inoculation** in guinea-pigs. The results were entirely successful.

Lustig and Galliotti³ have prepared a **toxin** from agar-cultures of the bacillus of bubonic plague by dissolving the bacilli in 0.75% solution of caustic potash, and then precipitating with ammonium sulfate or acetic acid. This precipitate gave the reactions of a nuclear proteid, was highly virulent, and when injected in less than lethal doses protected susceptible animals against the general and local manifestations of the disease.

W. M. Haffkine⁴ reports the results of the **inoculation** of healthy persons with sterilized bouillon-cultures of plague-bacillus: 154 prisoners out of a total of 345 were thus inoculated. On the day of inoculation 6 cases occurred in the noninoculated and 3 in the inoculated. Subsequently, 12 cases occurred among the noninoculated, of which 6 died, and 2 among the inoculated, both of which recovered. Besides these cases, 11,362 persons from the infected areas were inoculated, of whom only 45 were attacked by the plague, 12 dying.

J. Cantlie⁵ discusses the treatment of the bubonic plague, which, according to him, consists of **purgation and stimulation** from the onset; control of the delirium and pain by hyoscin or morphin; control of the temperature by tepid sponges and, if necessary, antipyrim. He does not believe in local treatment of the buboes before suppuration occurs, although he has observed good results to follow injections of bichlorid and potassium iodid. Camphor is recommended as a stimulant.

Prophylaxis.—Harvey⁶ gives a very thorough history of the various epidemics of bubonic plague. He concludes from these and the study of the

¹ Indian Med. Rec., Nov. 1, 1896.

⁶ Ibid., Jan. 1, 1897.

Indian epidemic that it is chiefly occasioned by unsanitary habits, and that the danger may be greatly reduced by the careful isolation of the sick and effective quarantine. A. H. Doty¹ considers that the short period of incubation of plague is the greatest safeguard against its introduction into any country where the disease does not exist. The virus may, however, be transmitted by clothing, articles of merchandise, etc., and it is therefore necessary to disinfect most carefully all articles coming from a suspected point.

VACCINIA.

Kaempffer² records an **epidemic of cowpox** among milkmaids. The disease first appeared in a cow that had been on the farm for 2 years. It became ill without any discoverable source of infection. In a short time 60 cows out of 90 were affected, the pocks being only on the udders and forming sluggish ulcers when broken. Of 16 milkmaids, 10 acquired cowpox without regard to the length of time after revaccination. The incubation was usually from 3 to 4 days, but 9 to 10 in 2 cases. General symptoms occurred only in cases in which complications like phlegmon occurred. In 6 cases there was only 1 pock, in the others from 2 to 6. They appeared especially on the flexor side of the fingers and on the back of the hand, and ran the same course as those in vaccination, except that the time was shortened to 12 days and the cicatrices were not so deep.

W. M. Jones³ reports a case of vaccinia that was contracted by a farmer from a cow that he was milking. The pustules developed upon the arm in localities where it had rubbed against an abdominal crust. Subsequently his father, who had had smallpox, developed a similar vaccine pustule.

C. F. Sutton⁴ reports a case of **vaccination of curious type**. The child was vaccinated in March with calf's lymph. After the usual course four perfectly healed marks were left. About a month later the same spots rose again, and resembled in every way a newly vaccinated arm, and ran the usual course; after complete healing the same thing occurred a third and fourth time in June and late in July; another attack occurred in October. The child suffered no inconvenience, and was subsequently perfectly healthy.

Weber⁵ has observed in several cases of **revaccination** in the Reserve Hospital at Warsaw that, instead of the typical vaccine pustules, one or more dark-red, smooth, shining nodules about the size of a pea appeared about the site of the inoculation, and finally disappeared after slow desquamation, leaving a pigmented area in the skin. In drops of blood taken from such nodules he observed amebæ varying from 10 to 16 μ in diameter. These contained granules which moved slowly about in a cloudy protoplasm. Sometimes the pustules undergo suppuration, and then he has observed the siren forms that he himself had previously described. Amebæ, however, are found in the blood taken from the surrounding areas of congestion.

F. H. Payne⁶ discusses the **history of vaccination**, and notes particularly the record of Chicago, where only 17 cases of smallpox have occurred in the last 15 years among the school-children, whose average number exceeds 200,000, and among whom vaccination is compulsory. C. S. Patterson⁷ calls attention to the report of Surgeon Hinde of the epidemic of smallpox that broke out among the soldiers of the Congo Free State. Altogether, there were 366 sol-

¹ Am. Jour. Med. Sci., Mar., 1897.

⁴ Lancet, Oct. 24, 1896.

⁶ Pacific Med. Jour., Nov., 1896.

⁷ Lancet, Oct. 24, 1896.

diers; of these, 158 had been vaccinated, and only 2 took the disease, neither of whom died. Of the 208 that had not been vaccinated, 105 took the disease, and among them the death-rate was over 76%. [Statistics such as these seem very conclusive.] Queirel¹ states that smallpox is endemic in Marseilles, because a considerable number of strangers, particularly Italians, inhabit the city and refuse all forms of vaccination. He advocates, therefore, **compulsory vaccination** of all persons.

VARIOLA.

Coste² reports an epidemic of smallpox that occurred at Marseilles in 1896, and was characterized by the appearance of a **secondary eruption** from 6 to 37 days after the commencement of the disease, after the pustules of the previous eruption had completely disappeared. All of the 33 cases that he observed recovered. The second eruption was usually milder than the first, and Coste holds that it is probably no reinfection, but simply a continuation of the original disease.

A. Newsholme³ reports a case of **recurrent smallpox** that was taken to the High Gate Smallpox Hospital and there treated. The patient apparently recovered and returned to his rooms. Shortly afterward 2 charwomen employed in cleaning the rooms and living in entirely different localities contracted the disease; 3 days after his return he developed a papillary rash that subsequently became pustular.

Prophylaxis.—E. H. Sargent⁴ reports an epidemic of smallpox that occurred in the Detroit House of Correction; 4 of the cases were very severe, 3 of them being confluent and hemorrhagic and terminating in death. One was partially confluent, and convalescence was retarded by an attack of furuncles. Only 1 patient had been vaccinated, and he when a child. Two other patients, both of whom had been frequently vaccinated, had the disease in a very mild form, 1 of these passing through her second attack. Two other cases, occurring in sisters, were remarkable for their virulence and the apparent susceptibility of the patients; 1 of these apparently contracted the disease at the hospital, and developed the symptoms after her return home. Her sister was then vaccinated very successfully, and whilst the vaccine pustule was still on the arm she was attacked with headache and fever, and a rash appeared over her face and body. She recovered perfectly from this affection, which was diagnosed variously as varicella and varioloid. Shortly afterward she was attacked by malignant, confluent variola, that became hemorrhagic, and from which she died. The mother of these children had been vaccinated a number of times unsuccessfully. A very severe case occurred in a man who had been successfully vaccinated 1½ years previously. Another case occurred in a girl of 7 who had never been vaccinated successfully, and subsequently appeared in a mild form in her parents, although both had been successfully vaccinated when she was first taken ill. [Some of these cases would seem to argue against the efficiency of vaccination. It must be recalled, however, that the histories as to successful vaccinations should not be too readily accepted in persons of this class.]

Weber⁵ has found in the **blood of patients** suffering from variola various round bodies, usually of high refractive index and measuring from 1.8 to 7.2 μ in diameter. There were also certain siren forms enclosed in the blood-

¹ Bull. de la P' Acad. de Méd., Oct. 20, 1896.

² Rev. de Méd., Dec. 10, 1896.

³ Brit. Med. Jour., Oct. 10, 1896.

⁴ The Physician and Surgeon, Sept., 1896.

⁵ Medycyna, 1896, No. 14.

cells. All these forms could be stained by methylen-blue, the round bodies, however, taking that stain more deeply than the siren forms. The latter he was able to cultivate upon partially solidified alkaline agar. They have been found, however, in other diseases, such as measles and scarlet fever; in variola they appeared to increase toward the period of suppuration, and at the same time to grow larger, sometimes attaining the diameter of $15\ \mu$. They resemble eosinophile-cells very closely, and can only be distinguished from them by the rapid movements of the granulations. [It appears to be so easy to find peculiar bodies in the blood and tissues of various diseased conditions that all such descriptions must be regarded with a certain degree of conservatism; the author, however, makes no claims for the pathogenicity of those he found.]

V. Düring¹ gives the statistics of the **mortality** from smallpox in Constantinople for the last 10 years. The deaths range from 659 in 1887 to 30 in 1889. Vaccination is not obligatory, and he explains the great variations by supposing that in times of epidemic all the children have the disease, and it requires a certain length of time for the births to increase the number of the susceptible population until the epidemic can again break out.

Treatment.—Bryan² reports a case of discrete smallpox to which he applied his method of **sterilization of the epidermis**. This consists of careful scrubbing with a strong alkaline soap, washing in alcohol, and the subsequent application of some mild antiseptic. The parts treated were only the forearms. No pustules developed here, whereas on the other parts of the body the vesicles became pustules and left pits.

F. S. Furman³ has treated 2 cases of discrete smallpox according to **Bryan's method** for arrest in the vesicular stage. He carefully sterilized the surface, and then, having opened each vesicle, touched its interior with carbolic acid. Only a few pustules appeared, the vesicles drying up without the formation of a pit. Casrelly,⁴ in order to **prevent pitting** after smallpox, recommends the spraying of the face with a solution of corrosive sublimate in alcohol and ether, and subsequently painting the face with sublimate of glycerin.

J. F. O'Leary⁵ reports 53 cases of smallpox treated with **muriate of cocain**. There were 11 deaths, 6 of the patients suffering severe complications. All the others recovered, and had very satisfactory convalescences. The dose was usually $\frac{1}{4}$ of a grain every 4 hours.

SUNDRY INFREQUENT INFECTIONS.

Relapsing Fever.—Tietin,⁶ having had occasion to observe an epidemic of relapsing fever in Odessa in which 10,000 cases occurred, was struck by the fact that it seemed to originate in the small inns near the wharves. It occurred to him, therefore, that the **medium of transmission** might possibly be **through suctorial insects**. In order to test his theory he allowed hungry bedbugs to bite a monkey that had the spirilli in his blood, and then examined the blood that was obtained by crushing them. In this he found organisms that were active for some time; he then collected the blood from the bedbugs, and with it injected another monkey, which rapidly developed the disease. He suggests that infection might take place directly from the bedbugs in 2 ways: either from the proboscis of a parasite that had fed upon the patients in whose blood the spirilli were present, or as a result of scratching the skin where one of these animals had been killed.

¹ *Dentsch. med. Woch.*, 1897, No. 15.

³ *Ibid.*, Sept. 5, 1897.

⁵ *New Orleans M. & S. Jour.*, June 1, 1897.

⁶ *Centralbl. f. Bakt. Parasit. u. Infek.*, Feb. 15, 1897.

⁴ *Gac. Med. Cat.*, Dec. 15, 1896.

Gabritchewsky¹ has carefully examined the blood of monkeys and human beings affected with recurrent fever, and finds that as the crisis approaches it becomes possessed of marked bactericidal power. He finds that the spirilli will live in normal blood for 160 hours at a temperature of 37°. In the blood of a person who has just passed through a crisis they die often within an hour at this temperature. These facts led him to experiment whether it would be possible or not to treat the disease with the **serum of monkeys** that had been cured of it, and in which a considerable degree of bactericidal power had been found. In a single experiment he found it was possible by injecting such serum to limit the pyrexial period to 2 days and to avoid absolutely the relapse. Metchnikoff in the same journal criticises the theoretic consideration upon which this treatment is based, but admits the partial bactericidal action of such serum.

Mamurowski² reports a case of **relapsing fever in a pregnant woman** who aborted in the 4th month. In the blood of the fetus numerous spirilli were found.

Typhus Fever.—Lewaschew³ has found in the venous blood of patients suffering from typhus fever small bodies from 2 to 5 μ in diameter, occasionally with a long cilium. These grow on human ascitic fluid and form small grayish-white colonies. No details are given concerning the differential staining, nor records of any attempt to test the virulence of the organism in lower animals.

Spillman⁴ reports an **epidemic of typhus fever** that occurred in Nancy in 1893. The disease was remarkable for its fatality (5 of 9 cases dying) and for the nervous and secondary complications. The former consisted of abolition of the reflexes, paresis or ataxia of the lower limbs, anesthesia, and trophic disturbances. The latter were divided into 2 groups, local and general. The former consisted of otitis media, bronchopneumonia, and suppurative parotiditis. The general infection was septicemia, resulting from a local lesion. The toxicity of the urine was diminished. Bacteriologic investigations were largely negative, although in many of the secondary lesions the staphylococcus aureus was found. At the autopsies the spleen and liver were found to be enlarged; there were acute parenchymatous nephritis and changes in the central nervous system.

Yellow Fever.—Havelburg⁵ has carefully studied the **pathology and bacteriology of yellow fever**. He found that in the liver there were considerable fatty degeneration and some areas of necrosis. In the kidneys he found marked parenchymatous degeneration of the epithelium of the renal tubules. The spleen showed no alteration; the mucous membrane of the gastrointestinal tract was pale, rather thin, congested, and blood was found in the lumen. Occasionally the lymphatic follicles were swollen. Cultures were made from nearly all the organs, and all the known staining-methods employed in order to determine the presence of microorganisms. In the contents of the intestinal tract he finally found very constantly a certain bacillus pathologic for guinea-pigs, and very similar to the bacillus coli communis; but it could be distinguished from it by its peculiar action upon guinea-pigs, causing death in from 8 to 24 hours. Its characteristics are as follows: its size is 1 \times 0.3 μ ; it is straight, usually isolated, and more distinct at the poles. It is apparently motile. On a gelatin plate the growth appears as a fine white point at the end of 24 hours; 2 days later it is somewhat larger and shows a

⁴ Rev. de Méd., Aug. 10, 1896.

⁵ Berlin. klin. Woch., June 7, 1897.

yellowish discoloration. It renders bouillon turbid, ferments sugar solutions, and coagulates milk. Injected into guinea-pigs, it causes lesions not unlike those found in yellow fever. Although he did not obtain a reaction with it similar to the Widal reaction of typhoid fever, he concluded that this was the specific germ of the disease, and, furthermore, that the prospects for effective serum-therapy are very promising, because injections of the blood of yellow-fever patients into guinea-pigs protected them against its pathogenic action.

J. Sanarelli¹ has studied the pathology of yellow fever with especial reference to the **bacteriology**. He summarizes the morbid anatomy as follows: hyperemia, infiltration and even hemorrhage of the serous membranes, fatty degeneration of the organs, catarrhal inflammation of the mucous membranes, enlargement of the lymphatic structures, moderate disintegration of the red blood-cells, and the presence of urea in the blood. He made cultures in a number of cases from the blood antemortem, from the organs postmortem. In the second case he was able to isolate a peculiar bacillus that he designates as the **bacillus icteroidis**, and obtained the same organism repeatedly in subsequent cases. It has the following characteristics: it is from 2 to 4 μ long, motile and ciliated; it decolorizes by Gram's method, and grows readily at room-temperature upon the ordinary media. Under certain circumstances the growth is sufficiently peculiar to render it possible to make a diagnosis within 24 hours. This occurs when an agar-culture is kept at 37° for several hours and then at room-temperature, when the colonies will be found to have raised edges and a depressed center, or, if the process be reversed, depressed edges and a raised center. Occasionally some difficulty may be caused by the tendency of the bacillus to pleomorphism. This microorganism is pathogenic for most of the lower animals, giving rise to a disease with characteristic stages, and causing fatty degeneration in the organs, especially in the liver and kidneys. In human beings it is often associated with other microorganisms, giving rise to abnormal clinical types of the disease. When inoculated it may cause an intoxication due to the development of a toxin, and this is especially apt to be the case in the lower animals when the infection takes place through the respiratory tract; in these cases it is usually found in relatively pure cultures throughout the body; or there may be a condition of septicemia due to mixed infection, in which case only other microorganisms are found; or death may be due to uremia, the tissues giving no cultures and the proportion of urea in the blood being greatly increased. This bacillus appears to have 3 specific properties—emetic, hemorrhagic, and steatogenic, the two former giving rise to the black vomit, and the latter to the icterus. [It is to be regretted that Sanarelli has not described experiments for the production of immunity in this paper; although it is stated that the serum of the one animal that survived inoculation (a dog) possessed some slight protective powers. Reasoning from analogy, there would seem to be few diseases more adapted both to inoculation and to serum-therapy than yellow fever. It is unfortunate also that he has not tried the Widal reaction, for it would add much to the presumptive evidence in favor of the specific pathogenicity of the bacillus icteroidis.]

Malta Fever.—M. L. Hughes² suggests the term **febris undulans** for the disease variously known as Malta fever, pseudotyphus, etc. It is a specific endemic and sometimes epidemic malady of long duration, and is marked by characteristic undulations in the fever. Constipation, neuralgic pains, swelling of the joints, and profuse sweating are frequent symptoms. The lesions of

¹ Ann. de l'Inst. Pasteur, June, 1897.

² Lancet, July 25, 1896.

typhoid fever are absent. Wright and Smith¹ treat of the **diagnosis** between cases of **typhoid, Malta fever, malarial fever**, and other varieties of continued fevers. The means at our disposal are the examination of the blood in malaria; of the stools in typhoid and possibly Malta fever; and, lastly, the sero-diagnosis in typhoid and Malta fever, using a modification of the first method of Widal. Eight cases of Malta fever gave positive reactions with dilutions of 1:10 and 1:25; 1 with as high as 1:1000; 15 cases, diagnosed as typhoid, gave a positive reaction with a 1:25 dilution; 3 cases, diagnosed as typhoid, were negative with the typhoid culture, but gave a reaction with the microbe of Malta fever; 1 case, supposed to be Malta fever, was negative with the organism of that disease, but reacted with that of typhoid fever; 3 cases, supposed to be malaria, reacted with the Malta-fever organism. Finally, 14 cases, diagnosed as typhoid fever, were without result on either the typhoid or Malta-fever microbe. [These results show the importance of this test in distinguishing between certain tropical and subtropical febrile conditions. They also strengthen the assertion of Bruce that his micrococcus *Melitensis* is the true cause of Malta fever.]

A. E. Wright² has tested the blood of 10 soldiers invalided home from India for the **reaction with the micrococcus Melitensis**. In 7 cases agglutination occurred in a proportion of 1 to 150 or 300; in 2 cases in a proportion of 1 to 1000; and in 1 case in a proportion of 1 to 10, although in this case higher dilutions were not tried. Only 6 of these patients had previously served in the Mediterranean, and only 1 had fever whilst on this service. Wright therefore believes that Malta fever is endemic in India. [It is not unlikely that the disease is even more widely distributed.]

G. E. MacLeod³ reports a case of rapidly fatal **purpura hæmorrhagica** that followed an attack of Malta fever. [It does not appear, however, that the diagnosis was confirmed by bacteriologic examination.]

Foot-and-mouth Disease.—Bussinius and Siegel⁴ in the blood and tissues of a patient who died, apparently, of foot-and-mouth disease found, among various other microorganisms, a small oval bacillus that was pathologic for animals. The results, however, were not entirely satisfactory until they were able to obtain the same microorganism in the saliva and fluid from pustules in the mouths of 3 children suffering from the same disease. With this saliva they inoculated a calf, some chickens, a cat, sheep, and dog. Of these, the calf became affected apparently with typical foot-and-mouth disease, and from its blood the same oval bacillus was obtained in pure culture. Later they were able to study 2 epidemics of foot-and-mouth disease in cattle, and again found the same bacillus. Subsequently, with the material thus obtained, they inoculated 3 calves and a young pig, all of which became diseased and were certified as suffering from foot-and-mouth disease by a qualified veterinarian. The authors therefore believe that they have discovered the common cause of foot-and-mouth disease in man and the lower animals, but reserve their description of its morphologic and biologic characteristics for a later paper.

Cerebrospinal Fever.—Diagnosis.—Heubner⁵ has recently demonstrated the meningococcus *intracellularis* of Weichselbaum during life in several cases of meningitis. The organism was found in the liquid obtained by puncture of the spinal membranes. The specific properties were demonstrated by the action of the cultures upon goats, rabbits and guinea-pigs being immune.

¹ Lancet, Mar. 6, 1897.

² Brit. Med. Jour., Apr. 10, 1897.

³ Lancet, May 22, 1897.

⁴ Deutsch. med. Woch., Feb. 4, 1897.

⁵ Ibid., No. 27, 1896.

The inoculations were made into the spinal canal, and showed that the organism is of lesser virulence than the pneumococcus. Jemma¹ describes a case of meningitis in which the microscopic examination and cultures showed the presence of diplococci (regarded as pneumococci by the author) in the liquid obtained by spinal puncture. Fürbringer² describes an instance of meningitis in which a diplococcus was demonstrated in the liquid obtained by spinal puncture. It was probably the meningococcus. [These cases are of great interest in the differential diagnosis of cerebrospinal fever and tuberculous meningitis, and illustrate the value of puncture of the spinal membranes in diagnosis.]

Weil's Disease.—Bignone³ reports a case in which a man, after dietetic error, had chill, acute pharyngitis, then icterus at first, with typhoid, and finally hemorrhagic symptoms. At the end of 7 days there was critical discharge, and 5 days later a typical relapse. The author concludes that the case is one of Weil's disease, and believes that the best theory of its pathogenesis is the formation of a toxalbumin by some infectious agent that irritates the epithelium of the biliary passages and the cells of the liver.

Streptococcus Infection.—Jemma⁴ reports a case of meningitis due to streptococci and secondary to facial erysipelas. He first points out that meningitis is less frequently present than is diagnosed in erysipelas; and in the cases in which meningitis is actually present other microorganisms are usually associated with the streptococci. In his own case the patient, who had erysipelas in January, developed bronchopneumonia in February, and finally, on March 4th, symptoms of meningitis. Fluid removed by lumbar puncture 24 hours before death gave pure cultures of streptococci. The same result was obtained from the exudate on the brain and from the liquid obtained by puncture of the spleen. The examination of the blood was negative; nevertheless, Jemma believes that the meningitis resulted from infection through the circulation, and not through the lymphatics. [It is to be observed that the erysipelas had subsided more than a month previous to the development of the meningitis. This does not, however, exclude the direct etiologic relation between the two diseases.]

Two cases are reported from the Royal Infirmary of Edinburgh⁵ of chronic recurrent erysipelas, 1 having lasted 12 and the other 2 years. Both were greatly improved by the use of antistreptococic serum.

Infection with the Bacillus of Friedländer.—Brunner⁶ records a case of general infection due to the bacillus of Friedländer. The patient, previously a healthy person, suffered with suppurative middle-ear disease, from which abscesses of the mastoid sinuses developed. Operation was undertaken, but suppurative meningitis with general pyemia occurred. The patient died after 14 days. Pure cultures of the bacillus of Friedländer were obtained from the pus obtained at the operation and from the various organs post-mortem. Reiche⁷ reports a case that commenced suddenly with fever, profound stupor, and slight meteorism. On the 3d day of his admission to the hospital and on the 17th day of the disease extreme indicanuria developed, and a thick, confluent papillary eruption appeared upon the breast and soon spread to the whole body. There was slight leukocytosis. Acetone and diacetic acids were not found in the urine, but there were slight albuminuria and considerable in-

⁶ Münch. med. Woch., Nos. 13 and 14, 1896.

⁷ Wien. med. Woch., Jan. 9, 1897.

crease in the ethereal sulphates. A diagnosis was made of autointoxication from the intestinal tract, and was apparently confirmed by the autopsy, which showed parenchymatous degeneration of the kidneys, hemorrhagic cystitis, and a chronic gastrointestinal catarrh, with several transverse ulcers in the colon. Bacteriologic investigations of the intestinal contents showed that they contained a pure culture of a long, thick bacillus resembling the bacillus of Friedländer, and markedly pathogenic for guinea-pigs.

Pyocyaneus Infection.—Charrin¹ reports a curious case observed by Dr. Bardon, in which the patient, a woman of 45, could voluntarily cause a greenish liquid to issue from the breast. This, when examined bacteriologically, was found to contain the bacillus pyocyaneus.

Hydrophobia.—Kraïouchkine² states that in the year 1895 269 persons were treated in St. Petersburg for hydrophobia by Pasteur's method. In 2 cases the disease developed before the treatment was completed; 1 other patient died after the treatment, giving a mortality of 0.4%.

Febrile Diseases of Unknown Nature.—Ruge³ describes a peculiar fever that occurs on the east coast of Africa and is characterized by a painful swelling of the inguinal glands. The course was variable. In the acute forms the fever was very high; in the more chronic forms, which lasted sometimes for months, the fever was lower or entirely absent. The temperature is not typical, but approximates the remittent type. Swelling is sometimes extreme and the local pain intense, and there is often infiltration of the periglandular tissues. In 38 cases resolution without suppuration occurred 23 times, suppuration occurred 3 times during the stage of decline, and in 12 cases early incision was necessary. The conditions must be distinguished from venereal, tubercular, leukemic, and pseudoleukemic buboes, and the bubonic plague, although the latter condition can usually be easily excluded. In regard to the etiology, it appears that it cannot be a malarial condition, as the fever disappears as soon as the glands are removed and it is not influenced by quinin. [This is probably one of the conditions that have been included among the group known collectively as *pestis minor*.]

D. J. Caddy⁴ reports the case of a ship's captain on the west coast of Africa. The disease commenced with chills and moderate rise of temperature, apparently producing no great exhaustion and not influenced in the least by large doses of quinin. Subsequently some blood was vomited, the temperature rose to 107°, the patient became delirious, then rapidly passed into a state of collapse, and died. [It is unfortunate that a microscopic examination of the blood was not made.]

E. Way⁵ describes the so-called **fish-slime disease** endemic at Cape May, which is apparently a peculiar form of septicemia resulting from punctured wounds by fish-spines.

Beri-beri.—A. Beale⁶ reports an epidemic of beri-beri that broke out amongst Mohammedans of a crew of native sailors in an English ship. Altogether, 19 were attacked. The Hindoos and Christians escaped entirely. No cause was discovered for this peculiar selection, as the men lived under the same conditions and had the same diet. He divides the cases into 4 types: the incompletely developed or rudimentary form (5); the atrophic form (2); the dropsical form (6); the pernicious form (6). The first was characterized by edema of the legs and fever, some numbness of the lower extremities, and

⁶ Indian Med. Rec., Mar., 1897.

profound anemia; the second by anemia, edema, and fever that persisted in 1 case for 30 days; the third type by symptoms of scurvy in addition to those before described and a subnormal temperature; the pernicious form by an exceedingly severe anemia, violent palpitation of the heart, great anxiety, and collapse. All 6 of this pernicious form died. *Ankylostoma duodenalis* was suspected, but no eggs nor ova were found, and treatment by thymol had no effect.

Gibbs¹ describes a disease, endemic in the Singapore Lunatic Asylum, that he names "**pseudo-beri-beri.**" It is noncontagious, prevails during the wet season, and, for the most part, in the damp, low-lying levels. Clinically, it is characterized by slight anemia and considerable soft anasarca, and a tendency to sudden death from shock. The hygienic conditions surrounding the asylum are most unfavorable, and, on account of the fact that those most frequently affected drank well-water which contained numerous living organisms, it was supposed that this might be the cause. However, it attacks exclusively Asiatics, and continues to attack them when the water-supply is changed. The urine is normal, which serves to distinguish the disease from nephritis. *Ankylostoma* are not found. It can be distinguished from beri-beri by the softness of the edema and absence of spastic and paralytic conditions of the muscles and by the rapidity of recovery. The period of incubation apparently lasts from 1 to 2 days, and is characterized by malaise. There is some fever, and edema develops, commencing in the feet and spreading very rapidly. The blood contains irregular masses of pigment free and in the leukocytes; no malarial organisms have been found. Cultures of the blood showed the presence of a bacillus forming yellowish-brown colonies, and a micrococcus forming yellow colonies. These were possibly contaminations. The treatment consists in removal to a more favorable locality and free purgation. Subsequently iron and stimulants may be of use.

Intoxications Resembling Infections.—F. W. Burton Fanning² describes a number (11) of cases of what he regards as **sewer-air poisoning.** He admits the difficulty of proving that these are really instances of sewer-air poisoning, but was led to believe them such from the facts that they did not correspond to any definite disease; that they presented many features in common; that some grave sanitary defect was found in all cases, and most of them recovered after this was removed. As to the clinical features, most of them presented fever, this, as a rule, being of the hectic type, and in 3 cases distinguished by remarkable abatement of the symptoms during the febrile remissions. Rigors were met with in 3 cases; headache quite generally; but pains in the limbs were more significant. Epigastric pain was found in 2 children, petechiæ on the legs occurred in 3 severe cases, and erythema annulare in 1. Of the 8 adult cases, 5 had lymphangitis on the legs or arms and glandular enlargement without wounds or local injury. In 1 case there was phlebitis; in 2 a suspicion of endo- and pericarditis. In 3 cases the spleen was enlarged, and in 6 of 10 in which the urine was examined at the height of the disease albumin was discovered. Regarding diagnosis, he states that ulcerative endocarditis, typhoid fever, and rheumatism are most difficult to exclude. In 1 of his cases bacteriologic examination showed the presence of staphylococci and an undefined bacillus in the blood. [While there are interesting points in this paper, it furnishes no data for the solution of the question, whether or not sewer-air poisoning occurs. Other possibilities in the way of etiologic factors were not excluded.]

¹ Indian Med. Rec., Feb. 15, 1897.

² Lancet, Oct. 24, 1896.

A. Crawford¹ reports an epidemic of **food-poisoning** that occurred in Iowa in 1895. More than $\frac{1}{3}$ of 300 guests assembled at a wedding were affected, and there were 7 deaths. The first cases occurred 3 days after partaking of the food, and the last cases about 28 days. The symptoms were those of intense gastroenteritis or gastritis. In many there was severe pain in the limbs with tenderness in the muscles. All the patients appear to have suffered from fetid sweating. There were 2 autopsies, in both of which the liver and spleen were enlarged and soft. In 1 there was hyperemia of the cecum; in the other, ulceration. Both of these cases were examined microscopically, and the pathologist made a diagnosis of typhoid fever. It is also stated that another pathologist made a diagnosis of trichina-poisoning from the examination of the muscles. [The symptoms certainly resembled those of trichina-poisoning more closely than those of typhoid fever, but the description of the cases is so unsatisfactory that it is difficult to draw any conclusions.]

J. Dixon Mann² considers the subject of **meat-poisoning**, and notes that, aside from parasitic diseases and accidental poisoning, meat may be injurious from—(a) preexistence of disease in the animal prior to its slaughter, or (b) from the invasion of microorganisms in the meat subsequent to slaughter, and (c) from the presence of toxalbumoses or ptomaines. The symptoms may be either infectious or toxic. In the first group the characters of the disease are those of any infection, as in an instance in which the symptoms suggested typhoid fever in 600 people who had eaten from an animal killed while moribund. In the second group of cases the symptoms resemble those due to acute gastroenteritis, among these being violent vomiting and purging, rapid loss of strength, and cramps in the legs, subnormal temperature with general coldness, although occasionally there is fever. The symptoms are variable according to the form of poison, and sometimes also in different persons poisoned with the same meat. The latter fact may be explained by the unequal distribution of the poison in the meat or by the fugitive nature of the poison. Prolonged cooking does not necessarily render the poisons harmless, as many of these resist heat. Sometimes the flesh of animals having some form of infection is not toxic immediately after slaughter, but becomes so when kept, and the flesh of healthy animals may readily become contaminated by various microorganisms when it is kept.

Van Ernengen³ reports investigation of some **sausage and smoked beef** that had produced severe symptoms similar to those of cholera nostras in a number of persons. Portions of these submitted to a skilled investigator appeared so tempting that, in common with several of his assistants, he partook of them, and soon developed symptoms of violent enteritis and nephritis, leading to death in 6 days. At the autopsy there were found gastroenteritis, acute nephritis, and fatty degeneration of the liver. In the feces and tissues a peculiar bacillus was found, morphologically and culturally similar to the bacillus enteritidis of Gärtner, and the same organism was found in the meat. It remains to be shown whether the flesh of the animal from which the sausage had been made was diseased or not, or whether the sausage had been subsequently infected.

Hick⁴ holds that the disposition to **autointoxication** consists of a peculiar reaction of a special organism to a definite irritant. As soon, however, as the products of the decomposition of albumin have entered the organism and produced toxic effects microorganisms unquestionably begin to act in conjunction with them.

¹ Jour. Am. Med. Assoc., June 19, 1897.

² Med. Chron., July, 1896.

³ Rev. de Hyg., 1896, p. 761.

⁴ Wien. med. Woch., No. 1, 1897.

E. D. Fergusson¹ reports 8 cases which he believes to be due to **auto-intoxication** with ptomaines from the intestinal tract. The symptoms consisted of sudden onset with regurgitation of food. The regurgitated material subsequently became more serous in character, contained brown specks, and finally became coffee-ground in character. There were great prostration and rapid, feeble pulse and some fever. In those cases in which autopsy was obtained the intestinal tract was found to be hyperemic and the liver softened and fatty. He finally reports a 9th case in which vomiting became stercoraceous; he succeeded in washing out the intestinal tract by continuous rectal injection until the vomited material was clear. This patient recovered.

C. J. Whitby² discusses **self-poisoning**, of which he reports 4 cases. He assumes that the toxins are ordinarily produced in the intestinal tract, and in normal conditions chiefly eliminated by the kidneys. He therefore advocates treatment by intestinal antisepsis, diuretics, and especially by Turkish baths.

W. G. Thompson³ believes that **hysterical fever** is due to pure malingering, the patients causing the mercury to rise by some manipulation akin to prestidigitation. He mentions several cases in which, upon taking the temperature himself, the rise failed to occur.

TUBERCULOSIS.

Etiology.—Kelsch⁴ gives a *résumé* of 7 theses upon "**Heredity and Contagion in Tuberculosis.**" The authors attempted to solve the question in various ways, and agree that contagion is by far the most important element in the spread of tuberculosis. They, however, differ very much as to the part played by heredity, most of them believing that it is of little or no significance, although one, who based his conclusions chiefly upon laboratory experiments, concluded that it was more important than was generally believed. [Reliance on experimental work must not be too implicit, as the dosage and general conditions differ from those in spontaneous infection; but with clinical and pathologic evidence pointing in the same direction it may be confidently asserted that occasional intrauterine transmission does occur.]

I. H. Hanco⁵ has performed a number of experiments upon the **infectiousness of dust in dwellings and public conveyances**, with the following results: of 16 guinea-pigs inoculated with dust taken from 4 tenement-houses, where the families had paid attention to the instructions and regulations given them, 5 died of acute infection, and none were affected with tuberculosis. Of 12 pigs inoculated with dust from suspected rooms, 2 died from acute infection, 1 was indicative of tuberculosis, and 5 were tuberculous; 2 tenements out of 3 were found not infected. In the Bellevue and Charity Hospitals 11 wards were examined with negative results. Of 4 animals inoculated with dust from the waiting-rooms of the out-door poor department, 2 died of acute infection and 1 was tuberculous. Tubercle-bacilli were found in none of the elevated railroad cars, but the dust contained other highly infectious germs, which rapidly proved fatal. Of the street-cars, 1 of the 2 examined was infected with tubercle-bacilli. Two experiments with dust kept sealed in a dark drawer for 2 months showed that the acute infectious nature of the material had died out. The small amount of dust obtainable for the experiments (averaging but little over 3 sq. in. per room) makes these results all the more striking. A large number of the animals that died of acute infection might,

¹ Med. Rec., Oct. 31, 1896.

² Bristol Med.-Chir. Jour., Dec., 1896.

³ Med. News, Jan. 2, 1897.

⁴ Bull. Acad. de Méd., Oct. 13, 1896.

⁵ Med. Rec., Feb. 15, 1897.

had they lived, have increased the number of positive results. The great contrast between the clean tenements and those where more carelessness was exhibited shows emphatically the value of the work being done by the N. Y. Board of Health. He advocates the establishment of State sanatoria for the segregation and treatment of all cases of consumption.

Bay¹ examined 351 separate specimens of **cow's milk** by centrifugation, and in 51 found tubercle-bacilli. In 204 mixed specimens he found tubercle-bacilli 4 times.

Wolff² suggests the following rules in order to determine the source of **hereditary tuberculosis**: If several children of the same family become diseased, the mother remaining healthy, she is not the original source; if, however, only the younger children become diseased, whilst the parents remain healthy, she possibly has a latent form of the disease. If the elder children alone are affected, the father has been the cause of transmission. He analyzed 250 cases, and found that one or both of the parents died of tuberculosis in 80, and in 2 cases had tuberculosis without fatal result. There were 38 cases in which brothers and sisters were tuberculous, and 64 in which there was a tendency on the part of other children of the family to die young. Malignant tumors occurred in the parents of 25, and mental or nervous diseases in those of 8 of the patients; 33 patients were without hereditary history. Of these, however, 22 were either sickly or had tubercular habitus.

[The following paper, which is only a confirmation of previous work, demonstrates very clearly the fact of direct transmission.]

Bugge³ has had an opportunity to examine the **fetus and placentas** of 5 tuberculous mothers. In 2 of the cases the examinations of the infants alone were negative; in 2 other cases both infants and placenta were negative; in the fifth case the child was born at the eighth month and died in thirty hours: the placenta could not be examined; but at the site of its insertion numerous bacilli were found in the wall of the uterus. Tubercle bacilli were also found in the blood of the umbilical vein and in the vessels of the infant's liver, but there were no gross tubercular lesions.

Charrin and Riche⁴ have carefully examined **3 children born of tuberculous mothers**, and found that they presented anomalies in weight, growth, nutrition, and the toxic qualities of the urine. The latter were increased, which they take to indicate a sort of humoral toxicity—that is, a condition favoring infection.

Otto⁵ discusses the relation of **phthisis and heart-disease**. He holds that there is truly an antagonism between left-sided disease and phthisis, phthisis rarely developing in a person suffering with left-sided valvular disease, especially if it is advanced to the stage in which passive congestion of the base of the lung is occasioned. Previous publications are contradictory. He himself has studied a number of cases, and in particular has searched carefully their histories to determine, if possible, whether, in the case of coincidence, the valvular lesion was first in development. He reports a case where the phthisis was primary, and where the appearance of the anatomical lesion was such that one might suppose the reverse. In other cases the cardiac lesions seemed to have impeded the extension of phthisis, for he found ancient tuberculous foci. In women he found, on the contrary, some cases in which phthisis developed in persons suffering with valvular disease; but he also found some cases of arrest of tuberculosis under the influence of cardiac lesions. In 2 other cases the mod-

² Münch. med. Woch., No. 40, 1896.

³ Ziegler's Beiträge, vol. 19, p. 432.

⁴ Compt. rend. de la Soc. de Biol., Apr. 16, 1897.

⁵ Virchow's Archiv, Bd. 144, H. 1.

erate degree of cardiac trouble had not even occasioned hypertrophy. From his observations he concludes that there are rare exceptions to the rule that phthisis is not apt to develop in the course of cardiac disease. The exceptions are explained for the most part by the poor development of the cardiac lesions or by cases of general debility which have rendered the cardiac muscle insufficient. It is also well to note that the antagonism manifests itself less strikingly in the female. [This subject has been studied and restudied. It may be true that valvular disease with failing compensation impedes or prevents the occurrence of tuberculosis; but the statistical evidence should take into account the limitation of individuals. It might, for example, be found that the number of cases of phthisis in any other condition (in a small number of cases) would be small as compared with the bulk of humanity; and yet no real antagonism could be asserted. It must be admitted, however, that there is considerable evidence to prove that congestion is antagonistic to the growth of tubercle.]

Rendu¹ reports the case of a man of 25 suffering from chronic cyanosis due to congenital narrowing of the pulmonary artery. In spite of the fact that he had spent all his life in hospitals exposed to tubercular infection, his lungs were free from the disease. [A single case of this kind proves little. There is undoubtedly evidence to prove greater susceptibility on the part of persons suffering with pulmonary stenosis.]

Jaccoud² contributes an interesting paper upon the **contagiousness of pulmonary tuberculosis**. Though the infectiousness of the disease is practically admitted by all, certain practical questions enter into the discussion of its contagiousness, and the experience of hospital managements must be taken into account. Regarding cases in which it has been alleged that infection has taken place within the hospital, he urges great care, and cites three instances in which the first consideration of the cases seemed to warrant this deduction, but in which subsequent study disproved the view. He particularly directs attention to autoinfection, as it might be called—that is, infection of the body by bacilli that previously existed somewhere in the body, though in a quiescent state. The tuberculosis itself may not appear until the patient has been reduced by some other affection or brought to the hospital with some form of injury. The author opposes the isolation in the hospitals of tuberculous cases, and states that there is greater danger to the tuberculous near to the phthisical than to the healthy near to either. He bases this upon the ground that infection with pyogenic micrococci occurs more readily than with the bacillus of tuberculosis, and that symbiosis of the former organisms with the latter renders the tuberculous process in the lungs or elsewhere particularly rapid and severe, while the pure tubercular bacillosis is less serious. In discussing this paper Pean rather favored the idea that infection frequently occurs in the hospital, and Terrier held that tuberculosis is exquisitely contagious, though this is not usually striking, from the fact that the symptoms of the disease are not marked at first. Debove took the same ground. Dumontpallier, on the other hand, stated that in his 40 years of experience in hospitals he had not been able to observe any marked contagion in this disease. In closing the discussion Jaccoud alluded to the investigations of Bollinger and Loomis, both of whom demonstrated the frequency of latent tubercular disease of the bronchial lymphatic glands.

W. Murrell³ reports a case of **phthisis acquired** by a woman, previously healthy and without tubercular family history, from her husband, who had died

¹ Bull. méd., Feb. 24, 1897.

² Bull. de l'Acad. de Méd., No. 4, 1896.

³ Lancet, Apr. 10, 1897.

from the disease, and in nursing whom she had taken no precautions. [It is only from a collection of a number of such cases that any definite results can be drawn, although it must be admitted that the present instance is very suggestive.]

R. Menger¹ has studied the **statistics** of tuberculosis at San Antonio, Texas, and concludes that the influx of consumptives has had no injurious effect upon the health of the inhabitants, as the mortality shows a relative decrease. Elaborate precautions to prevent infection, however, are exacted in the hospitals.

S. W. Abbott² states that the **death-rate** of consumption has been reduced $\frac{1}{2}$ in the State of Massachusetts in the last 50 years. [These conclusions are unsatisfactory, because it is impossible to place great faith in the diagnoses made at a period when autopsies were even less common than at present, and the tubercle-bacillus had not been discovered.]

Surmount and Predhomme³ find that the **mortality** from pulmonary tuberculosis has diminished from 1893, when it was 47.5%, to 25.7% in 1895. The general mortality-rate has not been affected. [These figures cover too short a period of time to be of value.]

Pathology.—The determination of the frequency and forms of secondary infection in tuberculosis is a matter of growing interest and importance.

Lannelongue and Achard⁴ have studied the question of **microbic association** in cases of **tubercular suppurations** and other tubercular affections. Sixty-two cases presented the clinical appearance of tuberculosis: in 16 of these positive proof was furnished by injections of pigeons and in 2 by injection with tuberculin. In 57 of these cases there were suppurative collections wholly closed to the external air, while in the other 5 similar collections communicating with the outer air were found. Of the first 57 cases, 51 were negative on culture; in 4 the staphylococcus aureus was found, and in 2 streptococci. In the 5 open cases the staphylococcus aureus was found in 2, the streptococcus in 2, and both forms with saprophytes in 1. Referring to the question of the bearing of these micrococci on the febrile movement, the authors point out that opinions have differed greatly. In their own investigations febrile movement was found in 14 cases, including 6 in which micrococci were found, but also 8 in which the culture was negative. They therefore hold that the fever is not connected with micrococcal infection. [This opinion is not by any means definite, as the absence of microorganisms from cultures does not exclude the existence of such. It is unnecessary to instance lesions in which microorganisms are difficult to demonstrate in culture, but in which they are known to exist.]

Luzetto⁵ has examined 15 cases of senile tuberculosis in order to determine the nature of the mixed infection. In 8 cases streptococci were present. These always presented the same characteristics, but were apparently either not pathogenic or only slightly so. Staphylococci were also present, and in all cases the following saprophytic types: the micrococcus candelaris, the bacillus fungoides, and a motile bacillus. There appeared to be no definite relation between the streptococci and the fever, nor were these organisms found in patients over 60 years of age. The virulence of the tubercle-bacillus was normal, and the author concludes that senile tuberculosis resembles that of early life, excepting that mixed infection is rarer and the microorganisms usually show slight vitality and virulence.

⁵ Centralbl. f. Bakt. Parasit. u. Inf'kr., Jan. 20, 1897.

Schabad¹ discusses mixed infection of phthisis, and includes only those microorganisms, other than tubercle-bacilli, that he has found in the blood, bronchi, and alveoli. These adventitious organisms frequently complicate the last stages of the disease and hasten death, though the hectic fever may exist when they are absent.

Complications.—Haus-halter and Etienne² report 3 cases of pulmonary tuberculosis complicated by thrombosis of the ascending vena cava. In 1 of these cases staphylococci were found in the clot. [Thrombosis in the late stages of tuberculosis is probably less uncommon than is generally supposed; we recall 2 striking cases, 1 of which was discovered accidentally at the autopsy.]

H. J. Godlee³ contributes an interesting study of the changes in the **bones and joints** that occur in connection with thoracic disease. He first refers to caries of the spine and chronic tuberculous joints; then to caries of the ribs in connection with phthisis, and to carious conditions of the lower jaw following disease of the teeth. A rare affection which has once come under his observation was "perforating necrosis of the skull." A number of fluctuating areas appeared on the head, and when these were opened small sequestra involving the whole thickness of the skull were discovered, whose rapid separation was in marked contrast with the tedious course met with in syphilitic cases. Finally, he discusses at much greater length the subject of pulmonary osteoarthropathy (*q. v.*).

Diagnosis.—A. M. Holmes⁴ contributes a paper on the diagnosis of tuberculosis from the **morphology of the blood**. He begins with the assumption that the processes affecting the body as a whole are accompanied by analogous processes involving the leukocytes; or, in other words, that individual cells present changes comparable with those involving the whole organism. He then details the blood-examinations with differential counts of the leukocytes in 35 cases, calling attention to the fact that there is not a single characteristic which permits of the diagnosis of tuberculosis, but that a number of conditions must be brought into relation. The relative proportion of the leukocytes and the occurrence of beginning or advanced degeneration of the same cells are the factors of importance. He finds that there is reduction of the relative number of small lymphocytes and increase of polymorphous elements; that the large mononuclear cells usually increase in number, and that giant lymphocytes with irregular outline and globules of hyaloplasm in the state of extrusion are frequent. The eosinophile cells are wanting, or reduced in number only in severe cases. Occasionally myelocytes may be found. Various degenerated forms of leukocytes may be observed. He then goes on to state the character of the blood in different stages. Beginning with the earlier and proceeding to the advanced stages of the disease, the number of lymphocytes decreases, while the polymorphous elements increase. [The paper is filled with crude speculations, and is marked by a disregard of known causes of alteration in the proportions of leukocytes. An increase in the polymorphous elements in such a condition as advanced phthisis is scarcely distinctive. The degenerations of leukocytes to which he calls attention are often due to the method of staining.]

Terrile⁵ injected the sputum of 33 patients suffering from acute disease of the respiratory tract, but none of whom were suspected of tuberculosis, into guinea-pigs, 11 of which developed **experimental tuberculosis**. Of these 11 patients, 10 were cured and 1 showed an old sclerotic focus at the autopsy.

Combelale and Raviart¹ employed **tuberculin** in doses of 0.2 to 0.3 mg., and found that the reaction was sufficient for the purpose of diagnosing tuberculosis, and without any bad effects upon the patient. In 2 cases, however, where 0.5 mg. was employed there resulted a maculopapular eruption, commencing on the third day after the injection and lasting from 3 to 5 days. In these cases the tubercular lesions were very extensive. They conclude that injections of 0.25 mg. may be of much use in obscure cases and cannot prove dangerous to the patient.

E. L. Trudeau² has used tuberculin for the purpose of diagnosing incipient tuberculosis in 14 cases. The highest dose given was 3 mg., but in 6 cases the reaction was obtained with 2 mg. or less. The symptoms usually occurred within 12 hours, although in 1 case they did not appear until 22 hours after the injection. Of the 7 negative cases, 5 have since been under observation, and remain perfectly well. [As this method appears to be perfectly safe when carefully employed, and as the results of various investigators agree that it is fairly accurate, it seems justifiable to employ it in doubtful cases where tubercle-bacilli cannot be found.]

Pulmonary Tuberculosis.—Symptoms.—Samuel West³ records a case of **acute phthisis** in a man of 20, remarkable for the **absence of fever**. The patient, a polisher by occupation, was in perfect health until 6 weeks before, when he got a slight cough. A month later pain in the left axilla developed, and he began to expectorate thin mucus and to emaciate. When he was admitted signs of pleurisy were discovered, and a few days later slight dulness. The sputa were thin, greenish, and frothy, slightly blood-stained, and contained tubercle-bacilli. On the first day his temperature was from 99.8° to 100.8°, on the 10th day between 99° and 100°, and from this time until the end of his illness rarely above normal, reaching 99° only once or twice. The physical signs made rapid progress, and the general condition rapidly deteriorated. Two months after his admission there was marked dulness down to the middle of the axilla, with defective entry of air and sharp crepitations. In spite of increase of physical signs, however, he began to improve, did not sweat so much at night, and gained 2 pounds in 5 weeks. He finally left the hospital 11 weeks after admission in an apparently subacute or chronic state.

J. P. Arnold⁴ reports 2 cases in which he detected **cog-wheel inspiration** in the apices. In the course of a few months both developed tuberculosis. He regards the sign as almost pathognomonic of a pretubercular state. [We can hardly agree with this sweeping conclusion, having observed this sign in a number of cases that certainly did not develop tuberculosis within the period he mentions.]

D. Riesman⁵ reports a case of miliary tuberculosis that during life had presented a **pleural friction-sound**, from the presence of which the diagnosis was made.

Potain⁶ states that in the first stage of tuberculosis, before the disease has been fully developed, **gastric disturbances**, such as pain, vomiting without nausea, but with cough, and occasionally dilatation of the stomach, are not infrequent. These disappear with the development of the second stage. They appear to be due to depressed gastric action.

Rumpf⁷ has studied the **diaphragm-phenomena** in 70 cases of tuber-

eulosis of the lungs. In 5 of these cases it was totally normal, and in a 6th it was practically so. It was practically equal on the two sides, though reduced, in 29 of the 70 cases, and was completely absent on the two sides in 1 person, a young man, emaciated, with double pleurisy and beginning inflammation of the right apex. It was reduced upon one side only in 34 cases of the 70, and was practically absent on the one side, while the other side was nearly normal in 6 cases. In these there was combination of pleurisy with involvement of the apices. The material furnished in the institution in which the author worked does not include cases of advanced phthisis. The phenomenon has no special diagnostic value, according to his observations. [Our own experience accords with this conclusion, not only in pulmonary tuberculosis, but in other diseases as well.]

David Newman¹ reports 6 cases of **hemoptysis**, in all of which tuberculosis was suspected, but which proved upon careful examination to be cases of laryngeal disease, and yielded to appropriate treatment. [It cannot be too strongly urged that all other conditions should be excluded before hemoptysis is ascribed to tuberculosis.]

Hanot² discusses the **termination of pulmonary phthisis**. He holds that it is curable, even spontaneously, and has himself observed a case in which complete recovery apparently took place. One of the signs of improvement, after cavity-formation has taken place, is dislocation of the heart, due to cicatricial retraction of the tubercular areas. He holds that the only satisfactory treatment, so far discovered, is climatological, and believes that if means were provided for the treatment of cases from their incipency, 60 per cent. of those who annually die of the disease could be saved. Among the peculiar features of tubercular cachexia is the fact that, even though it be extreme, the assimilation may be undisturbed and decubitus rarely occurs. A symptom that almost invariably announces imminent death is a melalgia described by Beau. It consists of an exquisitely sensitive point just above the knee, due, Hanot believes, to a form of neuropathy.

Treatment.—[Greater attention is constantly given to **prophylaxis**, and we select the following as representative opinions upon this point:]

Granjux³ makes an exhaustive study of **tuberculosis in the French army**, and finds that it affects 7 men in every 1000, a greater proportion than occurs among the civilians. The statistics show that it is gradually increasing from year to year, this increase corresponding to the proportion of young soldiers and the obligations imposed upon them to learn their duties in the least time possible. In order to diminish this comparatively large proportion he recommends that the medical examination should be stricter and more thorough, in order to exclude those who become tubercular on account of predisposition or the development of a latent form of the disease—that this medical examination should take special account of tubercular heredity. Further, the circumference of the thorax should be carefully noted and its proportion to the height and weight of the individual; and in those cases where instead of increasing, as is usual in military life, it decreases, the individual should be discharged from the army. Finally, in order to prevent those cases that are due to contagion, he recommends the periodical disinfection of the barracks, a supply of spittoons, and the enforcement of the ordinary measures of hygiene, such as the restriction of crowding and the careful examination of food.

Grancher and Thoinot⁴ have reported to the Commission de l'Assistance publique of Paris their conclusions regarding the **prophylaxis of tuber-**

¹ Brit. Med. Jour., May 29, 1897.

² Sem. méd., 1896, p. 289.

³ Rev. de la Tuberculose, July, 1896.

⁴ Ibid., Dec., 1896.

culosis. These are as follows: the best way of combating and treating tuberculosis is to isolate the patient, for the reason that by this means only is the risk of contagion diminished and better therapeutic conditions obtained. In the special hospitals every effort should be made to secure thorough antiseptics: the floors should be washed with an antiseptic solution; the sputum should be collected and carefully destroyed, and it should never be permitted to fall upon the floor; all the objects that the patients touch or use should be subjected to the same precautions, which should also extend to the furniture; and in order to make this as effectual as possible it is suggested that the mattresses be made of fireproof material. The patients should only wear clothing provided by the hospital, which should be washed at stated intervals. In regard to the personnel of the hospital, they regard it desirable to obtain better service than has hitherto been employed, and admit that for this purpose salaries must be considerably increased. As the risk of infection on the part of the nurses is very great (at least one-third die of this disease in France), they advise that only unmarried persons should be selected, or, at least, that they should be given the preference. In those unfortunate cases where it is still necessary to treat the patient at his house the rules should be all the more rigorously insisted upon.

In the congress of Russian physicians held at Kieff in the spring of 1896¹ Kostkevitch urged the **isolation of tuberculous patients** in special sanatoria, particularly cases in the advanced stages of the disease, when mixed infection exists, and not only the tubercle-bacilli, but also other pyogenic microorganisms are liable to be disseminated. He holds that the climate is of little consequence, as the sanatoria of the north give as good results as those of the south, the essential conditions being life in the open air, superalimentation, and complete change of habits. Helmann, in the same meeting, distinguished 2 categories of patients: those with slight expectoration and those with abundant expectoration; the latter, being the more dangerous, should be especially isolated. He believes that it is important to keep the two classes separated.

In a discussion on tuberculosis held in the Dublin Medical Society Moore² laid emphasis upon the necessity of closer government supervision of the disease, and urged particularly that in case of death the local health board should be notified and the dwelling be disinfected.

H. T. Tillotson³ objects to the **segregation of consumptives**, and also to the deteriorating effects of too much **isolation**. He suggests, as a compromise, the establishment of small camping-parties in some favorable climate.

E. A. Edlen⁴ believes that the popular opinion can be educated to object to the unrestricted **association with tuberculous patients**, and suggests the following rules: the destruction of all tuberculous cattle; the registration of all cases of tuberculosis, which shall then be instructed how to prevent infection; forbidding all tuberculous patients to marry until all signs of the disease have disappeared; and, finally, the disinfection of all houses in which tuberculous patients have died.

T. C. Craig⁵ calls attention to the close **analogy between tuberculosis and leprosy**, and to the great inconsistency in the municipal control exercised over the two diseases. He thinks that it is very important that more precautions should be taken to prevent the spread of tuberculosis; particularly all food capable of conveying germs should be carefully investigated, and meas-

ures taken to prevent reckless expectoration either in dwellings or in public conveyances.

[The efforts to obtain an efficient antitubercular serum are being continued with great enthusiasm. Confidence is, however, somewhat shaken by the fact that the best results are usually obtained by the persons that have produced the serum, although Maragliano's report appears to be both sincere and frank.]

Maragliano¹ gives a summary of all the cases of tuberculosis that have hitherto been treated in Italy by his antitubercular serum. A cure is to be understood when all the symptoms of the disease have disappeared and remained absent permanently as determined, where possible, by frequent control-observations of the discharged patients. Altogether, 712 cases are reported. These are divided into 6 groups, according to the nature of the lesions: 168 cases suffered from bronchopneumonia with cavity-formation, of which 129 are reported to have had fever; this latter symptom disappeared after treatment in 55 cases, was diminished in 22, and remained stationary in 52. The expectoration disappeared in 27, was considerably improved in 75, and was unaffected in 66. In only 59 cases are there records of the discovery of tubercle-bacilli. These disappeared in 10 cases, were diminished in 27, remained as before in 19, and were increased in 3. In 129 of these cases the body-weight was increased; in 38 it was unaffected, and in 16 it was diminished. Altogether, 14 cases are recorded as cured, 75 as improved, 50 as stationary, and in 29 the symptoms grew worse. 127 cases are classified as destructive bronchopneumonias without cavity-formation or with mixed infection. In 94 of these cases temperature-records are given; in 54 cases the fever disappeared, in 15 was diminished, and in 25 was uninfluenced. In 22 cases all expectoration disappeared, in 66 cases it was diminished, and in 39 was unaffected. In 52 cases there are records of the bacilli, in 13 they disappeared after the treatment, in 27 they were diminished, and in 12 unaffected. In 13 cases there are records of the body-weight. This was increased in 74, unaffected in 35, and diminished in 4. Altogether, 12 of these cases were cured, 71 improved, 35 remained stationary, and 9 became worse. The third group included diffuse febrile bronchopneumonias with or without destructive symptoms. Altogether, there were 220 cases collected. Fever disappeared in 107, remained stationary in 60, was diminished in 37, and became worse in 16. Expectoration disappeared in 36, was diminished in 93, was unaffected in 72, and grew worse in 19. Of 81 cases in which examination for bacilli was undertaken, these disappeared in 31, diminished in 53, remained stationary in 12, and increased in 3. The body-weight is reported for 151 cases: it was increased in 90, remained constant in 49, and diminished in 12. Of the whole number, 10 were completely cured, 120 improved, 67 unaffected, and 22 grew worse. The fourth group included diffuse apyretic bronchopneumonias with or without symptoms of destruction of pulmonary tissue. Of 68 cases, the catarrhal symptoms disappeared in 13, improvement took place in 41, and 14 remained stationary. In only 17 cases were bacillary examinations made. Of these they disappeared in 7, were diminished in 9, and remained as before in 1. Of 58 for whom there are records of the body-weight, 43 increased and 15 remained stationary. The total result was 2 cures, 54 improvements, and 12 unimproved. Group five were cases of circumscribed bronchopneumonia with fever. Of 81 cases, fever disappeared in 69, was diminished in 7, was stationary in 4, and increased in 1. The catarrhal symptoms disappeared in 46, were improved in 31, were unaffected in 3, and grew worse in 1. Of 44 cases where records are given, the tubercle-bacilli disappeared in 27, were dimin-

¹ *Gaz. degli Osp.*, Nos. 125, 126, 1896.

ished in 16, and unaffected in 1. Thirty-three cases are reported as cured, 45 as improved, and 30 as stationary. The sixth group included 48 patients affected with circumscribed apyretic bronchopneumonia. All signs of catarrh appearances disappeared in 35, in 11 they were improved, in 2 remained stationary. Of 36 cases, the bacilli disappeared in 33 and were diminished in 3; of 45 cases, there was increase in the body-weight in 44; in 1 it remained stationary. Altogether, there were 33 complete cures, 13 cases of improvement, and 2 unaffected. That is to say, of the 712 cases, 104 appear to have been completely cured, 379 improved, 169 remained stationary, and 60 grew worse. Maragliano contends that in many of these cases the fact that no deterioration appeared must be taken as in some sense a positive result. The best results appear to have followed the regular injection of from 1 to 2 c.c. The most unfavorable for the treatment appeared to be cases of mixed infection.

Among the other papers dealing with the **antituberculous serum** of Maragliano, the following may be briefly alluded to: Derenzi¹ injected 22 cases, and has found no disadvantages or dangers. The patients improved in appetite and general feeling. In some cases the disease appears to be arrested. The improvement is slow, and increasing the dose does not render it more rapid. The best results are obtained in circumscribed and uncomplicated cases without high fever. Regnier² describes 3 cases in which he obtained good results. De Bernardi³ claims to have cured an advanced case in a relative. After 40 injections in 1 month the cough ceased and the weight increased 1800 gm. F. Carlucci⁴ has used the serum in 5 cases, and has found it of use in bronchopneumonia. It is harmless, and to be preferred in cases of phthisis to any medicinal treatment. The action is gradual. Cattaneo⁵ reports 2 cases in children, aged 3 and 5, in which he obtained useful results. Crescinano⁶ reports a case of laryngeal and pulmonary tuberculosis that was cured. Tubercle-bacilli had been found in the sputum.

[Unfortunately, in some of these instances showing remarkable success the exact details of the cases are not furnished, and doubt may exist as to the definiteness of the diagnosis. In many of them tubercle-bacilli had not been demonstrated.]

De la Jarrige⁷ reports an interesting case of pulmonary tuberculosis. The patient, a young girl, had had a dry cough at the age of 17 years, and at the age of 20 presented the symptoms of cavity at the left apex, a tuberculous infiltration of the larynx, and multiple cavities in the lower third of the left lung. The treatment at first instituted having been interrupted, the disease progressed rapidly. It was then determined to employ subcutaneous injections of the **antitubercular serum of Richet and Hericourt**. Neither the first nor the second injections were followed by any reaction. The third, however, produced intense general urticaria with violent headache, high temperature, and intense congestion of the right lung. Death appeared imminent, but gradually the temperature fell, and in 8 days the patient had resumed her previous condition. New injections were practised, in spite of the serious symptoms that had been previously produced, usually without result, but occasionally giving rise to inflammatory action less marked than before. In 2 months improvement was manifest, particularly in the larynx. Finally, the girl seemed to be cured. The cavity in the left apex persisted, but was appar-

⁶ Riforma Med., No. 67, 1896.

⁷ Compt. rend. de la Soc. de Biol., July 3, 1896.

ently dry. She became stout, vigorous, and capable of enduring considerable exposure.

P. Paquin,¹ referring to his results in the treatment of tuberculosis with the **antitubercle-serum of horses**, summarizes his cases up to September 1, 1896. There are 226 cases tabulated; among these 37 were bronchopneumonias with cavities; 66 destructive bronchopneumonias without cavities; 19 diffuse febrile pneumonias with or without destructive processes; 19 diffuse nonfebrile pneumonias with or without cavities; 35 circumscribed febrile bronchopneumonias; 13 circumscribed apyretic pneumonias; 32 indefinite; 2 hip-joint disease; 2 laryngeal tuberculosis; 1 ovarian. The fever subsided in 60 and was reduced in 56; the night-sweats subsided in 69; the weight increased in 125; strength increased in 54; the appetite was improved in 114; the local signs disappeared in 46, improved in 58; the tubercle-bacilli disappeared in 40, diminished in 103. As to the results, the following summary may be made: recoveries, seemingly complete and permanent, 40; apparent recoveries with existing lesions, 3; improved cases capable of returning to work, 41; improved to less degree, 69; deaths, 32; disappeared or ceased treatment, 41. The author points out that most of the cases coming under this treatment are in the late stages, and that in the vast majority of such cases nothing can cure the disease.

W. H. Prioleau² reports 13 cases of tuberculosis treated with Paquin's antitubercle-serum. Of these, 2 cases are reported as practically cured. In the sputum of 1 no tubercle-bacilli were ever found, and it is doubtful if the case was really tubercular in character. The other suffered from hemorrhages, and, although he improved considerably, still had cough and continued the treatment. Of the remaining 11 cases, it is stated that all but 1 were benefited; 6 died, and in 5 the ultimate result was not known. [It is difficult to discover what grounds the author has for his very favorable conclusions as to the value of this treatment.]

Allen³ also reports 4 cases treated with Paquin's antitubercular serum: 1 case was apparently cured; 2 improved, but 1 of these died of femoral thrombosis; and 1 patient was not improved and died.

A. Worcester⁴ reports the results of a year's treatment of various cases of tuberculosis with **antiphthisin** and **tuberculin**. Of 7 cases treated with tuberculin, 3 improved; 3 were obliged to change to antiphthisin; 2 are still under treatment: of these 7, 4 were in an advanced stage. Of 22 cases treated with antiphthisin, 10 were in advanced stages, and yet 4 of these improved markedly; 9 in less advanced stages showed no special improvement. Altogether, he believes that the patients that improve under tuberculin do better afterward and show less tendency to relapse than those which improve under antiphthisin.

[The results of experimental work in serum-therapy are more definite and satisfactory than the reports of its clinical use. The following papers are not favorable to its employment:] Tourkine⁵ has carried out a number of experiments with the design of testing the **value of serum-treatment** in tuberculosis. He finds that the horse withstands very well the injection of the living bacilli, and that its serum becomes in time, to a certain extent, resistant to the action of the organism. When this serum was injected into animals that had previously been inoculated with tuberculosis he noticed some favorable results, indicated by the diminution of the temperature and a longer duration of life.

¹ N. Y. Med. Jour., Oct. 24, 1896.

² *Ibid.*, June 26, 1897.

³ Jour. Am. Med. Assoc., May 29, 1897.

⁴ Boston M. and S. Jour., Aug. 2, 1896.

⁵ *Wratch*, Oct. 2, 1896.

However, all these animals finally died as a result of fatty degeneration of the viscera, and he concludes that the serum, as far as cats and guinea-pigs are concerned, has only a retarding action upon the invariably fatal result, and that therefore Maragliano's proposition to treat human tuberculosis with anti-tubercular serum is, at the least, premature.

Peron¹ immunized 10 guinea-pigs by inoculating them in the peritoneal cavity with small quantities of tubercular pus that had been heated for $\frac{1}{4}$ hour to 150° C. These and 6 control-animals were then injected with caseous material that had been heated to 150°. All of the 6 control-animals showed tumefaction. Of the 10 that had been immunized, 2 only showed a manifest induration after 17 and 24 hours respectively. Somewhat later all were injected with living cultures of tubercle-bacilli, and it was found that the protected animals became infected more rapidly and more severely than the control-animals. He concludes, therefore, that it is possible to vaccinate the guinea-pig in a certain measure against the toxins contained in the tubercle-bacillus, but that this **vaccination** does not give **immunity** against living virulent organisms.

Koch² obtained a **new form of tuberculin** by rubbing dried cultures in a mortar until only few tubercle-bacilli were left, adding serum and removing those remaining by centrifugation; the resulting product is completely absorbed by the tissues and never gives rise to abscesses. This liquid could be separated into two portions—*i. e.* that obtained after the first centrifugation, which Koch speaks of as T. R., and that in the following centrifugations, which he speaks of as T. O. The former contains those constituents of the tubercle-bacilli which are insoluble in glycerin; it has a distinct immunizing action, although it produces a slight reaction when injected into tuberculous patients. A curious effect, showing that it contains all the immunizing principles of tuberculin, is that the patient immunized by it fails to give the reaction when treated with ordinary tuberculin. The technic for the production of immunization in animals is as follows: in healthy guinea-pigs the dose may be as high as 2 or 3 mg.; in those suffering with tuberculosis it must be very much less, in order to avoid, as far as possible, any reaction. The object to be attained is the giving of doses as large as possible in the shortest possible time. In tuberculous pigs more or less pronounced retrogressive changes could always be found in the tubercular lesions. Upon human beings it has already been used quite extensively in cases of pulmonary tuberculosis and lupus. In the latter, although there was but slight local reaction, progressive improvement always occurred.

Buchner³ discusses the **new preparation of tuberculin** that has been described by Koch, and concludes that we are justified in expecting much greater success with it than with the older form, because it ought to be possible to produce specific immunization. He, however, claims the priority of the suggestion for his brother, and believes that his brother's method is infinitely better, as it does not subject the preparer to the same amount of danger.

V. C. Vaughan⁴ reports the further history of 12 of the 24 cases of **tuberculosis treated with nucleinic acid** that he had reported 2 years previously. In 1894, 12 cases had died; of the 12 then living, 2 have since died; 3 are still affected; 5 now show no evidences of the disease; and in 2 the result is unknown. He reports 52 additional cases, making in all 76. Of these, 70 were suffering from pulmonary tuberculosis, and 3 have died; 17 have been continuously free from the bacilli, and are apparently cured; 2 more are appar-

¹ Compt. rend. de la Soc. de Biol., May 7, 1897.

² Deutsch. med. Woch., Apr. 1, 1897.

³ Berlin. klin. Woch., No. 15, 1897.

⁴ Med. News, Feb. 27, 1897.

ently well, but have not been examined; 20 were still affected at the last examination. Of these, 16 had been apparently improved: 5 were cases of urinary tuberculosis; 4 have been apparently cured; 1 developed acute miliary tuberculosis; and the 1 case of joint-tuberculosis was benefited. Vaughan, as a result of his studies in these and in some 40 more recent cases, concludes that in the advanced stages of disease, in which the area of inflammation is great, only temporary improvement, if any, occurs. In initial cases it not only arrests the progress of the disease, but may act as a curative agent.

H. M. King¹ has treated 37 cases of pulmonary tuberculosis with hypodermic injections of **nuclein**; of these, 7 were in the incipient stage, 15 in the advanced stage, and 15 in a far-advanced stage; 8 were apparently cured, 7 arrested, 6 improved, and 16 were unimproved, of whom 3 died. He observed that during the treatment the number of red blood-corpuscles was almost invariably increased.

[**Röntgen Rays.**—It has been claimed that these rays have decided bactericidal power, though experiments have not borne out the assertion uniformly. The experiments in tuberculosis have been fragmentary and inconclusive.] Lortet and Genoud² exposed some guinea-pigs that had been inoculated with tuberculosis to the Röntgen rays, and found that at a time when some control-animals were seriously affected these remained comparatively well.

Fiorentini and Laraschi³ also believe that the resistant power of the animals was increased, although their results were not conclusive.

Ravillet⁴ reports a case of pulmonary tuberculosis occurring in a young man of 18 with tubercular family history, treated by the Röntgen rays. During a *séance* the patient always slept quietly and the fever was diminished. Tubercular laryngitis was noticeably improved. All these symptoms reappeared when, on account of the breaking of the apparatus, the treatment was suspended for a short time. The local results were the appearance of an erythema upon the anterior and posterior surfaces of the body, which subsequently became vesicular. In spite of transient benefit the patient subsequently died.

Rendu⁵ reports the case of a man of 20 who became ill with the symptoms of beginning typhoid fever, changing to those of an infective pneumonia. The sputum contained pure cultures of staphylococcus. The fever declined partially, but returned, and the evidences of suppuration of the pleura or lung were discovered. Another examination of the sputum showed a few tubercle-bacilli. At the end of 6 weeks the patient seemed nearing the end. He was exposed to the **Röntgen rays** at this time for 55 minutes every day. After the fourth exposure the temperature fell and did not arise again. There were diuresis and diaphoresis, and the patient became quite well. The author does not believe the result to have been purely coincidence. After 10 of the applications erythema and ulceration of the skin were found, and he holds that equally marked trophic changes may have taken place in the deeper tissues. [The typical decline of the symptoms so strongly suggests a pneumonic process that we should hesitate to accept the reporter's statement without further confirmation.]

Jakoby⁶ has endeavored to produce hyperemia of the pulmonary apices by means of his thermo-therapeutic apparatus, which consists essentially of the local application of heat. He hopes by this method to increase the collection of the alexins in this region and thereby hinder the development of tuberculosis.

⁶ Münch. med. Woch., No. 89, 1897.

J. K. Crook¹ reports 45 cases of pulmonary tuberculosis treated with large doses of **creasote**. Of these, 5 were apparently cured—that is, there was complete disappearance of the symptoms and physical signs of phthisis; 5 showed marked signs of improvement, and 8 received some degree of benefit; 13 showed no influence at all from the treatment, and 8 died. The remainder were not treated long enough to enable the author to draw any positive results. Of the 5 cases that were cured, 2 were in the 2d stage and 3 in the 1st stage; of the 5 that were benefited, 2 were in the 1st stage and 3 in the 2d. Crook believes that creasote is a remedy capable of arresting certain cases of tuberculosis.

A. Chaplin and F. W. Tunnicliffe² have employed **guaiacolate of piperidin** in 14 cases of pulmonary consumption. There was some improvement in the cough, and often the lungs seemed dryer. The temperature was usually unaffected. While under its influence the patients improved in appetite and general strength. As much as 30 gr. was given 3 times daily without bad effects.

Leannau³ has employed **ichthyol** in the treatment of pulmonary phthisis. He gives it in capsules that contain .025 of a cgm., and administers from 4 to 24 of these per day. All the symptoms improve; the cough becomes less severe, the dyspnea less, excepting in those cases complicated with valvular heart-disease; the intercostal pains disappear, and physical signs are altered for the better. All the general symptoms improve; weight is increased, and the sweating greatly diminished. In conclusion, he reports 10 cases, in all of which great improvement occurred.

J. H. Thompson⁴ reports 5 cases in which he has used inhalations of **cinnamon oil** in the treatment of consumption. Expectoration and cough were the first symptoms to improve; then the temperature tended to become normal, and finally the weight began to increase. These changes were accompanied by a gradual diminution in the number of tubercle-bacilli in the sputum.

Schröder⁵ suggests **peronin** for the treatment of the **irritating cough** of pulmonary tuberculosis. It appears to be almost equally effective as codein, and very rarely causes disagreeable symptoms. It is particularly valuable when the patients have become accustomed to the use of the latter drug or to morphin.

Joquet⁶ has used **sodium tellurate** in the treatment of the **night-sweats** of phthisis. The drug is given in the form of a pill or solution, the sodium salt being readily soluble in water or alcohol. The dose is $\frac{3}{10}$ gr., but in bad cases $\frac{3}{4}$ gr. may be taken daily. For a lasting effect the drug should be administered 3 days. Large doses tend to disturb the stomach.

Hemoptysis.—R. H. Babcock,⁷ in a paper on the treatment of hemoptysis, records the opinions of 27 physicians of experience in Chicago. Of these, 18 insisted upon absolute rest; 13 apply cold to the chest; 17 use opium and morphin to allay cough or promote calm; 15 use ergot, though some state that they have doubts of its utility—11 others are positive that ergot is not efficient; 6 use acetate of lead, either with or without opium; 2, tannic acid; 2, gallic acid; 1, dilute sulphuric and 1 aromatic sulphuric acid; 6 use ipecac; 4, aconite; 2, veratrum viride. Finally, the author states his own views. He quiets cough with phosphate of codein, $\frac{1}{4}$ to $\frac{1}{2}$ gr. hypodermically, or $\frac{1}{2}$ to 1 gr. by the mouth. He gives ipecac in frequent doses until nausea is produced, and a saline aperient like Hunyadi water. When the

⁷ Medicina, Sept., 1896.

hemorrhage occurs from a cavity, he gives an immediate injection of gr. $\frac{1}{50}$ to even gr. $\frac{1}{25}$ of sulfate of atropin. Absolute rest is always insisted upon.

C. E. Quimby¹ advocates the employment of his **pneumatic cabinet** for the arrest of **pulmonary hemorrhage**. The patients are obliged to expire into a negative pressure of from $\frac{1}{2}$ to $\frac{3}{4}$ inch of mercury. This produces a general capillary dilatation and lowering of the systemic vascular tension, so that the venous system is distended, while the pulmonary vessels suffer corresponding depletion and slowing of their circulation—a condition that favors clotting. The statistics of 50 cases suffering from hemoptysis are reported, and in only 2 this treatment failed to prevent recurrence, 1 of these being acute phthisis involving the larger part of the right lung, and the other acute diffuse infiltration of both lungs; 2 cases in particular had hemorrhage while under observation, which was immediately arrested by treatment in the cabinet, and after systematic treatment failed to return.

J. W. Brannan² recommends morphin, gallic acid, ergot, etc., and lays particular emphasis upon careful respiratory gymnastics in the interval between the attacks.

V. Y. Bowditch³ discusses the treatment of phthisis in **sanitaria near our homes**. He refers to his previous papers upon the results obtained in 40 cases of consumption treated at Sharon: 10 of these cases were reported as arrested. Since that time (that is, during the last 2 years) 26 cases have been admitted, but 2 remained only a short time. Of the 24 remaining cases, 7 left the sanitarium as "arrested" cases; of the remaining 17, 1 was an uncertain case, which was apparently cured; 12 others were more or less advanced and little was expected of the treatment; 8 of these improved somewhat; 4 were not benefited; 4 other cases were really incipient cases, and 2 of them left for Colorado, and after 3½ and 6 months decidedly improved. One other left in 2 months much improved, and the 4th is still at the sanitarium the picture of health, with little cough and no bacilli in the sputa. In addition to the 10 arrested cases previously reported, 5 who were then under treatment, classed as "much improved," have been since discharged as arrested. Altogether, of 64 cases treated at the sanitarium in the last 5 years, 22 are classed as arrested; of these, 4 have since died, and in 2 others the symptoms of the disease soon returned after leaving Sharon, though they are still living: 1 of the 4 that died succumbed to an operation. Good accounts are obtained of all the others.

Lymphatic Tuberculosis.—Duelion⁴ believes that the greater number of **enlargements of the lymph-glands** are due to either lymphosarcoma or tuberculosis. The differential diagnosis is important, as in the latter case operative procedure is indicated, but is almost impossible clinically, and even histologically very difficult. He therefore recommends excision of a suspected gland and inoculation into some lower animal, a method he regards as the only positive one.

Frouz⁵ discusses the dangers which may arise from the **rupture of tubercular glands** into the air-passages. These he holds to be nothing more serious than the development of a putrid bronchitis, unless incomplete liquefaction of the glands has taken place, when the caseous masses may form serious obstructions, and occasionally require tracheotomy for their removal, as in 2 cases that he cites. He also suggests that hemoptysis without pulmonary lesions is probably due to the rupture of a small artery in one of these glands.

⁴ Thèse de Bordeaux, No. 32.

⁵ Jahrb. f. Kinderh., Feb. 5, 1897.

In conclusion, he urges the importance of the earlier diagnosis of these conditions, and suggests the use of mercurial injections in treatment.

Pluder and Fischer¹ have examined 32 cases of **hyperplasia of the faucial tonsils**, in 5 of which they found tuberculosis limited to the mucous layer. They consider that this condition represents a latent primary form of the disease.

Cardiac Tuberculosis.—Labbe² reports 2 cases of tuberculosis of the **heart-muscle**, and alludes to 36 previously published cases. Tuberculosis of the myocardium occurs in 4 forms: (1) small miliary tubercles, (2) large solitary tubercles, (3) the diffuse form, (4) tubercular myocarditis with diffuse sclerosis and miliary tubercles, but without caseation. The pericardium may or may not be involved; the endocardium is generally unaltered except in the diffuse form. The disease is most frequent in young subjects, 17 of 29 cases being under 15 years; and is usually secondary. The infection may occur by dissemination through the blood coming in the pulmonary veins or by direct extension from the tuberculous pericardium; the most frequent method, however, seems to be by way of the lymphatics—a fact which explains the deeply seated affection of the cardiac muscle and the secondary involvement of the mediastinal glands. The author's 2 cases are as follows: (1) A boy of 6 developed a persistent cough after bronchopneumonia. The heart-area was increased; the heart-action irregular, and later enlarged, and ascites prominent. Cardiac symptoms (pain, irregular pulse, and general edema) increased and sudden death resulted. Postmortem tuberculosis of the third form was discovered, the pleura and pericardium being adherent, and the latter much thickened and containing cheesy nodules. The heart-muscle was hard and lardaceous in appearance. (2) The second case, a girl of 1 year, had suspicious bronchitis and enlarged glands; had whooping-cough and chicken-pox, and died with the symptoms of pulmonary tuberculosis. At the autopsy a large cavity was found in the middle lobe of the right lung, with tubercles in both lungs. A cheesy tubercle penetrated the myocardium, being visible beneath the pericardium. Tubercle-bacilli were demonstrated in both cases. The latter case belongs to the second form of tuberculosis.

Renal Tuberculosis.—Plicque³ discusses **uremia** in tuberculous patients. He classifies the various forms into acute and massive tuberculosis of the kidneys. In addition to these, epithelial and renal lesions and albuminuria are exceedingly common. All these lesions favor the occurrence of uremia, and in addition fatty and amyloid degeneration occurs frequently. Uremia is, nevertheless, not frequent, chiefly because there are so many other methods of elimination that are active in these conditions, as, for example, the sweats, the sputum, etc.; and in addition there is a gradual development of tolerance of the alteration of the kidneys.

Louis-Dubois⁴ believes that the **pretubercular albuminuria** is not due to the elimination of the poison, but rather to a direct infection of the kidneys by the tubercle-bacilli, liberated for some reason or other from a latent focus and circulating in the blood. He supports this hypothesis by 2 series of experiments: in 1 he injected considerable quantities of toxin into rabbits without producing albuminuria; in the other he injected virulent cultures, and was frequently able to recover the bacilli from the kidney.

Intestinal Tuberculosis.—R. B. Shaw⁵ reports a case of pulmonary

¹ Arch. f. Laryng. u. Rhin., p. 372, 1896.

⁵ Montreal Med. Jour., Jan., 1897.

tuberculosis suffering from persistent diarrhea in which **tubercle-bacilli** were discovered **in the feces**. At the autopsy no anatomical changes were discovered in the intestinal tract. [The diagnosis of intestinal tuberculosis would doubtless be made in such a case, and would be justified. A warning, however, should be sounded that smegma-bacilli be as carefully distinguished as possible.]

Nové-Josserand¹ reports a case of **tumor in the right ileocecal** region about the size of a fist, easily movable and with irregular nodular surface. Exploratory incision showed that this consisted of a tubercular cecum. Although no treatment was undertaken, there was great improvement after the operation, and in less than 3 weeks the tumor had almost entirely disappeared.

Claud² describes a case in which severe **tuberculous ulcers** were found **in the duodenum**. This occurred in a patient who had not suffered with vomiting or diarrhea: 1 ulcer was found within a centimeter of the pylorus, and 7 others below this. The appearance of these was not like that of the ordinary tuberculous ulcers found in the small intestine in the same case. The histological examination, however, showed their nature, and tubercle-bacilli were demonstrated.

Peritoneal Tuberculosis.—Marchthurn³ reports 19 cases of tuberculosis of the peritoneum treated by laparotomy, and adds to these 17 cases that had been previously treated by this method: 21 were permanently cured; in the others, in which tuberculosis of other organs existed, the results were only temporarily favorable. Fever did not occur after the operations in those cases in which asepsis had been most rigid. Diagnosis was confirmed in all cases by microscopical examination.

Ovarian Tuberculosis.—Prochownik⁴ reports the case of a woman who, in the lower third of the abdomen, developed a tumor that was about two-thirds of the diameter of the colon. It was nodular and pedunculated. At the autopsy it was found to be tubercular in nature, probably springing from the left ovary.

LEPRA.

Etiology.—Ehlers⁵ in discussing the etiology of leprosy, particularly as it occurs in Iceland, shows that the disease has increased somewhat in recent years, and in particular has collected statistics bearing upon the transmission of the disease. He found 158 cases on the island in 1894–95, and of these he was able to examine personally 119. In 56 cases there was a history of the disease in the family. Of these, the father and mother were affected in 3; father alone in 15; mother alone in 4; sisters or brothers in 4; distant relatives in 14.

K. Grossman⁶ has also studied the etiology of leprosy in Iceland, which country he considers the most favorable field for such an investigation. The inhabitants themselves, according to him, appear to pay no regard to the possibility of contagion, associating freely and intimately with advanced cases. The natives take great pride in their ancestry and keep family records. He concludes, from a study of these, that leprosy is certainly not hereditary, and can only be spoken of as possibly contagious, an absolute demonstration of infection from direct contact being still lacking. He suggests the possibility that human beings are but temporary hosts of the parasite, it having possibly some extra-human habitat, in the same manner as the bacillus of tetanus.

⁴ Bull. de la Soc. anat. de Paris, No. 8, 1896.

⁵ Münch. med. Woch., No. 49, 1896.

⁶ Brit. Med. Jour., Dec. 5, 1896.

Havelburg¹ as a result of extensive observations in Rio Janeiro, where there are about 3000 cases of leprosy, has reached the conclusion that the disease is **contagious**; even in the hospitals some of the attendants have been attacked in spite of thorough precautionary measures. The period of incubation appears to be, in some cases at least, as much as 2 years, and may possibly be longer. The disease is frequently associated with tuberculosis; indeed, nearly all his patients ultimately die of phthisis. He holds that it is important to prevent the subjects of leprosy from travelling, and particularly to prevent them from entering countries where the disease is rare or practically unknown.

Diagnosis.—Gravagna² has been able to demonstrate the lepra-bacilli upon the skin in cases of leprosy with cutaneous manifestations. The bacilli are absent from the skin when cutaneous manifestations are wanting. He was able to demonstrate the bacilli in the fluid of blisters raised upon healthy portions of the skin of leprosy patients, but was unable to find them in sweat induced by pilocarpin or in fresh sperma.

Faber³ has examined the secretions and tissues of a case of leprosy, and found bacilli in the blood of diseased tissue, sweat, epidermis, and sperma, and failed to find bacilli in the blood of healthy tissues, in the urine and sputum.

Visceral Lepra.—Scageliosi⁴ examined the so-called lepra-nodules of the lungs occurring in a case of leprosy, but found only staphylococci and streptococci.

Doutrelepont and Wolters⁵ describe a case of leprosy with widespread visceral lesions. The lepra-bacilli were found in the lungs, mesenteric glands, intestines, bone-marrow, and the kidneys. The diagnosis of lepra may be made by the intracellular position and peculiar arrangement of the bacilli, by the abundance of vacuolated cells in the different tissues, and by the absence of structures resembling tubercles and of evidence of necrosis. They found the bacilli in the cavities of the heart, and therefore conclude that the disease is transmitted through the circulation.

Von Reisner⁶ describes 3 cases of lepra with **ulcers in the intestines**. In 2 of these there was at the same time tuberculous disease of the lung, as in the 13 cases described by Hansen and Looft. The ulcers, however, were distinguished by great thickening and bluish coloration of the edges. In the 3d case the ulcer was flat, rounded, and with a sharp edge. No tuberculosis of other organs could be discovered. Microscopically lepra-bacilli were found in the third case, while in the ulcers of the first and second bacilli could only be found after staining the length of time that would also stain tubercle-bacilli. The author believes that the third case was a true instance of leprosy ulcer of the intestine.

Treatment.—Prophylaxis.—P. A. Morrow⁷ urges that leprosy is not only exceedingly rare, but also very slightly contagious, and that the precautions taken to isolate patients are absurd when contrasted with the freedom accorded to consumptives and syphilitics.

Serum-therapy.—Juan de Carrasquilla⁸ injected animals with serum obtained from leprosy patients, then bled these animals and used their serum in the treatment of leprosy. He found that it caused discoloration of the spots, restoration of sensation in the anesthetic patches, and notable improvement in

⁴ Riforma med., No. 189, 1896.

⁷ N. Y. Med. Jour., Nov. 7, 1896.

the general condition of the patients. Occasionally there was reaction. In the nodular form there were desquamation and subsequent return of the skin to a normal condition. [There is not the slightest proof offered that the animals employed became more than normally immune, or that their serum acquired any curative properties. This method of preparing serum has not given satisfactory results in any other infectious disease.]

C. B. Maitland¹ reports 2 cases of leprosy treated by the **thyroid-gland** substance, in both of which there was considerable improvement in the local lesions and general condition.

H. R. Crocker² has treated 2 cases of leprosy with **corrosive sublimate** injected hypodermically. In both there was improvement in the general condition and no bad effects from the treatment.

Tuberculosis and Leprosy.—A. Ransome³ has made a careful comparative study of tuberculosis and leprosy, and concludes that the latter disease is limited mainly by general sanitary measures, and that it is scarcely affected by direct efforts to prevent contagion.

Ainhum and Leprosy.—Zambaco-Pacha⁴ considers the relations of ainhum and lepra, and concludes that the former is really a form of the latter. He reaches this conclusion from the consideration of cases described in Europe, as well as from the similarity in the clinical history and the localization of the disease to restricted districts for a long period.

De Bruin⁵ denies the identity of these diseases, as a result of his experience in Syria. He admits that the mutilations of leprosy may resemble those of ainhum, even to the formation of a distinct line of demarcation; but points out that such resemblance is rare, that ainhum fails to affect the fifth toe of the foot in only exceptional cases, and that it never causes other manifestations suggesting leprosy.

A. S. Ashmead⁶ also points out the dissimilarity of leprosy and ainhum, and alludes to **quigila**, another infectious and contagious disease of the skin occurring in Brazil. The author states that leprosy was carried to Brazil from Europe and Africa. The black race is particularly liable.

Berger-Lardy⁷ believes that ainhum and leprosy are the same disease, and describes a skiagraph of a diseased foot which showed that the soft parts were present, but that the bones had been absorbed.

Psittacosis.—Gilbert and Fournier⁸ have studied an epidemic of psittacosis. This is a disease transmitted from birds, particularly parrots, to man. In birds it is characterized by marked diarrhea, loss of appetite, depression, and loss of feathers. In man it runs the course of an intense typhoid fever, without abdominal symptoms but with marked pulmonary disturbances, resembling a severe infectious pneumonia. A marked epidemic occurred in Paris in 1892, affecting 50 persons or more. The cases studied by the authors occurred in February, 1896, and affected 5 persons, of whom 2 died. They were able to confirm the observation of Nocard regarding the occurrence of a definite bacillus, having found it in the cases under their observation as well as in the bone-marrow of the birds. They could not find the organism in the blood of the patients during life, but they did find it in one case in the blood of the heart postmortem. The organism resembles the bacillus of Eberth in a number of particulars. It is extremely virulent, causing death in rabbits, mice, and pigeons within 14 to 48 hours.

⁸ Ibid., Oct. 21, 1896.

An editorial in the *Gaz. heb. de Méd. et Chir.*, Apr., 1897, discusses psittacosis. It was introduced into Paris in 1891 by some parrots from South America. It may be transmitted either from the parrots to man directly, or through intermediate objects, or from other men. The period of incubation is from 7 to 12 days; the disease commencing with malaise, epistaxis, and disturbances of the digestion. This is followed by bronchitis or bronchopneumonia, with slight albuminuria; and finally there is high fever, which appears very early, and lasts 3 to 4 days, and terminates by crisis. These phenomena may recur several times; defervescence finally taking place by lysis. During the course of the disease the spleen is enlarged, and the signs of pneumonia may be more or less pronounced. In some cases an eruption has been present; at first roseolar, and subsequently petechial. Three forms are recognized: the slight, nervous, and ordinary. The duration of the whole disease is about 30 days. If no complications occur, recovery is the rule; but the mortality is about 37%. The cause appears to be the bacillus discovered by Nocard, which closely resembles the bacillus of typhoid fever. Curiously enough, a reaction analogous to that of Widal does not seem to occur in this disease. The treatment is purely symptomatic, prophylaxis being by far the most important part.

Actinomycosis.—Ruge¹ reports the results of the investigation of 25 tonsils, in 4 of which he found peculiar bodies that resembled the ray-fungus. These were not found in the tissue, but only in the crypts, which were sometimes surrounded by inflammatory changes. [These bodies are doubtless similar to those observed about carious teeth. Their exact nature is not as yet determined.]

Abée² reports 3 cases of fatal actinomycosis. The first patient was probably infected from the mouth. In 1887 he had pneumonia; in 1888 he developed a dry pleurisy on the right side, from which time he had suffered continually from cough, pain in the side, and pressure upon the chest. In December of the same year he developed an abscess over the sternum that did not heal after evacuation; at the same time infiltration of the right lung developed; the sputum became bloody, and death followed about 6½ months after the first symptoms. At the autopsy multiple abscesses were found in the lung and a large phlegmon in front of the cervical vertebræ, which had destroyed their substance and produced a pachymeningitis cervicalis. All the lesions were actinomycotic in nature. The second patient had pneumonia in 1882; in 1884 he injured his right side; several months later he had a chill and pain in the right side and expectorated yellowish masses. The condition rapidly grew worse, the expectoration became bloody, and there were signs of infiltration in the right lung. Later, abscesses developed on the shoulders. The patient from time to time had paroxysms of severe dyspnea, and finally died during an attack of hemoptysis. At the autopsy there was found a posterior mediastinitis with lesions of the spinal column and the meninges, and rupture into the esophagus; also a large actinomycotic abscess in the lung and thrombosis of the inferior vena cava. The third patient had influenza in 1895, since which time he had suffered from cough with occasional hemoptysis. When examined he was found to have infiltration in the lower part of the right lung, and shortly after that a large abscess developed in the thoracic wall. This was opened, but the patient rapidly became worse with severe intermittent fever. At the autopsy actinomycotic phlegmons were found in the retroperitoneal and mediastinal cavities. The vertebral column was involved and there was, as in the other cases, a peripachymeningitis. In all the cases very

¹ Zeit. f. klin. Med., vol. xxx., 1896.

² Ziegler's Beiträge, vol. xxii., H. 1, 1897.

accurate pathological studies were made. [In all of these cases there was history of previous disease or injury of the lung; but it is difficult to trace the connection between this and the subsequent infection.]

Habel¹ reports 5 cases of actinomycosis, with autopsy. In 3 there was simulation of tuberculosis of the lungs with complications in other organs; 2 gave the appearance of perityphilitis or peritonitis. In 2 of these cases there was a history of tuberculosis in the family, and in 1 tuberculosis coexisted with the other disease. [Sufficient attention has not been paid in the past to the cases simulating pulmonary tuberculosis; and the frequency of this form cannot as yet be properly estimated.]

Ducor² reports a case of actinomycosis that commenced in 1888 with moderate pains just back of the inferior angle of the right jaw; subsequently a tumor developed. This continued, varying in size for some time, and finally gave rise to a huge abscess, with all the symptoms of severe septic infection. This was relieved by the discharge of an enormous quantity of pus. Diagnosis, however, had not been made, but examination of the pus showed the typical ray-fungus and the presence of numerous streptococci. Treatment with potassium iodide and Marmorek's anti-streptococcic serum resulted in rapid improvement in all the symptoms. The causation of the condition proved to have been a habit that the patient acquired when a pupil in a convent of cleaning her teeth with various forms of grain.

Galli-Valerio³ reports a case of pseudoactinomycosis of the lower jaw characterized by the presence of a fungus that resembled somewhat the streptothrix madure, but which occurred in small masses.

Glanders.—Erich⁴ reports a case of glanders which was remarkable for the fact that the large joints—*i. e.* the elbow, the knees, and the ankles—showed suppurative inflammation, whilst the multiple abscesses in the muscles were absent.

A. G. R. Foulerton⁵ has applied the **serum-test** to the diagnosis of glanders, using it as Widal does in typhoid fever, and with the same results. The bacilli were obtained from the patient himself, and cultivated upon agar. They agglutinated very promptly at a dilution of 1 to 20. The reaction, however, was found to be not specific for glanders, diphtheritic serum and serum from 4 cases of typhoid fever producing agglutination in an emulsion of the bacilli. Normal human or equine serum had no effect. [It is possible that the reaction would have proved to be specific if higher dilutions had been used.]

Forestier⁶ reports a case of **acute glanders** which was characterized by the development in all the extremities of fluctuating tumors that contained hemorrhagic pus. There were numerous bronchopneumonic foci in the lungs. Toward the end of the disease a general pustular eruption appeared and periostitis developed over the frontal bones. The diagnosis was confirmed by bacteriologic investigation.

Brault and Rouget⁷ report a case of glanders which was characterized by 17 subcutaneous muscular abscesses and suppuration in 4 joints. Miliary nodules were not found in the lungs. A microorganism was found which in many respects resembled the bacillus of glanders, but was not absolutely typical.

MALARIAL FEVER.

Etiology.—J. M. Anders¹ contributes a statistical paper on the occurrence of malaria. He has collected 5044 cases from the records of 5 hospitals in Philadelphia. In tabulating these he finds that there has been a decline in the number of cases during the last half century and more especially during the last 25 years. Alluding to the statement sometimes made that malaria is increasing in certain localities, he states that investigation in all of the large cities, here and abroad, would probably show that increase is found in comparatively few places. He shows that there is no increase of the disease in the spring as there is in the fall. It grows progressively throughout the summer, reaching the maximum in September and then declines rapidly during October and November, and reaches the minimum in January and February. The figures are as follows: January, 134; February, 103; March, 155; April, 216; May, 304; June, 340; July, 408; August, 683; September, 969; October, 868; November, 409; December, 254. This table agrees almost entirely with that of Thayer and Hewetson.

[The evidence in favor of the rôle of the mosquito in conveying the plasmodia is increasing. Whether the insect acts as an intermediate host is more doubtful.]

Laveran,² after a critical study of the theories that attempt to explain the **transmission of the malarial poison**, concludes that the most rational is that it is conveyed by the mosquito; since all those precautions that are taken against malarial infection are likewise precautions against the mosquito. He still insists upon the unity of the various forms of the plasmodium. Patrick Manson,³ in a letter to the *Lancet*, makes a vigorous answer to Dr. Bignami, who had criticised his theory of the mosquito as an intermediate host for the malaria parasite. He declares that the movements of the flagellated form of parasite have nothing in common with the movements of dying protozoa; he also thinks that Mauritius and Reunion furnish good examples of the dissemination of malaria. The disease spread rapidly after its introduction from outside. Suctorial insects had always been present. He then takes occasion to express skepticism in regard to Bignami's hypothesis that the disease is spread directly by the mosquito from one patient to another, the organisms remaining adherent to the proboscis.

D. P. Ross⁴ also retorts against Bignami's criticism in regard to Manson's theory of the vital nature of the flagellate bodies. He maintains that the only valuable argument is the absence of chromatin, but contends that this absence is by no means universally acknowledged. Against the degenerative theory he urges the other forms of degeneration that may be noted in the crescents and spheres when they are kept in sealed tubes; furthermore, he has observed flagelli in the interior of living spheres. Moreover exflagellation never occurs in dying fever-forms or crescents, and invariably occurs in forms that we might suppose to be favorable to the continued existence of the organisms. Ross has devised a number of interesting experiments, all of which tend to prove his assertion, the most important being the behavior of crescents collected under vaselin and not exposed to the air. Under these circumstances neither spheres nor flagellate bodies develop. As a final result, he concludes that spherulation is produced as the result of abstraction of water from the blood, and thinks he proves this by permitting some evaporation of the blood collected under vaselin, when the spheres develop rapidly. He therefore builds the

¹ Univ. Med. Mag., May, 1897.

³ *Lancet*, Dec. 12, 1896.

² *Rev. de Hyg.*, Bd. 18, No. 12.

⁴ *Brit. Med. Jour.*, Jan. 3, 1897.

theory that the flagella represent the reaction of the parasite to the increased viscidness of the media in which it finds itself, and supposes that the organism changes into this form as a result of its possibility to further development. In regard to Bignami's arguments against the mosquito water theory, Ross states that in 2 cases, after 21 experiments, he was able to produce a slight malarial reaction by administering to patients the mosquito water; and in 3 persons who had allowed themselves to be bitten by mosquitoes which had previously bitten patients in febrile condition no reaction resulted. In conclusion, he speaks of the observations of Dr. Marshall, who reported that malarial crescents become spheres after the blood is diluted with water. This Ross claims to be due to degenerative changes, and not similar to that produced by increased density of the blood.

Ross¹ has performed a number of experiments as to malarial infection. In some he allowed **mosquitoes** that had bitten malarial subjects to die in water and then gave this water to other subjects to drink; in others he allowed mosquitoes to bite first malarial and then healthy patients. The results in the 2d series were negative (3 experiments). In the others there were, on 3 occasions, slight febrile reaction and twice very doubtful parasites were found in the blood. In no case was the febrile reaction persistent.

G. M. Sternberg² criticises Manson's **mosquito theory** of the intermediate existence of the malarial organism, and suggests that possibly the plasmodia finds its normal habitat upon the stems of water plants, urging in favor of this view the fact that contagion does not take place when these plants are submerged and that the mosquito, whose normal food is plant juice, could easily obtain them from this situation. Intermediate hosts, if we assume the necessity for their existence, can easily be found in other animals besides man; but if the analogy of tse-tse disease of South America be accepted as valid for the malarial organism, it is probable that the mosquito merely serves as a carrier of the contagion.

Rupert Norton³ discusses the evidence for and against the possibility of malarial infection being conveyed by **drinking-water**, and decides that all cases alleged in favor of it are at least doubtful and susceptible of other explanation.

Corinado⁴ found, beside the ordinary infusoria, numerous Laveran organisms in the water of a ditch that runs through the city of Havana. He was also able to cultivate organisms taken from the blood of malarial patients in the same water. No inoculation-experiments were made.

S. F. Mayfield⁵ believes that **drinking-water** invariably contains the sources of malarial infection, especially as, in those localities where the inhabitants have commenced to use artesian water exclusively, malaria has practically disappeared.

K. Winslow⁶ reports the case of a woman who, for two weeks before delivery, suffered from quotidian malaria. After the child was born it seemed weak and took its nourishment badly. Examination of its blood showed the presence of plasmodia.

The Plasmodium.—J. G. McNaught⁷ has studied the blood in malarial fever in Northern Deccan. He found the parasite in 50 cases, 130 examinations being made. When he found large intracorpuseular pigmented forms, the

¹ Indian Med. Rec., May 1, 1897.

³ Bull. Johns Hopkins Hosp., Mar., 1897.

⁴ Cron. Med. Quir. de la Habana, 1896, No. 9.

⁵ New Orl. M. and S. Jour., Aug., 1896.

⁶ Boston M. and S. Jour., May 27, 1897.

⁷ Brit. Med. Jour., Sept. 26, 1896.

corpuseles being swollen, he diagnosed tertian fever; but there were only 3 cases of this description. When he found hyaline intracorpusecular forms, the corpuseles not markedly enlarged and the pigmented intracorpusecular forms small and few in number, he diagnosed Summer-Autumn fever; 46 cases were of this type, and in 16 of these crescents were found. It is perhaps of some interest to note the relative frequency of the different pigmented forms. The numbers refer to separate examinations. Crescents alone occurred in 14; crescents and spheres in 17; crescents, spheres, and flagellated bodies in 12; spheres alone in 29; spheres and flagellated bodies in 4; crescents and flagellated bodies in 2; flagellated bodies only in 1.

W. B. French¹ has studied the cases of malarial fever occurring at the Washington Asylum and the Government Hospital for the Insane in the District of Columbia. Among these were 41 tertians, 50 of the estivo-autumnal, and 3 of the combined type. In 2 of the latter the tertian organism predominated. No cases of quartan infection were discovered.

W. Fisher,² who was stationed in upper Zambesi, found plasmodia in 40 cases of malaria, which were peculiar for the reason that none of the parasites contained any pigment. In general, the course of the disease was irregular, the attacks of fever occurring at intervals of from a few hours to several days. In some cases icterus was present without hemoglobinuria.

Hehir³ has looked for the malarial organisms in marsh-water and has been able to stain them by fixing first with osmic-acid vapor and then using a diluted solution of Löffler's alkaline staining-fluid. An interesting observation that he has also made is the fact that the malarial organism can retain its vitality a long time after the specimen has been dried. [Unfortunately no details are given of the appearance of the organism as found outside the body.]

Symptomatology.—A. Plehn⁴ describes the various forms of **acute malaria** that occur in **Cameroon**. These are the continuous, the remittent, and the intermittent types, and the blackwater fever. An effort was made in the first 3 groups to give the quinin in accordance with the results of microscopical examinations of the blood—that is, only when the small endoglobular forms were found. From 1 to 1½ gm. was given during the decline of the fever, and this sufficed to destroy the younger of the two generations that coexisted in the blood. Crescents were very rare, and only once were the flagellate forms discovered. Plehn regards these as retrogressive forms of the plasmodia, stating that they were found either in those entirely free from symptoms, or in those in whom the relapses occurred infrequently. Blackwater fever is the most frequent form in which malaria appears, and, according to the author, is due to an excessive destruction of the red blood-cells, although he admits that it is difficult to demonstrate this destruction under the microscope, the color-index being normal and poikilocytosis rare. Aside from the presence of hemoglobin, the urine is variable; albumin and tube-casts are present in some cases, but fail in others. A most important statement is that in all cases of this disease the active parasites die during the disintegration of the blood-cells. He therefore agrees with F. Plehn that quinin is superfluous, and, indeed, not without danger, because it predisposes to fresh paroxysms of corpusecular destruction.

C. E. Skinner⁵ describes a fever that is endemic in the malarial regions of **Corsica**. The chief etiologic factor is exposure to cold and wet toward sundown in a region where it is common. It attacks all ages and both sexes.

¹ N. Y. Med. Jour., Apr. 24, 1897.

³ Indian Med. Rec., Feb., 1897.

² Lancet, Jan. 16, 1897.

⁴ Dissert. Berlin, 1896.

⁵ N. Y. Med. Jour., Dec. 12, 1896.

The commonest forms are the remittent, continued, and frankly intermittent, the latter being usually quotidian. The prodromal symptoms consist of marked malaise lasting for a day or two, then a chill or sensation of chilliness, and, finally, a rise in temperature. Anorexia and thirst are common, and, if the disease is not promptly treated, considerable emaciation takes place. The spleen is not necessarily enlarged. The complications that have been observed are cystitis, pleurodynia, and megalosplenism, without fever. The disease usually yields readily to quinin; although this remedy, in cases of long standing, must sometimes be administered hypodermically in order to obtain any result. The prophylactic measures to be observed are to avoid Corsica between the months of April and November, to keep indoors at sunset, and to keep the windows shut at night. The author very naturally concludes that the disease is simply a peculiar form of malaria, although, most unsatisfactorily, he fails to mention the result of hematological investigations.

Doorga Das Sen¹ discusses malarial fevers of India, describing among others a **remittent fever** whose only peculiarity is that the temperature does not fall to normal. Boisson² reports 3 cases of malaria in the course of which **icterus** developed. He found no bile-pigment in the urine, but did find oxyhemoglobin, methemoglobin, and urobilin; he concludes that it was hemoglobinuria. Two cases were cured, in both of which there was great diminution of the red cells. Microscopically, the blood showed a small amount of black pigment partially free and partially in the leukocytes. In the third case an autopsy was made and the biliary passages found to be normal, but there were parenchymatous hepatitis and nephritis.

D. W. Torrance³ reports a case of malaria in which the temperature reached 109.2° during the second paroxysm. Recovery occurred promptly after administration of quinin.

Lodigiani⁴ holds that the ordinary form of **cirrhosis of the liver** may occur in cases of malaria. He is at variance in this view with Frerichs, Colin, and Liebermeister. This view is based upon a case of chronic malaria in which operation for enlargement of the spleen was undertaken, and the patient succumbed. At the autopsy cirrhosis of the liver was found, and this resembled that occurring in alcoholic subjects or from other causes. The author notices that some authorities have stated that the cirrhosis following malaria differs from that due to other causes. His own case does not justify this view. Regarding the cause, he holds that the products of the metabolism produced by the malarial plasmodium are the active agents. [In a case of our own in which malaria was the only likely causal factor, cirrhosis of the liver presented the ordinary appearances of the alcoholic variety.]

De Brun⁵ describes the clinical forms of malarial ascites. These he separates into three distinct varieties: 1st, those resulting from malarial atrophy of the liver—in this form the liver presents, microscopically and macroscopically, all the features of the alcoholic cirrhosis of Laenneck. He reports 2 cases occurring in women coming from a region where malaria is frequent in its most obstinate forms; both had suffered all their lives from various manifestations and neither had ever indulged in wine. The 2d variety results from the perisplenitis that occurs in the course of malarial splenomegaly. It is characterized by violent pains in the splenic region and by the gradual accumulation of peritoneal fluid. The 3d variety results from peritoneal congestion. It is indolent, develops insidiously, and gives rise to no subjective manifes-

¹ Indian Med. Rec., Nov., 1896.

³ Brit. Med. Jour., May 1, 1897.

⁴ Morgagni, Jan., 1896.

⁵ Sem. méd., p. 344, 1896.

tations. It can be distinguished from tubercular peritonitis by the absence of abdominal pain or peritoneal friction. It yields readily to the action of quinin.

Brault¹ reports 2 cases of malarial cachexia, with hypertrophy of the liver, spleen, and heart; chronic bronchitis, and **enormous ascites**. Both suffered extremely from dyspepsia. The ordinary malarial treatment having failed, they were both treated by laparotomy and the evacuation of ascitic fluid. Improvement was immediate, and within 3 weeks both patients were out of bed. Subsequent treatment consisted, in addition to the ordinary tonics, of the extract of bone-marrow, which apparently gave very good results.

Vidal² has made a clinical study of **malarial cachexia** and notes particularly **hypertrophy of the heart**. The heart-sounds are feeble; or often instead of a systolic bruit at the apex there is a murmur heard after the muffled second sound. These signs he attributes to myocarditis, and this he holds is largely the cause of the symptoms. He therefore advocates a form of treatment directed to the heart: diuretic medication and the employment of absolute milk-diet in those who can tolerate it. If the heart is feeble, digitalin in doses of 15 drops of a 0.1% solution of the crystallized substance. [The use of the milk-diet in a case in which the heart is weakened by myocarditis is scarcely rational.]

Topi³ emphasizes the importance of **lesions of the gastric mucous membrane** in malaria. Recalling the fact that gastric lesions have been met with in cases of severe pernicious anemia, he concluded that the same may occur in individuals presenting the malarial cachexia, and states that in these cases lesions of the gastric walls are not rarely found. The glands are found to be contracted and degenerated in the capillaries surrounding them—he has found, in a number of cases, large numbers of malarial parasites in various stages of development. He regards it as probable that the organism enters by way of the gastro-intestinal mucous membrane in such instances.

Diagnosis.—Wm. Osler⁴ calls attention to the frequency with which malaria is diagnosed as other diseases north of Mason and Dixon's line, and other diseases are diagnosed as malaria south of this boundary. Considering the facility with which a positive diagnosis can be made by blood-examination, or by a therapeutic test, he considers it very unfortunate that this disease should be the cause of so much inaccuracy in the vital statistics. Regarding the frequency with which infection with the bacillus of Eberth and the plasmodium malarie occurs simultaneously, he has himself observed but 1 doubtful case in 1500 patients suffering from one or the other disease.

Treatment.—Jancso and Rosenberger,⁵ in a paper upon the study of blood in malarial fever, based upon 100 cases, state that the use of quinin 4 or 6 hours before the attack reduces the number of parasites quite notably 1 hour or 3 hours later. The new generation is weak and represented by a few young spherules. These are roughly granular and without ameboid movements. When quinin is given 12 to 10 hours before the attack the number of parasites diminishes, but not so notably. The remedy has least effect upon the crescents. Quinin would seem to have least effect upon the organisms that are somewhat advanced in their growth, though 23 to 40 gr. serve to destroy these. In those in which sporulation had begun the spores of only a few proved to be devitalized.

Hemorrhagic Forms.—Luke Fleming⁶ records a case of malaria in a ser-

¹ Compt. rend. da la Soc. de Biol., Jan. 15, 1897.

² Gaz. degli Ospidali, No. 83, 1896.

³ Pest. med.-chir. Presse, No. 8, 1896.

⁵ Med. News, Mar. 16, 1897.

⁶ Med. Rec., Sept. 19, 1896.

vant 42 years old, in which purpura hemorrhagica covering a large part of the body was the principal manifestation. There were also hemorrhages from the mucous membrane of the mouth and of the vagina. For 3 or 4 days before she came under observation she had suffered with symptoms of malaria and had taken 15 gr. of quinin 24 hours previous to her first visit. Hemorrhagic symptoms soon appeared. The quinin in large doses was discontinued, and arsenic with Warburg's tincture was given instead. After a convalescence of 2 weeks she recovered. Five months later she suffered with malaria, and the same symptoms occurred on attempting to check the disease with quinin. The hemorrhages did not appear until the drug had been administered. The following summer she came under observation for the third time suffering with malaria. The author himself administered quinin to determine whether it was the cause of hemorrhage, and found that bleeding soon followed its administration. [Similar observations have frequently been made, especially in tropical climates, and some writers condemn quinin entirely. Cases in point are the following:]

C. D. Simmons¹ reports 3 cases of **hemorrhagic malaria** occurring in **pregnancy**. In the 1st case he administered quinin in spite of the fact that the patient stated that this drug had increased the hemorrhage in a previous attack. The next day the disease was more pronounced and the quinin was abandoned. Calomel followed by arsenic and digitalis was ordered and the patient gradually improved. In the 2d case, a woman who had chronic splenic enlargement was seized very suddenly with the symptoms of hemorrhagic malaria. Quinin was given freely during 2 days without good effects; arsenic and digitalis were also administered. There were no alarming symptoms until without warning the uterus expelled its contents. The patient died. In the 3d case the uterus was irritable and the author therefore administered morphin. The attack was cut short and the patient finally recovered, the pregnancy continuing. The author believes that when abortion or premature labor comes on death is almost sure to follow. Quinin he believes to be useless and often harmful in this form of malaria. In the acute forms with chills and fever pronounced and regularly recurring, and when the kidneys are active, quinin often does good.

Bacelli² discusses **hemoglobinuria** in its relations to malaria. In 1 group the hemoglobinuria is due to malarial infection and is cured by the administration of quinin; in another group the hemoglobinuria is independent of malarial infection and may be due to the quinin administered. In the latter cases individual idiosyncrasy is important. He offers no explanation of the mode in which this is brought about. The treatment of hemoglobinuria must be active. The author has found the persulphate of iron combined with inhalations of oxygen and careful hygienic regulations most useful.

W. D. Bush³ and H. Meek⁴ object to the administration of quinin in malarial hematuria.

Naame⁵ has treated 5 cases of malarial cachexia with hypodermic injections of **citrate of iron**. Four cases recovered completely. The 5th was greatly improved; but, probably on account of extreme sclerosis and hypertrophy of the spleen, it was impossible to restore the blood to the normal condition; 2 of the cases were examined 2 months after discharge and found to be well.

Celli and Santoni⁶ have employed the **serum** of animals that had been exposed to malarial infection in the neighborhood of Rome, for the pro-

¹ New Orl. M. and S. Jour., Oct., 1896.

² Gaz. degli Osped. e delle Clin., Feb. 15, 1897.

³ Med. Rec., Aug. 8, 1896.

⁴ Therap. Gaz., May 15, 1897.

⁵ Rev. de Méd. de Paris, Mar. 10, 1897.

⁶ Centrabl. f. Bakt. Parasit. u. Infek., Jan. 20, 1897.

duction of immunity. In the first series of experiments they injected 6 individuals that had never had malaria with 10 c.c. of serum at intervals of several days for some weeks, the serum being obtained from buffaloes, oxen, and a horse. At the end of this time 3 were inoculated with blood from a quartan case, and a control-person was inoculated at the same time. In the inoculated subjects fever occurred after 6 and 17 days. In the control-patient it occurred on the second day. Three were also inoculated with the parasite of the estivo-autumnal type. Fever did not occur until 25 days later, and at first was very light. As the longest hitherto recorded incubation-period for this type was 15 days, they ascribe the delay to the treatment. Finally, a family that was compelled to live in an excessively malarial district was treated with this serum, and but one member was attacked by malaria; in a neighboring family, not treated with the serum, all the members were attacked. [It seems doubtful, in spite of the success of these investigators, whether much can be expected from serum-therapy in malaria.]

Treille¹ has employed **Roux's serum** in 2 cases of quartan fever. In the first case there were 2 subsequent rises of temperature and then complete cure. The second case, even after a second injection, showed no beneficial result.

General Considerations upon Infectious Diseases and Fever.—G. M. Sternberg² classifies **infectious diseases**, according to the mode of infection, into (a) traumatic; (b) infection by contact; (c) infection through ingesta; (d) infection through the respiratory tract; according to the nature of the infectious agent, into diseases due to infection by vegetable parasites and those due to infection by the animal parasites; and finally, according to the special tissues of the organs involved, into general blood-infections and localized infections.

Lode³ has performed a number of experiments upon animals in order to test whether **diminution of the bodily temperature** produces susceptibility to infection. Diminution of the temperature was obtained in 3 ways. First, the animals were shaved, heated, and then exposed to a current of air, or they were simply shaved, or they were simply exposed to influences diminishing bodily temperature. Guinea-pigs, rats, and chickens were employed, the two latter being used for experiments with the anthrax-bacillus; the other organisms tested were the pneumobacillus of Friedländer, the vibrio of cholera, the staphylococcus pyogenes aureus, and sputum containing numerous tubercle-bacilli. The results in general were that, of 99 animals, 54 artificially cooled and 45 used for control, 46 of the former and 9 of the latter died from the infectious process, and 8 of the former and 36 of the latter survived. Of 9 animals exposed to air laden with tubercle-bacilli, the 5 cooled animals died, and of the control-animals, 2 died and 2 survived. As a result, Lode concludes that animals so treated are more susceptible to artificial infection than normal animals handled in the same manner.

[The author proceeds next to the consideration of various theories that may be advanced in explanation of the facts he demonstrated. We are less interested for the present in this side of the question. It is of greatest moment to have actual demonstration of an old belief that reduction of temperature causes increased susceptibility to infection. There has been an expansion of this thought of late, to the effect that authors assign a distinct conservative property to fever. This is seen in the following:]

Löwy and Richter⁴ contribute an experimental paper on the **curative influence of fever** from which certain deductions regarding treatment seem proper. They injected certain microorganisms into animals in which artificial

¹ Sem. méd., 1896, p. 312.

³ Arch. f. Hyg., vol. xxviii., H. 4, 1897.

² Am. Jour. Med. Sci., Dec., 1896.

⁴ Berlin. klin. Woch., Mar. 1, 1897.

fever had been induced, and noted the results as compared with control-animals not previously rendered febrile. The artificial fever was produced by puncture of the corpus striatum, rabbits being used. The fever following this is marked by elevation of temperature, increased destruction of tissue, and increased respiratory exchange; but differs from ordinary fever in that the animals seem well and preserve their appetite. It is, therefore, analogous with the so-called aseptic fever. They used cultures of the pneumococci, of the microorganisms of fowl cholera, and of hog cholera. They also injected the toxin of diphtheria. In the case of pneumococci they found that life was preserved from 1 to 3 days longer in the febrile than in the healthy animals; in 2 cases the trephined animals survived the infection, which in 1 case was caused by 4 times the fatal dose. In the experiments with hog cholera the increased length of life was from 3 to 4 days, and 1 animal survived. The experiments with chicken cholera were unsatisfactory, probably because the virulence of the organism was so great that very small doses sufficed to kill the animal, and the minimal dose could not be ascertained. When diphtheric toxin was used life was preserved 1 to 3 days longer in the febrile animals, and 1 of them recovered.

The authors do not deny that an objection might be offered to their work on the ground that this artificial fever is not, after all, natural fever; but they point out that it resembles natural fever in several particulars, and the definition of the term fever is still uncertain. They conclude, therefore, that, with this reservation, it may be said that fever does exercise a curative influence, and that the administration of remedies merely to reduce the fever, without regard to their other actions, is not justified. The favorable action of quinin in malaria and of salicylate of sodium in rheumatism is connected with the specific action of these remedies rather than with their antipyretic action, and the same may be said of the beneficial influence of cold bathing, the more important influence being that exercised upon the nervous system, circulation, and the respiration. They particularly hold that the artificial hyperleukocytosis induced by cold may play an important part in combating infection. [Clinicians have frequently maintained that fever is often a conservative process, and that its reduction may be harmful in some cases. This contention, however, has always been answered by the objection that antipyretic drugs used in the reduction of the temperature may have been the real cause of untoward symptoms. The facts brought out in the present paper are not entirely new and do not as yet definitely settle the question.]

Blumreich and Jacoby¹ found that animals from which the **spleen** had been removed exhibited greatly increased resistance to injections of virulent living bacilli, but the reaction to injections of toxins was unaltered.

Piccinino² has performed some experiments upon animals in order to test the influence of the **nervous system** upon the susceptibility to infection, using dogs refractory to tuberculosis, cutting the vagi nerves, and then subjecting them to tubercular infection. The results were negative.

H. A. Hare³ advocates the **intravenous injection of saline solutions** for the purpose of washing the blood in toxic conditions, and reports 2 cases, 1 of acute toxemia and 1 of uremia, in which it produced excellent results. The first case, however, died of gangrene.

CONSTITUTIONAL DISEASES.

Rheumatism.—Etiology.—Chauffard and Ramon¹ report certain examinations to determine the infectiousness of articular rheumatism. They examined the glands in the neighborhood of the affected joints, and found that sometimes those in the immediate neighborhood became swollen at the time of the attack. In most of the cases there was some pain in the glands, and at times the enlargement was so considerable that the patients themselves noticed it, and also that it increased with exacerbations of the disease. Cultures made on various media from 1 of the cases were negative, but cover-slips from the fluid in the joint and from the neighboring enlarged glands both showed a bacillus. The authors regard the glandular condition as evidence of the infectiousness of rheumatism. [A majority of modern writers agree with this view, but we must refer to the great variance in the bacteriologic studies. The authors quoted above and others presently to be referred to find bacilli, whereas many previous investigators report the discovery of micrococci of various kinds. No reliance can, therefore, be placed on any of the claims to the discovery of the specific cause.]

Jaccond² discusses the infectious nature of rheumatism, pointing out that local lesions of some kind or other have frequently been found preceding rheumatism, and that these may constitute the nidus from which the infection has occurred. Tonsillitis is by far the most common, and he calls particular attention to the fact that the microorganisms found in the pharynx are the same as those seen in the diseased tissues. He refers to a case in which a wound of the foot seemed to be the exciting cause. He believes the infectious nature of the disease to be beyond doubt, taking into consideration its mode of development, its character, and the occurrence of intrauterine transmission. In this connection he refers to a case in which a mother suffering from a severe attack of rheumatism gave birth to a child, which, in 12 hours developed fever, swelling, and pain in the joints; under treatment with salicylate of sodium the symptoms subsided. [As an illustration of the connection or coincidence of local lesions and the development of rheumatism we may cite a recent case in which violent polyarticular arthritis involving many of the large and some of the small joints occurred in a boy of 18 who had received a wound of the hand which was badly treated. When he was admitted to the hospital a wound was found which had been sutured, but was almost hidden from view by a filthy crust. On removal of the stitches about a dram of pus escaped. The patient had decidedly irregular fever and marked symptoms of general infection with glandular enlargement. After relief of the local lesion anti-rheumatic treatment caused speedy recovery.]

Achalme³ has examined the body of a woman dying of acute articular rheumatism, making anaërobic cultures of the blood, the cerebrospinal and the articular fluid, and found a bacillus similar to that described by him in 1891.

Thirolaix⁴ has examined the blood of two persons suffering from acute articular rheumatism. Anaërobic cultures were made, and in both cases there was a voluminous growth, which was found to consist of pure cultures of an anaërobic bacillus, slightly motile, which stained by Gram's method and was pathogenic for guinea-pigs, but not for dogs, rabbits, or mice. He holds that it is identical with the bacillus already described by Achalme.

¹ Rev. de Méd., Sept., 1896.

² Jour. de Méd., Feb. 10, 1897.

³ Compt. rend. de la Soc. de Biol., Mar. 17, 1897.

⁴ Ibid., Mar. 19, 1897.

In a discussion in the Congress for Internal Medicine in Berlin¹ Chvostek held that not only was acute articular rheumatism not a microorganismal disease, but that in fact there was no such disease, a number of conditions being included under this name. Singer, on the contrary, investigated 92 cases and frequently found streptococci and staphylococci in the urine. In 3 cases upon which autopsies were obtained he was able to find the same bacteria in 2. He holds that the pyogenic cocci are causes of the disease. Schuller has also found bacteria, particularly a form that caused villous swelling in the joints of rabbits. Michaelis reported that in 3 cases of endocarditis following rheumatism a diplococcus was found in the blood that could be cultivated upon blood-serum. In no case in Leyden's clinic was it possible to find bacteria either in the blood or joints.

McClymont² believes that the opinion that men are more frequently affected than women with acute articular rheumatism is probably incorrect. When the disease is hereditary it is usually derived from the mother.

Complications.—Widal and Sicard³ report a case suffering from recurrence of generalized polyarticular rheumatism. On the 31st day a sudden rise of temperature occurred; edema developed in the right arm, which gradually extended upward until it involved the shoulder. Palpation showed thickening of the humoral vein. At the autopsy this proved, as was expected, to be a **thrombosis of the vein** extending into the finest radicles of the hand.

Steiner⁴ calls attention to a complication of acute articular rheumatism that he claims has been hitherto seriously neglected. This consists of a **multiple peripheral perineuritis**, which may be subordinate to severe inflammation of the joints or else itself form the most prominent clinical manifestation, joint-affection being simply indicated by pain without swelling or other signs of inflammation. Of the first group he has observed 28 cases in which one or more joints were acutely involved, and many of the peripheral nerves were exquisitely sensitive to pressure. Of the second group he found 7 cases in which the nerve-involvement was exceedingly general. As none of these cases died, it was impossible to make any investigations in regard to the pathology of the disease; but he is inclined to believe that it is a perineuritis.

W. H. Washburn⁵ reports 5 cases, with 3 autopsies, of **pulmonary complications** in acute rheumatism. The postmortem findings were: in 1 case pericarditis with edema of the lungs; in another acute catarrh of the lungs; and in the 3d congestion and edema. In the 4th case the patient died with symptoms of edema of the lungs, but no autopsy was obtained.

F. Krauss⁶ reports a case of acute articular rheumatism, limited to the right side, occurring in a girl of 16, who subsequently developed **chorea**, also limited to the right side and associated with a rise of temperature.

M. L. B. Rodd⁷ reports a case of acute articular rheumatism in which, after the temperature had become normal under salicylates, there was a sudden rise to 110° F. In spite of the ice-pack the **hyperpyrexia** persisted until death.

V. Hanot⁸ includes among some of the varieties of acute articular rheumatism those which commence with syncope without localized symptoms, and those whose initial symptoms are purely visceral.

Salman⁹ reports a case of scarlet fever that after a normal course was fol-

¹ Centrabl. f. innere Med., June 26, 1897.

⁴ Deutsch. Arch. f. klin. Med., Mar. 15, 1897.

⁶ Med. News, July 25, 1896.

⁸ Presse méd., Dec. 2, 1896.

⁹ Deutsch. med. Woch., Dec. 21, 1896.

lowed first by acute nephritis. After this was cured the fever continued, and the joints of the right upper extremity showed an apparently serous exudate and excessive pain upon movement. Later the hip and knee became also involved—the former undergoing spontaneous luxation, the latter presenting the appearance of tumor albus. Salinan believes that the disease was infectious, but excludes tuberculosis on account of the rapidity and completeness of the cure that took place in the hip through ankylosis as soon as the process ceased to advance. Salicylates were not used until late in the disease, when they gave immediate relief to the pain and produced marked improvement in the general condition.

Diagnosis.—G. Parker¹ discusses the various diseases which have recently been differentiated from rheumatism, and enumerates (1) Henoch's purpura, of which he reports an interesting case that commenced with sharp pain in the gastric region, followed by swelling of the wrists and then vomiting and diarrhea. Later there was edematous swelling over the right side of the scalp and later a purpuric eruption upon the legs. Salicylates had no effect, and no satisfactory cause could be discovered. (2) Angioneurotic edema, of which he also reports a case; (3) rheumatoid arthritis; (4) the various septic arthritides and the joint-affections that occur in infectious endocarditis. Finally, he speaks of the hemorrhagic diseases—hemophilia, erythema multiforme, and purpura hemorrhagica.

Treatment.—Boucheron² believes that, in addition to the bacillus of Achalmé, staphylococci and streptococci invade the organism in acute rheumatism. In accordance with this theory he has used Marmorek's antistreptococcic serum in 6 cases with excellent results. [The number of cases is too small to furnish reliable data. All efforts in the direction of serum-therapy, using serum of convalescent patients, have thus far failed.]

E. Lee³ recommends hydrotherapy for rheumatism, using the following methods: (1) the administration of pure, soft water at frequent intervals, about 4 liters being given to an average man per day; (2) irrigation of the intestinal tract with water to which a little liquid soap has been added; (3) thorough moistening of the body, either by bathing, the wet pack, or by sprinkling. [It seems to us that the second element of this treatment at least might well be omitted.]

Jaccoud,⁴ in discussing the **contraindications** of the treatment of acute articular rheumatism with **salicylic acid**, states that he never gives the drug in the presence of endocarditis, believing, as he does, that it only exercises an influence upon the articular manifestations of the poison. This limitation of its use applies also to the other internal viscera.

Soulages⁵ reports a case of acute articular rheumatism treated with **electric currents** of high frequency. After the first 2 or 3 applications the pain was greatly diminished, and subsequently complete cure obtained.

J. R. Philpots⁶ recommends **methylen-blue** in acute articular rheumatism, claiming that it has a favorable effect upon the local inflammatory process in the joints and upon the general condition of the patients.

Myositis.—Risse⁷ reports a case of "acute polymyositis" that followed several attacks of acute articular rheumatism. The disease involved first the right, then the left leg, and spread slowly upward by a strictly continuous process until it involved also the muscles of the abdomen. The affected

¹ Lancet, June 26, 1897.

² Compt. rend. de la Soc. de Biol., April 9, 1897.

³ Jour. Am. Med. Assoc., July 25, 1896.

⁴ Sem. méd., p. 431, 1896.

⁵ Compt. rend. de la Soc. de Biol., July 11, 1896.

⁶ Brit. Med. Jour., March 27, 1897.

⁷ Deutsch. med. Woch., April 8, 1897.

muscles were swollen, painful, hard, and the skin over them edematous. After recovery had taken place a moderate degree of muscular wasting was observable, but the muscular power was apparently unimpaired.

Laquer¹ reports a case that at various times within the course of 15 years presented a marked **swelling of the right upper arm**. This was accompanied by the symptoms of inflammation—that is, pain, reddening, and edema, and the general symptoms of fever and malaise. The only treatment that seemed to be of use in any of the cases was a deep incision through the periosteum. On one occasion a portion of the muscle was excised and examined, but appeared to be normal. The author regards the disease as an acute intermittent interstitial monomyositis. As all forms of intoxication could be excluded, he believes that it is probably due to an infectious poison which may be similar to that of rheumatism.

RHEUMATOID ARTHRITIS.

Chauffard and Ramond² found disease of the **lymphatic glands** in the neighborhood of the affected joints in 7 cases of chronic deforming polyarthritis. These were sensitive, particularly when the joints were painful, and showed alterations in size. In 1 case bacteriologic investigation was made of the contents of one of the joints, and a diplococcus was found that did not decolorize by Gram's method. It was impossible to cultivate it.

Potain³ points out that **the deformities** that occur in rheumatoid arthritis may be due to alterations in the extremities of the bones and to abnormal muscular action. The thickening of the head of the bone may impede the movement, but does not cause ankylosis. The ligaments are rarely involved, though they are sometimes relaxed. The irregular swelling of the bones is only an accessory cause of the deformity, the contraction of the muscles with paresis or atony of certain groups being the principal cause. Then loss of muscular power is not dependent upon nerve-changes, but probably is reflex, as is suggested by the fact that sometimes similar paresis occurs in cases of traumatic injuries of the joints.

G. A. Bannatyne⁴ remarks that marked anemia is seldom found in **rheumatoid arthritis** except in the advanced and acute cases, but he has found a slight amount of blood deficiency in about 95 per cent. of the cases. Hemorrhages due to anemia are rare, but he refers to a case under his care, in a woman of 22, with advanced rheumatoid arthritis, in whom hematemesis developed without obvious gastric disease. The blood showed the following characteristics: red corpuscles 4,000,000 to 3,000,000; hemoglobin 80 to 40%; slight leukocytosis; the red corpuscles varied in size and shape, but there were no microcytes or erythroblasts. The hemoglobin seemed to be less firmly attached to the stroma; it crystallized out very readily and was more easily acted upon by such substances as common salt, acetic acid, and sulphate of sodium in solution.

Treatment.—W. K. Sibley⁵ reports a case of arthritis deformans treated by the Tallerman-Sheffield localized hot-air apparatus. After 9 baths the patient was able to resume her former occupation of dressmaker, and after 20 baths considered herself cured. [Others have reported favorable results in the same condition. In our own experience with some half dozen cases the effect of the baths was only temporary, and even then often slight. There was not the least general or lasting improvement.]

³ Sem. méd., Dec. 18, 1896.

⁴ Lancet, Nov. 28, 1896.

⁵ Ibid., Aug., 1896.

W. E. Burtless¹ suggests the treatment of chronic articular rheumatism with **plaster-of-Paris casts**, using the following *modus operandi*: the joints are packed in hot mineral water, and kept so during an entire night; the cast is then permitted to remain from 6 to 24 hours, according to the endurance of the patient, removed, and the joints of the leg thoroughly kneaded. He reports a case that had been suffering for 3 years, in which perfect cure was obtained.

W. Armstrong² has used **methylen-blue** in rheumatoid arthritis and found that it was particularly valuable in those forms due to autointoxication from the intestinal tract.

PULMONARY OSTEO-ARTHROPATHY.

[We consider this condition in this place from the conviction that it is caused by toxemia, and that it is akin to rheumatoid arthritis in this respect. Furthermore, the clinical features require differential diagnosis from rheumatoid diseases, and are therefore advantageously considered here.]

H. G. Godlee³ holds that the cases described under the name pulmonary osteo-arthropathy, or under the formidable title bestowed on these conditions by Marie in 1890, form a heterogeneous group of diverse conditions. He analyzes the symptoms as they have been described by Marie and others, and refers in particular to the conditions found about the ends of the bones. The hand proper is said not to depart perceptibly as regards size from the normal hand, except that there may be a little hypertrophy of the ends of the metacarpal bones possibly due to some thickening of the soft parts in the neighborhood. Where this occurs, as it certainly did in some cases that have

FIG. 1.—From a skiagram of the fingers of a marked case of pulmonary osteo-arthropathy (Brit. Med. Jour., Apr. 24, 1897).

come under his observation, though most observers deny its existence, it is most difficult to estimate the size of the subjacent bones. The Röntgen rays alone will prove satisfactory in the absence of postmortem examinations. He

¹ Am. Med. and Surg. Bull., Nov. 28, 1896.

² Brit. Med. Jour., April 24, 1897.

³ Ibid., July, 1896.

alludes to a few postmortem examinations recorded in the literature, quoted from Thorburn. Ranzier records an instance in a man who had a chronic empyema for 14 years before his death. Enlargement of the hands, feet, and wrist was noted, especially during the last 5 years of life. At the postmortem examination ulceration of the cartilages and slight excess of synovial fluid were found in the knee and elbow. The articular extremities of the bones were large, as were also the bones of the tarsus and carpus. There was, however, congenital enlargement in this case and also in the patient's father. Bamberger reports 11 cases of swollen joints associated with pulmonary and heart disease. In 5 of 7 in which postmortem examinations were made some periostitis was found near the articular ends of the bones. In a case reported by Thérèse there was osteoperiostitis with condensing and rarefying ostitis and great proliferation of the medullary elements. G. also considers the confused relationship of osteo-arthropathy and acromegaly, and reports a number of cases under his own observation, some of which he holds are certain cases and some doubtful. Two of his cases, in which marked clubbing of the fingers was observed, showed no decided change in the bones of the fingers, and 1 of them no change at all. He is convinced that there are at least two conditions included under the title osteo-arthropathie hypertrophique pneumonique, and that those which he has met with are examples of the form associated with chronic septic suppuration complicated with clubbing of the fingers. The latter, he thinks, has nothing whatever to do with the disease. [The author, it seems to us, underestimates the bony changes and overestimates the part played by the soft tissues in producing the deformity of the ends of the fingers, etc.]

Walton¹ reviews the subject of osteo-arthropathy and abstracts 65 cases reported in the literature. He separates 3 groups: (1) typical osteo-arthropathy with bone-changes and a peculiar form of club-fingers; (2) cases in which only the clubbed fingers have been noted; (3) mixed cases, embracing those in which the enlargement of the extremities appears to have been primary and others of uncertain nature, in which insufficient details prevent proper classification. He notes, as the characteristics of the typical cases, a history of previous thoracic disease with peculiar clubbing of the ends of the fingers and toes and bony enlargements mainly of the articular ends of the long bones, effusion and other changes near the joints, these being roughly symmetrical; then hypertrophy of the adjacent soft parts, and other less frequent features, including dermal, vascular, urinary, and other symptoms. The peculiarities of the fingers are the hypertrophy of the bones and the peculiar clubbing of the ends. The nail is curved in both directions and the root is long and mobile. The body is striated, furled, pink or cyanotic in color, and brittle; the growth is abnormally rapid. The thumb, middle finger, and great toe are mainly affected. Of the bony changes the most characteristic are those of the phalanges, heads of the metacarpal and metatarsal bones, the lower ends of the radius, ulna, and fibula. The bones about the elbow and knees may be affected, and, less frequently, the outer end of the clavicle, the acromion process of the scapulae, the ribs, the iliac crests, and the vertebrae. The main changes are referred to the periosteum and the subjacent bone. The disease may be progressive, or there may be paroxysmal changes with stationary intervals. There is no tendency to suppuration or necrosis. Clinically, there is no pain, and the joint-effusions are similarly sluggish. In discussing the cause he notes that the vast majority of cases follow empyema or bronchiectasis, and most of the remainder follow phthisis. It is likely, therefore, that

¹ St. Thomas's Hosp. Rep., vol. xxiv., 1897.

some change in the blood or liquids of the body is the cause, and he concludes that certain poisons of the nature of toxins or ferments, not necessarily identical in different cases, are the direct cause.

Teleky¹ reports 2 cases of hypertrophic osteo-arthritis. The first of these was a shoemaker, 40 years of age, who had had an attack of dysentery 2 years before his admission to the hospital. The lungs were absolutely negative; the heart slightly hypertrophied; there was slight kyphoskoliosis in the dorsal region; the end-phalanges of the fingers were increased in all diameters; the lower part of the forearm was broader than normal; and the toes were also, though to less extent, enlarged. The subjective symptoms consisted of severe pains in the joints. Specific treatment produced no effect. As the pneumonic element was entirely lacking, Teleky therefore concludes that the dysentery, being a suppurative disease, had some connection with the causation. The second patient was 40 years of age, and suffered from advanced pulmonary tuberculosis and great cachexia; however, about 10 years before his admission to the hospital the end-phalanges of 2 fingers that had been injured became enlarged to such an extent that they interfered with his work. When examined the drumstick alteration of the fingers was very marked, and they were greatly increased in thickness. When examined by the Röntgen rays the bones gave the appearance as if their thickness had been increased by fine exostosis upon the surface. Although the pneumonic element was evident in this case, nevertheless the enlargement seems to have commenced as a result of severe traumatism before the pulmonary disease developed. Based upon these cases and a number of others collected from the literature, the author suggests the following classification of the causes of this condition: (1) diseases in which suppuration and gangrenous decomposition occur in the organism; (2) infectious diseases and chronic intoxications; (3) heart-lesions, especially congenital; (4) malignant tumors; (5) diseases of the nervous system, such as syringomyelia and neuritis; and suggests in the place of the term proposed by Marie that of secondary hyperplastic osteitis. [It seems to us that the author confuses several distinct conditions. Mere clubbing of the fingers does not constitute Marie's disease.]

F. H. Westmacott² states that the postmortem examination of cases of hypertrophic pulmonary osteo-arthritis showed almost universal osseous and articular change. The limb bones were covered with a rough, finely porous layer of subperiosteal bone, specially marked in the long bones and at the attachments of the muscles and fasciæ, and in nearly all cases confined to the diaphyses. The cartilages of the joints were almost invariably eroded, especially at the margins. The viscera showed a general but subdued tuberculosis. The liver and spleen were amyloid. The present case supports the theory of Thorburn that the disease is a mild tuberculous osteoperiostitis.

Guerin and Etienne³ have examined the condition of the urine in cases of hypertrophic pulmonary osteo-arthritis for lime, urea, magnesium, and phosphates. There were, from time to time, marked deviations from the normal during the period of examination. The quantity of lime reached double the normal on many days for the period of 4 months, but after that diminished and became less than normal. The quantity of magnesium did not vary markedly. The phosphates were always extremely low and urea was present in minimum normal amounts. The authors believe that this examination justifies the view that in the first period of the disease the bone becomes decalcified. They explain the enlargement of the ends of the bones as being due to second-

¹ Wien. klin. Woch., Feb. 11, 1897.

² Brit. Med. Jour., Oct. 3, 1896.

³ Arch. de Méd. expériment., July, 1896.

ary ossification following the primary process, this period being that in which the lime reaches its minimum excretion.

GOUT.

Etiology and Pathology.—Malfatti¹ subjects the theory of Kolisch, who looked upon bodies of the uric-acid group as of considerable influence in connection with gout, to severe criticism. He denies that the alloxur bodies, or even the total nitrogen, is increased during a gouty attack. In fact, in the only investigation that he was able to make himself the total nitrogen for 24 hours during an interval was 12.333 gm., while during the attack it was but 10.8 gm. Phosphoric acid, however, showed a reduction of from 2.8 to 1.023 gm. As the formation of uric acid in the kidney seems to be exceedingly questionable, the transformation of xanthin bodies into uric acid there seems still less probable. Malfatti then undertook to see what would be the influence of renal extract upon the transformation of the xanthin bases found in the spleen, and his results were negative. He therefore concludes that the only explanation of gout that is at present possible is that it is a process in which the normal metabolism is so changed that the excretion of nitrogen no longer corresponds to the ingestion; but that periodically nitrogen is excreted in excessive quantities and at other times retained in the body. As, however, the slight increase in the body-weight in the latter condition does not permit us to assume the deposition of the nitrogen in the form of albumin, we must always suspect other nitrogenous combinations. In the former condition we must suspect renal insufficiency in relation to these bodies, or rather a congenital or an acquired increase of the normal irritation-point at which these combinations in the circulating blood are excreted.

Rommel² also objects to the theory of Kolisch, that the excretion of alloxur bodies is increased in gout. He calls attention to the failure of various investigators to find this condition, and has himself failed to discover it in a typical case of chronic gout. On the other hand, he has found an abnormal amount of the alloxur bodies in the urine of a patient without symptoms of gout, and with the characteristic symptoms of contracted kidney.

A. E. Garrod³ takes occasion to disagree with both Klemperer and Kolisch in regard to the pathology of gout; holding that, as yet, the only firmly established facts are the excess of uric acid in the blood and the deposition of urates in the tissues.

Laquer,⁴ in alluding to recent works upon the excretion of **uric acid and alloxins** in gout and other conditions, calls attention to the fact that the method of Krüger and Wulf, now so commonly relied upon, is often fallacious. In proof of this he cites his recent experiences, which give quite paradoxical figures. The author points out that the alloxins and uric acid are estimated by first determining the alloxin nitrogen in the precipitated alloxins and then the uric-acid nitrogen by the Salkowski-Ludwig method, and subtracting the latter from the former. In his own figures it happened a number of times that the latter figure was greater than the former, showing that some error must exist in the method employed; further, he denies the significance of the excretion of alloxins as indicating pathological processes. [The uncertainty in this and other methods probably accounts for the varying results of different investigators.]

¹ Wien. klin. Woch., Aug. 6, 1896.

³ Practitioner, Sept., 1896.

² Deutsch. Arch. f. klin. Med., H. 1 and 2.

⁴ Centrabl. f. innere Med., Oct. 31, 1896.

A. Luff¹ holds that uric acid is not normally present in the blood, but is produced by the kidneys. However, in gouty conditions it may be formed in excess, and then appear in the blood as soluble sodium quadriurate. Gout is probably always preceded by some affection of the kidneys. In regard to the treatment, he does not think that the reaction of the blood increases or decreases the tendency to deposition of the uric acid, but that the solubility is considerably increased by the presence of the saline constituents of vegetables, and diminished by the presence of the saline constituents of meat.

Futcher² contributes a paper on the relations of the perinuclear basophilic granules of Neusser and the excretion of alloxins. He believes that the bodies in question probably represent results of karyorrhesis rather than specific products, and he was able to produce them artificially by subjecting pieces of tissue to a temperature of 40° C. He has observed clinically that the number of granules varies very greatly in different diseases, and in the same disease, and often in apparently healthy persons, from time to time. To determine the exact relation between the occurrence of these bodies and the excretion of alloxins he made careful studies of the metabolism in 8 individuals. These studies showed that there is no regular coincidence between the number of perinuclear granules and excessive excretion of the substances named, nor a strict confinement of the occurrence of these granules to cases of alloxin-diatheasis. Very abundant granulations were sometimes found with relatively small quantities of alloxins, and the reverse.

Cornillon³ reports a case of gout that appeared after dislocation of a shoulder-joint, another after sudden muscular effort, and a third 3 months after severe contusion. He believes that the **injury** was the direct cause of the development of the disease.

Symptoms.—A. Haig⁴ discusses the effect of certain diets on the excretion of uric acid, showing by tables the relative as well as the actual quantities of uric acid and urea. He still holds that the uric acid taken in the food constitutes the bulk of the uric acid eliminated; and he concludes that the avoidance of animal food containing xanthin-compounds or uric acid, and also tea, coffee, and cocoa, whose alkaloids are similar xanthin-compounds, will gradually eliminate excess of uric acid in the system. The time when this is accomplished may be determined by administering a dose of salicylate of sodium. If any of the excess of uric acid still remain in the system, this drug will cause an immediate great increase of the uric acid as compared with the urea. His rule is that, if any one taking a dose of salicylate of sodium gets as a result an excretion of uric acid greatly above the relation to urea of 1 to 30, such person is not free from uric acid.

C. E. Nammack⁵ reports a case of chronic gout and one of rheumatoid arthritis with Röntgen-ray illustrations of the hands of the patients. These show very clearly the essential difference between the two conditions. In gout the joints are surrounded by splint-like deposits of crystals of sodium urate and the bones do not present exostoses.

A. L. Fisk⁶ also reports a case of gout, with skiagraph.

W. Wade⁷ calls attention to the frequency with which **periarticular neuritis** may be observed in gout, and rather doubts that the attack itself is necessarily due to the deposit of urates in the joints, having observed these deposits in joints that presented no symptoms and found them absent in those that had been repeatedly attacked.

¹ Brit. Med. Jour., Mar. 27, 1897.

² Centralbl. f. innere Med., Sept. 26, 1896.

³ Program. méd., Jan. 29, 1897.

⁴ Brit. Med. Jour., Oct. 3, 1896.

⁵ Med. Rec., Apr. 24, 1897.

⁶ Med. News, Apr. 17, 1897.

⁷ Brit. Med. Jour., Feb. 27, 1897.

Kittel¹ reports 4 cases of deposition of urates in the soles of the feet, which he looks upon as an irregular form of gout.

Diagnosis.—W. H. Thomson² has compared 34 cases of gout with 49 cases of rheumatism. In the former the attack is more apt to be monarticular, the pulse is almost invariably of high tension, tophi can be occasionally observed, and in all cases of inflammation of the joints the points of greatest tenderness to pressure were the condyles or malleoli. In the latter disease the pulse is most frequently of low tension, the heart is commonly affected; a number of cases exhibit tonsillitis or pleurisy, and the first attack is nearly always polyarticular. When the joint is acutely inflamed there is much more superficial tenderness, and at the same time there are points of special sensitiveness, usually situated over the tendons in most immediate relation to the joints. When the hips and shoulders are affected it is exceedingly difficult to make out special points of tenderness in either condition.

Treatment.—Levison³ agrees with Kolisch that renal degeneration is an important element in the causation of the disease, and he advocates the exclusion of thymus gland, liver, kidney, and pancreas from the diet. Further, he objects to yolks of eggs, as these, according to Kossel, contain notable quantities of paramecin. He also is favorable to the employment of **electricity**, using a battery of 48 large Leclanché cells, and applying the positive pole connected with a carbon electrode in a 2% solution of lithium chlorid rendered alkaline with lithium carbonate, and the carbon negative electrode in a very weak solution of sodium chlorid. The part of the body treated is placed in the lithium bath and a convenient part, as a hand or a foot, in the salt solution, while a current of 10, 20, or 30 ma. is passed for 30 minutes. In 10 of 15 cases he found useful results, the joints becoming more pliable and the pains subsiding. He believes that the lithium is disassociated by the electric action and carried into the body in available form.

John Fawcett⁴ has analyzed the urine in 13 cases of gout, and has studied the effects of **colchicum** and **salicylate of sodium**. The total acid and the daily excretion of urea and uric acid were determined. The amount of uric acid was distinctly subnormal between acute attacks, and decidedly greater during the attacks themselves, though it did not reach the normal average. There was no relation between the amount of urine and the quantity of uric acid, but the acidity of the urine and the quantity of the urea corresponded closely. Colchicum did not increase but rather decreased the uric acid, while salicylate of sodium constantly caused decided increase.

Hans Froehlich⁵ does not hold that uric acid is the original cause of gout, but believes that its removal from the affected joints is the most important part of the treatment, either by direct surgical intervention or by subcutaneous injections of weak solutions of sodium bicarbonate into the joints with massage.

M. A. Boyd⁶ believes that the clearing of the system of uric acid by alkalis or salicylates leaves the principal part of the work undone, which is the use of suitable remedies to correct the faulty metabolism in whatever system the disease first arose.

Laquer⁷ contributes an interesting paper on the metabolism in the course of a milk-diet and under other conditions. These studies show that the administration of **milk** increases the excretion of xanthin-bases and reduces that of uric acid. Increased quantity of liquid (water) in the diet increases the

⁶ Lancet, Aug. 8, 1896.

⁷ Berlin. klin. Woch., Sept. 7, 1896.

alloxin bodies (uric acid and xanthin-bases) in healthy individuals. Fat milk, according to Gärtner's formula, is recommended as a suitable diet for all cases of gout. [Salkowski points out that this formula furnishes no advantages over ordinary milk.]

G. Harley¹ discusses the relations of **sugar and champagne** to gout. He denies the importance of sugar, and calls attention to the fact that those accustomed to a saccharine diet have no special tendency to gouty arthritis, and that the urine of herbivorous animals, in whose diet sugar plays an important part, is alkaline in reaction. His own son, a subject of gout, took at one time 400 gm. of sugar daily until he suffered with total anorexia, and on another occasion 525 gm. in 24 hours, without producing any gouty manifestations. The relation of champagne to gout is difficult to determine, as the constituents of various preparations vary greatly. Of its constituents, sugar is, according to his view, the least and acetic acid the most harmful. [These views are so at variance with accepted belief that far greater proof than the author adduces will be required to gain for them any general credence.]

T. J. Mays² recommends the use of **salicylate of sodium** in the treatment of certain forms of **hemoptysis** that he holds are due to a rheumatic or gouty diathesis. This form has the following characteristics: the patient generally seems in fair health, and is usually seized while at work with sudden hemorrhage that tends to recur. There is neither history nor signs of phthisis, alcoholism, or syphilis; and a rheumatic or gouty history is frequently obtainable. The author cites 2 cases of this description benefited by salicylate treatment. He is particular to state that he does not advise the salicylates in every case of hemoptysis, nor exclusively in any.

GLYCOSURIA.

Strümpell³ contributes a study of **dietetic glycosuria**. He points out that as far as our knowledge of carbohydrate metabolism is concerned there is one important process, that of oxidation of the saccharine bodies, and providing the amount of carbohydrate food is sufficiently great this oxidation will fail to be adequate and sugar will appear in the urine. He has administered varying quantities of glucose to persons suffering with nutritional diseases, and has found that in ordinary cases of marantic conditions, such as in the severe anemias, moderate quantities of sugar (100 to 150 gm.) did not cause glycosuria. This may be due to the slow absorption of the sugar in such cases. In cirrhosis of the liver and in catarrhal jaundice the result was not uniform; and in 2 patients with chronic gout no glycosuria was produced. He was interested to study the effect in patients suffering with progressive muscle-atrophy, on account of the part supposed to be played by the muscles in carbohydrate metabolism. In 3 cases, however, no glycosuria was produced. The most positive results were obtained by him in alcoholics, particularly habitual and excessive beer-drinkers. In such he was able almost regularly to obtain striking results, and he is disposed to rank beer-drinking as an important cause of glycosuria. It was sometimes possible to demonstrate sugar after excessive indulgence in beer without the use of glucose in the diet; but it was not possible to produce glycosuria after copious meals of other starchy foods, such as bread, doubtless because of slower absorption.

L. C. Wadsworth⁴ reports a case of a man of 25, who accidentally discovered the presence of sugar in his urine. He had no symptoms whatever

¹ Lancet, Aug. 1, 1896.

³ Berlin. klin. Woch., Nov. 16, 1896.

² Phila. Polyclinic., Oct. 24, 1896.

⁴ Med. Rec., May 29, 1897.

of diabetes. He was the oldest of 11 children, and examination of specimens from the other 10 showed high specific gravity and the presence of more or less sugar in all. They were all healthy and passed a normal quantity of urine. The patient passed about 10% of sugar a day, but this quantity could be somewhat reduced by an exclusive milk-diet.

Mossé¹ has repeated the work of Seegen, who found that the venous blood coming from the liver contains as much as 100% more sugar than the portal blood. In order to avoid post-operative changes he received the hepatic blood through a catheter inserted into the jugular vein and pushed downward into one of the hepatic veins. He compared this with the blood of the arteries, which Seegen found to contain the same proportion of sugar as the portal blood. The average of 7 experiments was: arterial blood 0.093% of sugar, and the hepatic blood 0.107%, an excess in the latter of 0.014%. This difference is only about $\frac{1}{7}$ of that found by Seegen, and the author concludes that the **formation of sugar in the liver** is not so great as that author believed.

Neugebauer² reports a case of **incarcerated inguinal hernia** in which the urine was examined just before the operation and found to contain a considerable quantity of sugar. The operation was nevertheless performed, and the intestine, which was not in the least gangrenous, returned to the abdominal cavity. The urine passed the same night again contained sugar. When questioned regarding his previous life the patient absolutely denied any symptoms that pointed to diabetes, and, in fact, all further examinations of the urine proved negative. As no similar case of glycosuria as a result of intestinal obstruction had been recorded, the author undertook some experiments, using dogs, guinea-pigs, and human beings, and reached the conclusion that incarceration or ligature of the duodenum or jejunum, or incarceration of hernias in which the greater part of the small intestine is included may cause a temporary glycosuria, which disappears a few hours after the obstruction is removed. In conclusion, he reports another case which was almost identical with the first one, sugar being found just before the operation and continuing present for little more than a day afterward, when it entirely disappeared. [Disturbances of abdominal circulation and of intestinal absorption doubtless play a part in these cases.]

Loeb³ reports several cases illustrating the **method of onset** of diabetes mellitus, which show that small amounts of sugar may appear in the urine for some time—even years—before the appearance of any definite symptoms. He does not believe that such cases invariably lead to diabetes.

DIABETES.

Etiology.—Senator⁴ analyzed 770 cases of diabetes which came under his observation to determine its **frequency in married couples**. He found this coincidence in man and wife in 9 couples—viz., in 1.19% of the cases. Three of the cases were markedly disposed by hereditary influence, and he omits these; in 4 others the time that elapsed from the date of possible transmission to the occurrence of the disease was so long that it was difficult to assume a causal relation. In 1 case, for example, the husband had been dead 5 or 6 years when the disease occurred in the wife. There are, therefore, only 2 cases in which the disease arose without obvious causes, and this number is so small that he prefers to regard the coincidence as purely acci-

¹ Pflüger's Archiv, Bd. lxiil., p. 613.

² Wien. klin. Woch., Sept. 10, 1896.

³ Centrabl. f. innere Med., Nov. 21, 1896.

⁴ Berlin. klin. Woch., No. 30, 1896.

dental. [This analysis agrees very well with that of Opler and Kütz; see *Year-Book*, 1897.]

H. A. Hare¹ has studied the **statistics of diabetes**, and finds that the disease is apparently increasing very rapidly in frequency. [It must be remembered, however, that much more attention is paid to urinary analysis at the present time than was paid to it 20 years ago.]

Pathology.—James² has studied the **blood** in 13 cases of diabetes. The number of red cells was over 6,000,000 in 5, 5,000,000 in 5, 4,000,000 in 2, and 3,000,000 in 1. The quantity of hemoglobin was over 100% in 3, 80% in 8, and 50% in 2. The specific gravity was estimated according to the method of Roy, and was found to be only 1054 to 1060—*i. e.*, about normal. This last fact is against the view that there is a concentration of the blood due to polyuria. The condition of the blood maintains itself, according to the author, until the general strength of the constitution begins to weaken, when the character of the blood deteriorates. His own theory is that the blood of the diabetic patient, as also the digestive power of the stomach, increases in order that the great mass of the oxidizable material may be disposed of by increased oxidating power of the blood.

Kalmus³ reports 3 cases of diabetes mellitus, in 2 of which there were remarkably extensive degenerations in the posterior columns of the **spinal cord**, particularly in the columns of Goll.

Teubbaum⁴ has found, as a result of investigation upon 12 cases of diabetes, that the amount of **calcium** excreted in the urine is in great excess in the severer forms, but only slightly increased in those that are milder. He believes that this is due to the increased amount of food ingested, although, in certain cases where the quantity excreted is in great excess he is inclined to consider that it represents, in part at least, the disintegration of the body albumin.

Symptoms.—Triboulet⁵ notes that there are comparatively few accurate observations upon the liver in diabetes, and the reports of the findings are at variance. As **hepatic symptoms** are frequent, such as tenderness, increase of size, and functional disturbances, he holds that further observations are required to establish the exact pathology.

A. B. Elliott⁶ classifies the causes of **albuminuria** in diabetes mellitus as follows: irritation by the sugar during its excretion, suppurative conditions of the urinary passages, increased ingestion of albuminoid foods, and increased liability of diabetics to various morbid changes the result of disassimilation and coexisting nephritis.

Rendu and De Massary⁷ report a case of acute diabetes complicated by pigmentation of all the tissues excepting the voluntary muscles and the semi-lunar ganglion. The pigment was of a yellow ochre color and contained iron. No pigment-emboli were found in any part of the body. A diagnosis was made of **bronzed diabetes**.

Diagnosis.—R. T. Williamson⁸ describes a method of determining the existence of diabetes by **testing a drop of the blood**. As the chemical examination requires a large quantity of blood, the author was led to study the reaction with anilin dyes, and found that methyl-blue was very sensitive. His method is as follows: a narrow test-tube is well cleaned and at the bottom are placed 40 c.c. of water, using Gowers' hemoglobinometer pipette for this

¹ Med. News, June 12, 1897.

³ Zeit. f. klin. Med., vol. 30, H. 5 and 6.

⁵ Rev. de Méd., No. 2, 1896.

⁷ Presse méd., No. 11, 1897.

² Edinb. Med. Jour., Sept., 1896.

⁴ Zeit. f. Biol., 1896, p. 379.

⁶ Jour. Am. Med. Assoc., Dec. 26, 1896.

⁸ Brit. Med. Jour., Sept. 19, 1896.

purpose; the finger is cleansed and pricked, and a large drop is drawn into the small capillary hemoglobinometer tube to the 20 c.c. mark. The blood is then mixed with the water in the test-tube, and 1 c.c. of a 1 to 6000 aqueous methyl-blue solution is added; finally, 40 c.c. of liquor potassæ are added and the tube well shaken. A control-test is made with normal blood. The fluid in each tube is now deep blue in color. Both tubes are then placed in a beaker containing water, and this is heated until it boils and continued at this point for 4 minutes, at the end of which time the tube containing diabetic blood changes to a dirty yellow. Shaking must be avoided. He has made over 30 examinations in 6 cases of diabetes, and has found that the reaction was characteristic. In 4 the disease was severe, and a solution of methyl-blue of double strength (1 to 3000) was decolorized. In a large number of normal cases the reaction was not obtained. The author believes this reaction is dependent upon the reducing power of the sugar. If this were the case, larger quantities of normal blood should give the reaction, and he has found that 60 c.c. of normal blood plus 1 c.c. of methyl-blue plus 4 c.c. of liquor potassæ react. [If this reaction be due to the cause stated, it will probably be found in other conditions, such as carcinoma, in which increase of sugar occurs in the blood. Also, it is likely that other reducing agents will give the reaction and interfere with the usefulness of the test.]

Bremer¹ has studied the **color-reactions of normal and diabetic urine**, finding that both dissolve eosin very well, but that normal urine does not dissolve gentian-violet or only very imperfectly. Diabetic urine, on the other hand, dissolves the latter substance very poorly and slowly, whether it contains sugar or not. The solution of gentian-violet does not mix easily with a solution of eosin, and this gives rise to certain peculiar appearances in the liquid.

Lepine and Lyonnet² have found the **reaction of the red blood-corpuscles** described by Bremer as occurring in diabetes in a case of this disease and also in a case of leukemia, and attribute it to the reduced alkalinity in the 2 cases examined. There is nothing to substantiate the view of Bremer that diabetes is based upon disease of the red blood-corpuscles. [We have also obtained this reaction in normal blood that had been carelessly fixed.]

Treatment.—Samuel West³ contributes a further article on the value of **uranium nitrate** in the treatment of diabetes. One of his previous cases declared that the remedy made her ill; and although he does not feel assured that this was the case, he does not deny its possibility. He then reports 5 new cases in which the remedy was more or less successful. The first, a young woman of 22, had suffered with the disease for 2 years; the drug was taken without any disturbance. The amount of the urine remained the same, but the percentage of sugar fell from 6% to just above 4%, and lost its previously marked fluctuations. In the second case, in a woman of 44, the quantity of sugar was greatly reduced and the fluctuations disappeared. The same was true of the third case, and in this it was noted that the quantity and specific gravity were but little affected. In the fourth case, under the combined action of the drug and diet, the quantity was reduced by about 1 pint in 24 hours. The specific gravity remained the same and the percentage of sugar fell slightly. In the last case the drug had no good effect and dyspepsia was produced by its use. He concludes that this drug is of considerable value, though it cannot be relied upon to produce equally good results in all cases.

J. Gibbs Blake⁴ has tried **phloridzin** as a remedy for glycosuria. He recalls

¹ N. Y. Med. Jour., Mar. 13, 1896.

² Lyon méd., No. 23, 1896.

³ Brit. Med. Jour., Sept. 19, 1896.

⁴ Birmingham Med. Rev., July, 1896.

that nitrate of uranium, which has lately been lauded in diabetes, was long since known to be capable of producing artificial glycosuria. This led him to think that phloridzin, which is capable of causing glycosuria, might prove an efficient remedy. He has tried it in several cases and found it useful, especially in middle-aged persons, finding that in children and phthisical subjects, like uranium nitrate, it had little advantage.

D'Arsonval and Charrin¹ have employed **currents of high frequency** in a case of diabetes, with the result that after 1½ months of treatment the sugar had decreased from 622 to 186, and the volume of urine from 12 to 8 l. per day. In another case the glucose was decreased from 144 to 57, and the patient presented considerable improvement in all his physical signs.

Diet.—Edward L. Munson² reports a case of diabetes whose urine before diet failed to give the reaction for diacetic acid, but this substance appeared within 48 hours after the withdrawal of carbohydrates. His condition rapidly grew worse and there was considerable increase in the amount of ammonia present in the urine. Finally, it was decided to permit him to partake of carbohydrates, whereupon he improved very remarkably, although there was a slight increase in the amount of sugar excreted. The author believes that sugar is always present in the blood and is not obtained exclusively from carbohydrates. As the diabetic patients are still able to burn sugar, it is necessary to permit them at least as much as would be given a healthy person, and, if given, it prevents altered metabolism of the albuminous bodies and the formation of toxic substances. This sugar is absorbed in the same way as if it were ingested in a healthy organism. More sugar, however, is excreted because the isomeric albuminous sugar, which would otherwise be burnt up, is not needed, and is excreted as a waste product.

Chas. W. Purdy³ objects to a too exclusive milk-diet in diabetes, particularly when skimmed milk is employed. He also prefers a limited quantity of table-bread to any of the so-called nonstarchy substitutes.

Renzi and Reale⁴ have investigated the value of levulose in supplying the place of dextrose in the diet of diabetic patients. They find that as much as 82 gm. per day are completely burned in the organism and to a considerable extent economize albumin.

OSTEOMALACIA.

Hoffmann⁵ has investigated the urine of 2 cases of osteomalacia in order to see whether the theory that the solution of the bone-salts is due to the presence of lactic acid in the blood could be inferred from the presence of this substance in the urine. In one case 15 l. and the other 20 l. were tested; neither contained any traces of lactic acid.

Senator⁶ reports a case of osteomalacia to which he gave thyroid gland and oöphorin. Under both substances the amount of calcium excreted was considerably increased, but the patient showed marked improvement.

Seegleken⁷ reports a case of **multiple myeloma** occurring in a man of 61. He had had rheumatism and had suffered a severe injury to the head. The disease commenced with deep-seated pains in the neck and breast. During its progress the sternum sank inward and the spinal column became kyphotic. The cardiac impulse was vigorous; there was a systolic murmur at the pul-

⁷ Deutsch. Arch. f. klin. Med., vol. lviii. H. 2, 3.

monary cartilage, but otherwise all the organs were normal. The urine contained the peculiar albumose that has been described in similar conditions by Bence-Jones. At the autopsy numerous soft vascular tumors were found in the skeleton, which in places had destroyed large portions of the osseous tissue.

DISEASES OF THE BLOOD.

General Considerations concerning the Blood.—Knopfmacher¹ has examined the blood of the newborn, particularly to determine its relations to infantile jaundice. He determined that the red corpuscles bear no etiologic relation to icterus neonatorum. The number of erythrocytes during the first week of life is independent of the occurrence of jaundice. The fluctuations in particular are more dependent upon the changes in the volume of plasma. The "resistance" of the red corpuscles is the same at the time of birth as in the adult, and it is not altered in consequence of jaundice. He could find only evidences of rapid formation of corpuscles, never any indications of destruction.

Epstein² describes the changes in the blood in a case of carcinoma with **metastatic involvement of the bone-marrow**. The patient was a woman who had suffered with mammary carcinoma and extensive metastasis; the proportion of white to red cells in the cover-glass preparations was from 1 to 25 to 1 to 40; the hemoglobin was 19% and there was marked reduction of the red corpuscles. The latter were exceedingly irregular in size and many of them contained nuclei. Of the latter there were normoblasts and megaloblasts, often with irregular clover-leaf and rosette-formed nuclei or with nuclear fragmentation. Polychromaphilia of the nucleated and of the non-nucleated cells was detected, and the white corpuscles, especially the large mononuclear forms, for the most part contained neutrophile granules and were increased in number. Myelocytes corresponding to Cornil's description and a few eosinophile cells were found. The author concludes that the involvement of the marrow was shown by the great number of the "*markzellen*" and the enormous number of nucleated red corpuscles, especially the megaloblasts. He points out, however, that it is impossible to determine the nature of the changes in the marrow from the character of the blood, since marrow-changes are common in various conditions and the blood may or may not be altered.

Methods of Examination.—Rabl³ describes a method of **staining the blood-plates**. This consists essentially of the method of Heidenhain for centrosomes. The preparation of blood dried in air is fixed for $\frac{1}{4}$ to $\frac{1}{2}$ hour in a saturated solution of corrosive sublimate in $\frac{3}{4}$ % NaCl, then washed and placed in a solution of chlorid of iron for 1 hour, again washed and stained for $\frac{1}{2}$ to 1 hour in a saturated aqueous solution of hematoxylin. After all the cells have become stained a bluish-black the preparation is placed a second time in an iron solution; after $\frac{1}{4}$ or 1 minute the preparation becomes yellowish-gray in color and is ready to be washed, dried, and mounted. The red corpuscles are wholly decolorized. The blood-plates are dark bluish-black, and the leukocytes are somewhat similarly stained.

Zuntz,⁴ in investigating **Hammerschlag's method** for determining the specific gravity of blood, notes that blood shaken in a mixture of chloroform and benzol exerts a powerful attraction upon the latter, absorbing it and therefore becoming lighter. As, however, this absorption occurs slowly, it does not necessarily interfere seriously with the method. He suggests, however, that

¹ Wien. klin. Woch., No. 43, 1896.

² Zeit. f. klin. Med., Bd. 30, H. 1, 2.

³ Wien. klin. Woch., No. 46, 1896.

⁴ Pflüger's Arch., Mar. 31, 1897.

after the correction a new drop of blood should always be used in order to test the accuracy of the solution. He has been unable to replace the benzol with any of a variety of substances with which he experimented. [Used in this way Hammerschlag's method has given fairly accurate results in our hands, though it is somewhat tedious and in no way comparable with the pyknometer method in accuracy. The difficulty with the latter is that accurate chemical balances are indispensable.]

Gryn's¹ reaches certain conclusions regarding the **estimation of the volume** of corpuscles and serum in a study of osmosis and diffusion in regard to the red corpuscles. Then he considers the clinical method to determine the volume of the corpuscles by centrifugation, and finds that the same amount of sediment may be determined repeatedly in the same blood when accurately isotonic solutions are employed for dilution. He recommends for human blood a solution of NaCl of 0.84 to 0.88 % strength. To this crystalline ammonium oxalate or a solution of sodium oxalate is added to prevent coagulation. The solutions recommended for diluting by Hedin, Daland, and others should not be used, as they change the volume of the corpuscle.

Berend² describes a new method of **estimating the alkalinity** of the blood. He draws 0.1 c.c. of blood into a specially prepared pipette and then 5 c.c. of 1% solution of NaCl; the mixture is centrifugated and the diluted serum colored blue with litmus. It is then treated with acid solution in excess and titrated with alkali back to the neutral point. The corpuscles in the centrifugated sediment are first treated with 10 c.c. of neutral water and poured into a porcelain dish; the tube is washed with 5 c.c. of water and litmus added until a bluish-green opaque solution is formed; excess of acid is then added and the mixture is titrated back with alkali until the red color disappears and the opaque condition of the mixture is restored. In this way the total alkalinity of the serum and of the corpuscles is determined. He has studied the blood of 29 children with this method and finds that the normal in infants lies between 0.34 and 0.44. The alkalinity decreases in the first few days of life, and sometimes subsequent elevation occurs. In adults the figures are from 0.46 to 0.50.

Clinical Method.—J. H. Ford³ recommends the following method of his own for the discovery of the **total quantity of blood** in the body: venesection is performed, a definite quantity of blood removed, and its specific gravity determined; then a similar quantity of normal salt solution of known specific gravity is injected into the vein. After 5 minutes the same quantity of blood is drawn again and the specific gravity again determined. The mass of blood is determined from these facts by simple calculation. [While this method seems perfectly simple and has been occasionally considered by previous writers, it is subject to so many fallacies that we should scarcely deem it reliable. It must be remembered that the abstraction of blood in sufficient quantity to make substitution of salt solution practically useful in the determination brings about changes in the vasomotor system and probably in the lymph-stream that would tend to vitiate the results. It is still uncertain whether the withdrawal of blood quickly determines the inflow of lymph into the circulation or not, but this is at least probable. Further, it may be that the altered blood after addition of saline solution rapidly discharges part of its fluid element to equalize the specific gravity.]

The Leukocytes.—Clarisse⁴ has studied the modifications that take place in the **number of leukocytes** produced by massive injections of saline

¹ Pfüger's Archiv, Bd. 63, p. 86.

² Zeit. f. Heilk., Bd. 17, H. 2-3.

³ N. Y. Med. Jour., Jan. 18, 1896.

⁴ Compt. rend. de la Soc. de Biol., July 24, 1896.

solutions **in febrile conditions.** In one case of general streptococcus infection they were ordinarily reduced about $\frac{1}{2}$, although there were a rapid reaction and increase in temperature after each injection. In another case of a man suffering from a phlegmonous inflammation of the arm the leukocytes were decreased from 26,000 to 11,000 per mg.; in the third case, one of intense puerperal infection, the reduction was again $\frac{1}{2}$. In all cases, after the primary reaction there were a rapid fall of the temperature and a temporary improvement in the general condition of the patient. The author refrains from drawing any conclusions.

Burian and Schur¹ have made a number of experiments upon **digestive hyperleukocytosis**, with the usual result that they find it somewhat variable. At the same time they estimated the amount of nitrogen in the urine, and found that it was distinctly increased for some hours after the ingestion of considerable quantities of albumin, and that this increase did not necessarily bear a close relation to the degree of leukocytosis. They therefore conclude that the absence of the digestive hyperleukocytosis is not of itself a symptom of imperfect resorption. In an endeavor to discover the nature of this leukocytosis they start with the observation that more lymphocytes are found in the radicles of the portal vein than in the arteries leading to the digestive tract, and infer from this that the lymph-glands of the intestines and mesentery have an active part in the increase in the leukocytes, assuming that their action is one of protection to the organism, and that the leukocytosis is simply the expression of their effort to destroy digestive substances that are attempting to penetrate into the tissue. In cachectic states, after the introduction of nourishment, there is hypo- instead of hyperleukocytosis, and they report 3 cases of gastric carcinoma in which this condition was very marked.

G. L. Gulland² holds that it is impossible to devise a thoroughly satisfactory classification of the leukocytes, as the different forms are all variations of one body at different stages and no sharp dividing-line can be drawn. It is convenient to distinguish hyaline cells (without granulations), acidophile and basophile leukocytes, all 3 being derivatives of the lymphocyte. The neutrophile and amphophile cells he places among the acidophile, as do Kanthack and Hardy. He holds that the granulations of the leukocytes are not products of the cellular protoplasm, as Ehrlich maintained, but only microsomes. [The paper is one of great value, but cannot be more extensively noted in this place.]

R. J. M. Buchanan³ believes with other observers that in their mature stage any one leukocyte exhibits only one form of specific granules. It is not improbable, however, that the cells may at one period of their existence contain oxyphile and at another basophile granules. In abnormal instances a deviation may occur and both stages may be represented in the cells at one time. His observations on leukemia have persuaded him that this is a not infrequent occurrence. He noted among cells identical with the large uninucleated marrow-cells some in which only fine basophile granules were brought out by staining with methylen-blue and eosin (the stains being used separately) and others in which both forms of granules, oxyphile and basophile, occurred, the specimens being stained with a mixture of methylen-blue and eosin, and then further stained with methylen-blue. [One of the editors has found similar results not only in leukemia, but in other conditions. It is necessary to call attention to the fact that the author is in error in regard to the novelty of this view. Arnold, among others, called attention to the occurrence of different forms of granules in one cell some time since. We have found that staining with methylen-

¹ Wien. klin. Woch., Feb. 11, 1897.

² Jour. of Physiol., 1896.

³ Liverpool Med.-Chir. Jour., July, 1896.

blue and eosin, or with strong methylen-blue, is prone to produce results different from those we have seen in specimens stained with Ehrlich's triple mixture and with other combinations. Even the granules which take up the Ehrlich triple neutral stain very well (the polymorphous leukocytes) may be intensely and sharply stained with methylen-blue, provided this acts sufficiently long upon the specimen. In using Chenzinsky's mixture, and heating the specimen in the oven for some hours, as was done by Canon, the frequency of this result is striking.]

Gumprecht¹ discusses the subject of **leukocytic degenerations** in leukemia and in severe anemias. The author's paper, which was read before the German Society for Internal Medicine at the meeting of 1896, has already been briefly referred to (*Year-Book*, 1897). The full paper is now published. He has studied the question from the side of the morphology of the leukocytes as bearing upon the chemical changes in leukocytic destruction, and points out that in most cases of leukemia there is increase in excretion of uric acid and the alloxins, and that there is a close relationship between the destruction of cells in the blood and the excretion of uric acid. Morphological evidences of cellular destruction are recognized in the blood and elsewhere, and 2 forms in particular may be described, known as hyperchromatosis and hypochromatosis. The author's investigations show that lymphocytes of different origin (thymus glands, lymph-glands, etc.) degenerated outside the body, or when subjected to heat exhibit hypochromatosis. The circumference of the nucleus becomes irregular, its structure is lost, and the chromatin gradually disappears. The same type of degeneration is seen in the leukocytes in certain severe anemias, especially in leukemia. In the acute forms of the latter disease the number of such degenerated cells is very great and is an indication of the nuclein destruction. Practically the same morphological changes are seen in the lymphocytes and in the myelocytes as are seen in the artificially degenerated cells. In normal blood the evidences of degeneration are slight.

Kuhnau² has studied the **effect of the dissolution of the blood upon the leukocytes**, and concludes that there are marked leukocytosis, increase in the excretion of uric acid and xanthin-bases, and increase at first in the excretion of phosphoric acid, followed by marked diminution; and an increase ultimately in the excretion of the chlorids, which appear to be affected inversely as the phosphoric acid. The increase of the alloxin bodies is caused chiefly by the disintegration of the leukocytes. The leukocytosis is due to the direct leukotactic action of the poison in the blood, to the liberated nuclein substances, and to the fragments of blood-cells in the circulation.

Uhlman³ has studied the effect of certain substances upon the white corpuscles by placing mica disks impregnated with toxic substances in the anterior chamber of the eye of rabbits. The leukocytes find their way into the crevices, and after the experiment is finished the disks are split and fixed in concentrated sublimate or 1% osmic acid and stained. Various forms of nuclear or protoplasmic changes were discovered. Among others change of shape, fatty degeneration, swelling and vacuolation, and fragmentation of the protoplasm, and indefiniteness of contour, nuclear destruction, or increase or decrease of size of the nuclei. The author did not determine any specific change for individual poisons.

M. L. Perry⁴ has studied the blood of 10 insane patients during the administration of thyroid gland. The number of red and white corpuscles was little

¹ *Dentsch. Arch. f. klin. Med.*, Bd. 57, H. 5-6.

² *Dentsch. med. Woch.*, June 1, 1897.

³ *Ziegler's Beiträge zur path. Anat.*, Bd. 19, H. 3.

⁴ *Med. Rec.*, Aug. 27, 1896.

influenced. The **differential count** of leukocytes, however, showed increase in the mononuclear forms (lymphocytes) at the expense of the polymorphous forms. The increase began about the 3d day and lasted several days after the administration of the remedy had ceased. It was proportional to the amount of thyroid extract given and constituted about 10 to 20% of the whole number of leukocytes. At the height of the administration the lymphocytes seemed smaller than normal, and their nuclei stained more deeply than before the administration.

The Erythrocytes.—Lafon¹ has examined the **relation of the red blood-corpuscles to the body-weight** in a number of persons with the uniform result: that with the decline of the body-weight the number of red corpuscles and the quantity of hemoglobin decreased, and with the increase of the body-weight the corpuscles and hemoglobin increased, while the leukocytes decreased proportionately. An increase of 500 gm. of body-weight indicated an increase of 200,000 red corpuscles; an increase of 1500 gm. an increase of 1,500,000, and 8 kilos increase almost 20,000 more corpuscles. The hemoglobin increased in these instances from 1 to 2 or 5%. [It is impossible to establish so simple a relationship as the author attempts. So much depends upon quantities of serum or plasma, upon conditions of the circulation, etc., that any direct relation of mere weight or strength to the condition of blood cannot be determined.]

Conditions affecting Constitution of the Blood.—Breitenstein,² in a study of the **relation of cold to the circulation** of healthy persons and those suffering with fever, alludes particularly to the condition of the blood. In 26 subjects suffering with typhoid fever he found after cool baths (22° C., 10 min.) that the red corpuscles increased at the least 50,000 per c.mm., and that with corresponding increase in the hemoglobin measure a similar, though less pronounced, result was obtained in 11 healthy persons. The increase of corpuscles bore no relation to the fall of temperature in these cases; and antipyretic remedies, such as antipyrin, caused no such result. No relation could be found between the changes in the blood and the alterations in blood-pressure, respiration, and pulse-rate. The apparent explanation was that the change in the number of red corpuscles is due to a transfer of the corpuscles previously massed in some part of the circulation into the peripheral circulation in consequence of the increased blood-pressure. After the bath this view was confirmed by experiments upon rabbits. When these animals were heated the erythrocytes in the peripheral circulation decreased and were found to be massed in the liver. This condition corresponds closely with that observed in typhoid fever.

Löwy³ has studied the **effect of heat** upon the constitution of the blood. He placed rabbits in an incubator and maintained them at a temperature of 30° to 36° C. for 24 hours, when the blood was found to have lost in sp. gr. and solid residue, while the serum had increased in solid residue. This result was rather surprising in view of the loss of water which the entire organism must suffer under the conditions of the experiment. He examined portions of muscle in order to determine the loss of water, but found no uniform results, though in the majority there was some loss. In 11 cases the average normal solid residue in the blood was 16.88% and the average after heating 15.43%. Omitting 1 case in which the estimation was doubtful, the average after heating was 16.11%. The sp. gr. in 3 cases declined respectively 6.0, 0.5, and 1.8 points, while the serum in the same cases increased respect-

¹ Compt. rend. de la Soc. de Biol., No. 18, 1896.

² Arch. f. exper. Pharmakol., Bd. 37, p. 253.

³ Berlin. klin. Woch., Oct. 12, 1896.

ively 3.5, 2.75, and 6.9 points. It is therefore evident that the sp. gr. of the entire blood did not suffer in consequence of dilution simply. The author concludes that it is due to the retention of the corpuscles in the smaller vessels or capillaries, and to prove this shows that the number of corpuscles in the blood taken from the ear of a rabbit at parts removed from the large blood-vessels increases after heating. He does not believe that any exchange of water by evaporation through the lungs, or any noteworthy addition of serum from the lymphatic channels occurs in these cases on account of the condition of the serum of the blood, as well as from the fact that practically the same results are obtained by heating the animals for from half a minute to 15 minutes at 60° to 70° C.

Grawitz¹ replies that his previously published explanation of the occurrence of diminished concentration of the blood in animals subjected to heat—viz. that it is due to increased influx of lymph into the circulation—is unaffected by Löwy's observations. He points out that the solid residue of the serum in the experiments of the latter increased only slightly, from 6.88 to 7.06%. He holds that this proves his own point, since the loss of water by evaporation must have produced greater thickening of the serum if there were no additions of lymph to the blood-stream. [It is evident that Grawitz does not deny the possibility of disturbances of circulation and peripheral corpuscular congestion, though he maintains also and especially the addition to the circulating blood of lymph. This view seems to us to correspond very accurately with the probabilities, and we are therefore disposed to accept it as likely.]

Eger² contributes an interesting paper on the **regeneration of blood after hemorrhage**. His experiments were performed on dogs. He summarizes his results as follows: the animal organism reproduces the blood after the loss of $\frac{1}{3}$ of its total bulk very slowly and imperfectly, and sometimes not at all, when the diet is comparatively poor in iron. The addition of inorganic preparations of iron increases the rapidity of regeneration, but is not as satisfactory as a diet containing a sufficient quantity of iron in combination (meat). Even in the cases of the latter diet, however, the addition of iron in inorganic or organic form hastens regeneration. After a severe loss of blood, therefore, he holds that milk-diet is contraindicated, and that the ordinary diet and iron salts should be administered. He studied the changes in the sp. gr. and dry residue of the blood and the serum after and before hemorrhage, and discovered that in severe traumatic anemia the sp. gr. (and therefore the albumin) of the latter corresponds with the decrease in the number of blood-corpuscles and hemoglobin. He does not, therefore, confirm the view of v. Jaksch and others, that the serum maintains itself at practically a constant condition, despite the change in sp. gr. of the blood as a whole.

Tarchetti³ has studied the **effects of hemorrhage** upon the constitution of the blood. He found that in dogs, after considerable venesection, producing acute anemia, the hemoglobin-value of the corpuscles is unaltered; when a subacute or chronic anemia is produced by repeated hemorrhages, each small in amount, the hemoglobin of the corpuscles is relatively deficient, and this persists after the number of corpuscles has returned to the normal; and even after it has become greater than the original number. He explains these effects by assuming that the production of hemoglobin is independent of that of the red corpuscles. The tendency of the organism is to reproduce red corpuscles more quickly than hemoglobin, and the increased number of corpuscles

¹ Berlin. klin. Woch., Nov. 9, 1896.

² Zeit. f. klin. Med., Bd. 32, H. 3-4.

³ Arch. fer la Scienze Mediche, No. 1, 1896.

is, perhaps, in a measure, a compensation for the tardy development of hemoglobin. He explains the reduction in hemoglobin-value by the assumption that youthful, often nucleated, and hemoglobin-poor red corpuscles of the marrow are cast into the circulation in the process of regeneration.

Eubank and Hall¹ report a series of experiments upon the regeneration of the blood. Dogs were bled and at the same time a slightly excessive amount of artificial serum was injected. This increased the rapidity of the regeneration. The regenerative processes were more rapid in the third and fourth than in the first and second weeks, and once started they carried the blood into a condition in which the corpuscles and hemoglobin were in excess of the normal. The amount of hemoglobin per volume of red corpuscles was not constant, and during the regenerative period the hematocrit ordinarily gave higher readings than the hemocytometer, the differences being due to increase in the diameter of the red blood-cells as determined by the micrometer.

Limbeck² discusses the effect of biliary salts upon the blood. He noted some years ago that the **isotonicity** of the corpuscles was regularly less in icterus than in health, being 0.38% or less, instead of 0.46 or 0.48% as in health. The explanation of this was that the more fragile corpuscles had been destroyed by the biliary salts, leaving the more resisting in the circulating blood. He found the hypertonicity of the serum somewhat reduced, which led him to investigate the volume of the corpuscles, as Köppe has recently shown that this bears a certain relation to the tonicity of the serum. In each of 3 cases he found a rather notable increase in the volume of the corpuscles and decrease in that of the serum, and he found that a similar increase of corpuscular volume could be produced artificially by addition of biliary salts to horse's blood. He was unable to produce, artificially, any change in the isotonic relations of the corpuscles; and he concludes, with Hamburger, that the isotonicity of the corpuscles is independent of the condition of the serum. Finally, he inclines to believe with F. Hoppe-Seyler that the hemoglobin of the corpuscles is in some form of actual combination with the stroma of the corpuscles, and that the influences which cause changes of tonicity affect this combination in one direction or another.

Camus and Gley³ have found that the **injection of peptone** into the blood produces considerable increase in the number of red blood-corpuscles and the amount of hemoglobin. As there is no hemoglobinuria, they believe this to be due to diminution of the plasma.

Strauss⁴ has studied the **alkalinity of blood** from the median vein after the method of Löwy. The measure of the alkalinity in healthy persons was found between 320 and 325 mg. of NaHO; the figures, however, varied somewhat in individuals, and he therefore assumes that alkalinity is abnormally high when it is above 400 and abnormally low when it is below 250. There are no great variations at different times of the day in consequence of food or exercise, although small differences may be determined. In cases of gastritis with subacidity or hyperacidity no decided differences were found. In febrile cases there was normal alkalinity in a number of cases and decided increase in some, but never any reduction. An attempt to alter the alkalinity experimentally showed that the blood of man offers considerable resistance to such procedures as compared with that of herbivorous animals. Alkalies are quickly eliminated through the kidneys, and the acids are soon combined with ammonium and eliminated in that form.

⁴ Zeit. f. klin. Med., Bd. 30, H. 3 and 4.

Caro¹ has studied the **variations in the alkalinity** of the blood and their relation to leukocytosis. After injections of spermin, tuberculin, and pilocarpin there are moderate and temporary alterations in the alkalinity, usually increase and then reduction. The amount and duration of these changes are so slight, however, that it is difficult to explain their occurrence. He could find in men no such relation between alkalinity of the blood and the number of white corpuscles as Löwy and Richter claim for rabbits.

Ehrlich and Lindenthal² describe a case of "**nitrobenzol**"-poisoning with certain peculiar features in the blood. The patient, a woman of 50, had stupor, cyanosis, and collapse. Artificial respiration restored her to a certain extent, and she gained in strength; but, finally, after the development of jaundice, death occurred in coma on the 17th day of the disease. The blood was dark colored and showed the spectroscopic peculiarities of methemoglobin. There were distinct poikilocytosis and many nucleated red corpuscles and leukocytosis. At first the nucleated red corpuscles were of both kinds, normoblasts and megaloblasts, but as the case progressed the latter predominated. They noted with particular interest certain clover-leaf-shaped nuclei in large red corpuscles. The fact that these took on a polychromatophilic stain led them to regard these corpuscles as degenerative. Altogether, the blood resembled that of pernicious anemia.

Abnormal Constituents.—H. F. Müller³ describes certain very small, colorless, sometimes light-colored, sometimes dark, strongly refractive bodies, showing active molecular movements in the fresh preparations. They are not colored dark with osmic acid, and therefore do not contain fat. Acetic acid does not dissolve them, and they are independent of fibrin-formation, as they are invariably outside of the fibrin network. He has found them in all normal specimens of blood, although in different quantities in different persons and at different times. They are sometimes present in enormous numbers, and they seem to be decreased in states of hunger or cachexia. The author does not decide as to their exact significance, but terms them hemokonie. [We have frequently observed these bodies and have concluded that they are minute fragments of red corpuscles. They find almost exact analogues in artificial fragments produced by heat and other destructive agencies.]

Winterberg⁴ investigated the presence of **ammonia in human blood**. In a normal dog he was able to demonstrate a considerable quantity. In a dog from which the kidneys had been extirpated it was not altered. In 2 patients, one suffering from uremia and the other from chronic nephritis without uremia, the amount of ammonia was only slightly increased in the second. He concludes that normal human blood contains preformed ammonia to about the amount of 1 mg. in 100 c.c. In fever this quantity varies considerably; usually it is increased, but not infrequently notably diminished. It is not increased in chronic disease of the liver or in acute yellow atrophy, and we cannot conclude that uremia is due to poisoning with carbaminic acid; he therefore holds that ammonianemia as a pathological condition does not exist. [See also Fever.]

ANEMIA.

General Considerations.—F. Taylor⁵ opened a discussion on **anemia** with a general consideration of the causes, varieties, and pathology, devoting particular attention to chlorosis, pernicious anemia, and splenic anemia. He

¹ Zeit. f. klin. Med., Bd. 30, H. 3 and 4.

² Ibid., H. 5 and 6.

³ Centralbl. f. Allg. Path. u. path. Anat., p. 529, 1896.

⁴ Wien. klin. Woch., Apr. 8, 1897.

⁵ Brit. Med. Jour., Sept. 9, 1896.

defined anemia as an abnormal pallor of the tissues due to diminution in the quantity or some defect in the solid constituents of the blood, an essential condition being the diminution in the total quantity of hemoglobin. The diminution in the number of leukocytes is not essential, and he therefore omits this from the definition. Speaking of secondary anemias, he notes that though we recognize the occurrence of anemia after various diseases, we do not know all the links in the chain of causation—for example, between the deposition of tubercle or the growth of cancer and the want of hemoglobin or corpuscles. [The definition of anemia given by the author seems to us too restricted. It is true that distinct changes in number and character of leukocytes indicative of anemia are unknown, but it is altogether likely that changes in these as well as in the plasma are a part of anemia as much as the better known changes in the erythrocytes.]

Diebala¹ contributes an elaborate study on the relations existing between the quantity of **hemoglobin and the specific gravity of the blood in anemia**. The specific gravity was estimated by the benzol-chloroform method; the hemoglobin by Fleischl's instrument. He concludes from these studies that the former is in great measure dependent upon the latter, though it may vary as much as 13.5 parts per thousand, with similar hemoglobin quantity. A difference of 10% in hemoglobin indicates, on an average, a difference of 4.6 per thousand in specific gravity. With equal quantities of hemoglobin the specific gravity of the blood of women is 2 to 2.5 parts lower than the blood of men, both in physiologic and pathologic conditions. The variability in the specific gravity is greater in cases in which there is considerable hemoglobin than in those in which anemia is marked. The specific gravity in nephritis is from 4 to 5 points lower than in other conditions, this being due to hydremia of the plasma. The specific gravity in leukemia is greater than the hemoglobin would indicate, this disproportion being according to the number of leukocytes. In chlorosis the specific gravity is about 2.5 parts higher than in secondary anemias; but this peculiarity of the blood rapidly disappears during regeneration. In cases of pernicious anemia, in which the number of the red corpuscles is decreased greatly in comparison with the quantity of hemoglobin, the specific gravity is generally about 2 parts lower than in the secondary anemias; this peculiarity also disappears during regeneration of the blood. From these facts he concludes that the number of the red corpuscles (their stroma) exercises a positive influence on the specific gravity, so that in spite of equal quantities of hemoglobin there may be a difference due to this factor of 4 to 5 parts per thousand.

Moraczewska² has examined the blood in 34 cases of **chronic disease associated with anemia**. In pernicious anemia she found a marked reduction in alkalinity, and high specific weight, due to the presence of an increased quantity of the mineral salts. The blood contained an excess of nitrogen. In chlorosis there were similar changes, excepting in regard to the red blood-corpuscles. The anemias due to carcinoma showed increased alkalinity, diminished specific weight, and, relatively, a considerable number of red blood-cells that stained faintly.

R. Schmidt³ has observed that in severe chronic anemic conditions the excretion of the alloxur bodies is increased if a large quantity of albumin, poor in nuclein, is added to the nourishment. At the same time there are an increase in the neutral sulphates and a diminution in the earthy phosphates.

² Virchow's Archiv, vol. cxliv., p. 127.

³ Wien. klin. Woch., June 10, 1897.

Mann¹ has given 22 male patients of anemic appearance a dram of extract of bone-marrow, 3 times daily. The average increase of red corpuscles was 1,360,000, and the average increase in hemoglobin 12½%. There was usually a decrease in the number of leukocytes in cases with leukocytosis.

CHLOROSIS.

Etiology.—Taylor² discusses the nature and causation of chlorosis. Referring to certain published cases of chlorosis in males, he states that the mere fact of greater decrease in hemoglobin than in corpuscles does not suffice to constitute true chlorosis. "I must allow, however," he says, "that if there is no distinctive feature in the blood, it is difficult to know what we are to regard as the characteristic of the disease." Among the more likely theories are the mechanical action of the corset, causing ulcerations and hemorrhages from the stomach or by forcing the stomach into an abnormal position, and the supposed extraordinary demand that puberty makes upon the blood-forming organs. He does not venture upon positive conclusions as to these or other supposed causes. [We note that the author's comment upon certain published cases of supposed male chlorosis are the same as our own in reviewing this publication in the *Year-Book* for 1897.]

Biernacki³ discusses the nature of chlorosis, and is led to doubt whether reduction in hemoglobin is an essential element from the fact that considerable alteration in the blood may take place without the malaise experienced by chlorotic patients, and undoubted cases of chlorosis have been reported in which this reduction did not occur. He holds that more important blood-changes are hydremia and the diminution of potassium and of phosphoric acid. C. E. Simon⁴ discusses various problems connected with chlorosis, and has studied its etiology and treatment. He refers to the view of certain observers that visceral descent or **splanchnoptosis** is a factor of importance, and then analyzes a number of cases in which this point was studied. He found that it was associated with anemia in a fairly large proportion of 39 individuals, and this was true, more particularly, of nephroptosis. There was, however, a considerable number in which the amount of hemoglobin was practically normal and yet the descent of the viscera was striking. [The author does not state the method by which he determined the presence of nephroptosis in so large a proportion of the individuals examined.] In a second group of 25 cases he investigated the results of simple gastric atony and anemia, finding that there was no definite relation. He concludes that neither atony nor splanchnoptosis has any part in the causation of chlorosis. [We must, however, call attention to the fact that his method of excluding these factors is not entirely logical; it has not been held for example, even by enthusiasts, that atony or splanchnoptosis invariably causes chlorosis.] The examinations of the stomach-contents and of the urine are interesting. In $\frac{1}{3}$ of his cases the amount of HCl was normal, in $\frac{2}{10}$ excessive, in $\frac{1}{6}$ deficient, and in $\frac{1}{3}$ HCl was absent. Indicanuria beyond the normal was found in a minority of the cases (9 in 31). The author finally concludes that as none of the etiological factors usually referred to is entirely satisfactory, in the great majority of cases chlorosis is essentially a disease of malnutrition; the result of abnormal feeding in early childhood. As a groundwork of this view, he defines chlorosis as an anemic condition or simple anemia in which the percentage of hemoglobin is lower than 70, and the number of corpuscles approximately

¹ Am. Jour. Insan., Jan., 1897.

³ Wien. med. Woch., Feb. 2, 1897.

² Brit. Med. Jour., Sept. 9, 1896.

⁴ Am. Jour. Med. Sci., Apr., 1897.

normal. [This view seems to us to express a great fallacy in the author's work. Nothing is more certain than that chloranemia and chlorosis are independent and separable conditions, and rather than adopt the view of the author that the term chlorosis should be displaced because it refers to but one of the symptoms, we would hold that this term, or a similar one, should be retained for that very reason. There is too great a disposition to diagnose chlorosis from the condition of the blood. Hematologists are united in declaring that this cannot lead to satisfactory results. The blood examination must be considered together with the clinical symptoms.] Next the author refers to the question of treatment, and alludes particularly to cases in which iron does not relieve the condition. He recommends extract of bone-marrow or the marrow itself as a valuable article of diet, and suggests that it may have a specific action as well. Suitable diet is always essential.

Schroth¹ studied 44 cases of chlorosis, and was unable to determine any secretory or motor disturbances of the stomach, and he believes that the occurrence of a certain amount of gastro- or enteroptosis is of no significance. His own view is rather that chlorosis results from reflex nervous impressions, originating in disturbances of the genital organs.

Pathology.—Hayem² presented specimens from a case of chlorosis before the Société méd. des Hôpitaux; the patient died from the effects of sudden emotion while under treatment for chlorosis. She had previously had phlebitis in the left leg. When she came under observation she had the usual signs of chlorosis, with small pulse and strong, irregular action of the heart. There were a thrill at the apex and a bruit sometimes resembling a friction-sound, sometimes a valvular murmur; there was an additional bruit at times, giving the rhythm of *bruit de galop*. Change of position did not moderate the sounds. Postmortem the pulmonary artery was found entirely obstructed by clots, some old and adherent, others more recent and extending from the heart upward. The heart itself was small, and there were numerous papillary cauliflower vegetations in the right ventricle and on the intraventricular septum. Near the infundibulum was a large clot partly adherent, portions of which were encrusted with calcareous deposits and covered by prolongations of the endocardium; the extremity of this clot was also covered with debris of recent formation, like that in the pulmonary artery. He believed that the phlebitis had been accompanied by endocarditis, then by obstruction of the pulmonary artery of a slowly developing form. There was no pulmonary embolism, but the lungs were collapsed, infiltrated, and suffused with blood.

J. O. Affleck,³ in discussing Taylor's review of anemia, alludes to a fatal case of extreme chlorosis in a girl of 17, who died of acute pneumonia, in which postmortem examination was obtained. The aorta was found to be extremely small, and the pathologist compared it to the size of a normal innominate artery. No other details were given.

Talma⁴ discusses the **relations of the conus arteriosus** to chlorosis, and the significance of murmurs heard over the base of the heart. The conus, which in normal conditions contains more blood than the remaining portions of the right ventricle, is, according to his observations, particularly dilated in chlorosis. The distention occurs in a direction upward and to the left, and alters the cardiac dulness so that the upper border on the left side is found in the third, or even in the second or first interspace, in consequence of the displacement of the root of the pulmonary artery. The pulmonary sounds are

¹ Ann. der Stadt. Allg. Krankenhaus. zu München, ii., 3, 1896.

² L'Union méd., No. 12, 1896.

³ Brit. Med. Jour., p. 726, Sept. 19, 1896.

⁴ Berlin. klin. Woch., No. 44, 1896.

heard with greatest intensity pretty far to the left of the sternum. Frequently systolic murmurs are heard over the dilated conus, and the author believes it possible to distinguish whether these are produced in the dilated conus or in the pulmonary artery by the position of greatest intensity. In the latter case the murmur is heard further to the left and above. Finally, he contends that this enlargement of the conus forms a sign of much diagnostic value, occurring most regularly in chlorosis, although it occurs in cases of cardiac weakness due to intoxications and in myocarditis. [This paper seems to us one of considerable importance, and the subject presented is worthy more extensive study.]

Ventrini¹ has studied the **resistive powers of the red blood-cells** in 2 cases of chlorosis and found them diminished. After subcutaneous injection of iron salts, however, he found them considerably increased, and this appeared to be more or less constant. In 2 cases of anemia the iron salts did not appear to have this beneficial effect.

Symptoms.—Gilbert and Garnier² carefully studied the **venous murmur** in a case of chlorosis. They found that it was heard best along the line which corresponds exactly to that of the superior vena cava, and concluded that it arose from disturbance of this vessel. As the murmur was distinctly increased by rotation of the head to the left, they assumed that it was due to pressure which might have been exerted by the sterno-mastoid muscle upon the internal jugular vein or by the clavicle upon the brachiocephalic trunk. This particular venous murmur has not previously been recognized.

Treatment.—Spillmann and Etienne³ have employed *ovarïn* and fresh and dried **ovarian tissue** in the treatment of chlorosis. In 2 of 6 cases they observed marked improvement. The treatment, however, sometimes caused increased rapidity of pulse, elevation of temperature with pain in the abdomen and kidneys, headache, and vague myalgias.

J. L. Corish⁴ reports 3 cases of chlorosis which were treated by **inhalations of oxygen** under pressure, in addition to iron and arsenic. In all improvement occurred. He believes that chlorosis may be due in part to absence of oxygen in the blood-corpuscles without much diminution in the amount of iron.

PERNICIOUS ANEMIA.

Etiology.—Taylor⁵ holds that it is too great a restriction of the term pernicious anemia to apply it only to apparently idiopathic cases. It ought to include, or at any rate we must recognize as very obscure, those cases in which a temporary cause is followed by persistent anemia. For example, continuous loss of blood may be expected to cause severe anemia, but that pregnancy, a course of lactation, or a single hemorrhage should leave behind anemia which persists or progresses long after the complete cessation of the ordinary phenomena of the confessed cause, requires as much explanation as those cases in which the anemia has appeared to be entirely spontaneous. In reviewing the opposing views of Hunter and Stockman, he rather sides with Hunter, and very properly points out that if the symptoms of the disease result, as Stockman states, from innumerable small hemorrhages due to primary disease of the vessel-walls, it remains to be shown by that author what caused this vascular disorder to arise.

J. B. Herrick⁶ discusses the relations of **shock** to pernicious anemia in connection with a report of one of his cases. The patient, a woman of 63, of good

¹ Gaz. med. di Torino, No. 52, 1896.

⁶ Alienist and Neurol., July, 1896.

appearance, and weighing 137 pounds, was an active practitioner of medicine. Her family history was good. She was married and had 5 children. She fell on a sidewalk, hurting her back and left side extensively. After this she became physically and mentally weaker. Soon her legs began to swell, dizziness and faintness developed, pallor was noted, and she was confined to bed a large part of the time. She was suspected of malingering, but this could scarcely be proved. Later physical examination showed signs of pernicious anemia, numerous retinal hemorrhages, cardiac murmurs; the blood was pale, the corpuscles varying greatly in size, a few containing nuclei—most of these being normoblasts. The leukocytes were increased relatively, and there were many lymphocytes. Red corpuscles 666,000; hemoglobin 25%; the temperature varied from 97° to 102°. The patient later passed from observation. In discussing this case the author shows that there was no distinct organic lesion discoverable, and refers to shock as the possible cause. He alludes to the papers of Curtin, Musser, and others, and concludes that shock or injury to the nervous system may have a predisposing causal relation. In the discussion of the paper Musser referred to 2 recent cases under his care in which pernicious anemia was secondary to, if not due to, nervous influence.

Ralph Stockman¹ reports a case of pernicious anemia occurring in a pregnant woman. 2 months prior to delivery she began to grow weak and pale and was greatly troubled with distention of the abdomen. Physical examination of the heart, lungs, and liver was negative, and the blood showed red blood-corpuscles 1,680,000, hemoglobin 24%; subsequently, red blood-corpuscles 920,000, hemoglobin 20%. The patient died. At the autopsy dilatation of the stomach and enormous distention of the ascending and descending colon were observed. The transverse colon and rectum were normal and there was no obstruction. A suspicion had been entertained before death that the case was one of malignant obstruction of the large intestine. There was no excess of iron in the liver or spleen. The patient did not suffer unusual loss of blood at time of labor. [A case under our own care showed a similar relation of **intestinal disease** to pernicious anemia. The patient recovered almost completely, but is now under our care again with even more typical symptoms.]

Ransom,² in discussing his pathologic observations in 18 cases of pernicious anemia, comes to the following among other conclusions: that there is always **hemolysis**, and often evidences of **absorption of the hemolytic poison** from the alimentary canal. In some cases the poison may arise elsewhere, as from the uterus or from other situations in various infections. Increase of iron pigment is usually found in the liver, spleen, and kidneys, but may be absent in any one of these. It may also be found in the lymphoid tissues of the intestines, more especially the colon, where it is in process of excretion. It is probably brought to the organs in a soluble form other than hemoglobin. Hemolysis by itself probably rarely causes pernicious anemia. Insufficient hemogenesis must be superadded. In some cases abnormal hemogenesis is the initial phenomena, the corpuscles being too fragile to resist the normal hemolytic influences of the system. He could find no evidence that multiple small internal hemorrhages could cause pernicious anemia. [These views coincide very accurately in most respects with our own opinion. One of the editors particularly has insisted upon the necessity of assuming that a reduced power of hemogenesis must play an important part in the development of the disease. We cannot, however, agree that there is decided evidence in favor of the view that the hemogenetic deficiency is ever primarily operative.]

² Brit. Med. Jour., Dec., 1896.

Wharton Sinkler and A. A. Eshner¹ report 3 cases of profound anemia occurring **in one family**—the father and 2 daughters—with development of the symptoms of posterior spinal sclerosis and a fatal termination in 1 case. Briefly they were as follows: (Case 1) A salesgirl of 16, presented herself at the clinic with the history that her father had died of locomotor ataxia and pernicious anemia at 45. She had been weak and often ill, but her habits, mode of eating, and daily life accounted for this. She had cardiac palpitation, pain in the chest, numbness and cramps, and frequently staggered in walking. Cough with considerable expectoration was present. She had suffered with chills, flushes, dyspnea, and headaches. Her blood was examined and showed 3,000,000 red corpuscles and 20% of hemoglobin. Under treatment with arsenic and iron she improved and was discharged practically well. A sister (Case 2) presented herself complaining of vertigo, nausea, and weakness when in the erect posture; anorexia, constipation, and shortness of breath. She ascribed these symptoms to grippe, with which she had suffered nearly 2 months earlier. She was anemic in appearance, but no blood-examination is recorded. She improved greatly under arsenic and iron. The father of these 2 patients (Case 3) had been treated at the infirmary previously. He was then 41 years of age; a laborer. His only children were the 2 girls and a brother. His wife had had several miscarriages. He had suffered with great derangement of the digestion for 8 years, vomiting sometimes thrice daily. He had had a sudden attack, like a "giving way" in the back, while wheeling a barrow 4 years previously, and for a time was unable to straighten himself; he seemed to recover perfectly. His subsequent trouble began with a feeling of numbness in the legs and later distinct ataxia developed. The patient was pale, presenting a somewhat muddy tint. His blood-examination showed at first 2,700,000 red blood-corpuscles and from 27 to 35% hemoglobin; later about the same figures; and, finally, 4,475,000 blood-corpuscles with from 60 to 80% hemoglobin. Subsequently it again declined, and there was poikilocytosis with irregularity in size, but no nucleated red corpuscles. He was in bed for the anemia, but recovered and returned to work. He then had a relapse, and finally died in the second attack. The case is of interest, as being one of somewhat irregular ataxia associated with anemia. The authors are disposed to rank it as a case of ataxia secondary to anemia. The cord has not yet been studied. [The exact nature of these cases is uncertain.]

Pathology.—R. F. Ruttan and J. G. Adams² have studied the composition of the **blood-serum** in a case of **pernicious anemia**. The blood was obtained postmortem from the distended right heart 5 hours after death. As the temperature of the room was near zero, it may be assumed that but little change took place. The case was typical, and gastric lesions were discovered postmortem (gastritis polyposa). The serum was clear, almost colorless, and had a sp. gr. of 1026. It contained only 5.2% of proteids by weight. Of these, 2.3% was globulins precipitated by saturation with magnesium sulfate and 2.9% was serumalbumin. There was 0.875% of ash. The total proteid was about 40% below the average normal quantity. The normal ratio of globulin and serumalbumin was considerably altered, while the amount of ash was about 12 times the normal. Analysis of the liver for iron showed 0.2433% by weight calculated for the fresh, undried tissue and 0.72% in the dried tissue. These represent a great increase.

Venous Disturbances.—Petren³ records 9 cases of pernicious anemia in which the **spinal cord was found more or less diseased**. Two

¹ Am. Jour. Med. Sci., Sept., 1896.

² Brit. Med. Jour., Dec. 12, 1896.

³ Nord. Med. Arkiv, No. 7, 1896.

showed spinal symptoms during life. In the first, disturbances of sensibility, paresis, ataxia, loss of knee-jerk, and finally incontinence of urine developed. Anemia had existed 6 months and spinal symptoms for 2 months. The spinal cord showed degenerations of the posterior columns and swelling of the glia-cells, but never of the axis-cylinders. These changes were found in all parts of the cord except the dorsal region. In the second case the patient was attacked with paresis of the legs 3 years before death and 25 years after a specific infection, which, however, had never given rise to any symptoms. Two days before his death he was examined and the characteristics of severe pernicious anemia with paraplegia were discovered. There was complete degeneration of the column of Goll and moderate degeneration of those of Burdach that did not reach the lower half of the lumbar cord. The author does not deny the probably syphilitic nature of this case. Taking the entire 9 cases, it may be noted that hyaline degeneration of the blood-vessels in the white matter of the cord was found in 4, while small hemorrhages or focal sclerosis secondary to hemorrhages were found scattered throughout the cord in the other 5.

R. C. Cabot¹ contributes a careful study of 50 cases of pernicious anemia. Of these, 8 came to autopsy and the others were recognized by the clinical features. He defines pernicious anemia as a profound and almost invariably fatal anemia without adequate known cause, characterized by an extreme diminution in the number of red blood-cells and usually by other changes in the blood as well as by the absence of emaciation and a tendency to spontaneous temporary improvement followed by relapse. In regard to the etiology, 3 of the 17 female patients dated their symptoms from the time of the menopause. Atrophy of the gastric tubules was not found in any of the autopsies. Hemorrhage occurred in 17 cases; in 12 after symptoms of profound anemia; and in 5 before that time. Symptoms affecting the nervous system especially were found in 20 cases; paresthesia of the extremities in 2; numbness in 8, of which 5 also showed motor weakness and pain or tenderness along the nerves; the knee-jerks were absent in 4, and in 1 of these there were shooting-pains; 1 case had blurred sight and marked constipation; 1 case had atrophy, weakness, and numbness of the left arm and leg, and tremor of the left hand was noted; in another, a spastic gait with increased reflexes and clonus; 2 cases had total paralysis of all the extremities and loss of control of the sphincters toward the end of the disease. Aphasia was found in 2, 1 of which had suffered sudden coma sometime previously. Sudden inability to swallow, with paresis of the arm and leg on one side and drawing of the veins on the opposite side, occurred in 1 case. Regarding the urine, the author notes that the sp. gr. was low, averaging 1015, and the color high in but 3 of the cases. The red blood-corpuscles are usually about 1,000,000. Partial improvements are frequent, and in these the corpuscles increase somewhat, but not as much as the symptoms would indicate. The white corpuscles are usually diminished or normal in number, and the hemoglobin was apparently higher than the corpuscles in 13 cases, and lower than the corpuscles in the rest, as in secondary anemias. The last point, however, the author regards as of little value, as an estimation of hemoglobin by Fleischl's apparatus is inaccurate. Regarding the red corpuscles, he lays particular stress upon the occurrence of large megaloblasts as well as upon various other forms of large cells which he distinguishes from normoblasts. Altogether he recognizes 9 types of nucleated red corpuscles. The differential count of the leukocytes shows the lymphocytes relatively in excess, and the almost invariable presence of a small percentage of myelocytes. [We are surprised at the proportion of cases in which marked nervous symptoms occurred.

¹ Boston M. and S. Jour., July 30, 1896.

It would have been interesting to know to what extent arsenic (used in the treatment) could be regarded as having caused these symptoms. Some of them could easily have been so caused. The discussion of the blood-condition is thorough, but we cannot admit the advisability of distinguishing a large number of forms of nucleated corpuscles. The matter of morphology is already overdone by many writers.]

Colquhoun¹ describes a case of pernicious anemia in which **spinal symptoms** were observed. At first there were loss of knee-jerks, pain in the muscles of the calf, and loss of coordination. The author regarded these symptoms as due to arsenical neuritis, but subsequently the reflexes became much exaggerated and another explanation seemed necessary. The condition resembled that seen in mixed sclerosis (posterior and lateral) of the cord, and though arsenic may be the cause of these lesions, the author notes that he has frequently given large and continuous doses without such results.

Teichmüller² reports a case of pernicious anemia with nervous symptoms—paresthesia and increased knee-jerk. The patient had arteriosclerosis and evidence of chronic enteritis. Postmortem small hemorrhages were found in the corpora quadrigemina and in the corpora striata. Microscopic examination discovered changes in the posterior columns of the cord, as well as hemorrhages in the gray and white matter, with degeneration in the anterior lateral column of the cord. The author regards the changes in the gray matter as the most important.

Treatment.—Delmis³ states that the **pernicious anemia of pregnancy** differs from ordinary anemia only by the greater intensity of the symptoms. Treatment with iodid of iron is generally successful, even in severe cases. He gives from 1 to 2 tablespoonfuls of a syrup of iodid of iron with each meal and increases in the later stages. The food should be nutritious. If the treatment is begun early, especially in primiparæ, as soon as symptoms develop, the severer grades may be prevented. Even in multiparæ, who had previously suffered with anemia, the subsequent pregnancy was freed from any complications by this treatment.

H. A. Hare,⁴ in describing a series of cases of leukemia and pernicious anemia, details 1 in which the patient improved markedly under the use of **arsenic and iron sulfate**, the red corpuscles increasing from 886,000 to 4,360,000 during one period of the treatment. The last-named figure was found at the last visit, and the author regards the case as cured. The patient had previously improved greatly several times and subsequently relapsed, but the amelioration after the last attack was more prolonged. [Although it seems scarcely proper to speak of the case as one of cured pernicious anemia, the improvement in the blood is certainly remarkable.]

J. M. Clarke⁵ reports a case of anemia with a blood-count of 810,000 and hemoglobin 31%. Arsenic having failed to give any beneficial effect, transfusion of blood in solution of phosphate of sodium was employed. Several days later this was followed by hematuria, which recurred again after a second transfusion. **Inhalations of oxygen** had been systematically employed from the beginning. At the autopsy the lesions of pernicious anemia were found. Three cases of profound anemia are also reported in which oxygen inhalations were employed, apparently with great benefit, all the patients making a good recovery.

LEUKEMIA.

Etiology.—Bonvicini¹ found that the organs of a dog that had died of leukemia contained a diplococcus that, when inoculated into dogs, produced swelling of the lymphatic glands, and when injected into mice, guinea-pigs, and cats produced typical leukemia. [Similar reports have been made before, but the matter is by no means so easily determined.]

Pathology.—C. F. Martin and G. H. Matthewson² discuss the relation between **leukemia and pseudoleukemia**, and contend that these diseases are closely allied and often not to be distinguished readily by the conditions of the blood. They refer particularly to a case in which there were purpuric spots, and hemorrhages from the stomach, gums, and intestines in a patient who had previously suffered with malaise, enlargement of the spleen, and some fever; the leukocytes were increased (1 to 10), and chiefly of the mononuclear variety. Within a week the patient died, having developed nodules in the skin, high fever, and great weakness. Shortly before death mononuclear leukocytosis was more marked, and a diagnosis of leukemia was made. The necropsy showed primary sarcoma of the cervix uteri and secondary nodules. In a second case, admitted for hemorrhage from the stomach and purpuric spots, the disease ran a rapid course of 2 weeks, terminating fatally. The ratio of white to red cells was 1 to 21, the leukocytes being chiefly lymphocytes. From the knowledge of the last case and from the published records of Fagge, they made a diagnosis of sarcomatosis, and the autopsy revealed such lesions. In another patient, a girl of 11, admitted to the hospital on account of marked hematemesis, there were great anemia, enlargement of the spleen, and the ratio of white cells to red probably "between that usually seen in leukemia and in leukocytosis." After a few days the patient died, and presented the typical lesions of leukemia or Hodgkin's disease. They conclude, therefore, that an enormous increase of white cells is not in itself diagnostic of leukemia. They then study the nature of the leukocytosis that occurs in leukemia, and develop the fact that in Hodgkin's disease there may be considerable leukocytosis and that small mononuclear elements are prone to be numerous. They finally report a case of lymphatic leukemia illustrative of the difficulties of distinguishing the diseases. In this case the leukocytes at first numbered only about 24,000 per c.mm.; subsequently they increased to 60,000; and fluctuations were noted ranging between the last figure and 17,000. The authors state that myelocytes were not present. A point of interest in this case was the fact that the patient had suffered an injury to the mouth with inflammation and swelling, and the general disease followed this condition. [All writers in recent years agree that no sharp dividing-line may be drawn between leukemia and Hodgkin's disease, and it is a matter of regret that so frequently irrelevant statements are incorporated in the discussions, and badly observed cases are ranged by the side of those carefully worked out. We note, for example, in the present author's paper allusion to cases of Litten and others in which the transformation of pernicious anemia into leukemia was said to be observed. The occurrence of terminal leukocytosis in pernicious anemia and other severe anemias is now so well known that such cases (observed many years since) ought not to be included among others well studied as instancing transformations of one disease into another. Thus, too many of the cases of supposed transformation of Hodgkin's disease into leukemia are probably of the same sort, but there are other instances in which actual and positive transformation has occurred. Some authors state positively that cer-

¹ Bologna, 1896.

² Brit. Med. Jour., Dec. 5 and 12, 1896.

tain cases were instances of diffuse sarcoma, though previously regarded as leukemia, ignoring the great difficulty and the practical impossibility in some cases of distinguishing the lesion of leukemia from lymphosarcoma. We agree with the conclusions of the authors that there is no line of demarcation between these diseases, and we hold them to be similar or identical in their pathology; but we cannot agree that there is very frequently difficulty in establishing a diagnosis of the clinical picture of the one or the other disorder.]

Benda¹ examined 7 cases of **acute leukemia** postmortem, and found hemorrhages into the organs and swelling of the lymph-glands. The spleen was neither as large nor as soft as in acute infectious diseases. The blood invariably showed great increase in the mononuclear elements. The cause of the hemorrhage appears to be a disease of the walls of the veins.

Vanderwey² has studied **metabolism** in 2 cases of leukemia. In the first, which was examined at 4 different periods, there was always abnormal tissue-destruction, despite the fact that the diet was satisfactory. In the 2d case, during 7 days, the nitrogenous balance was maintained despite the existence of fever. In the 1st case the amount of tissue-destruction seemed in a measure parallel with the elevation of the temperature; still this rule was not absolute. There was a constant excess of uric acid in the urine, the greatest quantities occurring at the acme of the febrile paroxysm; and, although no constant relation could be made out between the amount of uric acid and the amount of nitrogen excreted, still both of these increased at the same times, and this increase was accompanied by increase in the quantity of urine. In this respect he substantiates the results of Jacob and Salkowski.

Symptoms.—R. J. M. Buchannan³ reports 6 cases of leukemia and recognizes 2 divisions of the disease: (*a*) characterized by predominating increase of small unimuclear lymphocytes of gradually increasing size and accretion of basophile granulations; (*b*) splenomyelogenous, with large unimucleated myelocytes and atypical oxyphile and basophile cells, and, as a special feature, no increase of lymphocytes. Mixed forms occur probably in all cases. So long as the abnormal elements are found in the blood, no matter if the number of leukocytes returns to normal under treatment, a relapse invariably occurs. The primary factor giving rise to one or other form of the disease still remains unknown, but the peculiarities shown by the persistent multiplication of a certain class of cell strongly favor the idea that the result is a proliferation of cellular elements analogous to the growth of certain tumors.

Von Hayek⁴ reports a case of leukemia that was under observation for 3½ months. During the whole period there was a **daily rise of temperature** followed by a gradual fall. The highest point was usually reached late in the afternoon, and was frequently accompanied by chill. Night-sweats were almost constant. The proportion of leukocytes to red blood-corpuseles was about 1 to 5, the leukocytosis being less in the morning and greater in the afternoon. The differential count was, polynuclear, 29%; transitional, 21%; large mononuclear, 42%; myelocytes, 1%; and lymphocytes, 7%; 3% of the cells showed eosinophile granulations. There was no ground for suspecting the presence of malaria, tuberculosis, or a local focus of suppuration. At the autopsy a diagnosis of uncomplicated leukemia was fully sustained.

Sharon and Gratia⁵ report a case of **splenic leukemia** occurring in a

¹ Centralb. f. innere Med., June 26, 1897.

² Deutsch. Arch. f. klin. Med., vol. lvii., H. 3 and 4.

³ Jour. Path., Bd. 4, No. 2.

⁴ Wien. klin. Woch., May 20, 1897.

⁵ Bull. de la Soc. roy. des Sci. med. et nat. de Bruxelles, No. 7, 1896.

girl of 8 years, who had been under observation with an abdominal tumor for 6 years. The child was brought for operation, but examination showed that enlargement was due to a hypertrophied spleen. The liver was also increased in size. The subcutaneous veins were dilated, but there was no marked ascites. The blood showed 1 white to 5 red corpuscles. Subsequently it became worse, and death took place with symptoms of dyspnea.

J. Craig¹ describes a case of **lymphatic leukemia**. The patient, a lad of 19, died after an illness of about 2 months. There were universal enlargement of the lymphatic glands, bleeding from the nose, persistent diarrhea, severe pain in the stomach, priapism, and marked increase in the number of white blood-corpuscles, the small lymphocytes being especially increased. The autopsy showed great involvement of the lymphatic glands in all parts of the body, and also some enlargement of the spleen and liver. The condition of the bone-marrow was not noted.

H. A. Hare² reports a number of cases of diseases of the blood, including one which he describes as "lymphatic leukemia or lymphatic anemia." The patient, a barber aged 24, was a man of good habits, who had been well until 7 years previous, when he had an attack of grip that confined him to bed for 4 weeks, during which he was sometimes delirious. He had a severe attack of double pneumonia 2 or 3 years before, and later in the same year fell down a declivity and suffered considerable injury to the head and neck. The next year he first came under observation, complaining that some time previously he had felt a severe pain beneath the clavicle. This persisted for 3 days and then descended to the left hypochondriac region. Profuse sweating with rapid pulse and moderate fever was noted, and he states that he was unconscious for 3 days. He began to lose weight and remained in bed for a month. He then began to improve, but the pain continued and there was a feeling of weight in the left side. On admission to the hospital he was noticeably pale, and the temperature was 102.4°. A large spleen occupied the left side of the abdomen. There were retinal hemorrhages and subsequently hematuria. Anemic murmurs were heard in the neck. Examinations of the blood at various times showed from 1,000,000 to 2,800,000 red corpuscles, and from 14 to 48% hemoglobin. The leukocytes varied from 4000 to 9000, and the differential count showed 84% of lymphocytes, 4% of mononuclear cells, 8% of polymorphous cells, and 3% of eosinophiles. The author states that the large proportion of the lymphocytes would apparently place it under the head of lymphatic leukemia, though there was an entire absence of enlargement of the lymphatic glands and no leukocytosis. [The excessive number of lymphocytes in this case cannot be given the importance the author attributes to it. Lymphocytosis is a condition so frequently observed in various diseases or abnormal states, particularly in cachectic or anemic persons, that its significance is doubtful. The case cannot, by any possibility, be spoken of as leukemia from the facts presented in the paper. The further progress of the case might however justify the diagnosis.]

Fränkel³ states that as the **hemorrhagic diathesis** is one of the characteristics of **acute leukemia**, the latter is frequently mistaken for purpura hemorrhagica when the blood-examination is not carefully made. The condition of the blood is characteristic. There is an increase exclusively in the mononuclear leukocytes with the absence of Ehrlich's neutrophile granulations; it can, therefore, be spoken of as an acute lymphocytomia. He reports a case with peripheral facial paralysis following leukemic neuritis. The proportion of white

¹ Dublin Jour. Med. Sci., Sept. 1, 1897.

² Med. News, Mar. 27, 1897.

³ Centralbl. f. innere Med., June 26, 1897.

to red cells was 1 to 94. Magnus Levy investigated the urine and found that 12 gm. of uric acid were excreted per day.

Complications.—Ebstein¹ describes a case of leukemia in a woman of 76, with hoarseness and cough. Later, symptoms of laryngeal obstruction developed and tracheotomy was required. The cause of the obstruction was found during life to be infiltration of the epiglottis on its laryngeal surface, of the false cords, and of the mucous membrane below the cords. The color of the mucous membrane was a pale grayish-red. The absence of any sign of ulceration and the general condition of the patient led to the diagnosis of leukemic infiltration, and this was confirmed by the histological examination post-mortem. The epithelium was healthy, but immediately beneath it there was an irregular cellular infiltration containing a large proportion of eosinophilic cells. It is of some interest to note that Chareot-Leyden crystals were found in the glands in the mucous membrane.

Mager² describes a case in which a diagnosis of leukemic **infiltration of the larynx** was made by Schrötter. The patient, a man of 58, presented the leukemic characters of blood, the ratio of white to red corpuscles being 1 to 4. At first the larynx showed only signs of acute catarrh, but 3 weeks later there were diffuse redness and infiltration, especially over the right arytenoid cartilage. After a few days there was irregular elevation of the posterior surface of the right arytenoid cartilage and a nodule on the middle of the arypiglottic fold. Tracheotomy was performed on account of dyspnea, but death occurred 8 days later. At the autopsy there was found perichondritis of the arytenoid cartilage in addition to the leukemic infiltration. The periosteum in the right half of the larynx was evidently partly infiltrated by the leukemic and partly by a simple inflammatory process. In the left half the infiltration was purely leukemic.

Marischler³ reports a case of leukemia occurring in a man 61 years of age. Upon admission to the hospital the erythrocytes were 3,450,000, the leukocytes 96,000, the hemoglobin 50%. The differential count of the leukocytes showed 82% mononuclear and only 15% polynuclear forms. The lymph-glands were everywhere considerably enlarged and the spleen extended 3 fingers' breadth below the border of the ribs. The course of the disease was not unusual. At one period hematuria occurred, and some 2 months after admission a tumor could be detected beneath the edge of the liver. Some time later a fragment of tissue was passed in the urine that was diagnosed as coming from a neoplasm. During the latter period there was considerable change in the character of the leukocytes: they became progressively less numerous till, toward the end, they sank to 72,000. The polynuclear forms increased rapidly, the myelocytes of Ehrlich appeared, and the mononuclear forms diminished. At the last differential count the mononuclear were 40%, the polynuclear 57%, and the myelocytes 0.16%. At the autopsy a perithelioma carcinomatodes supraglandulare was found in the right kidney, with extension into the ureter. Neither the lymph-glands nor the spleen showed any traces of malignant new growth, but only typical changes of leukemic infiltration. Hitherto but 2 cases of the **coexistence of carcinoma and leukemia** have been described, in neither of which are there any definite statements as to the influence of malignant growth upon the course of the disease. It has, however, been observed in cases of leukemia complicated by various septic processes that considerable improvement, at least in the leukocytosis, occurs as the infection develops. Marischler is inclined to believe that

¹ Wien. klin. Woch., No. 22, 1896.

² *Ibid.*, No. 26, 1896.

³ *Ibid.*, July 23, 1896.

in the present case improvement took place, but was manifested more by a change in the character of the leukocytes than by any great diminution in their number. [From the description of the tumor, and the fact that it extended without giving rise to metastasis, we are inclined to regard it as an endothelioma, a form of neoplasm that is not especially malignant nor apt to give rise to general symptoms.]

Thorsch¹ discusses the **effect of acute infectious diseases** upon leukemia. A patient under treatment for liemolymphatic leukemia died in consequence of an intercurrent migratory croupous pneumonia. There was at first a rapid decrease in size of the lymphatic glands, the spleen, and the liver, and a striking decline in the number of leukocytes. These had been steadily increasing in number before the pneumonia began, but rapidly sank to 43,500 afterward. When it was fully developed, however, the number of leukocytes again increased and by the time the fatal termination occurred had become greater than originally.

SPLENIC ANEMIA.

Taylor² holds that splenic anemia, as described by Banti and Bruhl, is a distinct disease. He refers to the case of a little girl who began to be ill at 9 years of age, and came under his observation at 13. There was paroxysmal pain in the left side recurring at intervals. A swelling was noticed in the left side of the abdomen, and a year later she began to grow pale. There were no hemorrhages, but when first seen she was thin and very anemic, and the spleen extended almost to the iliac crest. The red corpuscles numbered 2,700,000, but there was no leukocytosis, no malarial plasmodia could be found, and there were no retinal hemorrhages. Hemoglobin was greatly diminished. Treatment was unavailing; at one time there were indications of a splenic infarct—tenderness, pain, and palpable and audible friction. She died 3 months later. The author excludes amyloid disease and tumors. He points out that, pathologically, the chief change is in the spleen, which is greatly enlarged and presents sclerotic or fibroid change with atrophy of the Malpighian bodies and considerable thickening of the trabecule; changes that differ from those observed in the splenic form of Hodgkin's disease. Finally, he cites without particular comment a case of Dr. Coupland, in which a diagnosis was made and the spleen removed. Death occurred some years later, and at the autopsy extensive syphilitic disease of the liver was found. This case he includes by way of illustrating certain pitfalls in the diagnosis. [The paper merely expresses a personal view without any attempt at its elaborate defence. For ourselves we see no reason as yet to admit the existence of a distinct disease—splenic anemia. The cases are, many of them, instances of secondary anemia with splenic enlargement, and some no doubt have been cases of splenic Hodgkin's disease.]

Terrile³ discusses a case of **idiopathic enlargement of the spleen**. The organ extended from the fifth rib to the iliac fossa. The patient was cachectic in a high grade, but presented no other symptoms, excepting a moderate enlargement of the liver and a soft blowing murmur at the apex, and the reduction of the red blood-corpuscles, which was very striking and suggested pernicious anemia. There was no etiological factor to account for the condition. There was no leukemia, swelling of the glands, pseudoleukemia, nor cirrhosis of the liver. The condition persisted for several years. He holds that cases

¹ Wien. klin. Woch., No. 20, 1896.

² Brit. Med. Jour., Sept. 9, 1896.

³ Gaz. degli Osped. e delle Clin., No. 86, 1896.

of this kind are not rare, and that they lead to cachexia by the formation of a distinct toxic principle. The best treatment is operative interference. [We cannot agree with the author in so readily excluding pseudoleukemia, though the limitations of this disease remain to be established. The anemia and distinct disease of the spleen in this case would warrant its classification as one of splenic Hodgkin's disease, as far as we are able to classify such cases. This course would at least seem to be more justifiable than to consider the case as one of a special and obscure disease.]

PSEUDOLEUKEMIA.

Pathology.—Dietrich¹ discusses the uncertainty regarding the nature of pseudoleukemia and its relation to tuberculosis, and concludes that combinations of malignant lymphoma and ganglionic tuberculosis exist, and that there are cases in which a differential diagnosis is almost impossible. Necrosis of the gland is not of itself sufficient indication of tuberculous infection, but the presence of numerous eosinophile cells is more significant. (See also *Leukemia*.)

Jolles² has examined the urine from a case of pseudoleukemia and was able to determine the presence of **nucleohiston**, which he was convinced is identical with the albuminous bodies that are precipitable by acetic acid.

G. D. Robins and J. F. Argue³ record a case of "**so-called acute Hodgkin's disease.**" The history was as follows: a young man of 19 was well until July 1, when he noticed great weakness after his work, headache, giddiness, anorexia, pallor, slight bleeding from the gums, and a vesiculopustular eruption on the skin of the hands and face. July 15, he first noticed swelling under the jaw which grew rapidly worse; mental stupor increased, and on August 3 there was marked epistaxis. He was admitted to the hospital and found to be dull and apathetic, with slight edema of the lower extremities and pronounced pemphigus of the hands and face. The left leg showed signs of old infantile palsy. All the lymph-glands of the neck, occipital region, axilla, epitrochlear region, and groin were distinctly enlarged, movable, and slightly tender. The skin over the glands nowhere showed signs of inflammation. The temperature was $102\frac{2}{3}^{\circ}$ and the pulse and respirations rapid. The spleen was distinctly palpable below the ribs, but not greatly enlarged. The liver was not palpable. The blood showed 3,160,000 red corpuscles, 8000 white corpuscles, and 42% of hemoglobin. The retina was edematous and a few hemorrhages were found in the outer granular layer. Subsequently the temperature declined to normal, but immediately rose again and continued intermittent. At the same time the leukocytes increased to 66,600 per c.mm., the red cells at this time numbering 2,000,000. Stained specimens showed the leukocytes to be mainly lymphocytic. There was again a decline in the number, until the day before death the leukocytes were 14,000. The authors state that at no time during the leukocytosis was the uric acid increased in the urine, but a distinct increase occurred in the week following the subsidence of the leukocytosis. This opinion seems to be based upon the character of the urinary sediment, and is therefore of no value. [The authors refer to the similarity of this case to one recorded in Ebstein's monograph. We would point out, however, that they ignore the possible significance of the pemphigoid disease. There was here undoubtedly a form of infection in which glandular enlargement may occur. We are far from ready to accept the diagnosis "acute Hodgkin's disease" so frequently proposed, and furthermore agree with the

¹ Beiträge z. klin. Chir., vol. xvi., p. 377.

² Wien. klin. Woch., May 29, 1897.

³ Montreal Med. Jour., Oct., 1896.

authors in deprecating hasty changes of diagnosis from leukemia to Hodgkin's disease according as the number of leukocytes suffers temporary increase or decrease. We should, therefore, look upon this case as one of obscure infection with skin-eruption and glandular enlargement, and regret that accurate bacteriologic examinations of the blood were not undertaken.]

Revilliod¹ reports an interesting case of obscure **abdominal tumor**. The patient, a man of 38 and strongly built, entered the hospital on account of rheumatic pains. A tumor was found in the left hypochondrium and epigastrium, reaching to the umbilicus. This was hard, uneven, and did not move with the respirations. The liver was somewhat enlarged. The examination of blood showed 4,000,000 red corpuscles, 9000 leukocytes, and 60% of hemoglobin. The urine contained no sugar. A left-sided pleurisy occurred and 3000 c.c. of opaque, reddish liquid were withdrawn. The patient died, and at the autopsy a tumor weighing 11 lbs. was found. This consisted of a conglomeration of enlarged lymphatic glands, in the center of which was a hyperplastic spleen. The mesentery was studded with enlarged glands and the thoracic duct was surrounded by them. [There was no disease of the other organs. The nature of this case is very doubtful. It does not seem to have been one of Hodgkin's disease, but may be considered in connection with that affection.]

Stein² reports a case of splenic and glandular enlargement without leukocytosis. A diagnosis of pseudoleukemia was made, but the patient failed to improve under arsenic or after extirpation of the spleen. Syphilis was then suspected and rapid recovery ensued under mixed treatment.

THE HEMORRHAGIC DISEASES.

J. N. Matthews³ records a case of **purpura hæmorrhagica** presenting certain interesting features. The patient, a girl of 13, was extremely pale with tense pulse and rapid respirations. Several purpuric spots appeared on the legs and arms. Her temperature was 101°. Later there was severe epistaxis, blood appeared in the urine and in the bowel-movements, spots were found on the gums and in one of the nostrils, and there were retinal hemorrhages. Successive crops of spots appeared, these being flat or raised and indurated, and a few being elevated in the centre and having a ring of purpuric discoloration around them. Five days later the tongue was thickly coated, and the patient was attacked with hæmatemesis. Eight days after she was first seen the symptoms were those of typhoid fever, and she continued under treatment for this at the time of the report, about a month after she first came under observation. [This case presents features of a case of typhoid fever beginning with hemorrhagic manifestations. It is, however, one of unusual character.]

W. Steer⁴ records a case of purpura of some interest. The patient, a lad of 14, had always been healthy; the present attack began with the eruption of a number of small purple spots on the front of his legs. Three days later the rash appeared on his wrists, his elbows and knees became tender, and he had muscular pains. Blood appeared in the bowel-movements, and vomiting of greenish liquid was observed. No cause could be discovered for the illness. On admission the symptoms were about the same, but in addition the purpuric spots were found on the mucous membranes. The gums were healthy in appearance. There was some tenderness of the abdomen, especially near the stomach and spleen. He improved, but twice after slight relaxations in diet

¹ Rev. Méd. de la Suisse romaine, No. 9, 1896.

² Wien. klin. Woch., June 5, 1897.

³ Brit. Med. Jour., Sept., 1896.

⁴ Ibid., Sept. 26, 1896.

relapses with moderate fever occurred. The usual drugs administered in purpura were without effect, but iodoform in pills of 1 gr. each given 3 times daily seemed to be beneficial. The boy made a good recovery.

E. Apert¹ believes that the eruption of purpura is due to 3 conditions: lesions of the arteries, influence of the nervous system, and the action of microbes. He describes the various lesions that are associated with purpura in the internal organs, and finally divides the disease into 4 groups: exanthematic (or rheumatoid) purpura, infectious purpura, Werlhoff's disease, and secondary purpura.

J. Clifford Perry² reports a case of **hemophilia** in a man of 20 who was incised for alveolar abscess. The incision was only $\frac{1}{8}$ of an inch long through the mucous membrane. The bleeding was profuse and continued in spite of styptics and pressure. It was then learned that the patient was one of a family of bleeders, two brothers having died from hemorrhage in infancy from very trivial injuries. He himself had on several occasions bled until he fainted. When this history was obtained the patient was given chlorid of calcium in doses of 1.3 gm., and in a few hours the effect was said to be marvellous. The blood, which had shown no signs of clotting, began to form a firm clot and the hemorrhage was completely arrested. The remedy was continued for 3 days. [While it seems likely that the remedy was of use in this case, it must be remembered that after loss of large quantities of blood the coagulability is normally much increased.]

Hutschneker³ reports 4 cases of hemophilia, being all the male children of a family of 7. There was no history of hemophilia in the ancestors.

ADDISON'S DISEASE.

Pathology.—Rispa⁴ observed a case of Addison's disease in a man of 24 that lasted about 10 months. At the autopsy no tuberculous lesions were found. The suprarenal capsules were absent. There was no lesion of the abdominal sympathetic ganglia.

B. Bramwell⁵ reports 3 cases of Addison's disease. The 1st, a man of 50, suffered with weakness and emaciation after an attack of influenza he had had 3 months before. He suffered with extreme debility and cardiac asthenia, and with marked and rapid emaciation. His face, neck, and the backs of his hands were darker than normal, but no darker than might be expected from the exposure to which the man had been subjected. There was a distinct pigmented patch on the inner side of the left cheek. At the autopsy there was found extensive tuberculosis of the peritoneum, the membrane was studded with recent miliary tubercles, and the suprarenal capsules were decidedly enlarged and extensively diseased, being typical examples of fibrocaseous change. In connection with this case the author refers to certain of the more important symptoms of the disease; among others, to extreme asthenia, to the pigmented patches on the mucous membrane of the mouth, and emaciation. He notes that a few cases have been reported in which pigmentation identical with that of Addison's disease was found in other conditions, always, as far as he knows, cases of phthisis or tuberculous diseases. He notes that some authorities have held that emaciation is a point against the diagnosis of Addison's disease, but to maintain his own view he quotes the 2d case of his series, which occurred in a man of 36, who had progressive weakness during 6

¹ Gaz. hebdom. de Méd. et Chir., May 23, 1897. ² Jour. Am. Med. Assoc., Mar. 13, 1897.

³ Wien. med. Woch., May 1, 1897. ⁴ Sem. méd., 343, 1896.

⁵ Brit. Med. Jour., 2 and 9, 1897.

months. There was distinct anemia, and the corpuscles numbered 3,500,000. They were normally shaped and formed rouleaux in the ordinary manner; there was no leukocytosis. The patient had lost 45 pounds in weight. The only pigmentation visible was found over the spines of some of the dorsal vertebrae. There was a brown discoloration on the inner side of the left cheek. Postmortem the only lesion found was a simple cirrhosis and atrophy of the suprarenal bodies. The 3d case was a man of 37, whose illness was said to have commenced 2 years before, following an attack of influenza. He was extremely weak but not much emaciated. He was much pitted by smallpox, which he had had 30 years before. The skin of the face was dark yellow and the smallpox pits were much more deeply pigmented than other parts—in places they were almost black. There were numerous pigmented patches on the lower lip and on the buccal mucous membrane. The examination of the blood showed 5,600,000 red corpuscles, 85% hemoglobin, and no leukocytosis. The patient passed from observation and subsequently died. The organs were removed by the physician in charge and sent to the author. Above the kidneys were found masses of fat, and in the center of that over the left kidney was seen a brownish streak, suggesting the outline of the suprarenal capsule. Microscopically no evidence could be found of suprarenal structure, and the physician who made the autopsy stated that he was certain the glands had not been left in place. [It seems to us rather questionable to regard the suprarenal capsules in this case absent or completely degenerated upon the evidence offered.] Finally, the author, in discussing the diagnosis and the nature of the disease, states that 3 factors are necessary to establish its presence: (1) the occurrence of characteristic weakness, vomiting, abdominal pain, etc.; (2) pigmentation of the skin and mucous membranes; (3) the absence of any local disease other than the lesions of the suprarenal capsules. He is inclined to favor the glandular theory of the disease, holding that disturbed secretion or function of the gland accounts for its presence. Regarding the treatment, the beneficial effect reported in his last case after the administration of suprarenal extract is noteworthy.

J. S. Berry¹ reports a case of Addison's disease that occurred in a girl of 13. As an infant she had suffered from rickets and diarrhea and had always been very delicate; 2 years before admission it was noticed that her skin was becoming darker; this, however, disappeared. A year later she suffered from symptoms of gastric disturbance, and in a short time the pigmentation reappeared and progressed until all parts of the surface of the body were of a brownish color. Upon admission there were obstinate vomiting, emaciation, and great weakness. In spite of energetic treatment with suprarenal bodies, she grew rapidly worse and died. Tuberculosis of both suprarenal bodies was found at the autopsy.

Treatment.—Savenu² reports 2 cases of Addison's disease, the first of which was remarkable for the extensive distribution of the pigment; in the second, which had occurred late in life, the pigment was not so well developed. Both showed great improvement without treatment when placed under favorable hygienic conditions.

Milham³ reports a case of Addison's disease in which there occurred an abundant papular eruption associated with intense pruritus. Extract of suprarenal capsules produced considerable improvement.

Cervellini⁴ reports a case of Addison's disease occurring in a young peasant about 22, complicated with tuberculosis of the testicle. The extirpation of this

¹ Lancet, June 19, 1897.

² Ital. de clin. Med., Punt 1, 1896.

⁴ Riforma Med., No. 154, 1896.

organ and an exploratory incision into the abdomen, together with iodid of potassium and a strict albuminous diet, led apparently to a complete cure. The author suggests laparotomy in future cases of Addison's disease. [The case is of interest, although the diagnosis must remain to a certain extent doubtful.]

DISEASES OF THE PERICARDIUM.

W. Ewart¹ ascribes the **dorsal area of dullness** occurring in pericardial effusion to some condition diminishing the normal resonance over the region of the liver. As it is normally present in childhood and abnormally present in some wasted adults, it cannot be due to the effusion.

Perez² describes a new auscultatory sign which he discovered in a patient subject to attacks of mediastino-pericarditis. When the patient raised either arm from his side to a vertical position over the head, or lowered it again from that position, most remarkable sounds were audible over the whole length of the sternum. As these were independent of any friction-sounds synchronous with the heart-action or breathing, they were ascribed to dragging upon adhesions surrounding the great vessels external to the pericardium, in consequence of the traction by the vessels of the arms.

G. G. Sears³ reports the statistics of **100 cases** of pericarditis. Of these, 54 were dry, 41 serous, 4 hemorrhagic, and 5 purulent. Seventy-four were males and 26 females. The great majority were persons in early adult life. Occupation seemed to have little influence. The majority of the cases occurred in January. Thirty-four had previously suffered from heart-disease and still showed valvular lesions. The temperature was usually low, rarely reaching 103°, although in 1 case, complicated by pneumonia, 107.4° was recorded. Acute rheumatism was the cause in 51 cases; pneumonia in 18; chronic nephritis in 7; pleurisy in 5; chronic rheumatism in 2; gonorrhoea in 2; and various causes in the others, 9 cases being classed as idiopathic. Forty-three cases died and 4 were discharged unrelieved. The etiology seems to have much influence upon the prognosis, only 5 of the cases occurring in the course of acute rheumatism being fatal.

Acute Pericarditis.—[The question of surgical interference in purulent pericarditis seems to have been settled in the affirmative. The following cases are instances of the success that may attend this method of treatment.]

G. B. Shattuck and C. B. Porter⁴ report a case of **purulent pericarditis** following pneumonia in which, after aspiration, and then free incision of the pericardial sac, recovery ensued. The pneumococcus was found in the pus. The authors have collected 24 cases of this condition, with 8 recoveries and 16 deaths. Frank W. Garber⁵ reports a case following punctured wound of the chest. As the symptoms became very severe and all the signs of collection of pus in the pericardial sac were present, operation was decided upon and the sac opened and drained. Recovery was uneventful.

T. L. Coley⁶ reports a case of **malignant endopericarditis** with recovery. The diagnosis was made from the existence of soft blowing murmurs, extreme prostration, and hectic temperature. There were gastric irritability and considerable delirium. Bacteriologic examinations of the blood were negative. There was no leukocytosis and neither symptoms of infarcts nor abscesses. [The diagnosis, therefore, is at least doubtful.] Recovery finally occurred after an illness of 6 months.

L. Dickinson¹ contributes a study of **adherent pericardium** as the cause of fatal enlargement of the heart. He limits the term to complete obliteration of the pericardial sac by organized tissue. There may be no alteration of the heart nor even atrophy or arrested growth, although in most cases the heart is enlarged. In many cases diseases of the cardiac valves or muscle, the kidneys, or lungs may explain the enlargement, but in some there is no such explanation. The author refers to cases of the latter kind, of which he has observed 9 fatal instances during 3 years. The ages ranged from 8 to 21 years, the average being slightly over 15. During the same period adherent pericardium was found in 28 other patients dead of various diseases, in no instance, however, presenting the great enlargement referable to simple adhesion. The ages were mostly over 15 years and averaged upward of 36. In 12 cases the history of the initial trouble could be obtained, and the pericarditis was known to have occurred at an age later than that of puberty. In 5 cases it occurred in childhood, and 4 of these had advanced valvular disease and died at early ages with great enlargement of the heart, for which the adhesion was only partly responsible. The fifth is the solitary case in which adhesion, certainly contracted in childhood, proved harmless. Pericardial adhesion contracted in adult life is comparatively unimportant. In children it generally causes early death, and is associated with great enlargement of the heart. Pericarditis in children, if the very young be excluded, is almost always rheumatic and accompanied by endocarditis. Much fluid effusion is exceptional, and death results in the acute stages from failure of the cardiac muscle and dilatation of the ventricles. In the cases that recover from the acute attack enfeeblement and dilatation of the heart are often severe and prolonged. Hypertrophy may follow, but compensation is never attained. The right heart suffers more than the left, as was evidenced by the fact that dropsy occurred in 7 and nutmeg livers in 2 of his cases. This failure of the right heart was not due to backward pressure from the left, for there was no congestion of the lungs in 5 cases, and in only 4 well-marked congestion or pulmonary apoplexy, indicating primary disturbances of the left ventricle. Regarding the relations of the mitral valve and the ventricle, it was noted that the valvular disease was gradual and of the kind that would ultimately develop into stenosis, although this had not actually occurred in any case, being antagonized by the tendency to regurgitation from dilatation of the mitral orifice by the traction of the pericardium. The diagnosis is made from the combination of symptoms and physical signs. Systolic retraction of the lower ribs is practically pathognomonic, but rarely observed. One of the most characteristic indications in the rapid progress of the cases to this fatal end is the failure of the remedies ordinarily useful in cardiac diseases.

Pick² describes a form of ascites suggesting ordinary cirrhosis of the liver, but due to pericarditis. He describes 3 cases, and terms the condition **pericarditic pseudocirrhosis of the liver**. The disturbance of circulation in the liver due to pericarditis leads to hyperplasia of the connective tissue surrounding the portal blood-vessels and ascites results. Clinically, the cases resemble mixed forms of cirrhosis of the liver, with enlargement and marked ascites, but no icterus. He distinguishes the conditions by the absence of any etiological factor pointing to cirrhosis, the pre-existence of symptoms pointing to pericarditis, and previous edema of the feet. A certain diagnosis is only possible when a careful examination of the heart has been made.

Ewart³ suggests that pericarditis may arise gradually without severe symp-

¹ Am. Jour. Med., Sci., Dec., 1896.

² Zeit. f. klin. Med., Bd. 29, H. 5 and 6.

³ Lancet, Nov. 21, 1896.

toms. He noticed the fact that bands of adhesion, etc., may be found post-mortem in cases in which there was no history pointing to pericarditis. He reports 3 cases (nephritis, valvular disease, acute rheumatism) in which pericardial effusion came on without notable symptoms, persisted a few days, and then disappeared. Diagnosis was only made by careful examination. He concludes that effusions may take place independently of acute pericarditis, and if moderate may be reabsorbed without manifesting marked symptoms. In some cases subacute inflammatory processes may be present; more often the effusion is passive or mechanical.

DISEASES OF THE HEART.

Methods of Examination.—H. C. Thomson¹ advises the use of the **fluoroscope** for the estimation of the size and shape of the heart, and has found it highly satisfactory. A permanent tracing is easily made by holding a sheet of paper over the fluorescent screen and tracing upon it with a metallic pencil. A metal button may be used to mark the position of the nipple and the ribs may be traced so as to aid further in establishing the relations. [We have also used this method and have been enabled to study the outline of normal as well as pathological hearts. Occasionally we were deceived by the fact that the shadow thrown upon the screen was larger than the heart itself; but the outline determined by the use of rays as nearly perpendicular as possible usually agreed very closely with that obtained by careful percussion. For the reason given above radiographs were not as satisfactory as the screen. The following author has apparently had a similar experience, but assigns a different reason:]

F. H. Williams² contributes a paper on the study of **internal diseases**, and especially the determination of the outlines of the heart by means of the fluoroscope. The heart may be more or less well seen. The ventricles are distinct, as a rule, and in favorable conditions also the auricles; but it is difficult to distinguish the left from the pulmonary artery. The constant movements of the heart and diaphragm interfere with radiography, and therefore render fluoroscopy of more value. The position of the heart, as a rule, makes it impossible to see more than a certain portion of its outline, but by contracting the diaphragm a better result is obtained, the abdominal organs then being depressed and the heart exposed surrounded only by the lungs. Several cases, in which the outlines as determined by percussion and those found by fluoroscopy are contrasted, show that the fluoroscope gives a wider area than percussion. Consolidation of the lungs obscures the cardiac outlines and the border contiguous with the liver is normally not easily determined. Fluid in the pericardial or pleural sacs and various diseases of the lungs causing consolidation may be readily detected. Sometimes areas of consolidation not readily detected by physical examination are discovered. He has found fluids withdrawn from the body less permeable to the rays than water.

C. F. Disen³ marks a normal outline of the heart upon the chest by means of a copper wire, then puts a fluoroscopic screen at the back of the patient, and is able to recognize whether the shadow of the heart is within the wire or extends beyond, in which case he assumes hypertrophy.

Auscultatory Percussion.—W. D. Herringham⁴ has studied the value of direct and auscultatory percussion upon the cadaver. He found that the former method gave strikingly accurate results, as tested by inserting pins into

¹ Lancet, Oct. 10, 1896.

² Boston M. and S. Jour., Oct. 1, 1896.

³ Med. Rec., Jan. 9, 1897.

⁴ Brit. Med. Jour., Sept. 19, 1896.

the body and determining their position when the sternum was removed. Auscultatory percussion was fairly accurate, but had a number of drawbacks. He confirms Dr. Herschell's statement regarding the area of about $1\frac{1}{2}$ in. around the stethoscope in which the vibrations transmitted in the skin interfere with the vibrations dependent upon deeper structures. Beyond this "useless area" good results may be obtained for a certain distance, but as the distance is increased the note is decreased and cannot well be judged. The stethoscope must be on a resonant area. In percussing the heart, for example, it must be placed over the lung. The method deprives us of aid which the feeling of the fingers gives in percussion; the note is very different if obtained over the rib or over an interspace. Finally, the note over the sternum is so shrill as to make the discrimination of changes of pitch impossible within 3 in. of the stethoscope. [We are surprised at some of these results. They do not accord in the slightest with our experience. The statement regarding the necessity of placing the stethoscope over a resonant structure is as far as possible from the fact. We never follow this rule. It may be said here that some experience with this method is necessary, and that those who would put it to the test should first acquaint themselves with its limitations by a certain amount of practice. It is striking that those who have proclaimed most loudly against its value are those who have, without previous experience, entered upon an investigation of its defects.]

P. W. Williams¹ states that he has followed the method of auscultatory percussion detailed by Jackson, of New York, and has come to the conclusion that though it is not an absolutely accurate method to determine the deep cardiac dulness, it is more accurate than any other. He points out, however, that the area of cardiac dulness does not absolutely determine the size of the organ, since the relations of the curved surface of the heart to the curve of the thorax cause apparent differences in size that may not be real. He has practised the method on living subjects and also on 12 cadavers, controlling the results by the insertion of pins into the chest-walls. [It is striking that the author's results vary so greatly from those of Herringham in regard to the test on the cadaver. We can only explain the difference by the assumption mentioned in commenting upon Herringham's paper, that greater experience leads to more satisfactory results.]

A. Stengel² advocates very strongly auscultatory percussion in diagnosis. He prefers the simplest method of placing the stethoscope directly over the organ to be outlined. It is important to percuss always with strokes of the same force. He warns against mistaking the change of note which occurs as a result of the approximation of the pleximeter to the stethoscope, and is due to vibrations in the chest-wall, from the more characteristic change which occurs only at the edge of the organ, no matter in what part of its area the stethoscope may be placed. The most satisfactory application is to the heart, the point of election for the stethoscope being near the apex. Over the lung it is chiefly valuable for delimiting areas of consolidation; applied to the stomach, it is most useful in connection with inflation. It is also possible to determine the size and position of the colon, of the liver, of the spleen, and, under possibly favorable circumstances, of the kidneys.

Holowinski³ has devised a method for the **graphic representation of the cardiac sounds** by means of 2 small glass plates upon the diaphragm of a telephone. Between these Newtonian lines appear and vary with the

¹ Brit. Med. Jour., Sept. 19, 1896.

² Boston M. and S. Jour., Apr. 15, 1897.

³ Zeit. f. klin. Med., vol. xxxi., p. 201.

vibrations produced by the heart-sounds; by means of a special apparatus it is possible to photograph these changes.

General Symptomatology.—T. Fisher¹ contributes a brief study of the **bruit de galop** and its causation. He shows by sphygmographic and cardiographic tracings that there is in this condition a rise of the lever, indicating a wave, preceding the ordinary impulse, followed by a recession, and then by the regular impulse. This was shown in one case on several occasions when the bruit was present, and could not be demonstrated when the latter was temporarily absent. In seeking for an explanation of this phenomenon he considers several of the theories that have been held regarding the bruit. Potain and others have attributed it to the distention of the left ventricle during the inflow of blood from the auricle. This fails to explain the recession of the wave. "One would suppose," says Fisher, "that the ventricle would remain distended and keep the chest-wall raised until the commencement of the ventricular systole, when a further rise would occur." Dr. Sansom suggests that the first inrushing of the blood strikes the apex, but that afterward a considerable quantity rebounds toward the base behind the great anterior mitral flap. Fisher believes that some such movement of the blood does take place, but doubts the explanation. His own explanation is—the region of the base of the heart being strengthened by the contractions of the papillary muscles and chordæ during the auricular systole, distention occurs at the relatively unprotected apex; afterward, when the necessity for contraction is relieved and the outward pressure upon the mitral flap has ceased, the intraventricular pressure is left to distend the heart as it will. In consequence of this there is displacement of the blood in the direction of the base, tending to throw the mitral flaps together, and there is simultaneous recession of the apex. The author's theory agrees closely with Sansom's, although not in his explanation of the recession. He points out that clinically the bruit occurs most frequently when the muscle of the heart suffers without valvular disease. In hearts recovering from poisoning by toxins, in dilated hearts associated with arterial disease, interstitial nephritis, overwork, or alcoholism the bruit is common; and it may occur in severe cases of anemia. In all such cases there is impairment of the power of the heart-muscle. As regards prognosis, he holds that the sign is one of importance, dependent upon the nature of the heart-failure with which it is associated. In cases of hypertrophy without valvular disease he has seen it come and go without much reference to the general condition. In one instance it was the only abnormal sign present, when sudden death overtook a patient who had not been considered seriously ill.

Braun² discusses the significance of the **cardiac impulse** transmitted by the thoracic wall. He had the opportunity to observe for some time a patient who, as the result of a gunshot-wound, had had the left 4th, 5th, and 6th ribs excised between the parasternal line and the sternum on the left side, leaving nothing but the transparent pericardium between the heart and the observer. The following cardiac phenomena were observed: the wave commenced at the base with a slight dilatation of the muscular wall and then contraction. This was transmitted downward, and as it reached the apex became associated with the upward movement of that part of the heart. The movement of the apex was very sudden, and corresponded apparently to the 2d part of the wave: as it was thrust upward, it was also observed that the heart underwent a spiral rotatory movement from the left forward and then upward. Braun therefore holds that the apex-beat is caused solely by the systolic change of form of the heart-muscle, and is an expression of the cardiac movement against

¹ Am. Jour. Med. Sci., Sept., 1896.

² Wien. klin. Woch., Nov. 28, 1896.

the 5 cases of unequal left-sided hydrothorax the left auricle was stated to have been particularly dilated. He concludes, then, that this mechanical theory is the one most generally applicable.

A. H. Smith¹ calls attention to the presence of **anemia in heart-disease** as a result of the combined action of rheumatism and the salicylates. Clinically it can be recognized by the pallor, hemic murmurs, the venous bruit, and the examination of the blood. He has had the greatest success from the treatment with rectal injections of defibrinated blood.

Acute Endocarditis.—[The evidence in favor of direct infection of the endocardium by the gonococcus appears to be increasing, although in some cases it is unquestionable that post-gonorrhoeal endocarditis is due to other microorganisms.] Keller² records a case of **malignant endocarditis following gonorrhoea**. The patient, a man of 25, had gonorrhoea followed by rheumatism after an interval of 4 weeks. Two months later he entered the hospital and then had endocarditis of the pulmonary valve with intermittent fever and enlargement of the spleen. Three weeks later hemorrhagic nephritis developed. The heart gradually weakened, and dyspnea developed; pericarditis occurred, followed by death 6 months after the beginning of the attack of gonorrhoea. Postmortem verrucose and ulcerative endocarditis of the pulmonary leaflets, thrombosis of the left ventricle, infarcts in the kidneys and spleen, and emboli in the pulmonary arteries with hemorrhagic nephritis were the lesions found. The patient had leukocytosis and considerable anemia. Bacteriologic examination of the blood from the right ventricle was negative, but abundant streptococci were obtained from the pericardial fluid, from the endocardial vegetations, and elsewhere. Diplococci (staining by Gram's method) were found with the streptococci in the kidneys. Gonococci could not be demonstrated. The author believes that the urethral disease furnished a portal of entrance for the streptococci.

Alfred Stengel³ reports a case of endocarditis occurring in a woman of 20 years of age. She had suffered from gonorrhoea, and shortly before admission to the hospital had shown symptoms of acute general infection. There were dyspnea, considerable enlargement of the heart, and, at the apex, a loud presystolic followed by a systolic murmur, and a systolic murmur in the aortic region. Death occurred 7 weeks from the onset. At the autopsy a congenital lesion of the mitral valve was found, and the wall of the left auricle showed both old and recent endocarditis. Bacteriologically, the vegetation from the aortic wall showed diplococci that in all respects resembled microscopically the gonococcus. No growth was obtained upon agar and ordinary serum culture-tubes. The author is inclined to regard the case as one of gonorrhoeal origin, although he admits that the evidence is not conclusive. He collects 13 other cases in which careful clinical and bacteriologic studies have been made, in only one of which characteristic cultures were obtained from the vegetations. These cases were all characterized by the symptoms of malignant endocarditis, the aortic valve being the most frequent seat of the disease.

Wieghein,⁴ in the Berliner Verein. f. in. Med., presented the specimens of a case of acute endocarditis secondary to gonorrhoea. Cultures from the vegetations on blood-serum were negative, but microscopically organisms were found in them that corresponded exactly to gonococci. [It is generally admitted now that other cocci occur that cannot be distinguished either morphologically or by their staining reaction from gonococci. The only positive tests

⁴ Centralbl. f. innere Med., Apr. 17, 1897.

are either inoculation or the culture. The absence of growths in culture-tubes is important.]

Hitchmann and Michel¹ describe a case in which a chill, fever, and evidences of acute endocarditis developed a few hours after dilatation of a urethral stricture. Jaundice, hemorrhage, and death followed, and at post-mortem ulcerative endocarditis with pyemic abscesses was discovered. The bacillus coli communis was demonstrated in all of the secondary lesions. The authors conclude that the **infection** occurred primarily from the **urethral mucous membrane**.

Geo. Doek² reports a case of endocarditis due to **infection with the staphylococcus aureus**, with rhythmic paroxysms of fever simulating exactly the double quotidian type. [See *Year-Book* for 1897.]

Edmond Gladmon³ reports a case of malignant endocarditis coming on apparently as the sequel of a series of attacks described as **bilious** that consisted of sudden vertigo followed by vomiting and violent pain, either centering solely in the umbilicus or radiating to the liver. These attacks usually lasted about a week and occurred irregularly for 5 years before his death. The case finally developed severe pyemic symptoms. At the autopsy there were large, irregular vegetations upon the sclerotic endocardium, containing the diplococcus lanceolatus, metastatic abscesses of the spleen and kidney, and fatty infiltration of the liver; the intestines were normal.

Jas. W. Walker⁴ reports a case of **acute vegetative endocarditis**, confirmed by autopsy, in which during the early period of the disease the symptoms closely resembled typhoid fever, and there was nothing to call attention to the heart. Murmurs were absent throughout.

Reichel⁵ believes that recent **rheumatic endocarditis** occurs more frequently than the older authors admit; that is, in from 60 to 70% of all cases of acute articular rheumatism. Its diagnosis is quite impossible when it is restricted to the cavities of the heart. Ordinarily it presents the following clinical picture: a rough murmur appears at the apex covering the systolic tone and the apex deviates to the left. Then there is accentuation of the second aortic sound, which subsequently yields to a greater accentuation of the second pulmonic. This develops into a mitral insufficiency. If stenosis occurs, the earliest symptom is diminution in the strength of the pulse, with accentuation of the systolic tone at the apex. Aortic regurgitation is sometimes indicated by the presence of a presystolic murmur. In those mild forms of endocarditis that occur in the course of gonorrhoeal rheumatism the symptoms are essentially the same.

W. M. Gibson⁶ calls attention to a febrile form of **endocarditis in the aged**, which he claims is frequently overlooked. It usually occurs in patients already suffering from valvular lesions, in the course of articular rheumatism or other infectious diseases. He holds that in old patients suffering from such valvular disease fever, even if transitory, should arouse suspicion of acute endocarditis.

H. Sainsbury⁷ records a case of ulcerative endocarditis in a lad of 13. On July 1, **streptococci** were found in the blood. There was a variable temperature from 100° to 104.4°, vomiting, cough, and bloody sputum. The spleen was slightly enlarged, the abdomen tender, and a symmetrical erythematous rash developed on the buttocks, spreading over the rest of the body.

⁴ Jour. Am. Med. Assoc., Apr. 3, 1897.

⁶ Internat. Med. Mag., Sept., 1896.

⁷ Lancet, Oct. 17, 1896.

On August 17, 20 c.c. of **antistreptococcic serum** were injected; the temperature was 99.8° ; there was no reaction. On the 18th, 20th, 22d, and on the 25th, 10 c.c. were administered, and there was great improvement. On the 31st the patient was up and walking in the ward. The area of cardiac dulness had become normal, and the heart's apex was well within the nipple-line. On September 1, again 10 c.c. were injected, and there was local and general reaction. After this the patient became normal in every way and was discharged soon after apparently cured. [The results of the employment of antistreptococcic serum, experimentally as well as clinically, are so conflicting that it is difficult to decide as to its value. It seems questionable in the present case whether the treatment was beneficial.]

CHRONIC VALVULAR DISEASE.

J. K. Crook¹ reports the **statistics** of 503 cases of heart-disease. Of these, 277 were functional disorders and 226 organic diseases. The latter were classified as follows: mitral regurgitation, 60; mitral stenosis, 35; aortic regurgitation, 7; aortic stenosis, 36; tricuspid regurgitation, 6; pulmonary stenosis, 1; double combined lesions, 46; lesions of double character, 7; simple hypertrophy, 10; and other conditions, 15. Functional diseases predominated in females and organic diseases in males. [The very large proportion of cases of aortic stenosis does not correspond with the results of the autopsy-room. A systolic murmur at the base does not necessarily or even usually imply a narrowing of the ostium.]

Symptomatology.—Kasem-Beck² refers to the significance of the **presystolic murmur** at the apex of the heart. He points out that numerous cases have recently been reported in which this murmur was detected and the autopsies showed no narrowing of the mitral orifice, although in some aortic narrowing was discovered. In 16 cases out of 19 the symptoms of aortic insufficiency and mitral stenosis coexisted during life, but the autopsy showed no stenosis. In another group of cases neither valve was found diseased, but adhesive pericarditis existed, and a few instances are recorded in which there was merely dilatation of the left ventricle. Picot has recorded cases in which a presystolic murmur was heard at the apex in hysterical patients, and holds that it is due to contractions of the papillary muscles. After this introduction the author refers to the case of a man of 63 who entered the hospital complaining of severe pains in the breast extending to both arms and severe dyspnea. Positive pulsation was found in the veins of both sides of the neck; the left and right ventricles were hypertrophied; the peripheral arteries were sclerotic; there was a loud presystolic murmur with a muffled first sound at the apex, while the second sound was loud. Auscultation over the tricuspid area discovered no murmur. The second sound was accentuated over the pulmonary region. Stenosis of the mitral orifice was supposed to be present, but the autopsy showed no narrowing at all. There was found near the apex of the heart an aneurysmal dilatation the size of a small apple. The author believes that the presystolic murmur was due to diversion of the stream of blood into this cavity. Although both auriculo-ventricular orifices were dilated, no systolic murmur was discoverable. Finally, he believes with Skoda that a strong pulsation in the intercostal space at the apex and a small pulse at the wrist are sure signs of aneurysm of the left ventricle. [While we cannot agree with the last statement of the author's, the report is of interest in furnishing another instance of presystolic murmur without mitral stenosis. Authors who

¹ N. Y. Med. Jour., June 19, 1897.

² Centralbl. f. innere Med., Feb. 13, 1897.

have reported such cases appear to us to have laid too little stress upon the character of the first sound. We have repeatedly distinguished Flint's murmur from the murmur of mitral stenosis by the weakness of the first sound in conjunction with other evidence.]

Leube¹ discusses the diagnosis of **systolic heart-murmurs** and gives the following summary of the principles to be observed in their examination. First, an accidental murmur is present if the area of cardiac dulness is normal, the second pulmonary sound not accentuated, and the murmur heard either only in the pulmonary area or also at the apex of the heart. If the murmur is accompanied by a heart-sound, it is to be assumed that it is due to a transient dilatation of the pulmonary arteries resulting from the diminished tone of the vessel-wall. If not so accompanied, it is due to a diminution of blood-pressure in the large vessels. The diagnosis is slightly more difficult if the area of cardiac dulness is slightly enlarged and the pulmonary second sound is accentuated. Under these circumstances an acute endocarditis with secondary acute mitral insufficiency is to be diagnosed, if the enlargement of the cardiac area is only slight and chiefly toward the left, and there are fever and the presence of some infectious disease. Should, under these circumstances, the right ventricle also show increase in size, it must be assumed that there is some weakness of the heart-muscle, and that therefore, in addition to the endocarditis, a myocarditis is also present. A relatively subacute or chronic insufficiency of the mitral valve is to be diagnosed if there are considerable enlargement of the area of cardiac dulness over both sides and accentuation of the second sound in the pulmonic area. If the murmur is purely systolic, of moderate intensity, and not always of the same force, whilst at the same time the cardiac impulse is weak and the second tone only moderately accentuated, with a relatively small or even irregular pulse, the insufficiency of the mitral valve is probably relative or functional. This condition occurs in anemia, in cases with enfeebled heart-muscle, or of excessive dilatation of the left ventricle, and also if there are myocarditic changes in the muscles controlling the valves. A constant loud systolic murmur with a relatively small cardiac impulse, and a relatively good pulse with great accentuation of the second pulmonary sound, indicate the presence of mitral insufficiency resulting from chronic endocarditis. The intensity of the second pulmonic sound depends upon a variety of conditions, such as the perfection of compensation obtained by the hypertrophy of the right ventricle or the duration of the diastolic pause. In these cases the diagnosis is often rendered more certain by the discovery of a presystolic murmur in addition to the systolic one, a combination that occurs in no other condition. The distinction between endocarditic and relative mitral insufficiencies is more difficult when compensation is lost. Under these circumstances, however, the clinical picture is of much value, for the relative insufficiencies occurring in the course of anemia present incomparably milder symptoms. If, however, the relative mitral insufficiency with loss of compensation is due to myocarditic changes, the differential diagnosis from a pure mitral insufficiency due to endocarditis is impossible. This, however, is rarely the case, as an insufficiency due to endocarditis is almost invariably accompanied by more or less stenosis. As a result, in addition to the systolic there is almost always a presystolic murmur, which enables one to make the differential diagnosis.

Heitler² discusses the **localization of the mitral systolic murmur**, and declares that it may be heard simultaneously in various portions of the cardiac area with equal intensity. Thus, it may be loud at the apex, diminish

¹ Deutsch. Arch. f. klin. Med., Nov. 5, 1896.

² Wien. klin. Woch., Feb. 18, 1897.

toward the base, and reappear in the aortic region with full intensity. Various modifications of the generally accepted rule often occur. Sometimes the murmur is loudest at the apex, diminishing in intensity in all directions; at other times a similar condition exists, excepting that it reappears at distant points, where it may be heard even more loudly than at the apex. Usually when it does reappear it is found at the left border of the sternum; sometimes, however, it is quite weak at the apex, being loudest in the parasternal line. In general, it may be said that systolic mitral murmurs may be heard most loudly at almost any point in the area lying to the left of the left border of the sternum and below the second intercostal space. The intensity of the murmur depends to a large extent upon the energy of the heart's action and varies considerably from time to time. This alteration may be qualitative as well as quantitative, so that the whole character of the murmur becomes different. He then considers the **tricuspid murmurs**. These, when systolic, have a peculiar acoustic character and are heard in a definite area; they are usually faint, delicate, and breathing, and only exceptionally rough, superficial, and short. Usually they are higher in pitch than the corresponding mitral murmurs. The area in which they are best heard varies in height and breadth according to the intensity of the murmur. Loud murmurs may be heard over any part of the sternum up to the first intercostal space, with the maximum intensity usually between the levels of the 3d and 5th ribs. Usually they are somewhat louder in the left half of the sternum than in the right. The murmur is transmitted to the right, sometimes more strongly to the left, as far as 6 cm. from the median line. On the right side transmission is rarer, and it is very unusual for the murmurs to be heard more than 3 cm. from the edge of the sternum. The differential diagnosis between tricuspid murmurs and mitral murmurs is usually easy, and is to be made by a consideration of the acoustic character and the points of the greatest intensity and areas of transmission.

T. Fisher¹ emphasizes the importance of careful **discrimination** as to the existence of mitral regurgitation when systolic murmurs are heard over the heart, even in cases of rheumatism. Many of these murmurs disappear spontaneously under the influence of rest, and it is likely that they are the expression of moderate dilatation of the left ventricle and similar to the murmurs heard over the pulmonary area when the right ventricle is dilated.

Mitral Stenosis.—R. G. Curtin² describes cases which he regards as instances of moderate **congenital narrowing of the mitral orifice** manifested by irritability of the heart with "dwarfed life." The first case, a young woman, had blue lips and extremities, and was regarded as a case of vasomotor and trophic affections of the fingers. A year later he observed similar cases in 3 young boys. In all of these the symptoms were rapid, irritable heart, suffused face, shortness of breath, loss of strength and appetite, and a murmur over the heart. On inquiry he found that the boys had previously led quiet lives, were easily fatigued, and even in early childhood had been unable to cope with their fellows in active play. Their subsequent occupation, as "cash-boys" in a large store, led to the development of the symptoms. He then details 6 additional cases, calling attention to the inability of the affected persons to engage in active work or play, and the tendency to lung and pleural trouble of a chronic kind, with hemoptysis and night-sweats. The lesions in the lung and pleura were generally on the left side. In the severer cases auricular pulsation was marked, and a murmur could be developed in all of them that was heard above and outside the usual apex-region, and either presystolic or

¹ Lancet, July 18, 1896.

² Tr. Am. Climat. Assoc., 1896.

in the early part of systole. It was not transmitted except when conveyed by a consolidated lung. Accentuation of the pulmonary second sound was generally present. Most of the patients were boys and growing men. Post-mortem examinations were obtained in 3 cases, but with negative results in all so far as the size of the mitral orifice was concerned. The difficulty in this was to determine the normal size of the orifice for a heart of given size. In all cases the endocardium was healthy, but the left auricles were hypertrophied and dilated. The author concludes from the clinical symptoms and physical signs that a moderate amount of mitral stenosis exists in these cases, and that the orifice permits sufficient blood to pass during the quiet state, but not enough when the heart becomes more active. The most suitable treatment consists in hygienic regulations.

Samways¹ maintains that hypertrophy of the **left auricle in mitral stenosis** predominates over dilatation until the failure of compensation. He explains the competence of the relatively weak auricle as compared with the ventricle upon the ground that a hollow sphere of small size requires a much greater pressure to bring on dilatation than one of larger size. He believes that the contraction of the auricle encroaches upon the ventricular contraction and this prevents regurgitation. In the later stage, when the auricle fails, a murmur of valvular incompetency develops.

H. D. Rolleston and W. L. Dickinson² report 3 cases of what they term "**relative mitral stenosis.**" In these the mitral valves presented the usual appearance of stenosis, but the orifice and leaflets were of such a size that there was not actual obstruction. Clinically, there were a mitral regurgitant murmur and frequently a more or less characteristic presystolic murmur. They do not believe that the condition was due to subsequent dilatation of the ventricle in cases of mitral stenosis, thinking that it is hardly probable that the valve having attained so high a grade of rigidity could subsequently become so much dilated. Their view is that the valve, while tending to stenosis, has been held open by the primary dilatation of the ventricle. Most of the cases of relative stenosis are found in cases of adherent pericardium in young persons arising from rheumatic pericarditis, dilatation of the ventricle and mitral endocarditis occurring simultaneously. Other cases are instances of aortic regurgitation, the dilatation of the ventricle having prevented the usual contractions of mitral stenosis.

Wm. Osler³ reports a case of mitral stenosis with signs of cardiac insufficiency. Death occurred suddenly. At the autopsy the mitral orifice was found to admit the tip of one finger, and in the left auricle there was a firm **ball-thrombus** unattached to the walls, but occupying a funnel-shaped space leading to the mitral orifice. It was ovoid and about 3 cm. long. [We have seen two specimens of this condition, in one of which the ball was perfectly round; in the other, attached by a pedicle to the wall of the auricle.]

A. A. Eshner⁴ reports a case that at first presented the symptoms of mitral stenosis, but, after taking digitalis, developed a diastolic murmur of booming character transmitted toward the axilla. Still later there was also a systolic murmur at the apex; nevertheless he regards the case as one of typical mitral stenosis.

Cheveau⁵ describes a form of mitral stenosis that he believes to be due to **spasm of the papillary muscles**, resulting directly from nervous influence. This occurs particularly in hysterical or saturnine persons, and is charac-

¹ Thèse de Paris, 1896.

³ Montreal Med. Jour., Mar., 1897.

⁴ Phila. Polyclinic, Dec. 19, 1896.

⁵ Sem. méd., 1896, p. 288.

terized by the presence of a harsh fremitus and a presystolic murmur, but without the other phenomena characteristic of mitral stenosis. The pathognomonic sign is the extreme variability, with a transient or final disappearance of all the abnormal auscultatory phenomena. The duration is naturally uncertain. The only complication that it can produce is pulmonary congestion, and even this never reaches a serious grade. Treatment should be directed wholly to the nervous condition, sedatives, such as bromid of potassium, having been found most useful.

Servin¹ has recently studied the question of **heredity in mitral disease**. He holds that it is not unusual for the parents to transmit visceral peculiarities, and that the heart is especially liable. Pure mitral stenosis often seems rather a variation of structure than an actual disease, and he notes that its transmission has been actually observed, and that it constitutes at times a real family affection. He holds, therefore, that when one of the parents suffers with mitral stenosis the children should be carefully examined, so as to institute proper hygienic measures.

Mitral Regurgitation.—Theodore Fisher² discusses the frequency and seriousness of mitral regurgitation due to valvular disease, which appears to be much more frequent at the bedside than it is postmortem. Mere thickening of the flaps may be frequently discovered, but actual contractions are very rare. It is not likely that the small, bead-like vegetations seen in early endocarditis interfere with the competency of the valve. A slight degree of ventricular dilatation may occur in many cases, and this may be sufficient, in attacks of rheumatism, to cause a systolic murmur at the apex. The frequency of a systolic murmur audible over the pulmonary area is of importance in this connection. Foxwell ascribes this to the dilatation of the *conus arteriosus* of the right ventricle, and Fisher has observed a case during life and postmortem of striking character. "We have then," he states, "a systolic murmur audible over the pulmonary area occurring in attacks of rheumatism, but we have reason to believe that this is sometimes due to dilatation of the right side of the heart;" similarly we may suppose that dilatation of the left side occurs. In Dr. Caten's recent paper he alludes to the disappearance of murmurs in patients who were kept in bed for a considerable length of time, and attributes it to the cure of the endocarditis. Fisher believes it due to the subsidence of the dilatation. Referring to his postmortem experiences and to other records, he finds that death due to uncomplicated mitral regurgitation is rare. The records of the Bristol Royal Infirmary for 20 years showed only 11 cases. The records of Guy's Hospital for 10 years showed only 5 cases. In these statistics he excludes cases in which there were other lesions, such as general adhesions of the pericardium and aortic valve-disease. When the mitral valves suffer acute endocarditis stenosis is almost invariably the result. The usual explanation of the regurgitant murmurs then is dilatation of the ventricle. [We heartily endorse these views. In a very considerable postmortem experience we have rarely found pure mitral regurgitation due to valve-disease, but have repeatedly seen a dilated ventricle (and, therefore, presumably mitral leakage) in cases in which there were the usual indications of acute rheumatic or infectious endocarditis.]

E. H. Starling³ states that mere perforation of the mitral and tricuspid valves in a heart otherwise normal may give rise to very little disturbance of the circulation or in the conditions of the heart itself, because of the sphincter-like action of the circular band of fibres surrounding the orifices. If, however,

¹ Jour. de Méd., Sept., 10, 1896.

² Lancet, Oct. 18, 1896.

³ Ibid., Feb. 27, 1897.

the muscle becomes feebler, these relax and regurgitation develops. He performed a number of experiments in order to determine the effect of cardiac insufficiency upon the blood-current, and found that the number of corpuscles was usually increased to a greater extent than the hemoglobin. This, in connection with the fact pointed out by Lloyd Jones, that in failure of compensation there is marked diminution in the specific gravity of the blood, leads him to believe that in heart-disease there is not a condition of plethora, hydremic or otherwise, but that the lowering of specific gravity is due to the diminution of the solids of the plasma—that is to say, hydremia without plethora. [This view is not shared by others and certainly needs further demonstration.]

A. O. J. Kelly¹ mentions the case of a man in whom there was distinct Corrigan pulse, but no diastolic murmur. The diagnosis of **aortic insufficiency** was confirmed at the autopsy.

Pulmonary Stenosis.—[See also the section upon Tuberculosis.] Henry Hun² reports a case of **pulmonary stenosis complicated with pulmonary tuberculosis**. At the autopsy the pulmonary leaflets were found united, leaving a small triangular opening. The right ventricle was hypertrophied. The ductus arteriosus was not examined. There was extensive caseous tuberculosis of both lungs. Hun regards the lesion as of inflammatory nature, occurring during fetal life. R. H. Babcock³ reports an interesting case of pulmonary stenosis complicated with pulmonary tuberculosis, which was recognized during life from the presence of a loud, harsh systolic murmur, best heard in the second intercostal space to the left of the sternum. At the autopsy the pulmonary artery was found occluded by a smooth membrane without ridges in the form of a truncated cone, with a small hole at the top. The right ventricle and right auricle were both hypertrophied and dilated; the ductus arteriosus was not examined.

Robt. B. Preble⁴ reports a case of **relative insufficiency of the pulmonary leaflets**. Both sides of the heart were enlarged; there were a systolic murmur and a presystolic thrill at the apex, and 2 diastolic murmurs at the base, 1 transmitted toward the apex, the other along the sternum. Both second sounds were absent. At the autopsy aortic and mitral insufficiency were found and the pulmonary valves were insufficient by the hydro-static test; they showed no pathologic alteration.

J. B. Herrick⁵ reports 3 cases of **tricuspid stenosis**. All showed associated mitral stenosis, and in 1 there was also aortic regurgitation. The patients were all females in early adult life; 2 gave rheumatic histories and the other rheumatic antecedents. None of them presented symptoms of heart-disease until after puberty. Forty cases collected since 1868 are abstracted in this paper.

J. Mackenzie⁶ has taken tracings of the jugular pulse during **tricuspid regurgitation**, and finds that it consists of a low wave due to auricular contraction, a fall due to auricular diastole, a very high wave due to the ventricular systole, and finally a 2d fall due to the diastole of the ventricle. In cases of debility these waves are similar in order but less pronounced. In cases of hypertrophy of the right ventricle and dilatation of the auricle the auricular wave disappears and the ventricular wave becomes higher. If, however, tricuspid stenosis exists at the same time, then the auricle is to a certain extent protected, although the hypertrophy of the right ventricle still produces a high ventricular wave, so that we have a diminished auricular and an ex-

¹ Med. News, July, 1896.

³ Medicine, May, 1897.

⁶ Boston M. and S. Jour., Mar. 18, 1897.

⁴ Jour. Am. Med. Assoc., May 29, 1897.

⁵ Brit. Med. Jour., May 8, 1897.

aggerated ventricular wave in the tracings. As in these conditions pulsation of the liver almost invariably occurs, and as it fails to occur in slight conditions of tricuspid regurgitation without dilatation of the ventricle, a tracing taken from the pulsating liver with an auricular wave is probably pathognomonic of tricuspid stenosis. Mackenzie has examined 7 cases of this condition, 5 of which have been confirmed by postmortem examination, and in all he has found this form of tracing.

CONGENITAL LESIONS OF THE HEART.

Josephine E. Young¹ reports a case in which the finger-ends were clubbed, the heart enlarged, and a loud systolic murmur was heard over the whole precordia. There was no cyanosis, and the patient died from heart-failure in the course of an attack of acute erysipelas. At the autopsy stenosis of the conus pulmonalis was found about 4 cm. below the upper margin of the semilunar valves. The foramen ovale was patulous, and there was a defect in the ventricular septum more than 2 cm. in diameter. There was recent vegetative endocarditis of the pulmonary tricuspid valves.

W. Moore² also describes a case. The patient came under observation at the age of 8 and remained alive until 13. She was fairly well developed, but had marked cyanosis and clubbing of the fingers and toes. There was a confusion of bruits over her heart. At times she would suffer with pyrexia and cough, and sometimes had severe hemoptyses. She was transferred to the consumptive wing of the hospital and died of tubercular meningitis. The heart showed an aperture in the ventricular septum and the aorta entered just above this point, so that it communicated equally with both ventricles. The opening of the pulmonary artery was considerably contracted. The foramen ovale was open. The lungs contained fresh tubercles.

Rheiner³ reports 2 cases of extreme malformation of the heart. The first seemed a healthy infant, but was attacked with bronchitis. A loud double cardiac murmur was heard and the child died after 8 months. The septum between the ventricle was deficient, and the aorta sprang from the right ventricle. The pulmonary artery was stenosed. The 2d patient, a girl of 5, almost an idiot, and suffering with caries of the temporal bone, became cyanosed and died of purulent meningitis at the age of 5. The heart-sounds were very puzzling, but she had been in a fairly good condition. The autopsy showed extreme pulmonary stenosis; the pulmonary valves showed hardly any division and the septum between the ventricles was deficient.

F. A. Packard⁴ reports a most interesting instance of **imperfect closure of the auricular and ventricular septa** in a man who died at the age of 50 from abscess of the brain. The patient was a sailor, and came under observation with a history of having suddenly lost consciousness and having remained in a semiconscious condition for 10 minutes. There was localized convulsion of the right side and later a numb feeling of the entire right side. Physical examination discovered a blowing systolic murmur over the heart with enlargement of the organ. The lungs were negative. The postmortem examination showed a collection of pus beneath the pia, covering the lower surface of the cerebellum, and there was a large abscess in the parietal lobe of the left brain and extending into the ventricles. The basal nuclei were softened. The heart was filled with agonal and antemortem clots. It was globular, the apex being made up of the right ventricle. The right auricle was dilated. The

¹ Medicine, June, 1897.

² Intercol. Med. Jour. Austral., Oct. 20, 1896.

³ Virchow's Archiv, Dec., 1896.

⁴ Med. News, Aug. 29, 1896.

muscle-substance of all the chambers was a deep brown, and the weight of the organ, free from clots, 15 oz. The endocardium of the auricles was smooth and the foramen ovale patulous. Immediately below it there was a deficiency in the septum; and there was a deficiency in the ventricular septum, the undefended space being closed merely by the posterior tricuspid and anterior mitral leaflets. The aortic and pulmonary orifices and the endocardium were normal. The author reviews the opinions of pathologists regarding the development of malformations of this kind, and particularly remarks upon the great lack of development of the auricular septum, the smallness of the left and the great hypertrophy of the right side of the heart, and the peculiar arrangement of the anterior mitral leaflets and of the chordæ tendineæ, the latter springing for the most part from a single papillary muscle. Clinically, the case is of interest from the lack of symptoms despite the arduous duties of the patient, and from the occurrence of cerebral abscess, the only cause of which, as far as could be discovered, being a slightly diseased vermiform appendix.

Geronzi¹ reports an **extraordinary anomaly** occurring in a woman of 23. Her previous history was that she had always been slow in her movements, easily fatigued, and of impaired intellect; her color was pale without cyanosis and without edema of the face; but there was moderate swelling of the lower extremities. The area of cardiac dulness was greatly increased; there was gallop rhythm, and a murmur that resembled a pericardial friction-sound could be heard over the whole heart. There was

also considerable effusion into the left pleural cavity. A diagnosis of pericarditis was made. Death occurred shortly afterward as a result of anuria from a renal calculus. At the autopsy complete absence of the interauricular septum was found. The right ventricle was enormously hypertrophied, the left appearing to be merely an appendix to it. The opening of the pulmonary artery was 10 mm. in diameter, of the aorta 5 mm. The mitral orifice was very narrow and slightly stenosed; the tricuspid orifice very wide. The author explains the absence of cyanosis, in spite of the mixture of arterial and venous blood in the auricle, by the fact that the enormously enlarged right ventricle and pulmonary artery and the narrowness of the aorta in a way compensated the congenital anomaly.

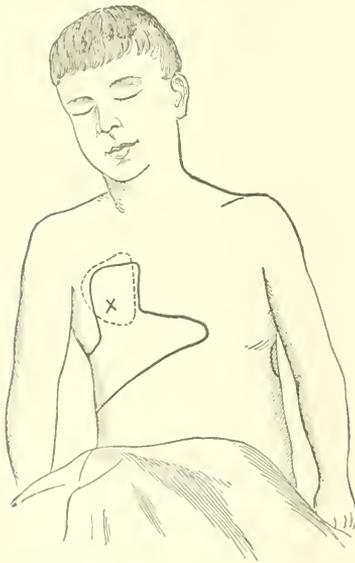

FIG. 2.—Dr. Maclellan's case of dextrocardia (Brit. Med. Jour., Oct. 31, 1896).

also considerable effusion into the left pleural cavity. A diagnosis of pericarditis was made. Death occurred shortly afterward as a result of anuria from a renal calculus. At the autopsy complete absence of the interauricular septum was found. The right ventricle was enormously hypertrophied, the left appearing to be merely an appendix to it. The opening of the pulmonary artery was 10 mm. in diameter, of the aorta 5 mm. The mitral orifice was very narrow and slightly stenosed; the tricuspid orifice very wide. The author explains the absence of cyanosis, in spite of the mixture of arterial and venous blood in the auricle, by the fact that the enormously enlarged right ventricle and pulmonary artery and the narrowness of the aorta in a way compensated the congenital anomaly.

Futran² reports an interesting case that presented the symptoms of cardiac insufficiency and signs of cardiac dilatation and mitral regurgitation. There was marked centrifugal pulsation in the veins of the neck, although both sounds in the tricuspid area were clear and sharp. A diagnosis was therefore made of **patulous foramen ovale**.

W. Maclellan³ describes a case of **dextrocardia** without displacement of other viscera in a lad of 15. The left lung was emphysematous and the left chest somewhat more voluminous than the right, the clavicle being noticeably

¹ *Riforma med.*, Nos. 203 and 204, 1896.

² *Berlin. klin. Woch.*, Feb. 8, 1897.

³ *Brit. Med. Jour.*, Oct. 31, 1896.

elevated on that side. The entrance of air seemed somewhat impeded on the right and the percussion slightly duller than normal. Probably this was due to pressure of the displaced organ upon the right bronchus.

Vehsemeyer¹ reports a case of dextrocardia complicated with chronic pneumonia of the left lung. The great vessels and the abdominal organs did not share in the transposition. Anschutz was able to take a satisfactory radiograph of the condition.

Ferrind² reports a **curious case** of cardiac disease. At each pulsation of the heart the left side of the thorax was elevated, the greatest elevation being observed in the 4th to 6th intercostal spaces. These pulsations were very vigorous and accompanied by a fremitus which could be felt as far as the right clavicle. The apex was in the 6th intercostal space to the left of the mammary line. The area of dulness was greatly increased. At the base systolic and diastolic murmurs were heard. In the 4th and 5th intercostal spaces there was a kind of mesosystolic rubbing, somewhat rougher in quality than a murmur. The arteries of the neck showed typical Corrigan pulsation, but in the lower limbs this condition was much less marked. A systolic murmur was heard in the femoral. In view of the history, which pointed to a congenital cardiac lesion, and the peculiar symptoms, Ferrind felt compelled to make a diagnosis of **congenital stricture of the aorta** at the end of the transverse portion of the arch.

Lytten³ presented a patient of 22 years, suffering from a congenital lesion of the heart, with marked **drum-stick fingers**. A radiograph showed that the thickening was due entirely to hypertrophy of the soft parts.

Diseases of the Myocardium.—De Domenico⁴ holds that the so-called **idiopathic hypertrophy** of the heart is undoubtedly due to increased activity with corresponding increase in the amount of nutrition absorbed, and that this increased activity may be due to a variety of irritating influences acting directly upon the heart-muscle.

Wm. C. Krauss⁵ discusses **the danger of bicycling** and reports a case of acute cardiac dilatation due to this cause. The patient was not accustomed to the exercise, and collapsed after riding 8 miles. Physical examination some weeks later showed a heart extremely dilated but with no murmurs. The pulse varied from 130 to 150 per minute.

R. Van Santvoord⁶ reports a case that he regards as **traumatic myocarditis** occurring in a man of 24, who, after a severe concussion, had an irregular, feeble pulse of about 106 per minute, which continued for several days, when death occurred from edema of the lungs. [Unfortunately no autopsy is reported.]

Cardiac Syphilis.—S. Phillips⁷ discusses syphilis of the heart-wall, reporting first a case of his own that was suddenly attacked with pain in the precordial region. This was relieved by morphia, but 18 days later the patient suddenly died while reading a newspaper. At the autopsy a gumma was found in the left ventricle. The author collected 25 cases of this condition, in all of which the diagnosis was confirmed by autopsy, and then reports 14 cases without autopsies of his own, dividing them into those suffering from severe angina without physical signs of cardiac disease; those suffering from dilatation of the heart, only distinguished from similar conditions due to other causes by the more pronounced symptoms; those in which there is gradual, progressive loss of

¹ Deutsch. med. Woch., Mar. 18, 1897.

⁴ Wien. klin. Woch., May 22, 1897.

⁵ Jour. Am. Med. Assoc., Oct. 10, 1896.

⁶ Med. Rec., Aug. 11, 1896.

⁷ Lancet, Jan. 23, 1897.

cardiac power without dilatation of the left ventricle, which he ascribes to diffuse fibroid change; and, finally, cases with hypertrophy of the heart not apparently due to valvular disease. He also reports 1 case in which a gummatous growth had evidently preceded the development of cardiac aneurysm. In regard to diagnosis the most important element is, of course, evidence of syphilitic infection. Gumma of the left ventricle may be suspected in any individual with such syphilitic antecedents if there occur signs of derangement of the left ventricle with symptoms of defective or embarrassed action, especially angina pectoris, tachycardia, or syncopal or epileptiform attacks; in the right ventricle when dyspnea otherwise unaccounted for occurs. Syphilitic disease is also indicated by extreme feebleness of the heart without dilatation or hypertrophy and without ascertainable cause. In regard to treatment, Phillips believes that it is probable that gummata or even extensive fibroid change may be relieved by mercury and potassium iodid. [The author is too prone to make the diagnosis of syphilis, according to our view. Accepting his points for diagnosis, we should probably be led to regard myocardial syphilis as a very common disease, which is not the case.]

F. Cöggelshall¹ reports a case of cardiac syphilis occurring in a man who in youth had been extremely dissipated, and later had indulged to excess in physical exercise and hard study. The attacks at first resembled syncope, the patient becoming slightly cyanosed, pulseless, and very weak, but not unconscious. Later they became more epileptic in type and accompanied by signs of cardiac failure, particularly extreme bradycardia, the pulse being only 15 to 20 per minute. These attacks occurred several times a day, but the patient reacted well to stimulation. The physical signs during these attacks consisted of a loud, rough murmur heard all over the cardiac area, but most distinctly at the base, that replaced both sounds. The presence of a large thrombosis in the right ventricle was suspected. At the autopsy, however, syphilitic myocarditis was found.

Rosenthal² reports a case of syphilitic myocarditis. The patient after numerous relapses appeared to be cured of the specific disease; he then commenced to exercise and used alcohol to excess. On one occasion, after a severe bicycle ride, he had a feeling of oppression in the region of the heart and dyspnea. This continued until he came under treatment. He was then found to have a rapid pulse, arrhythmia, and a split second sound at the base. The aortic second tone was accentuated; the area of cardiac dulness extended somewhat to the right. Treatment with tincture of iodine and strophanthus caused rapid improvement in the subjective symptoms; a systolic murmur developed over the pulmonary artery, and occasionally one could be heard in the mitral region. The arrhythmia continued. The author believes that the strain to which the heart-muscle was subjected caused it to be particularly selected by the poison in the system.

Aneurysm of the Heart.—A. N. Davis³ describes a case of aneurysm of the heart in a woman of 57 who had been insane for a number of years. Four months before her death dyspnea, pain in the heart-region, moderate cough, hemoptysis, and night-sweats developed. At the autopsy an aneurysm of the left ventricle was found on the anterior wall of the heart, and hemorrhagic infiltration of the heart-muscle.

T. S. Short⁴ reports a case of aneurysm of the ventricular septum that during life caused profound dyspnea unless the patient occupied the recumbent position. Murmurs were occasionally heard, both systolic and presystolic in time,

¹ Boston M. and S. Jour., Dec. 10, 1896.

³ Lancet, Aug. 8, 1896.

² Deutsch. med. Woch., Apr. 1, 1897.

⁴ Brit. Med. Jour., May 8, 1897.

but were inconstant. At the autopsy the aneurysm was found projecting into the cavity of the right ventricle and partially occluding the pulmonary orifice.

Cardiac Tumors.—Kayserlink¹ reports a case of tumor of the heart. The patient was emaciated, the heart was enlarged, and there was decided fremitus beside the apex-beat and over the base of the heart. Tenderness on pressure was observed posteriorly, and there was severe pain in the breast and arm. Paraplegia developed suddenly and was followed by cystitis and decubitus. The patient succumbed. Postmortem there was found a pericardial effusion, a tumor of the auricles, and a tumor, probably primary, in the hilum of the left lung. This extended along the bronchi into the lung. There were metastases in the second and third dorsal vertebræ, the collapse of which had caused the paraplegia. The tumor was a lymphosarcoma. Leroux and Meslay² report a case of multiple sarcomata of the heart secondary to orbital sarcoma. The heart's action had been rapid and irregular, but there had been no murmurs.

Rupture of the Heart.—F. O. Simpson³ describes a case of rupture of the heart in a man of 62, a senile dement. The patient had regular but slow action of the heart and atheroma of the vessels. One day while sitting quietly in a chair he suddenly became unconscious and very pale; his radial pulse could not be felt, and the sounds of the heart were inaudible; the breathing was frequent, and death followed in about 25 minutes. At the autopsy the pericardial sac contained 210 gm. of blood-clot. The heart weighed 370 gm. There was a rupture of the posterior wall of the ventricle about 1 cm. in length. The myocardium was markedly degenerated. A. N. Kelynack⁴ also reports a case. The patient, a man of 68, was brought to the hospital unconscious. He had worked all day but felt unwell. In the evening he went into the back yard and was shortly afterward found unconscious. During the 6 months previous he had had 2 or 3 fainting attacks; his memory had been deficient, and he acted strangely. On admission there was no paralysis, tremor, or rigidity; the pupils were equal and reactive. He began to recover in about 5 minutes, and soon was able to speak, although dazed, and was able to walk feebly. He slept all night, and the next morning felt quite well. About midnight the next night he became restless and insisted on getting out of bed. The next morning he was apparently well, but about midday had an epileptiform attack with spasms of the right hand and arm and with traction of the mouth toward the left side; breathing was stertorous, then irregular, and he died in 10 or 15 minutes. Just before death the heart-sounds could not be heard. The autopsy showed a rupture of the heart along the postero-external border of the left ventricle. The heart-muscle was softened at this point, and the ventricular wall was soft and flabby; the coronary arteries were extremely atheromatous. There was no focal lesion in the brain. The case is of interest as showing that death may not be instantaneous and that cerebral symptoms may complicate the clinical history. W. Groom⁵ reports a case occurring in a boy of 16 a month after an injury. The rupture took place in the right ventricle, which at this point consisted only of epicardium.

Bernstein⁶ has collected about 121 cases of cardiac diseases ascribed to traumatic injuries or contusions, and points out that there is no specific traumatic heart-disease. He gives the details of 13 cases of his own, in only 1 of which was the contusion directly over the heart. Nervous disturbances were relatively uncommon. The only positively ascertained immediate results are rup-

ture of the heart-muscle or valves. In the former case some disease of the muscle has usually preexisted, while in the latter case healthy segments and those of the right heart particularly are affected. The clinical effects of these injuries, as a rule, do not manifest themselves until some time after the injury, probably on account of the reserve power of the organ. The inflammatory lesions of the endocardium are prone to become chronic, while in traumatic pericarditis both acute and chronic forms are met with. Acute endocarditis may be simple or septic in character; traumatic pericarditis may be benign or purulent. The author could find no instance of isolated traumatic myocarditis.

James Jamieson¹ reports the case of a young butcher who was suddenly subjected to severe strain and immediately felt as if something had given way in his chest, and was seized with pain in the region of the heart. Upon admission there were some cyanosis and the signs of cardiac dilatation; on auscultation a double murmur was heard at the aortic region, and an inconstant mitral systolic murmur. He improved upon digitalis, but died suddenly after eating. At the autopsy it was found that the partition between 2 of the segments of the aortic valves was partially torn away from the wall, throwing the 2 pouches into one. The valves were otherwise normal. The author believes that the septum was suddenly ruptured.

W. J. Hanna² describes the case of a criminal who stabbed himself in the region of the heart with a sharpened wire. There were pain of moderate severity and dyspnea, but no very marked symptoms for 29½ hours, when the patient was hanged. The autopsy showed the left ventricle **completely penetrated** and 12 oz. of blood in the pericardial sac.

Treatment of Cardiac Disease.—[The Schott method for the treatment of heart-disease is still exciting considerable discussion. In general, the evidence is favorable, although warnings against its indiscriminate use are not lacking.] H. N. Heineman³ describes the **Schott method**. He lays particular stress upon the local effects of carbon dioxid, holding that its action is to dilate the capillaries in the skin and prevent cooling of the surface, having observed that when the bubbles are brushed away from any portion of the skin it remains white and is subjectively cold. He believes that the salts in the bath are absorbed as far at least as the cutaneous nerves, upon which they act and cause the reflex stimulation. The artificial baths are slightly inferior to the natural baths at Bad Nauheim. Usually the first bath consists of a 1 or 2% solution of NaCl, to which a ½% solution of CaCl₂ is added; subsequently the bath may be made stronger and carbonated by the addition of Na₂CO₃ and HCl. The movements must be adapted to the peculiarities of the patient. When interruption of the heart-beat occurs exercise should be at once suspended. Outside of Nauheim, it is well to use also the ordinary methods of treatment. In conclusion, he reports 12 cases, all of which were greatly improved.

Alex. Morison⁴ commends the Schott method very highly. He uses Potain's method for indicating the size of the heart, which is as follows: the greatest height of the cardiac area is multiplied by the greatest breadth and the product by an empirical coefficient, 0.83; the result in sq. em. is approximate if the figure obtained does not depart far from the usual outlines. In one of the cases under Dr. Schott's treatment the measurements were reduced from 22 by 12 cm. to 17 by 9 cm. Using the formula, from 219.1 cm. to 126.9 after. Such a shrinking of the cardiac area or encroachment of the lung can only be temporary, but a repetition of the treatment is sufficient to establish permanency.

¹ Intercol. Med. Jour. Austral., Nov. 10, 1896.

² Occidental Med. Times, July, 1896.

³ Med. Rec., Dec. 12, 1896.

⁴ Practitioner, Sept., 1896.

Schott¹ has employed the **Röntgen rays** for the determination of the alterations produced in the size of the heart by his methods. As the tube always occupied a definite position with relation to the patient, it was possible to apply mensuration to the results; thus, in a boy of 8½ years suffering from mitral insufficiency the breadth of the heart at the 3d rib before gymnastics was 9.7 cm.; after, 8.8 cm. It is not possible to determine variations in the vertical diameter of the heart. The effect of the baths was the same. In a 14 year old girl the greatest diameter diminished 0.8 cm.

George Herschell² is still uncertain of the value of the baths in use at Nauheim and elsewhere, but admits freely the utility of resisted movements. He prefers mechanical resistance, especially an apparatus consisting of rubber cords with handles attached somewhat in the manner of pulley-weights. He warns against careless use of this treatment, and urges that the pulse and sphygmographic tracings be taken before, during, and after the exercise; that the rate of the respirations be noted, and the area of cardiac dulness and the apex be carefully observed.

S. Solis Cohen and C. West³ report a case of cardiac dilatation occurring in a woman of 58 years with, apparently, considerable myocarditis, treated by the **Schott method** of passive movements. As a result, the apex receded from 1 in. to the left to the right of the nipple-line, and from the 6th to the 5th interspace. The pulse diminished from 96 to 58. Contraindications are advanced arteriosclerosis, degeneration of the myocardium, and aneurysm.

H. N. Heineman⁴ reports 4 cases of stenocardia in which the Schott method was employed with excellent results.

J. W. Bell⁵ suggests the use of **saline baths** of suitable temperature for the purpose of freeing the peripheral circulation and thus relieving the venous engorgement due to an insufficient senile heart.

T. G. Stewart⁶ opened a discussion on the treatment of "cardiac failure" before the British Medical Association, with a general consideration of the various plans of treatment. The most important elements are **rest**, particularly serviceable in individuals accustomed to severe physical exertion, and diet. Some patients require increased allowance of food, some a diminution, while some require alteration in the quality. In patients who have been underfed, or in hospitals or institutions of other kinds, a more liberal amount of meat than is the rule may be advised. Alcohol in moderate doses is useful, but excess, even though slight, and forms that disturb the stomach must not be employed.

He then considers the effects of **exercise**, and, first, passive exercise. He has practised the method of Ling in a number of cases, and concludes that the area of cardiac dulness perceptibly diminishes during each administration, and that the sounds and action of the heart and pulse correspondingly improve. The patient experiences subjective improvement, which may pass off in a few hours completely or incompletely. Repeated applications may give permanent improvement. Occasionally these exercises are not well borne.

He next refers to the "**resisted movements**" of Schott. His experience with this method leads him to the following conclusions: that in a large proportion of cases there is immediate improvement in the condition of the heart as shown by percussion or auscultation, the sounds becoming more distinct and the area of dulness diminishing; in many cases the rhythm of the pulse improves and the beat becomes stronger; the results are temporary, but

¹ Deutsch. med. Woch., Apr. 1, 1897.

³ Phila. Polyclinic, Mar. 6, 1897.

⁵ Ibid., Sept. 26, 1896.

² Lancet, Aug. 15, 1896.

⁴ Med. News, Jan. 9, 1897.

⁶ Brit. Med. Jour., Sept. 19, 1896.

the heart rarely goes back to its original condition; while repeated treatment leads to gradual and lasting improvement. The author refers to a number of cases. He points out that in this treatment the blood-vessels of the muscles dilate during contraction; this leads to lessening of the peripheral resistance and increased inflow of blood by contraction of the veins. In spite of the latter, however, the amount of blood in the heart is diminished because of the arterial dilatation. Excess of muscular work would lead to an inordinate inflow of blood into the heart and its work would be increased.

The Schott method is so conducted as always to fall short of this point. He believes that it is not impossible that increased proportions of CO_2 in the blood may be one result of the method and may contribute to peripheral dilatation of the vessels through the vasomotor system. He concludes that the Schott method is best suited to cases in which there remains a certain power of the heart, while the mere passive exercises of massage are applicable to weaker conditions of the organ. The **method of Oertel** of climbing heights is not widely applicable.

He has experimented with artificial baths, finding as follows: baths of ordinary Edinburgh water at a temperature of 95° led to no change in the size of the heart after 15 min., either in normal cases or in cases with dilated heart. Practically the same results were obtained with saline baths. When, however, large quantities of carbonic acid gas were disengaged in the saline bath peripheral reddening and diminution in size of the heart were noted. The author points out that, as a rule, diminution of peripheral resistance should be followed by a quickened action of the heart and fall of arterial pressure, and not by a slower rate of beat, as is the case. He suggests, as an explanation, that the heart has been previously acting irregularly and too quickly, in consequence of its unfitness to meet the demands upon it; but he does not deny that the carbonic acid and the baths in general may have some direct influence upon the nerves of the skin. Finally, he concludes that none of these methods is entitled to displace the **older methods of treatment**—rest, diet, and medicine. In this opinion he believes Dr. Schott concurs. The methods of treatment referred to are valuable auxiliaries, and may allow us to dispense with remedies that are not well borne.

In the discussion which followed a number of gentlemen participated, including Leith, Sandby, Byrom Bramwell, Thorne, Morison, Savill, and Fisher. The opinion was quite general that the mechanical methods of treatment afford decided advantages.

J. Neumann¹ believes that **sodium iodid** is useful in certain cases of chronic insufficiency that are not adapted to the method of Schott or Oertel. He usually prescribes it in combination with the infusion of digitalis.

Hirschfeld,² in discussing the question of **diet in cardiac disease**, states his belief that the former custom of administering small quantities of food during stages of broken compensation in heart-disease is more or less well founded. Reduction in the amount of nutrition does not prevent proper cardiac nourishment, as Timofejeff saw hypertrophy develop in dogs after artificial valvular defects had been established, in spite of starvation diet. Moreover, the periodical consumption of food places a certain amount of strain on the heart, especially the consumption of liquids, as Oertel taught; it requires considerable cardiac activity to supply blood for the functions of the glands concerned in active digestion, and the mere mechanical problem imposed by the periodical distention of the stomach may have further unfavorable influence. The best results with milk-diet have been obtained by those who used

¹ Brit. Med. Jour., May 3, 1897.

² Berlin. klin. Woch., Aug. 17, 1896.

very small quantities (600 to 800 c.c.) of milk per day. When the quantity was increased the cases did badly. He holds that the diuresis resulting in these cases is not due to the milk-diet, because the addition of other food or of milk at once stops the beneficial action. He himself has made some 20 experiments with reduction of the diet, some of which have been previously published. Of the first 5 cases 3 showed very positive results. Later he sometimes obtained useful results, but none so convincing. It seemed desirable, therefore, to determine in what cases this reduced diet is specially useful. One of the first results is the reduced demand for liquid, and a beneficial result may therefore be expected when there is only a moderate grade of edema and when disturbances of compensation have not existed too long a time. Another consideration of importance is that the appetite of the patient shall have been previously satisfactory. Under these circumstances a sudden reduction of diet brings about the most striking results. The amount of nutriment irrespective of its quantity exercises a powerful influence, for in cases in which the same amount of food was introduced at different times, but with varying quantities of nutriment contained therein, he found the edema and dyspnea increased as soon as the nutriment was increased. He therefore opposes Oertel's view that an abundant or rich diet should be given to patients emaciated or reduced in vitality. As soon as compensation has failed it is advisable to reduce the diet. The nutrition may be improved after compensation has been restored. [This paper undoubtedly contains much that is true. The author does not deny—in fact, asserts—the importance of mere quantitative reduction of diet, but he gives this a place inferior to qualitative reduction. We should be less disposed to view the latter so favorably, though he is undoubtedly correct in asserting that cases of beginning failure of compensation with slight edema may be placed on reduced diet with advantage.]

Molderesen¹ advises the use of **calomel** in the treatment of cardiac diseases; he administers as much as 8 to 10 gr. divided into 6 doses, especially in cases in which there is a comparatively moderate valvular lesion, with marked dyspnea, hypertrophy, dilatation, albuminuria, or dropsies. After a few doses diuresis is usually established, and by the 2d or 3d day copious action of the bowels. As a rule, it is better to administer somewhat small doses for long periods of time, and in order to prevent salivation he employs a mouth-wash composed of chlorate of potash and tannic acid. Out of 170 cases of grave cardiac disorder treated in this manner, 14 died, 2 of pneumonia, after the heart-symptoms had been relieved, 3 before the treatment had been sufficiently under way; the 9 others were persons of advanced years in whom the disease was well established. [One of the editors, in a communication a year or two since, recommended this remedy as of particular value in certain forms of combined renal and cardiac disease. He did not find continuous use of the remedy advisable, and obtained results only when considerable doses were administered. The effect was most striking when opium was used coincidentally to prevent purgation. It does not seem likely to us that Molderesen's view, that the beneficial effect is due to relief of the congestion of the liver, is well founded. Copious diuresis is the most evident and doubtless the most desirable result.]

G. R. Lockwood² reports 9 cases of cardiac disease in which removal of all forms of nasal obstruction caused the cardiac symptoms to disappear.

Arnold Lorand³ urges that patients suffering from valvular heart-disease be sent, if possible, to **warm climates**.

Jaccoud⁴ believes that when perfect compensation exists it is not necessary

¹ Rev. de Thérap. médico-chir., June 1, 1896.

² N. Y. Med. Jour., Jan. 16, 1897.

³ Med. Rec., July 18, 1896.

⁴ Sem. méd., p. 357, 1896.

to forbid **marriage in heart-disease**, having observed a case in which a woman had 4 children without noticeable increase of a mitral lesion. After the 6th child, however, compensation was lost.

Cardiac Neuroses.—Van der Velde¹ reports some experiments upon normal individuals in regard to their ability to increase the **frequency of the cardiac contraction**. He found that by concentration of the attention it was possible to increase the rate on an average 20 beats per minute in all of the persons investigated, including himself; and he believes that this ability is probably shared by all to a greater or less extent. The cause, he considers, is due entirely to an effort of the will.

Kish² describes a nervous cardiac disturbance that occurs among the officers of the German Army. It consists of repeated attacks of **palpitation**, accompanied by a feeling of oppression and anxiety. Often there is some uncertainty in the gait, and dizziness and even unconsciousness. In the interval the pulse is usually rapid, from 80 to 100 per minute, and the arteries soft and less elastic than normal. As all the other conditions can be excluded he believes that the cause is some psychical influence.

T. Henderson³ reports a case of paroxysmal **tachycardia** which developed after a period of severe labor and anxiety. The heart was not enlarged and the sounds were clear and normal. The ordinary rate was about 80. At times it would commence suddenly to pulsate with such rapidity as to cause vibration of the precordia. The pulse apparently exceeded 200 per minute.

J. W. Ogle⁴ reports 4 cases of **bradycardia**, in all of which fibrous deposits were found in the myocardium. He believes that these morbid deposits act as foreign bodies and impede the action of the intracardiac ganglia. Two of these cases had epilepsy.

P. A. Dewar⁵ reports 2 cases of **slow pulse**. The first, a man of 63, had always been active, both mentally and physically; he had suffered from acute rheumatism, but made apparently a good recovery. For 2 years he had been pale, weak, and suffered from sighing respiration, and his pulse had averaged about 20 beats per minute, although the heart's action was strong and regular. The lowest rate recorded was 16 and the highest 36. Ultimately, he had attacks of what seemed to be petit mal, and convulsive seizures in which he bit his tongue. After this the heart became weak, rapid, and irregular. The second case was a man, apparently healthy, strong, and active. Nevertheless his pulse was irregular and running 20 to 25 per minute. From time to time he suffered from attacks of loss of consciousness, which, under bromids, became rarer.

W. E. Risdon⁶ reports a case of a man of 38 years who was suddenly seized with **faintness**. In the recumbent posture he recovered, but on attempting to stand he became pulseless and deeply unconscious for 2 hours. Then the heart recovered somewhat, beating from 24 to 30 times per minute. This was followed by intermissions and progressive cardiac failure. Death occurred 3 days later. At the autopsy a few streaks of fat were found at the apex of the heart, but otherwise it was normal.

Lewin⁷ states that in acute **lead-poisoning**, particularly that due to lead acetate, the pulse is sometimes small and very rapid. He has collected 5 cases in which this occurred, and 10 cases in which there was bradycardia; in 1

¹ Pflüger's Archiv, vol. lxxvi., p. 232.

⁷ Deutsch. med. Woch., Mar. 18, 1897.

case the pulse dropped to 15 beats per minute. In 1 case it was unaltered by the poison.

D. Drummond¹ reports 6 cases of **functional murmurs**, and concludes that these murmurs occur in highly neurotic people and are associated with violently acting ventricles independent of the lung conditions, or may be intimately connected with respiratory and structural alterations in the lung. They are not limited to any cardiac area or period, and usually alter under the influence of rest, position, or respiratory movement.

Melo² discusses the **nervous disturbances**, such as hysteria, neurasthenia, epilepsy, and even insanity, that occur **in the course of uncompensated heart-disease**. He considers that the valvular lesions act either as predisposing or exciting causes, particularly in persons with a hereditary predisposition, as all these cases are of the clinical type of the hereditary neuropathies.

A. A. Smith³ exhibited a patient in clinic with valvular heart-disease. Upon one occasion she became excited and had palpitation and evidence of want of heart-compensation. The **temperature** was taken and found to be at least 112°, the limit of the thermometer. The observation was repeated in the rectum with several thermometers and confirmed. The following morning it had fallen to 104.6°, but in the evening rose again to 108°. The patient exhibited many symptoms of hysteria.

ANGINA PECTORIS.

Wm. Osler⁴ looks upon angina pectoris not as a disease, but as a syndrome, characterized by a heart-pain and the fear of impending death. He recognizes the following abnormal cardiac sensations: consciousness of the heart's action—that is, palpitation and a sense of tension in the chest; pain of almost any variety and intensity, and a peculiar condition which consists of a sense of imminent dissolution (*angor animi*). He recognizes 2 forms—angina pectoris vera and angina pectoris notha—which he subdivides into hysterical, vasomotor, and toxic forms. It is not clearly understood how the common lesion, some obstruction of the coronary circulation, causes the disease. It is certain that gradually developing obstruction may not lead to serious symptoms. Osler recognizes 4 groups of the disease: 1st, sudden death without other manifestations of angina pectoris; 2d, death in the first well-marked paroxysm; 3d, recurring attacks extending over a period of months or years; 4th, rapidly repeated attacks over a period of days or weeks with rapid development of a state of cardiac asystole (*l'état de mal. angineux*). In further discussing the symptomatology, he calls attention to 4 interesting conditions, closely allied to true angina, that may either develop in the course of an attack or occur spontaneously in the subjects of heart-disease or arteriosclerosis. These are syncope anginosa—that is, a tendency to faint during the attack, although this is not common; 2d, Adam-Stokes' syndrome, characterized by permanent slowness of the heart and vertigo or syncope; 3d, angina pectoris sine dolore; and 4th, cardiac asthma. He next takes up pseudo-angina, which has 3 characteristic features: it occurs chiefly in women, in younger persons, and does not cause death. There are 3 main types—the neurotic (occurring usually in hysteria), the neurasthenic, and the toxic (most commonly observed among tobacco-smokers). In attempting to explain the nature of the lesions he calls attention to the remarkable phenomena known as intermittent claudication, a condition apparently due to the blocking of the main artery and the insufficiency

¹ Lancet, Apr. 6, 1897.

³ Med. News, Dec. 19, 1896.

² Thèse de Paris, 1896.

⁴ N. Y. Med. Jour., Aug. 8, 1896.

of the collateral circulation to meet the unusual demands. In explanation of the pain he offers 4 theories: (a) a cramp of the heart-muscles; (b) distention and stretching of the cardiac wall; (c) arterial pain; (d) neuralgic or neuritic pain. [It is impossible, with the limit of space at our disposal, to do justice to this remarkable series of lectures.]

D. W. C. Hood¹ states that the following clinical groups may present symptoms of anginoid character: 1, acute dilatation of the heart due to sudden, prolonged effort; 2, chronic dilatation of the heart due to slow degeneration; 3, dyspneal angina sine dolore; 4, neurotic—functional and organic; 5, gouty; 6, reflex—stomach, tobacco; 7, asthmatic—right-sided heart-disease; 8, renal; 9, pseudo-angina, fictitious angina—neuralgic, anemic, climacteric, alcoholic, etc. This classification, he admits, is artificial and purely clinical. In cases of angina sine dolore the patient frequently describes his symptoms as arising from dyspepsia, and the fact that discharge of flatus often gives relief seems to add confirmation. The author, therefore, advises that attention should be paid to flatulent discomfort after food or exertion, occurring in persons in advanced middle life.

Grocco² distinguishes 2 forms of angina pectoris—the neurotic and the arteriosclerotic. He has observed 3 cases of the former type with distinct lesions of the nerves at the base of the heart, consisting of interstitial neuritis and degeneration. In the arteriosclerotic forms myocardial degenerations are of great importance; but even in these cases he holds that the nervous mechanism within the heart may be the part that suffers first.

John Maddin³ reports 5 cases of angina pectoris, in none of which was it possible to detect by physical examination any organic disease of the heart. He looks upon these as the true **idiopathic form**.

H. L. Elsner⁴ reports the case of a patient of 46 who suffered from shortness of breath after exertion and attacks of angina pectoris, although repeated examinations by various physicians failed to detect signs of cardiac disease. Death occurred in the course of one of the anginoid crises. An autopsy could not be obtained. The author regards the case as one of **myocarditis**, probably specific in nature.

Treatment.—Schott⁵ recommends **nitroglycerin** as the most reliable symptomatic remedy for angina. The action is most satisfactory in cases in which the symptom is due to spasm, and next in efficiency in cases in which there are associated lesions of the aorta. It is less reliable when there is myocarditis or fatty degeneration of the heart. He advises administration in liquid form, as the tablets frequently prove inefficient. He claims that the doses should be larger than those usually administered.

Vierordt⁶ recommends the employment of **sodium iodid** in cases of angina pectoris, particularly those in which there is distinct cardiac weakness or the presence of albuminuria.

Ostwick⁷ has employed **hyoscin** in a case of angina pectoris that he believed to be of neurotic origin, with excellent results.

EXOPHTHALMIC GOITER.

J. Dreschfeld⁸ discusses Graves' disease, reporting 40 cases. He found that the most frequent symptoms, in addition to those peculiar to the dis-

¹ Lancet, Sept. 26, 1896.

⁶ Med. News, Sept. 5, 1896.

⁷ Centrabl. f. innere Med., June 26, 1897.

⁸ Practitioner, Aug., 1896.

ease, are tremor, muscular cramps, localized atrophies, and alteration of the reflexes. The 3 latter symptoms he was unable to observe in any of his own cases; however, he noted that psychological disturbances are chiefly depressing in nature, although occasionally the patient is irritated. In one case he observed epileptic convulsions. Profuse perspiration was present in all, but most marked in those where there were tachycardia, pyrexia, and emaciation. In 7 cases he observed pigmentation of the skin, and in 6 the areas of pigment were placed symmetrically. In 7 cases there was persistent vomiting, invariably associated with and probably due to acetoneuria. Diarrhea was present in 10 cases and paroxysmal dyspnea occasionally. In 1 case there was marked polyuria, in another swelling of the lymph-glands. Dreschfeld has been able to confirm the observation of Charcot, that patients usually improve markedly after delivery, if allowed to go to full term. In regard to the treatment, he doubts whether the benefit derived from surgical interference justifies the danger of the operation, the total mortality being at present 12%. He also is skeptical of the value of thyroid-feeding. He is more favorable, although he has never employed it himself, to the injection of the blood-serum of dogs whose thyroid glands have been removed.

Lemke¹ regards tachycardia and tremor as the most significant symptoms of Graves' disease. He holds that it results from some form of **specific muscle-poison** produced by the thyroid gland.

R. G. Curtin² believes that Graves' disease is hereditary, and that, therefore, the **marriage** of those suffering from it should be discouraged.

J. A. Booth³ reports a case of exophthalmic goiter presenting the unusual symptom of edema of the eyelids. After the removal of one lobe of the thyroid gland there was marked improvement in all the symptoms excepting this.

Treatment.—[This disease has, for some reason, appeared more suitable for organotherapy than almost any other. As a result, various organs have been utilized with more or less doubtful results.] H. Mackenzie⁴ has collected the reports of 15 cases of exophthalmic goiter treated by large doses of **thymus gland**. In 14 of these there was very considerable improvement. To these he adds 20 cases of his own: 1 died; in 6 no improvement was observed; in 13 there was some improvement. However, the effect produced upon the most important symptoms does not lead him to believe that the gland has any great value. The pulse was not altered in 12 cases; it was increased in 2; it was diminished in 6, but in 5 of these only slightly. In only 3 cases was there any material diminution in the size of the thyroid gland; in 2 it increased; in 1 only there was diminution in the exophthalmos. Comparison with the notes of 20 cases treated by other methods shows that the thymus has little, if any, advantage over them. A. Maude⁵ reports 4 cases of exophthalmic goiter treated with tabloids of thymus gland. All were extreme cases with typical symptoms; 3 of them presented considerable psychological alteration, and all had been treated by the ordinary methods without result. All showed remarkable improvement under the thymus treatment, but without much reduction of the size of the gland. Particularly the rapidity of the heart's action and the tremor were much diminished. R. M. Whitefoot⁶ reports a case of exophthalmic goiter occurring in a girl of 18 years, with a neurotic family history. There were all the characteristic symptoms, and in addition profuse menstruation. Treatment with extract of **thyroid gland** produced decrease in the size of the tumor, reduction of the eyeballs, and a greater regularity in the action of

³ Lancet, July 18, 1896.

⁴ Internat. Clin., vol. iv., series 6, 1897.

⁵ Am. Jour. Med. Sci., Feb., 1897.

⁶ Med. News, Oct. 3, 1896.

the heart, but at the same time the patient became melancholic and emaciated. On account of loss of appetite and nausea treatment was suspended at various times, but at the end of 60 days she had become apparently entirely well.

H. C. Wood,¹ in a paper on the functions and therapeutics of the ductless glands, refers to a case of exophthalmic goiter under his care, in which suppurative splenitis developed without apparent cause. The abscess discharged and there was a period of many months of severe sepsis, followed by recovery. In the second or third week of the splenitis the thyroid gland began to decrease in size, and eventually there was permanent cure. This case led him to use **splenic extract** in cases of Graves' disease. He has found, however, that doses sufficiently large to produce effects are apt to derange digestion, and hypodermically great irritation and even abscesses are caused by the extract. In one of his cases, which could be followed systematically in the hospital, the patient insisted that she had recovered after some weeks and refused to stay longer, although there was still some enlargement of the thyroid gland. In another case there was violent gastric irritation, and the remedy was therefore administered hypodermically; improvement soon manifested itself and continued until the enlargement of the gland entirely disappeared. The other symptoms had somewhat improved. [The evidence in favor of this treatment is certainly slight, and the possible elements that may have contributed to the spontaneous improvement in his first case after the development of splenitis are many. The most immediate suggestion is that the infection may have been instrumental.]

A. Carless² discusses the treatment of exophthalmic goiter. Of all the methods hitherto suggested, he is inclined to consider **phosphate of sodium**, suggested by Traebewsky, as the most likely to be of value. He admits that thyroid extract may be of use, but points out that in some cases, at least, it predisposes to heart-failure. He also mentions, without criticism, the use of thymus extract and the serum of myxedematous dogs. Finally, after discussing the operative methods, which he regards as dangerous, he mentions section of the cervical sympathetic as suggested by Jaboulay, a method too recent to have given definite results.

Tricomi³ reports 3 cases of Graves' disease in which **removal of part of the gland** resulted in benefit. These cases were typical and the goiter was very prominent. Palpitation, exophthalmos, frequent pulse, tremor, etc., were present, but Graefe's sign was absent. After operation the symptoms disappeared in 2 cases, and in the third there was noteworthy improvement. Two cases had begun after influenza.

Matthes⁴ has examined the **nitrogen-balance** in cases of exophthalmic goiter before and after strumectomy. Before the operation it was found that the excretion was in excess of the ingestion, although it was possible by the introduction of large quantities of albumin and calories to obtain a balance. After the operation the bodyweight increased, and disintegration of the albumin was diminished to 25% of the nitrogenous metabolism. When the gland that had been extirpated was fed to the patient, it was found that the amount of nitrogen excreted increased. [These results are important, because they indicate that partial removal of the thyroid gland may have an important effect upon the general nutrition, whether it improves the so-called cardinal symptoms or not.]

Jaboulay⁵ describes a case of Graves' disease in which the right lobe of

¹ Am. Jour. Med. Sci., May, 1897.

⁴ Centralbl. f. innere Med., June 26, 1897.

⁵ Lyon méd., No. 12, 1896.

the thyroid gland was removed; later the left one, this having become hypertrophied; the middle lobe then enlarged, and a third operation was undertaken, the sympathetic nerve between the upper and middle cervical ganglia being removed. The palpitations, tremor, and exophthalmos diminished, but the former returned after 3 months.

DISEASES OF THE ARTERIES.

Litten¹ discusses the physical signs of **pseudo-aortic insufficiency** and atheroma of the abdominal aorta. The former is characterized by a thrill in the carotids when they are lightly pressed upon, and considerable accentuation of the aortic second sound without a diastolic murmur. Atheroma of the abdominal aorta is also to be recognized by this abnormal development of an arterial thrill, associated with pains in the abdomen, particularly at night, that do not extend toward the spinal column. Palpation also reveals more or less enlargement of the aorta, and if the wall of the latter contains calcareous plates they may sometimes be felt crackling under strong pressure.

Gerhart² reports a case exhibiting **pulsus paradoxus** on one side of the body with unequal pulses of the arteries of the two arms. The patient was a woman of 66, who had for years suffered with ulcers of the legs and who had had a fracture of both bones of the forearm a few years before. In December, 1895, she suffered with dyspnea, fever, swelling of the feet, and diminution of the daily quantity of urine. On admission to the hospital it was found that she had bronchitis and mitral regurgitation. The pulse was irregular, from 80 to 90. There was a sharp blowing systolic murmur at the apex, and occasionally a diastolic murmur suggesting stenosis. She had moderate ascites, edema of the feet, and albuminuria with hyaline and granular casts. The left pulse was strikingly smaller than the right, not only in the radial, but also in the brachial and carotid arteries. The femoral pulses were equal. The arteries were thin-walled and soft. The pulse was irregular and showed irregular after-waves. In the left radial artery the beats became smaller and nearly impalpable during the height of inspiration. Counted at different times by different trained observers, the right and left radial arteries showed as follows: right 84, left 57; right 69, left 64; right 73, left 69; right 72, left 64. The brachial arteries showed: right 88, left 84. The carotids: right 84, left 76, the heart-beats at the same time being 86; at another time right 83, left 79, heart-beats 79. The sphygmogram showed these differences, and also the diminution of the pulse during inspiration. The cause of this condition is doubtful. The fracture of the forearm would not, of course, explain the difference in the brachial and carotid pulses. The author further alludes to a case of Heubner, in which a woman of 52, with fatty heart and atheroma of the aorta, had inequality of the pulse, the left being stronger in the radial, brachial, and subclavian arteries. The autopsy showed a thrombus in the subclavian artery. The fact that the pulse occasionally failed in the right radial must have led to irregularity in rate on the two sides. He also alludes to a case of Mainze in a man of 27, with a large left-sided pleural effusion. The pulse ceased with inspiration, this condition disappearing after aspiration and reappearing with subsequent collections of the fluid. The left pulse was always weaker than the right. He also reports³ a second case of this condition. The patient was a woman of 69, who had had an attack of apoplexy with subsequent paresis of the right leg. The left radial showed a smaller and

¹ Wien. klin. Woch., Sept. 26, 1896.

² Berlin. klin. Woch., Jan. 4, 1897.

³ Ibid., Apr. 5, 1897.

more irregular pulse than the right. When counted, the rate was l. 92, r. 112. A later observation gave a pulse-rate of r. 52, l. 42. Death occurred shortly after this. At the autopsy there were found recent purulent pleuritis and pericarditis. The aorta was normal, but the right subelavian artery was 2 cm., the left 0.8 cm. in diameter. [We have recently observed a case of this condition; the patient was a woman, about 70 years old, with the signs of atheroma of the aorta. The action of the heart was irregular, but there was usually a difference of 4 or 5 beats, the left pulse being the slower. The radials were apparently of the same size.]

Schlesinger¹ reports several cases that presented peculiar **venous phenomena**. These consisted essentially in prominence of the superficial veins, the walls becoming, apparently, very thick and resistant, and feeling like hard cords. All these changes disappeared at times, so that the veins were no longer palpable and appeared as fine blue lines beneath the skin. An extirpated portion of one of these veins showed that the walls were perfectly normal. The only explanation that he is able to offer is, that the thickening was probably due to the swelling of the endothelial lining. All the cases hitherto observed have been in very cachectic individuals.

T. D. Savill² reports 2 cases of what he regards as **idiopathic arterial hypermyotrophy**. The arteries in this condition show great increase in thickness, due almost entirely to hypertrophy of the middle coat. In one of his cases he found also atheromatous patches. The symptoms may be in abeyance for a long time if the compensation of the heart is sufficient. The characteristic thickening of the peripheral vessels can, however, be determined early. It is readily distinguished from the atheroma by the absence of bead-like inequalities. The characteristic of the pulse in the present disease is its constant high tension. Vertigo was a striking symptom in both the cases reported. Paroxysmal dizziness, headache, occasional hemorrhage, tendency to gangrene of the extremities, and angina pectoris are noted as symptoms. The urine presents no characteristic change, but is increased slightly, and the sp. gr. is usually a little too low. [In reading the description of these cases we see no reason for regarding them as other than instances of general diffuse arteriosclerosis. In one of them, indeed, there was associated nodular atheroma. It is surprising that the author does not take into consideration in his discussion the possibility of diffuse sclerosis. It has been often pointed out that the hypertrophy of the media may be in excess of the seeming thickening of intima or adventitia in this disease.]

Graf³ describes a case of **arteritis nodosa**, with interesting clinical symptoms. The patient, a laborer of 39, suffered with gastralgie pains, and later with swelling of the liver and jaundice. After a few months symptoms of cardiac weakness developed, including rapid, small pulse, increasing edema, and later albuminuria. From the very beginning of the illness the patient was cachectic, and later cachectic leukocytosis was observed. The patient died $3\frac{1}{2}$ months after the onset, and the characteristic lesions of Kussmaul's disease with multiple aneurysms were discovered. The changes were most marked in the arteries of the heart, spleen, liver, mesentery, and kidneys. The aorta and the large vessels were intact. There was no evidence of a specific taint in this case; but though the same was true of 8 others reported in literature, the author still inclines to the belief that this factor must be taken into consideration.

B. Bramwell⁴ reports an unusual case of **ossification of the arteries** occurring in a man 25 years of age. He suffered from extreme asthenia, car-

¹ Wien. klin. Woch., Dec. 24, 1896.

² Brit. Med. Jour., Jan. 23, 1897.

³ Ziegler's Beiträge zur path. Anat., Bd. 19, p. 181.

⁴ Edinb. Hosp. Rep., vol. iv., 1896.

diac debility, anemia, pigmentation of the skin, subcutaneous swellings, rigid arteries, polyuria, the urine containing phosphates and a small quantity of albumin. The rigidity of the arteries rapidly increased until they ceased to transmit pulsation. At the autopsy the heart was found to be in an extreme degree of calcareous degeneration, many of the muscular fibers being entirely ossified. Similar calcareous changes were seen in the left kidney, the right being almost entirely destroyed as a result of some earlier condition. There was no good reason for the condition, but it was supposed that the hardships to which the patient had been previously exposed had caused the blood to become loaded with calcareous salts, which were rapidly deposited in the vessels and kidneys. The fact that the patient was able to engage in laborious exercise until 3 months before his death seemed to indicate that the process was acute.

W. Bell¹ describes a case of **thrombosis of the abdominal aorta**. The patient, a man of 30, was suddenly seized with intense pain in the back and abdomen while walking along the street. He became powerless and fell to the ground. There were absolute paralysis of both legs and anesthesia and analgesia as high as the lower third of the thighs. There was hyperesthesia for 2 inches above the anesthetic area. The reflexes were absent; the sphincters were paralyzed. The legs became cold and finally gangrenous. The patient died in collapse. Autopsy showed no visible disease of the lumbar cord or cauda equina. The aorta and both iliacs contained a firm white coagulum from a point about $\frac{3}{4}$ in. above the bifurcation to 1 in. below in the left and $\frac{7}{8}$ in. below it in the right iliac. No change was found in the coats of the arteries. The author believes that the symptoms were caused by the sudden occlusion of the lowest lumbar arteries which supply the lumbar cord. Charrier and Apert² report the case of a woman, 51 years old, who had suffered for 20 years from mitral obstruction. She was suddenly attacked with severe pain in the left leg followed by symptoms of embolism in the iliac artery; 6 days later the same symptoms occurred in the right leg, but disappeared within a short time; 3 weeks later there was an attack of right hemiplegia, and shortly afterward the left foot became gangrenous. At the autopsy there was found complete thrombosis of the aorta, beginning just below the inferior mesenteric artery, and embolism with great softening of the left cerebral hemisphere.

A. Burton³ and J. B. Bradbury⁴ report together 3 cases suffering from high arterial tension that were greatly benefited by the administration of **erythrol-tetranitrate**.

Rumf⁵ holds that an **exclusive milk-diet** is by no means appropriate for patients suffering from calcareous infiltration of the arteries. He has made some experiments, and found that the amount of calcium introduced with a sufficient quantity of milk to nourish an adult is in excess of that excreted. He has endeavored, therefore, to find a diet that will nourish the patient, and, at the same time, introduce a minimum quantity of calcium, and recommends the following formula: meat 250 gm. and 100 gm. each of bread, fish, potatoes, and apples. The next indication to be met is to provide for the increased excretion. This can be, to a certain extent, accomplished by diuretics composed of the salts of vegetable acids, particularly lactic and citric acids. The quantitative estimation of the amount of calcium excreted under this medication showed that it was considerably increased. In conclusion, he reports 3 cases treated according to these principles in which, as long as the treatment and diet were continued, almost complete health existed.

Aneurysms.—Mir¹ in 436 autopsies observed 19 cases of **rupture of aortic aneurysms**. 5 of these were in the ascending aorta, 5 in the transverse aorta, and 9 in the descending aorta, which proves that the more freely the aneurysm can develop the more likely it is to rupture; as, for example, an aneurysm occurring in the pericardial cavity. He finds the chief lesion to be disease of the media, which may be the result of traumatism or of simple or specific inflammations.

Buberl² reports 2 cases of aortic aneurysm, neither of which produced symptoms of much distress until rupture occurred. The 1st patient, 12 days before his death, had a sticking pain in the right side and coughed up about 200 c.c. of blood. This was repeated twice. At the autopsy it was found that it had ruptured into the tissue of the lung which formed part of its wall. The 2d case presented an enormous swelling of the anterior part of the neck, which apparently consisted of blood, due to rupture of a large thoracic aneurysm. This had lasted for about 4 weeks and caused considerable dyspnea. At the autopsy an aneurysm of the aorta was found that had ruptured into the posterior mediastinum, causing infiltration in this region and extending upward.

Fränkel³ reports a case of double aortic aneurysm, one commencing above the semilunar valve and extending to a point where the arch crosses the left bronchus, the other commencing immediately beyond, so that the 2 embraced the bronchus, and at each systolic pulsation drew it downward, thus giving rise to a tracheal tugging.

A. McPhedran⁴ reports a case of aneurysm of the aorta that communicated with the left auricle. The patient had always been fond of violent exercise, and on one occasion, after severe exposure, was taken with a chill followed by, persistent shortness of breath. There were extensive precordial impulse, irregular, tumultuous cardiac action, and considerable edema. A loud systolic murmur was heard over the whole cardiac region and beyond, and even in the back. Treatment was without effect. At postmortem examination 3 small aneurysms were found in the aorta just above the sinuses of Valsalva. One of these communicated with the left auricle by an opening 4 mm. in length.

Otto Lerch⁵ reports a case of aneurysm of the descending aorta that pressed upon the esophagus and partially occluded and eroded the bodies of the 3d, 4th, and 5th dorsal vertebrae. Death finally occurred from hemorrhage. The aneurysm ruptured into the esophagus, and the first hemorrhage occurred 3 weeks before death. Great relief was given, curiously enough, by the passage of the esophageal sound.

J. H. Musser and J. D. Steele⁶ report a case in which a negro was suddenly prostrated with pain in the left iliac region, extending to the right hypochondriac. There were constipation and frequent hiccough; at times the patient was delirious. Upon admission he was in collapse, the abdomen scaphoid and excessively tender, and there was great emaciation. At the autopsy a sacular aneurysm was found springing from the abdominal aorta, from which the thrombus extended into the right renal artery. The left kidney was in a condition of acute inflammation and showed hyaline and fatty degeneration. Benedict⁷ reports a case of thoracic aneurysm which, on account of the presence of goiter, had been treated as a case of Graves' disease. The proper diagnosis was first made when the Röntgen rays were employed.

Fränkel¹ considers particularly the **pulmonary complications** of aortic aneurysm. He notes 4 groups: 1, fibrinous pneumonia; 2, indurative pneumonia; 3, gangrene of the lung; 4, tuberculosis. All of these are dependent more or less upon mechanical causes—that is, the pressure upon the main bronchus. At the point of greatest pressure necrotic ulceration occurs, and the excretion from this, flowing into the lungs, causes inflammation or coincident infection of tuberculous processes there. One of the points in favor of this mechanical theory is the greater frequency of inflammation in the left lung. In 2 of 30 cases he saw perforation into the vena cava superior. The clinical history of these cases was a feeling of constriction in the neck, followed by cyanosis and edema of the face and upper parts of the body. Autopsy was obtained in only one case. Syphilis was present in 36% of his cases, and in the arteriosclerotic plates of these, instead of finding calcium salts, he discovered granulation-tissue, sometimes with giant cells.

DISEASES OF THE RESPIRATORY TRACT.

General Considerations.—G. W. Fitz² made careful estimates of the ratio between **thoracic and abdominal respiratory movements**. His conclusions are as follows: (1) children of the two sexes differ very little in the character of their respiratory movements; (2) there is little difference between adults and children of either sex; (3) childbearing does not permanently affect respiration; (4) in the unrestricted individual the chest contributes the same bulk of air as does the abdomen, but constricting dress causes preponderance of the thoracic movement.

Francois-Franck³ contributes a study of the **relation of the nervous system to the pulmonary circulation**. Irritation of the sympathetic causes an increase of pressure in the pulmonary artery and a decrease in the aorta, not due, as was formerly supposed, to different activity of the cardiac chambers under the influence of sympathetic stimulation, but, according to his studies, to active contractions of the pulmonary artery. In case of excessive pressure in the aortic system this mechanism may be of practical advantage. Sensory impressions in such cases may serve to contract the pulmonary artery and thus to limit the quantity of blood reaching the left heart and the aorta.

Osteoarthropathy.—J. S. Billings, Jr.,⁴ reports a case of asthma with symmetrical enlargement of the arms, and nodular swellings over the parietal bones. The blood showed slight leucocytosis, and the differential count revealed more than 507 of eosinophile cells. Curschmann's spirals were present in the sputum. Although there were neither signs nor history of syphilis, the patient was put upon mixed treatment, with immediate benefit: reduction in the swelling of the arms, disappearance of the swellings on the parietal bones, and great reduction in the number of eosinophile cells.

Diseases of the Bronchi.—Symptoms.—Aufrecht⁵ discusses a new **symptom of tracheal stenosis** that he was able to observe in 3 cases; 2 of mediastinal carcinoma and the other of a syphilitic gummatous swelling situated on the lower portion of the trachea and occupying the left half of the wall. The symptom was elicited by placing the stethoscope upon the trachea just above the jugulum sterni, when a rough bronchial breathing, which is normally heard through the whole period of inspiration and expiration, was

¹ Centralbl. f. innere Med., Nov. 14, 1896.

² Jour. Exper. Med., Nov., 1896.

³ Bull. de l'Acad. de Méd., No. 6, 1896.

⁴ N. Y. Med. Jour., May 22, 1897.

⁵ Centralbl. f. innere Med., Jan. 9, 1897.

replaced by a brief, faint, soft breathing, or else was completely interrupted for a moment. He explains this as follows: when under normal conditions the air passes from the narrow glottis into the wide trachea eddies are formed just beyond the constricted opening that produce bronchial breathing-sounds. Before it produces these a certain rapidity of the current is necessary, which, under normal circumstances, is assured by the practically uniform size of the trachea. If this, however, is narrowed in one place, so that its lumen is only as wide as that of the glottis, the eddies of the air upon leaving the glottis are weaker, and produce a modification in the breathing that may be used as a diagnostic symptom. The same author¹ reports a case of severe dyspnea that preceded and was accompanied by a peculiar symptom—that is, the disappearance of the respiratory murmur over the trachea. A diagnosis was made of obstruction of both main bronchi, and at the autopsy a tumor was found at the bifurcation of the trachea that caused this condition.

Bronchitis.—Cassat² describes a form of acute bronchitis, accompanied by rapid emaciation, fever, and green and bloody expectoration, in which he is unable to find tubercle-bacilli, and often finds virulent forms of streptococci. He suggests that it is frequently confounded with pulmonary tuberculosis.

Ferret and Lorraine³ report the case of a man of 56 who was taken ill with bronchitis and at the same time had a swelling of the left sternoclavicular and the right shoulder-joint. After 3 days the fever subsided and he improved; but 2 days later chills and fever occurred with marked sweating and unconsciousness, and death followed in sequence. The autopsy showed suppurative meningitis of the base, and of the upper part of the spinal canal. There was congestion of the lungs without pneumonic foci. The sternoclavicular joint was swollen, and the serous liquid as well as the pus in the meninges contained pneumococci.

Klein⁴ reports a case of **fibrinous bronchitis** occurring in a girl of 19. The bronchial casts were sometimes enormous, producing marked obstruction, which was only relieved by their expectoration. In one case the total length exceeded 20 cm. In addition the sputum contained a large number of tubercle-bacilli. At the autopsy there were found chronic tuberculosis of the bronchial lymph-glands and lobular pneumonia in both lungs, with cheesy necrosis of the exudate, and, in addition, recent miliary tuberculosis. The bacteriologic examination revealed also the presence of typical pneumococci. The chemical analysis of the bronchial cast showed the presence of globulin, albumin, and, in much larger proportion, mucin; and it consisted, not of fibrin, as had been supposed, but of mucin. This opinion was strengthened by the fact that the other shreds were not colored by the Weigert method.

J. W. Brannan⁵ reports a case of fibrinous bronchitis occurring in a neurotic patient with rheumatic family history. The attacks came on suddenly with great dyspnea, that was relieved by the expulsion of bronchial casts. She had previously had attacks of angioneurotic edema.

Treatment.—Brunet⁶ has treated 5 cases of chronic bronchitis and emphysema with injections of **glycerin extracts of pulmonary tissue**. All the cases showed diminution and increased fluidity of expectoration, improvement in the physical signs, and considerable amelioration of the other symptoms. [There seems to be no reasonable basis for this treatment, a large part of the symptoms produced by these conditions being due to purely mechanical causes.]

⁶ Gaz. hebdom. de Med. et Chir., Apr. 1, 1897.

J. L. Barton¹ advocates the treatment of bronchitis, particularly when associated with incipient tuberculosis, by **intratracheal injection** of appropriate solutions.

Fronz² reports 3 cases of **bronchial tuberculosis**; the first 2 were admitted to the hospital with symptoms of severe expiratory dyspnea. Tracheotomy was performed and caseous masses representing broken-down bronchial glands, which had acted as foreign bodies in the bronchi, were discharged through the tube. The first patient recovered, but subsequently developed signs of pulmonary phthisis. The second died as a result of reobstruction by another caseous gland. The third patient presented paroxysmal hemoptysis, which, at the autopsy, was found to proceed from a small aneurysm of a branch of the pulmonary artery that had ruptured into a caseous bronchial gland. The author believes that early diagnosis in these cases is important, as tubercular lymph-glands can be cured by energetic mercurial inunction.

Buberl³ reports the case of a **foreign body** (fragment of pipe-stem) in the right bronchus which caused death by ulceration and perforation into the right pulmonary artery. The immediate cause of death was a profuse hemorrhage resulting from this condition, which had not been suspected during life, either by the patient or by the physician. Upon admission to the hospital there was a history of cough with considerable expectoration and occasional hemoptysis, and consolidation of the lower half of the right lung. Hector Mackenzie⁴ refers to an extraordinary case in which a half sovereign remained in the left bronchus for 24 years. The coin lay in the axis of the left bronchus, with its edge close to the septum of the first branch, in such a position that the air could pass freely. He also refers to a case cited in the monograph of Gross, in which a piece of bone was said to have been expelled from the bronchus 60 years after its reception; and adds that Durham refers to 28 cases of spontaneous expulsion followed by recovery in which the interval varied from 1 to 17 years. Godlee has reported 5 cases in which bronchiectasis resulted. In one of the author's cases the patient had symptoms of bronchiectasis for 2 years and finally died, the autopsy showing a piece of bone impacted in the bronchus. No history of the lodgement could be obtained; in another, multiple abscesses and consolidation of the lung followed the lodgement of a clove in the bronchus.

Diseases of the Lungs.—A. E. Tussey⁵ speaks of the importance of studying the **prolongation of the expiratory murmur** in pulmonary disease. He believes that when not due to asthma or emphysema it always indicates partial infiltration of the air-cells, and often precedes impaired percussion and resonance.

PNEUMONIA.

General Considerations.—C. F. Folsom⁶ contributes a **statistical study** of the prevalence and fatality of pneumonia. Since 1852 the death-rate from pulmonary consumption and from infectious diseases as a whole has decreased greatly; but in the case of pneumonia it has increased. In 1852 it was less fatal than typhoid fever, in 1856 their lines crossed, and in the last few years the average death-rate from pneumonia has been more than 5 times as great. It is possible that the great increase in mortality from pneumonia is due to a lowered general standard of vitality and habits in the community

¹ Med. Rec., Aug., 1896.

³ Wien. med. Woch., Aug. 22, 1896.

⁵ Am. Med. and Surg. Bull., Sept. 5, 1896.

⁴ Practitioner, Oct., 1896.

⁶ Boston M. and S. Jour., Dec. 16, 1896.

and more accurate diagnosis and better registration. [It seems to us that the question of registration is a most important one in this connection. The diagnosis, for example, of typhoid fever is much more frequently accurate at the present time than formerly, and many cases previously registered as typhoid are thus eliminated. In the case of pneumonia, a more generally fatal disease, a reverse effect upon the statistics would occur.] Tracing the frequency of pneumonia in different months of the year, he finds that the curve follows very closely that of scarlet fever and diphtheria. In all respects, then, pneumonia may be classed with the infectious diseases, and he urges compulsory registration.

Connolly¹ reports an **epidemic of pneumonia** that occurred during 1896 in Brisbane, Australia. Altogether he had 26 cases in private practice and 55 in the hospital. The death-rate from this disease during the year was the largest that has ever been known. The cases all presented the initial chill; none showed any marked expectoration, although what there was was usually rusty, and nearly all had hyperpyrexia. One case exhibited a distinctly maniacal phase with delusions of persecution, which disappeared with the crisis.

W. J. Tyson² recognizes the following **clinical types** of pneumonia as probably distinct: pneumonia of influenza, septic pneumonia, epidemic pneumonia, asthenic pneumonia, pneumonia of the aged, and alcoholic pneumonia.

Etiology.—A. D. Heath³ reports 3 cases of pneumonia in the same house, the 2d and 3d apparently arising as the result of **contagious contact** with the 1st. The disease was not prevalent in that district at the time.

Kohn⁴ refers to his **bacteriologic studies of pneumonia**, particularly of the blood taken from a vein of the arm. In 32 cases of acute pneumonia 18 gave negative results, and these all recovered. In 7 cases he found pneumococci; these cases died. Five cases in which the result was negative died, 2 of them in consequence of empyema due to staphylococci. He refers to 2 further cases in which pneumococci were found in the blood, which recovered, but only after general pyemic and metastatic abscesses. He concludes that the presence of pneumococci in the blood of pneumonia is most unfavorable in prognostic significance, and holds that there is a distinct **pneumococcus sepsis** which has to be reckoned as one of the causes of death in addition to those usually recognized. Weismayr⁵ has collected 39 cases of croupous pneumonia in which bacteriologic investigations were made. Thirty-four were associated with the Fränkel-Weichselbaum diplococcus, only 5 showed critical fall of temperature, and only 3 were fatal. Two cases were due to a mixed infection with staphylococcus and streptococcus. Both were remarkable for the persistence of the signs of infiltration. Three were cases of pure streptococcus infection, all of prolonged course. The presence of streptococcus, therefore, should lead one to expect deferred resolution.

Caprara⁶ has found that both the vitality and virulence of the **Frankel-Weichselbaum pneumococcus** are excellently conserved in milk. In one of his experiments a culture in milk that was kept at 15° C. for 14 days showed no diminution of virulence.

Fränkel,⁷ in *Verein f. innere Medicin* of Berlin, presented cultures from a case of pneumonia. The first was made 4 days before death, 1 c.c. of blood

¹ Australian Med. Gaz., Sept. 21, 1896.

⁷ Deutsch. med. Woch., Mar. 18, 1897.

giving 300 colonies of pneumococci; the 2d, a day before death, giving about 100 colonies, showing a distinct diminution of the number of organisms in the circulation. Neither culture proved to be as virulent as the cultures obtained from the sputum and, at the autopsy, from the pulmonary tissue, showing that the blood in some measure exerted its bactericidal qualities, and that the presence of the organisms in it cannot be supposed to have been the cause of death.

Bruhl¹ reports a case which began suddenly with the symptoms of acute pneumonia. On the 8th day, however, there was an abundant roseolar eruption, followed by the symptoms of typhoid fever, complicated by intestinal hemorrhage and ruptured intestine; the **bacillus of Eberth** was recognized in the pus of the peritoneum. In order to determine whether the pulmonary complication was due to the typhoid bacillus punctures were made, and these organisms were found in pure culture in the fluid obtained from the lung. The author reports a second case of the same disease which presented a picture of acute tuberculosis so predominant were the symptoms in the lungs.

Symptoms and Complications.—Dunin and St. Nowaczek² have examined systematically the amount of **uric acid secreted** in 5 cases of **croupous pneumonia**, in order to discover whether it bore any relation to the leucocytosis. They found a moderate increase for a few days before the crisis and a pronounced increase immediately afterward, so that sometimes 3 times as much was excreted as during the febrile stage. This enormous increase continued for from 2 to 4 days and then gradually decreased, reaching the normal point in about a week. This increase bore apparently no relation whatever to the polymia.

Zuber³ refers to **lesions accidentally provoked** in the course of pneumonia. The microorganism of pneumonia may cause various metastatic lesions, whose localization is probably dependent upon abnormal states of the organs or tissue in question. He mentions a case of osteitis in consequence of an old fracture, 1 in connection with osteomyelitis, and 1 of a suppurative arthritis occurring in a gouty joint. In the same connection it is interesting to recall that abscesses containing the pneumococcus not rarely develop in consequence of hypodermic injections of irritating substances.

Lemoine⁴ finds that beside the ordinary pleurisy which may follow pneumonia, the so-called metapneumonic pleurisy, there is another in which effusion comes on with hepatization or immediately after the latter. He calls this parapneumonic, and holds that the effusion in this case is apt to remain serous, and has been found to contain no microorganisms, especially no pneumococci. He believes, however, that it is due to the latter organisms, which for some reason are incapable of producing suppuration. The physical indications of these forms are those of pleurisy added to pneumonia. The effusion may disappear before the crisis, or may persist for some time, the processes, pulmonary and pleural, being independent. He suggests that aspirations should be performed.

H. P. Bowditch⁵ reports 4 cases of pneumonia with **pleural effusion**. All showed flatness, but over the dull area there was heard a loud, persistent bronchial respiration; tentative aspirations in each case showed the presence of fluid, and after this was removed the bronchial respiration disappeared.

Vogelius⁶ reports 2 cases of acute lobar **pneumonia**, complicated by

¹ Gaz. hebdom. de Med. et Chir., No. 9, 1897.

³ Thèse de Paris, Steinheil, 1896.

⁴ Jour. de Méd., Oct. 10, 1896.

⁵ Boston M. and S. Jour., Apr. 2, 1897.

⁶ Arch. de Méd. expér. et d'Anat. path., Bd. viii., No. 2.

arthritis, in which the pneumococcus was found in the exudate of the joint. He has collected 11 similar cases from the literature. In the majority of these the complication became apparent within 5 days after the onset of the pneumonia, but in 1, not until the eleventh day. The exudate was purulent in 6 cases, seropurulent in 2, and serofibrinous in 1. In the other 2 the nature is not mentioned. Considerable destruction of the joint occurred in 4 cases.

Banti¹ studied the bacteriology of a number of cases of pneumonia in which **icterus** was present. He found that the diplococcus present was strongly pathogenic for dogs. When injected it gave rise to the appearance of urobilin and bilirubin, as well as to a considerable quantity of hemoglobin in the urine. In rabbits marked hemoglobinuria occurred in all cases. This tendency to produce hemoglobinuria disappeared after a number of reinoculations. He concludes that the icterus of pneumonia is due to an accidental hemolytic action of the diplococcus, and is therefore hemogenic.

Widal² refers to a case of **suppurative hygroma** beneath the deltoid muscle in a case of pneumonia. At the end of 3 weeks he could not find any bacteria. The seat of metapneumonic suppuration is classic, the predilection of the pneumococcus for the serous membranes of the shoulder-girdle being well known. At the second puncture in his case, 20 days after the first, there was only serofibrinous liquid, and recovery soon ensued. The pneumococci (assuming that these were present at first) therefore survived only a short time in the diseased joint.

J. L. Spruill³ reports a case of pneumonia which, on the fifth day, began to show signs of heart-failure, progressing to death in the course of an hour. At the autopsy a large **fatty tumor** was found in the right auricle firmly attached to its walls.

Galliard⁴ records a case of pneumonia in the course of which severe vomiting and diarrhea occurred, leading to almost complete collapse. In consideration of the pathogenicity of the pneumococcus he believes that it is fair to call this condition a **pneumoenteritis**. The question arises how the organisms reached the intestinal tract. It seems unlikely that they could have passed through the stomach and maintained their vitality after having been exposed to the gastric juice, and it is altogether more probable that the inflammation of the mucous membranes represents an effort at their elimination from the body.

French⁵ reports a case of pneumonia occurring in a man of 75, in which, on the eighth day of the disease, persistent **hiccough** set in, some of the paroxysms lasting as long as 14 hours without a break. Recovery eventually ensued.

Prognosis.—Wm. Osler,⁶ in discussing the prognosis of pneumonia, refers to the uniformity of mortality in the various statistics. Of 124 cases in the Johns Hopkins Hospital, 37 died, a mortality of 29.8. He holds that, apart from certain complications, the death-rate occurs as a result of toxemia or mechanical interference with respiration and circulation, and he dwells particularly upon the danger of toxemia. This may develop early, and from the very first there may be cerebral symptoms; the latter sometimes quite out of proportion to the extent of disease in the lung. Other cases may be observed in which a large part of the lung is involved and scarcely any toxemia occurs. Many of the cases with decided intoxication show variations from the typical

⁶ *Am. Jour. Med. Sci.*, Jan., 1897.

course of the disease. Thus, there may be no cough nor expectoration, very slight fever, and no leukocytosis. Two cases are then detailed: one the case of an able-bodied man of 28, who became delirious and finally quite insane while on a train. He was afterward put in a straight-jacket, having made an attempt at suicide. There was no cough and little fever, but he complained of pain in the side. Physical signs were quite well developed; the patient improved somewhat, but subsequently died suddenly. The second case occurred in a man of 66, who complained of a slight chill and then of pain in the back with aching in the joints and legs. There was no cough nor shortness of breath, the fever was slight, delirium was quite marked. Regarding the cases in which sudden and unexpected death occurs, Osler believes that the action of the specific toxins on the heart-center is of greater significance than the effect of fever on the heart-muscle. He details 3 cases in which this termination occurred. In one there was massive pneumonia with blocking of the bronchial tubes and obscuration of the physical signs; death occurred on the sixth day. In the second case there was well-marked pneumonia of the lower left lung and death occurred on the fourth day; while in the third case cardiac weakness developed almost at once and the patient had 3 attacks of syncope, the last proving fatal on the third day of the disease. The author is not inclined to attribute much importance to mechanical obstruction of respiration and circulation, calling attention to the fact that the obstruction remains the same for some time after the crisis despite a most remarkable change in symptoms (dyspnea and cyanosis). [We can substantiate these statements entirely. Cases of sudden and unexpected termination have frequently occurred in our experience, and in some of these the disease of the heart-muscle has been very trivial. We have also been struck with the very rapid subsidence of all symptoms of cardiac and pulmonary embarrassment after the crisis, despite the persistence of the pulmonary conditions.]

Treatment.—[Considerable attention has been devoted to the production of an effective antipneumococcal serum. The experimental results are satisfactory, but the clinical reports are very conflicting. This may be explained in part, perhaps, by the frequent neglect of clinicians to make a careful bacteriologic diagnosis, and their tendency to use the serum in all cases presenting the physical signs of pulmonary consolidation irrespective of the nature of the process.] De Renzi¹ gives his experience of **serum-therapy** in pneumonia. Seven cases were admitted in the year 1894-95, and 2 of these received serum in addition to the usual alcoholic treatment; all recovered. In 1895-96, 27 cases were admitted; 13 were treated without serum, of which 3 died, or 23%; and 14 were treated with serum, of which 2 died, or 14%; of the 2 fatal cases, one was *in articulo mortis* when admitted, and the other had arterial and renal lesions apart from the pneumonia. The temperature usually dropped from 1° to 3° after the injections, and the latter never gave rise to any bad symptoms. In another paper² he gives slightly different figures. He was able to obtain serum from animals that had been rendered immune to the pneumococcus, and injections of this had given very satisfactory results. Of 16 cases only 2 died, 1 was in the death agony when the first injection was made, and the other suffered from a severe cardiac lesion.

A. Cooke³ reports 2 cases of acute lobar pneumonia treated with antipneumococcal serum. The first patient was injected on the sixth day of the disease; the following day there was slight improvement with a fall of temperature;

¹ Supplem. II. Policlinico, Oct. 31, 1896.

² Gaz. degli Osped. e delle Clin., No. 140, 1896.

³ Brit. Med. Jour., May 22, 1897.

subsequently she again passed into a febrile state, which was diagnosed as typhoid. Distinct crisis was not caused by the serum. The second patient was injected on the fourth day of the disease. Convalescence did not set in until the tenth day, the serum having apparently had no influence upon the febrile course. [No effort was made to find the pneumococcus.] Spurrell¹ reports a case of pneumonia which, on the third day of the disease, was given 660 units of pneumonia antitoxin. On the same day a second injection of the same strength was given; this was repeated on successive days 8 times. Nevertheless, death occurred on the tenth day, the only result observed from the injections being a slight fall of temperature, although occasionally a slight rise occurred. C. J. Harnett² reports a case of alcoholic pneumonia that on the sixth day of the disease was injected with antipneumococcic serum. The next day the patient was distinctly worse; vigorous stimulation, however, had good effect, and he ultimately recovered. Washbourne³ immunized a pony against the pneumococcus by the usual method, then bled the animal, and tested the protective properties of its serum, which he found to be considerable. He reports a case treated with this serum in which, on the eighth day of the disease, 660 units were injected; 2 hours later the temperature fell 3°, but soon rose again. Another injection was made a day later, and the condition of the patient was much improved. He reports another case in which, after numerous injections of 660 units of serum, great improvement occurred on the sixth day. Defervescence took place by lysis. Denys⁴ has performed a number of experiments with the serum of animals immunized against the pneumococcus. Serum procured from a horse that had been treated in this manner showed both preventive and curative action. It seems also to have an antitoxic action; causing reduction of temperature in an animal that had been inoculated with toxin 7 days before, and preventing a rise of temperature when mixed with toxin *in vitro* and then inoculated. Auld⁵ has inoculated animals with the toxin of virulent cultures of the diplococcus pneumoniae. If sufficient toxin was injected to raise the temperature to 105°, it was possible to produce immunity to the living organism, and the serum of the animals so treated was found to confer immunity upon animals into which it was injected.

E. H. Martin⁶ has employed **fowl serum** in pneumonia, reasoning that it must contain some antipneumonic element. Fresh blood was administered by the mouth, and his results, although as yet inconclusive, are encouraging.

Davis⁷ has used **nucleinic acid** in a number of cases of pneumonia; but although the results were favorable he cannot ascribe a distinctly beneficial action to it in any case.

Barth⁸ reports 2 cases of severe pneumonia treated by large doses of **digitalis** with prompt beneficial effect. He believes that all cases that are severe, or where treatment with baths is contraindicated, should be treated in this way. Particularly is it to be employed when the intensity of the fever, dyspnea, and frequency and softness of the pulse lead one to suspect cardiac weakness.

Gingoet and Degui⁹ report 10 cases of pneumonia treated by **digitalin**, with 10 recoveries, 2 of which were unexpected on account of the severity of the symptoms. The authors believe that digitalin exercises a specific action upon the disease, even going to the length of suggesting that it be employed

for the purpose of making a differential diagnosis between pneumonia, pulmonary tuberculosis, and typhoid fever.

Folsom¹ believes that the medical profession is too prone to rely upon medicinal treatment for pneumonia. He has used **cold sponge-baths** and occasionally applications of ice during the last 3 years, in all cases except those *in extremis*. The greatest number of baths in a single case was 25 and the effect was invariably pleasant.

R. W. Amidon² claims that the mortality of pneumonia has increased 10% in 50 years. He thinks that this is due to the neglect of **venesection** in the treatment of the disease, and cites 2 cases, in both of which great relief was afforded by spontaneous hemorrhage.

Sheeh,³ in discussing **asthma** and **emphysema**, holds that bronchial spasm comes first, bronchitis second, and overdistention of the lungs last. The latter disappears more or less rapidly in nasal cases, and there is no true emphysema. Cases of this kind may be regarded as emphysematous for a long time, and finally after removal of polypi, etc., the condition may greatly improve. Long continuance, however, leads to true emphysema.

Huchard⁴ believes that 3 elements are concerned in the causation of **pulmonary edema**—acute insufficiency of the right ventricle, disturbance of cardiopulmonic innervation, and impermeability of the kidneys with consecutive intoxication. In order to meet the first indication venesection should be employed; to meet the second strychnin; and to meet the third milk-diet and diuretics.

A. McPhedran⁵ reports a case of **gangrene of the lung** coming on after an attack of uremia. The breath was offensive, sputum dark, and there were frequent hemorrhages of varying amounts. There were moderate fever and emaciation. The physical signs consisted of restricted respiratory movements and increased percussion-dulness over the apex of the left lung, including rales and bronchial breathing. The symptoms improved, only to recur for several months. Finally permanent recovery ensued. In regard to the etiology of this condition, the author suggests the inhalation of a foreign body during the comatose state, or sclerosis of the pulmonary arteries with resulting thrombosis.

G. E. Bushnell⁶ reports 2 cases of **subpleural pulmonary abscess**. He calls attention to the fact that there has been much discordance between the observations of pathologists and clinicians, the former finding what seems irreparable destruction of the lung-tissue; the latter reporting cases which terminate in quick recovery. The diagnosis in cases which recover is often very doubtful, and the disease, when present, is frequently unrecognized. The first case, a young man in previously good health, suffered with mild bronchial catarrh and then with croupous pneumonia of the lower left lobe. Subsequently his condition became much depressed and an area of dulness with absent breath-sounds was discovered in the lateral and posterior parts of the lower left lobe. An aspirator-needle was introduced several times, and later an incision was made which showed the lung to be retracted. The pus was obtained only by inserting the needle into the lung. Subsequently the collection reaccumulated, but finally discharged through the bronchus and the patient recovered. The second case was less clearly one of intrapulmonary abscess. In discussing its nature the author points out that localized empyema, which is frequently the diagnosis made, would not heal so quickly after dis-

¹ Boston M. and S. Jour., Dec. 16, 1896.

³ Münch. med. Woch., Aug. 18, 1896.

⁵ Am. Med. and Surg. Bull., Aug. 29, 1896.

² Med. News, Mar. 6, 1897.

⁴ Bull. de l'Acad. de Méd., Apr. 27, 1897.

⁶ Am. Jour. Med. Sci., Oct., 1896.

charge of the pus. [In his first case ordinary sacular empyema was easily eliminated, but the author does not consider the likelihood of this case having been one of interlobar empyema. This condition could very readily have produced the symptoms, although it must be confessed that there are no special reasons for regarding the case as one of such nature rather than one of true abscess of the lung. The second case, it seems to us, was more doubtful in character.] A diagnosis between abscess and empyema may be made by microscopic examination of the aspirated pus, the discovery of elastic tissue in the latter pointing to abscess of the lung itself. Among his other conclusions are: 1, pulmonary abscesses affect the connective tissue, and the most favorable and common form is a subpleural abscess; 2, these may attain to large sizes without the corresponding destruction of pulmonary tissue, since the individual pulmonary lobules retract before the suppurative process, as the whole lung retracts before the pleural effusion; 3, the disease is more common than supposed and is generally mistaken for empyema.

Zagari¹ has studied 7 cases of **malignant intrathoracic tumors**, and has endeavored to obtain a more or less uniform clinical picture of this condition. He gives the following symptoms, the presence of a number of which should lead to a suspicion at least of the true nature of the disease: 1, gradual commencement; 2, pronounced general weakness; 3, absence of fever; 4, constant and increasing pain; 5, swelling of the glands chiefly upon one side, and eventually distention of the veins on the breast-wall; 6, increase of local sweating upon one side of the chest; 7, dyspnea and feeling of oppression such as occur in hydrothorax; 8, irregularity in thoracic expansion, especially in the upper portion; 9, neither bulging nor widening of the intercostal spaces; 10, absolute dullness, particularly noteworthy when in the upper and anterior parts of the thorax, and in juxtaposition to clear pulmonary resonance; 11, dullness over the sternum and near it, indicating dislocation of the mediastinum toward the healthy side, with the peculiarity that this dislocation is irregular; 12, Skoda's murmur over the clavicle and sternum; 13, bronchial respiration; 14, persistence of physical signs after the evacuation of a considerable quantity of liquid; 15, the character of liquid (fibrinous, of high sp. gr., hemorrhagic, and containing characteristic cells); 16, the sensation of a thick, compact tissue resisting the needle when exploratory puncture is made; 17, unsuccessful puncture before the rapid formation of an exudate; 18, slight dislocation of the heart and liver, such as would occur in large collections of liquid. [We have found it more satisfactory to consider the symptoms according to the location of the tumor in the thorax.]

Hampeln² discusses the diagnosis of **carcinoma of the lung**. He points out that it is an error to regard this diagnosis as of extraordinary difficulty, the prevalence of this view preventing the more frequent recognition of the condition. Sometimes the symptoms are practically wanting, as in other diseases; but when they are well developed the disease is easily recognized. Among the important indications are consolidation of one lung with increase of the thorax on the affected side, or retraction of the same side; bronchial irritation, cough, and expectoration; pleurisy, with fibrinous, serous, hemorrhagic, purulent, or putrid exudate; symptoms of pressure upon the nerves or veins, and finally cachexia. He then turns his attention particularly to the character of the expectoration, which he believes to be highly significant. The discovery of signs of consolidation of the lung of progressive character, and only a moderate catarrh of the bronchi with scanty expectoration may lead to suspicion; but hemorrhagic sputa is more significant. The color and

¹ Naples, 1896.

² Zeit. f. klin. Med., Bd. 32, H. 3 and 4.

character of this are not of great importance, but its duration may be. He refers to a case in which it persisted for 2 months, and to one reported by Israel, in which the duration was 9 months. There is never abundant hemoptysis. Nine cases are then briefly abstracted to illustrate the frequency of this symptom. One of these he reported a number of years ago in illustration of the diagnostic value of cancer-cells. *A priori* we should expect either particles of carcinoma or individual or aggregated carcinoma cells in the sputa. The former was recorded by Ehrlich in one of his cases, but has not been observed by any other clinician. The author himself lays stress upon the occurrence of large, non-pigmented polyhedral cells, and especially these in association with giant cells. Though these cannot be said to be specific forms of cells, it is true that they occur only when there is a productive growth. They may be found in any form of carcinoma, and do not indicate a particular seat. Thus a squamous epithelioma of the bronchi may present this form of cells, though one might expect a large squamous cell. The situation may be judged of by the occurrence of tissue-particles, but, as was pointed out, this is rarely possible. Betschart¹ reports a case of tumor of the lung in which the diagnosis was established during life by the character of the sputum. This varied in color, being often brownish-red, and microscopically there were discovered small fat-globules, leucocytes, and large numbers of epithelioid cells, more or less aggregated. There were also a number of particles visible to the naked eye of brownish-yellow color and gelatinous appearance, which proved to be carcinomatous on microscopic examination. The diagnosis was confirmed postmortem.

DISEASES OF THE PLEURA.

Pleurisy.—Étiology.—Aschoff² reports the results of his observations in 200 cases of serous pleurisy. Forty-one of these were idiopathic; of the remaining 159, 43 were associated with tuberculosis, 16 with rheumatism, 29 with pneumonia, 11 with influenza, and 41 with various other affections of the respiratory or circulatory organs. The effusion was investigated bacteriologically, chiefly microscopically or by smearing 3 drops upon agar. In 193 case the result was negative. Of the 7 positive results, 1 showed tubercle-bacilli, 1 pyogenic bacteria, 1 pneumococci, 1 streptococci, and 2, not associated with pulmonary disease, gave also pneumococci and streptococci; finally, 1 following gangrene of the lung also showed streptococci; the last 5 cases all developed pyopericardium. The exudate from 57 cases was injected into guinea-pigs in order to test whether tubercle-bacilli were present or not. Of these, 25 were associated with tuberculosis, and 12 apparently idiopathic; of the former group, 68% of the animals became tuberculous, and of the latter group 75%, from which the author concludes that the majority of the cases of idiopathic serous pleurisy are tubercular.

Peron³ states that the tubercle-bacilli are transported to the parietal layer of the pleura enclosed in leucocytes, and that they may almost invariably be found in the acute serofibrinous form of tubercular pleurisy, either in the liquid or in the false membrane.

Chauffard⁴ reports a case of pneumothorax due to simple alveolar rupture, and not to tuberculosis. Tuberculin prepared by Roux was injected at intervals of 4 days, and there was not the slightest reaction, while the control in a known tuberculous patient was followed by a decided reaction. The pneumothorax subsided and recovery was complete in 4 weeks.

⁴ Sem. méd., Feb. 12, 1897.

G. G. Sears¹ reports the results of the study of 30 cases of **hemorrhagic pleurisy** as follows: it may be either a primary affection or a complication of other diseases; tuberculosis is the most frequent single cause, but it is not necessary to suppose every case of hemorrhagic pleurisy to be of this nature. The next most important cause is the pneumococcus. Predisposing conditions are advanced age, alcoholism, and the presence of severe constitutional disease, particularly nephritis and rheumatism. Prognosis naturally depends largely upon the nature of the case, and unless it appears as a complication in the later stages of some other disease the hemorrhagic effusion may be expected to run a favorable course. Sometimes the case will terminate in empyema, and occasionally the recurrence of the liquid after aspiration will be so rapid as seriously to deplete the patient.

Pathology and Symptoms.—Auche and Carrière² have examined the liquid found in **hemorrhagic pleurisy** and found leukocytosis. Often the number of oxyphilic leukocytes is greater than normal.

Koll³ reports a series of cases of pleuritis that ran their course without the appearance of a liquid exudate and were particularly characterized by physical signs in the anterior pleural sinuses. Altogether about 30 cases were observed in the course of 9 months. The majority of these commenced suddenly with the characteristics of an acute infectious disease; 2, however, commenced more slowly, and 2 were associated with rheumatic phenomena in other parts of the body. The subjective symptoms were those of an acute or chronic affection of the stomach; diffuse or circumscribed pain in the gastric region often commencing abruptly and increased by taking food and pressure. The patients also complained of discomfort in the cardiac region, and in nearly all cases there was tachycardia. At the beginning there was always a chill and afterward moderate continued fever. The temperature rarely exceeded 38.5°. The physical sign consisted of a fine, soft friction-sound, heard best in the region of the pleural sinus, and sometimes extending along the lateral inferior boundary of the lung. Frequently this was also heard in the middle of the sternum; occasionally it was continued when the respiration was stopped, and was then synchronous with the heart-beat. In 2 cases the symptoms of perisplenitis developed, and in 1 those of perihepatitis; these attacks coming on after the pleurisy had subsided. The course was usually long. No influence was noticed from salicylic acid or phenacetin. In only 7 cases was the cure complete when they were discharged from the hospital. Although this disease has much in common with diaphragmatic pleuritis, nevertheless the author believes that the primary condition consists of an inflammation of the pleura in the localities mentioned, and prefers to call it **sinus pleuritis**.

C. H. Goodrich⁴ reports 10 cases of **pleurisy with effusion**. In 3 of these the general health of the patients had been excellent; 2 had suffered from pneumonia and 1 from acute articular rheumatism. Two of the cases had been preceded by acute bronchitis and 3 by lobar pneumonia; 1 case had all the physical signs of apical tuberculosis. Three cases commenced with chill, 6 with pain, and 1 gradually. In only 1 case was there much sweating, and in this it was excessive; in 4 cases bronchial breathing was persistent and indeed unusually loud below the level of the effusion. One case died, death being due to pneumonia.

Hervonet⁵ objects to the theory that the **bronchial breathing** occurring

¹ Boston M. and S. Jour., Sept. 17, 1896.

² Sem. méd., p. 344, 1896.

³ Deutsch. Arch. f. klin. Med., Dec. 18, 1896.

⁴ Am. Med. and Surg. Bull., Aug. 29, 1896.

⁵ Sem. méd., p. 343, 1896.

in pleurisy is due to compression of the lung on the ground that it should always occur in this condition, whereas it is quite inconstant. He prefers to consider it as an indication of a separate pulmonary disease, such as tuberculosis or pneumonia.

Langenhagen¹ observed severe pain accompanying eructations of gas in a patient suffering from diaphragmatic tubercular pleurisy. This he believes to be due to the vibrations set up in the diaphragm as a result of a sudden dilatation of the cardiac orifice.

Treatment.—Neumann² has used the alkaline waters of the Werzberg spring in 3 cases of pleurisy, 2 tubercular and 1 syphilitic. The effects were absorption of the exudate, polyuria, and stimulation of the appetite.

Macalister³ contributes an experimental investigation regarding the effect of **thoracic effusions**. He cites a case in a child 5 years of age of rapidly developed empyema, with the physical signs of a large effusion, though the amount of liquid was very small. Only 10 oz. escaped from the chest when this was opened, but the percussion-note was absolutely dull from base to apex and the dyspnea was terrible. To elucidate the effects of rapid effusion he inserted a rubber bag into the pleura of a dog and allowed water to flow in through a tube. The most important result of this experiment was the discovery that the diaphragm quickly showed a central bulging of the cupola on the affected side, and this bulging became extreme when the quantity of liquid was much. This bulging explained the early interference with respiration and also the fact that toward the end, when the pleural effusion is excessive, contractions of the diaphragm may actually interfere with inspiration, rather than aid the latter. The diminished breath-sounds over the pleural effusion, he holds, are explained by the lessened amount of inspiration due to diaphragmatic interference, as well as to the difficulty of conduction of sound through the fluid. Next he studied the effect of pleural effusion in producing displacements of the heart and other organs, citing in the first place the theory of Powell, "that this displacement is due to the traction of the elastic lung on the healthy side." Against this view he first notes that liquid is frequently ejected forcibly from the empyema when an incision is made, thus indicating pressure; and quotes a case of his own in which a double empyema existed and in which the position of the heart changed from side to side, according as one or the other side contained most fluid. He experimented upon a cadaver, by inserting a needle directly into the apex of the heart in a perpendicular direction and then injecting liquid into the left pleura. After the first 5 to 9 oz. of liquid had been introduced the heart moved horizontally toward the middle line, and continued to move in the same direction until 29 oz. had been introduced; the motion then began to be somewhat downward, and when 56 oz. had been inserted into the cavity the needle pointed toward the left axilla. A second needle was inserted into the left lobe of the liver, when the heart began to move downward. The second needle began to rotate in a way indicating that the left lobe of the liver was also travelling downward. The right side of the chest was bulging at this time, and on dissection the right pleura was found distended and partly covering the pericardium. He concludes from this experiment and from others upon dogs that the displacement of the heart is purely mechanical.

Senator⁴ describes a case of chylous ascites and chylothorax. This occurred in a woman of 47 in whom ascites was found as well as effusion in both pleural cavities. On aspiration a milky liquid was obtained, of alkaline reaction, and

¹ Sem. méd., p. 344, 1896.

² Deutsch. med. Woch., Jan. 28, 1897.

³ Liverpool Med.-Chir. Jour., July, 1896.

⁴ Charité Annalen, Jahrg. 20.

sp. gr. 1015.5; poor in albumin; there was no sugar. The microscopic examination showed fine granular particles, a few leukocytes, and a few round cells containing fat-granules. The fat obtained by extracting with ether melted between 27° and 31° C. After administration of olive oil and a second puncture of the abdomen and the pleura the liquid was found remarkably yellow, and seemed to contain more fat, the melting-point of this being reduced to 17° and 18° C. The sp. gr. of the liquid was 1011.5. A diagnosis of carcinoma of the pelvic and abdominal organs and of the thoracic duct was made and confirmed postmortem. Primary carcinoma of the ovaries and metastasis involving the mesenteric lymph-glands and the thoracic duct were discovered. Thrombosis of the lacteals of the mesentery and the intestines was found.

Sackur¹ examined rabbits and dogs in which he had produced an artificial pneumothorax and found that the blood-pressure was not reduced; and concluded that the stimulation of the respiratory centre could not be due to an inadequate supply of blood. He then examined the blood in the carotid artery and found that the quantity of oxygen it contained was only half the normal, and he believes that this diminution of oxygen accounts for the increased respiratory activity.

Samuel West² discusses the **prognosis of pneumothorax**. He collected altogether 160 cases of the disease, of which 104 died, giving a mortality of 62½%. It is, however, to be observed that the mortality in those cases in which the pneumothorax developed in the hospital was much higher (77%) than in those admitted some time after the condition had been established (33%). This West explains by the fact that the proportion of deaths is much greater during the first week than at any subsequent period. Of 39 cases in which the duration was exactly known, 10 patients died on the first day of the disease, 2 within ½ hour, and the other 8 within a few hours; 8 more died within the first week and 3 during the second week; finally, 6 died during the second fortnight. Death is due to 3 causes, either rapid suffocation or shock within a very short period after the rupture; or as a result of effusion; or as a result of the diseased-process which produced the pneumothorax, usually phthisis. The prognosis, therefore, even as regards the immediate risk of life, is rather doubtful. It depends upon, 1st, the urgency of the symptoms—that is to say, the amount of dyspnea and cyanosis; 2d, the condition of the opposite lung, the development of rales being a very bad omen; 3d, the ability of the right heart to overcome the increased resistance in the pulmonary circulation, any sign of dilatation being unfavorable; 4th, the general strength of the patient, particularly the development of the respiratory muscles; 5th, the nature of the disease which has led to the pneumothorax. As regards the duration of life, the prognosis of course depends upon the condition of the patient and the nature of the disease. Recovery is rare; it does, however, occur and may be apparently complete and permanent. The most favorable cases are those in which there is no pulmonary disease and in which no effusion has taken place. If the effusion does occur, but is purely serous in character; the prognosis is also good. When, however, it is purulent, the chances for recovery are reduced. Even cases occurring in the course of phthisis, however, do sometimes recover. He then reports in detail 11 cases in which recovery took place, although 2 subsequently died of phthisis.

Benda³ observed a case of **primary "carcinoma of the pleura"** in a man of 54, who had been ill for 2 years. On admission pleural effusion was discovered; 3 liters of liquid were removed; aspiration was repeated 16

¹ Zeit. f. klin. Med., Bd. 29, 1896.

² Lancet, May 8, 1897.

³ Berlin. klin. Woch., Mar. 1, 1897.

times, the exudate remaining clear. Finally, resection of a rib was undertaken and a tumor was discovered on the pleura. Exudate reaccumulated, pyemic symptoms developed, and the patient died after metastatic abscesses had formed. Postmortem numerous small nodules were found distributed over the left pleura, the latter being normal in very few places. The microscopic examination showed the characteristics of endothelioma. The author refers to multiple nodules of primary eruption and the failure of metastasis as characteristic peculiarities. Among the clinical characteristics he cites the marked hemorrhagic character of the exudate, which may, however, be absent, and the decided pain after aspiration resulting from the inability of the lung to expand.

DISEASES OF THE MEDIASTINUM.

Kiserling¹ presented to the Berlin Med. Society the specimens of a **mediastinal tumor** that Leyden had diagnosed as an aneurysm during life. The clinical symptoms had been: severe pain at the level of the nipples and over the vertebral column; increase in the area of cardiac dulness, especially toward the right side; and a double impulse at the apex. Later, the symptoms of total paraplegia appeared, and at the same time the painful symptoms vanished. At the autopsy a grayish-white solid tumor was found upon the posterior surface of the heart, which had invaded the posterior wall of the left auricle and partially that of the right. A second tumor was found at the hilus of the left lung and extended along the principal bronchus and invaded the bronchial glands. Finally, the second dorsal vertebra had also been invaded by the tumorous process and had been destroyed, with the production of pressure upon the spinal cord at this point. The tumor proved to be a lymphosarcoma.

H. D. Rolleston² reports a case of tumor of the anterior mediastinum. The patient was admitted with swelling of the face, neck, and left arm; dulness beneath the sternum and to the left, with bronchial breathing at the root of the left lung and dilatation of cutaneous veins. Later, signs of pleural effusion developed, and 40 oz. of blood-stained fluid were withdrawn, as was proved subsequently, from the pericardial cavity. At the autopsy a large tumor was found occupying the anterior and superior mediastinum and covering the upper half of the pericardium, to which it was firmly adherent. On microscopical section it was found to consist of a cortical part containing fibrous and unstriped muscle-tissue and small cysts lined with mucous glands, and a central part containing sarcoma-cells and spots of hemorrhage, and in which were also found numerous islands of almost normal cartilage. The author concludes that it was a sarcoma arising from the thyroid gland and resembling parotid tumor.

DISEASES OF THE MOUTH AND PHARYNX.

Futterer³ reports 2 cases of **salivary calculi**: the first occurred in the submaxillary gland in a man subject to biliary colic. The first symptom was a transient swelling of the gland that was repeated for 4 years, when permanent swelling with inflammatory symptoms rendered an operation necessary. The calculus was composed of potassium and sodium phosphates with traces of xanthin and hypoxanthin. The second occurred in Wharton's duct in a

¹ Sem. méd., 1896, p. 277.

² Journ. Path. and Bact., vol. 4, No. 2.

³ Medicine, July, 1896.

patient aged 50, who had frequently noticed a small lump after partaking of sour food. Stomatitis developed 2 months before the operation, when the lump had been continuously present for some time. Occasionally, however, the swelling would grow acutely worse, and at rare intervals disappeared spontaneously. Fütterer also reports a case in the practice of Dr. Verity, in which the calculus, in the duct of the sublingual gland, had given rise to suppuration. He then described the symptoms of calculi of the salivary glands as follows: rarely, well-marked severe pains in the initial stages, then transient swellings when eating or during attacks of stomatitis, and, finally, suppuration, which may recur several times or become extremely chronic. The treatment is always operative.

Stoos¹ has investigated the etiology of **aphthous stomatitis** and thrush. In 15 cases of the former condition he found regularly, besides other bacteria, a large diplo-streptococcus that stained well by Gram's method and formed clusters. As he has never found this in healthy persons or in other diseases, he is inclined to regard it as pathogenic. In thrush he has invariably found staphylococci and streptococci in addition to the ordinary organisms, and believes that these play an important part in preparing the mucous membrane for subsequent infection, setting up a preliminary erythematous stomatitis.

Stoos² has found various bacteria in **ordinary angina**, all of which, however, occurred in health. He concludes that angina is a form of auto-infection, in which the streptococci play a most important part. Staphylococci and pneumococci are less frequent. The micrococcus tetragenus, Friedländer's bacillus, and the coccus conglomeratus are doubtful in action; while the leptothrix is very uncertain. There are no distinct clinical types, but the severest cases are those in which the streptococci occur.

Blumenau³ describes a case of **primary gangrene of the pharynx**. The patient, a man of 22, had suffered with catarrhal jaundice, following which pharyngitis and laryngitis developed. Two weeks afterward gangrene began in the form of rounded spots of dirty black color on the right tonsil, eventually destroying the whole tonsil, the right half of the soft palate, and nearly the entire root of the tongue. The process then extended toward the epiglottis. There were horrible fetor and repeated small hemorrhages from the ulcerated tonsillar artery. Death occurred in 2 weeks, and at the autopsy numerous hemorrhages were found in the pia, pericardium, endocardium, pleura, and lungs. The author doubts an etiological relation of the jaundice to the gangrene. Bacteriologic examinations were not made.

DISEASES OF THE ESOPHAGUS.

Störk⁴ describes his **esophagoscope**. This consists of a stiff tube with a number of joints at the lower end, that may be introduced like a bougie. A solution of gum arabic is employed to make the operation more easy. The patient sits, with his head bent backward, upon a low stool, and the tube is introduced like a sound until it meets with resistance. An accurately fitting mandarin is then withdrawn and the inspection made with the aid of a reflector.

Rumpel⁵ reports a case of **fusiform dilatation** of the esophagus, in which the diagnosis was made during life from the following signs: the patient, a tailor 25 years old, had suffered with gradually increasing vomiting

¹ Mittheil. aus klin. u. Med. Institut. der Schweiz, R. iii. H. 1.

² Ibid.

³ Deutsch. med. Woch., No. 26, 1896.

⁴ Wien. klin. Woch., No. 28, 1896.

⁵ Münch. med. Woch., Nos. 15 and 16, 1897.

for 2 years. If the stomach-sound was passed shortly after a meal, the following phenomena were observed: in the upper portion of the esophagus it passed easily without obstruction; then the end appeared to enter a free space, and at the same time a considerable quantity of liquid material was expelled that could be proved to consist only of the contents of the esophagus. A little further on it encountered distinct resistance at a distance of about 49 cm. from the teeth, which was only overcome with difficulty and the causation of considerable pain. The sound then entered the stomach and the normal stomach-contents were expelled. The lesion could not have been a bend in the esophagus, as this would have been increased after the taking of food; on the contrary, it was then easier to pass the sound. An interesting experiment was now performed—a small tube was introduced into the stomach; alongside of this a still smaller tube was passed for 40 cm., and through the latter 300 c.c. of water were poured, all of which could be subsequently recovered by sinking the funnel, and none of which apparently entered the stomach. In order to determine now whether the second sound entered a sac or simply a dilatation of the esophagus, holes were cut in the first one, and it was found that the liquid flowed through these into the stomach, proving that a sacular dilatation did not exist. The author believes that this condition is due to the spastic contraction of the lower portion of the esophagus, and in the present instance treated the condition by feeding exclusively through the stomach-tube. He believes, however, that it might be possible to adopt surgical measures. Finally, he states that by means of an emulsion of bismuth subnitrate introduced into the esophagus it was possible to see the enlargement with the fluoroscope. He has collected 20 cases of this condition from medical literature, none of which were diagnosed during life.

Danel¹ has reported an interesting case of **tuberculous esophagitis**. The patient, a woman of 76, came under observation with the signs of pulmonary tuberculosis and bronchopneumonia in the lower part of the left lung, and several areas of superficial ulceration in the submaxillary regions. The patient died, and postmortem there was discovered ulceration of the posterior wall of the esophagus for a distance of nearly 4 in., involving the mucous membrane. The margins contained numerous granulations that also involved the anterior wall. A communication between one of the peribronchial lymphatic glands and the esophagus was found opposite the right bronchus. The stomach was enlarged and contained a number of granulations, probably tuberculous. The glands of the neck were tuberculous. [The disease of the esophagus in this case evidently was secondary to that of the lymphatic glands.]

Berger² describes a case of stenosis of the esophagus near the cardiac end in a man of 55 without definite specific history. There was considerable loss of weight after a year's duration. The long continuance of the disease and the absence of cachexia suggested a **syphilitic origin** and KI was prescribed. In a month it was possible to pass a sound into the stomach, whereas there had been before complete obstruction. The author excluded an ulcerating carcinoma.

Poncet³ reports a case of **esophageal actinomycosis**. A woman of 28 was suddenly seized with paroxysmal cough, and a few days later was found to suffer with inability to swallow properly, each attempt being followed by violent coughing and threatened asphyxia. Esophagotomy was performed and a tracheal perforation closed with ligatures. After 48 hours the

¹ Jour. des Sci. méd. de Lille, No. 22, 1896. ² Deutsch. med. Woch., No. 32, 1896.

³ Bull. de l'Acad. de Méd., No. 15, 1896.

patient could swallow without difficulty. The ray-fungi were found in the sputa.

F. Savery and F. Semon¹ describe a case of complete bilateral **paralysis of the recurrent laryngeal nerve**, due to **carcinoma of the esophagus**. The patient, a man of 54, had the usual symptoms (aphonia and dyspnea) and difficulty in swallowing when sitting in an upright position. He could swallow readily in the horizontal position, upon one side, or with the head hanging over the edge of the bed, as in cases of diseases of the larynx and epiglottis. [The occurrence of laryngeal symptoms due to involvement of the recurrent laryngeal nerve has been studied by MacKenzie and others; but bilateral palsy is extremely rare, and the condition is, in general, too rarely considered.]

Galliard² reports a patient whose repasts were frequently interrupted by severe coughs with expectoration of portions of food. A diagnosis was made of a fistula connecting the esophagus and a bronchus. At the autopsy a huge **carcinoma** was found, occupying the lower portion of the esophagus, with a fistula leading to the postero-inferior portion of the right lung.

DISEASES OF THE STOMACH.

Methods of Examination.—Haan³ has tested the value of different varieties of bread and tea when employed in the test-meal of Ewald, and finds that they exert considerable influence upon the results. The best bread is one composed of gluten and poor in starch. Tea is modified in various ways—by the temperature at which the mixture is given and the concentration of the infusion.

De Niet⁴ discusses the diagnosis of gastric malpositions. For general purposes he prefers **distention** of the stomach with **CO₂**, as the inflation with air requires the introduction of a tube. Theoretically, 5 gm. of tartaric acid and 6 gm. of sodium bicarbonate produce 2 l. of CO₂ at the temperature of the body. The determination of the lower border of the stomach is always made with reference to the normal position of the umbilicus—*i. e.*, a point midway between the ensiform process and the pubis. He examined only women, 58 in all. In 13 he found gastropptosis, in 11 subvertical position, in 17 a combination of these conditions; in 11, normal relations; while in 6 the exact condition could not be well determined. In every case he determined Rosenheim's line (the greatest diagonal measurement), the height and the breadth of the organ, and the position of the pylorus. Among 11 normal cases some liecd very tightly, so that the author cannot agree with Meinert, who holds that after one and a half year of laeing enteroptosis invariably develops. In speaking of gastrodiaophany the author states that this method is unreliable. [The introduction of a tube is not usually a matter of difficulty, and it has been our experience that inflation by this method gives more trustworthy results.]

Schmilinsky⁵ has tried **Boas's method of outlining the stomach** by means of palpation and a sound. He found it succeeded in 97 out of 100 cases. Besides determining the situation of the greater curvature, it was also of value in localizing gastric tumors and in excluding tumors that were not adherent to the stomach.

Meltzing⁶ has used the magnetic needle in connection with gastrodiaophany

¹ Lancet, Sept. 19, 1896.

³ Compt. rend. de la Soc. de Biol., May 28, 1897.

⁵ Arch. f. Verdauungskrank., Bd. 3, p. 3.

² Sem. méd., 1896, p. 285.

⁴ Diss., Leyden, 1896.

⁶ Ibid., Bd. 2, H. 4, Dec., 1896.

to demonstrate the reliability of **illumination** as a method of diagnosis in gastric diseases. He introduced a magnetic sound into the stomach and then, with the aid of a balanced magnetic needle, determined the position of its tip. The only error possible in this method, he holds, is that the sound introduced may depress the greater curvature of the stomach; but its delicate construction renders this unlikely. The instrument had previously been described by Martius. The results obtained by this method, in the empty and in the distended stomach, have corresponded with the results obtained by illumination, the difference being scarcely the breadth of a finger. Illumination has the advantage of showing the character of the entire wall of the stomach. He holds that the conditions during life are very different from those that exist in the cadaver; and, therefore, that Luschka's figures, based upon postmortem examination, do not contradict his own. Change of position and change of contents exercise a decided influence upon the position of the organ. [Confirmation of the work of Martius and Meltzing with the magnetic sound is necessary in order to decide its value as an aid to illumination. Other authors, using the ordinary method for control, have reached very different conclusions regarding the value of illumination, and this newly suggested method of confirmation may prove equally unsatisfactory.]

Lindemann¹ has been able to demonstrate the outline of the stomach by means of the **Röntgen** rays. He introduced a flexible sound containing a metal mandril and laid the patient prone upon the plate. He believes the sound passes closely along the greater curvature and that the pictures are quite accurate.

Hemmeter² describes his experiments to perform **duodenal intubation**. He distends the stomach with the aid of a rubber bulb and then passes a somewhat curved tube along the lesser curvature through the pylorus. [The technical difficulties in the application of this procedure appear so great that it is not likely to be of much practical service.]

Oppler³ objects to Hammerschlag's quantitative pepsin-estimation for exact work. By more careful methods he found that **pepsin digestion** never failed entirely in 26 cases that he examined, and that its extent was directly proportionate to the amount of HCl and the activity of the curdling ferment. He therefore concludes that variation in pepsin-secretion is not pathognomonic of any condition. [This is the most careful work that has been done upon this subject, but needs confirmation before it can be unreservedly accepted.]

J. Friedenwald⁴ contributes an interesting paper upon **the relations of saliva to gastric digestion**, and cites particularly the experiments of Biernaeki. This author concludes that the saliva exercises some sanitary influence upon the digestive processes in the stomach, this influence being exerted locally when the food is being swallowed. The same beneficial effect was not obtained from the saliva when it was introduced into the stomach after the test-meal had been administered, and it was not due to ptyalin or to sulphocyanid of potassium. He concluded that the beneficial effect of saliva is dependent upon its alkalinity, and that the starchy alkaline breakfast is in some way converted into a less alkaline condition by the action of the saliva. Friedenwald repeated these experiments in several healthy and diseased cases, and was able to confirm the results. He found that there was always a greater quantity of gastric contents in the cases in which the saliva was not swallowed than in those in which it was, and the acidity and free HCl

¹ Deutsch. med. Woch., Apr. 22, 1897.

² Arch. f. Verdauungskrank., ii, 1, 1896.

³ Ibid., vol. i, No. 1.

⁴ Internat. Med. Mag., Aug., 1896.

were always greater when the saliva was swallowed than when it was not. No especial difference could be noted in normal cases in pepsin digestion. The rennet activity, however, seems more pronounced when the saliva has mingled with the special test-meal than when it has not been swallowed. In pathological conditions the stimulation of the pepsin and rennet ferments when the saliva is allowed to mingle with the food is more striking. He determined that the mere act of mastication did not exercise the beneficial influence, and, further, that the saliva swallowed after the food exercised a much feebler influence than that swallowed with the food. The effect, he holds, is produced entirely while the food is passing through the mouth. The author differs from Biernacki regarding the influence exerted by the saliva upon the reaction of the food. Biernacki concluded, from the fact that an alkaline solution previously colored by phenolphthalein lost its color in the mouth, that the saliva has the power to reduce the alkalinity. Friedenwald maintains that this is due rather to the presence of CO_2 , from the fact that he was able to restore the color by boiling, and from the fact that the gases evolved caused turbidity in calcium solutions. He then cites experiments showing that a neutral or slightly acid reaction of the food stimulates greater gastric digestion than alkaline food, and points out that bicarbonate of sodium exerts a more beneficial influence than ordinary sodium hydrate, probably in consequence of liberation by the former of CO_2 when the salt combines with HCl . He is led to suspect that the saliva exerts a beneficial effect in part from the swallowing of carbon dioxide.

Changes in Form and Position.—Bial¹ considers the subject of vertical displacement of the stomach in the male sex. To determine the exact relations he has investigated the position of the stomach and the character of digestion in 50 men of various ages, using inflation with air to determine the position of the stomach, and incidentally placing himself on the side of Meinert and others, who have found this method most useful, and against Martins. He has studied particularly cases of narrow thorax due to rachitis and other causes, and cases of phthisis and of emphysema, and found that dislocation of the stomach in such individuals is very frequent, but not invariable. His figures show gastropnoia in 12 of 18 cases of malformation of the thorax, and in 18 of 26 cases of emphysema of the lungs. In 17 of 36 patients presenting this condition no disturbances of digestion were discoverable. In a few cases he found typical manifestations of nervous dyspepsia, some of which, however, were ascribable to disturbed secretion, probably the result of displacement. Finally, he concludes that the displacement alone does not explain the occurrence of the severe symptoms in women, these being in greater measure due to a general neurotic organization.

Kutter and Dyer² believe that gastropnoia is more frequently the result of tension from below due to the weight of the retained stomach-contents bearing upon the relaxed walls of the organ, than of pressure from above. The nervous and general conditions that are associated with it are probably more frequently its cause than result. In all cases of this condition there appears to be a considerable reduction in the hemoglobin of the blood, 38 cases that they counted giving an average of 77.2%. In criticism of Bial's paper (*vide supra*) they state that they cannot agree with his conclusions that gastropnoia is less frequently productive of symptoms in men than in women.

Wm. Pepper and Alfred Stengel³ contribute a discussion of the diagnosis of **dilatation of the stomach**. They first insist that atony cannot be sharply

¹ Berlin. klin. Woch., Dec. 14, 1896.

² *Ibid.*, May 17, 1897.

³ Am. Jour. Med. Sci., Jan., 1897.

separated from dilatation, as there is of necessity a certain amount of dilatation with even the least grades of atony. In the second place, they point out that the normal size of the organ is difficult to determine, and that cases of so-called megalogastria may be met with. To determine the limits of gastric capacity they made studies at the postmortem table, filling the stomach with water under a vertical pressure of about 25 em., and found wide variations. The smallest organ held only 500 c.c., and was found in a boy of 19, 1.73 m. in height, who had died of pulmonary phthisis. The stomach held but 500 c.c. The largest stomach held 2600 c.c., and was found in a woman of 29, of rather delicate construction, and 1.55 m. in height. A number of cases exceeded 1680 c.c., the maximum figure found by Ziemssen. After reviewing the principal etiologic factors in dilatation the authors discuss the physical signs. Attention is called to the depression frequently seen in the epigastrium, the distention of the abdomen being in the lower regions. Auscultation discovers splashing sounds, but these are comparatively valueless. Percussion, as ordinarily practised, is unreliable; but the method of auscultatory percussion has given them very satisfactory results. By far the most useful method is inflation, which they invariably practise with the aid of a stomach-tube and a rubber bulb. The effervescent powders are unreliable and unsafe in comparison. The motor power is best estimated by determining the presence or absence of food-particles in the stomach at long intervals after administration of the test-meals. If any particles remain 7 hours after a meal of meat, soup, and bread, atony may be assumed to exist. The differential diagnosis between megalogastria and dilatation, between gastropptosis and gastrectasia, and between atonic and obstructive dilatation is detailed, and finally that between malignant and nonmalignant obstruction at the pylorus. Of particular interest is the differentiation of gastropptosis, and the authors lay particular stress upon the determination of the position of the lesser curvature of the stomach. If this is displaced downward in equal proportion with the displacement of the greater curvature, there is probably more dislocation than enlargement, and the method of inflation finds its greatest usefulness in making the determination easy. A number of cases and diagrams are included in the report to illustrate the position of the stomach in different conditions and the reliability of different methods in differentiating these conditions.

Rosenstein¹ reports the case of a young man that 7 years before the observation had presented the symptoms of a gastric ulcer; 5 years later he had hematemesis, and then presented the appearance of a case of pneumothorax; it was, however, noticed that the metallic signs were very inconstant, and independent of the expiratory movement. At the autopsy it was found that the enlarged stomach had pressed the diaphragm upward as high as the 1st rib, thus giving rise to the symptoms.

Gastritis.—Chanutin² reports a case of **phlegmonous gastritis**, and tabulates the following as the most characteristic symptoms: chills, high temperature, frequent sweats, rapid pulse, and typhoid state; vomiting of bilious matters, the presence of pus-corpuscles in the vomita, or pure pus; burning or stabbing pains in the region of the stomach; constipation and sometimes diarrhea; tenderness in the region of the stomach and sometimes presence of swelling. His own case occurred in a woman of 26, and began with nausea, vomiting, and transient diarrhea, followed by pain in the region of the stomach and frequent vomiting; irregular chills with marked fever developed, and the vomita became purulent and fetid. Finally, pure blood was ejected; the

¹ Arch. f. Verdauungskrank., vol. ii., H. 3.

² Vrach, Nos. 32 to 36, 1895; Centrabl. f. innere med., No. 40, 1896.

abdomen was depressed and the region of the stomach extremely tender. Pressure on the epigastrium caused nausea and vomiting. The spleen was enlarged; microscopically pus-corpuseles were found in the vomita, and an almost pure culture of staphylococcus, with a few streptococci, was obtained. The contents were at first alkaline and later acid, and only once contained free HCl. The stomach could retain only ice pills. The patient gradually recovered.

Dorbeck¹ reports a second case from the same hospital in a woman of 63 who suffered with headache, chills and fever, coryza, cough, and pain in the limbs. The tongue was coated, the tonsils swollen, and there was herpes on the nose. There was no vomiting nor diarrhea; the lungs and heart were negative; the spleen was a little enlarged; the abdomen was slightly thickened. The temperature was 104° and the pulse and respirations rapid. On the third day bronchitis and diarrhea developed, the abdomen became distended, and the patient died. Autopsy showed superficial ulceration of the mucous membrane of the right side of the stomach, with extensive thickening of the deeper layers. The mucosa was partly detached by purulent collections and the infiltration extended as far as the peritoneum. The pus in the submucosa contained many streptococci. [Even with the symptoms present in the first case, the existence of a gastric phlegmon could hardly be established, particularly as considerable quantities of pus may be found in the vomita in other conditions.]

Roux² refers to a case of **febrile gastritis followed by paralysis**. The patient, a soldier of 22, presented paralysis of the upper and lower extremities, without noteworthy sensory manifestations, suggesting a lesion of the anterior horns of the cord. The whole course of the disease had analogy with the spinal paralysis of Duchenne-Aran. The cause of the paralysis was undoubtedly the gastric disturbance and the overwork and fatigue incurred about the same time. [Spinal muscular atrophy has occasionally developed after an acute disease, but the etiological relation of the latter has not been established beyond doubt.]

Thiemich³ has studied **32 cases of gastroenteritis** in children and has found lesions of the liver in a large proportion. In 9 cases there was no change, in 20 moderate and focal, and in 3 high grade and diffuse fatty degeneration. The changes in the nuclei of the cells led to the conclusion that it was a true fatty degeneration. The periportal accumulation of fat, such as is characteristic of ordinary infiltration, is explained by the view that the poison is most active at the point where it first comes in contact with the liver-structure after leaving the blood coming from the gastrointestinal tract. [While the author's paper is not entirely convincing that the changes noted are of peculiar type, or directly related to the gastrointestinal disease, it is suggestive in indicating the existence of a general toxic condition. This is, of course, particularly true of children, but plays an important part in the intestinal disturbances of adults as well.]

Functional and Neurotic Disturbances.—Schreiber⁴ defends his previously expressed view that **chronic gastrosuccorria** is not an independent disease, but rather a symptomatic condition occurring in the course of certain diseases of the stomach; notably atony and dilatation. He states his own view regarding Reichmann's disease, and proposes, instead of gastrectasia, the term *Stauungsmagen* to indicate the retention of food. As there is always some remnant of food retained in such a stomach and there is

¹ Vratel, Nos. 32 to 36, 1895; Centrabl. f. innere med., No. 40, 1896.

² Gaz. hebdom. de Méd. et de Chir., No. 67, 1896. ³ Ziegler's Beiträge, Bd. 20, H. 1.

⁴ Arch. f. Verdauungskrank., Bd. 2, H. 4, Dec., 1896.

constant or permanent digestion, the term *Stauungsmagen with permanent digestion*, or permanent digesting stomach, would seem to be justified. Chronic gastrosuccorhea, he believes, is a frequent condition, and is usually supposed to occur either pure and uncomplicated or complicated with gastrectasia. The uncomplicated cases do not differ in any notable particular from the cases of gastrectasia, and it is possible to relieve the increased gastric secretion by relieving the gastrectasia. He points out that the exclusion of gastrectasia in the so-called typical cases of gastrosuccorhea by authors who admit the existence of such a distinct disease rests upon very poor foundation, such as existence of sarcinæ in the dilated organ or the like. He has demonstrated that abstinence from food for the period of 48 hours after careful and systematic lavage had been practised for some time, with rectal feeding, leads to the disappearance of the symptoms. He alludes to a case in which the gastrosuccorhea disappeared promptly after gastroenterostomy had been performed.

Dauber¹ reports a case with symptoms of gastritis and continuous excessive secretion of mucus, and proposes the term "**gastrosuccorhea mucosa.**"

Martius² discusses **achylia gastrica**, which, according to him, is not a disease but merely a symptom, and is characterized by the total absence of ferments of the gastric juice. It occurs in gastric carcinoma, in acute and chronic gastric catarrh, in atrophy of the gastric mucous membrane, and in gastric neuroses. He has examined 17 cases, which he divides into 2 groups: those in which the symptoms of progressive pernicious anemia are present, and those in which health is apparently unimpaired. All show the characteristic change in stomach-contents—that is, after a test-meal neither ferments nor HCl were secreted, nor were there any signs of decomposition of the stomach-contents. In the 2d group the motor functions of the stomach are normal and the intestinal digestion and absorption are perfect. The 1st group appears to be invariably associated with some severe general condition, such as tuberculosis.

Rosenheim³ discusses **motor insufficiency of the stomach**, by which term he implies all injuries to the motility of the stomach, whether considerable or slight, and whether they occur in a small, normal, or enlarged organ. This condition may arise acutely or suddenly, whilst in the interval the stomach is entirely normal. Diagnosis can usually be made without difficulty by the use of the sound. The most important feature, however, is the discovery of the etiology of the condition. There is by no means invariably stenosis of the pylorus, and Rosenheim reports 2 interesting cases in which diminished contractility and secretive power occurred as manifestations of tabetic crises. Traumatism also is a not infrequent cause, acting either reflexly or else by producing a perigastritis. Another is ventral hernia. Nevertheless, when ventral hernia exists it must not be rashly concluded that it is the cause of gastric disturbance. Prognosis is not invariably unfavorable, even in the severer forms, for almost complete cure can, as a last resort, be secured by gastroenterostomy.

Max Einhorn⁴ reports a number of cases illustrative of the fact that chemical derangements of the gastric secretion are frequently the cause of either diarrhea or constipation, these latter conditions disappearing as soon as the gastric disturbances are corrected.

Sutherland⁵ has described a case of **gastric flatulence** of a peculiar

¹ Arch. f. Verdauungskrank., Bd. 2, H. 4, Dec., 1896.

⁴ Med. Rec., Feb. 27, 1897.

⁵ Lancet, Aug. 1, 1896.

type. The patient, a man of 51 years, began to suffer in 1871 with gastric pain, heartburn, and flatulence, the result of drinking ice-water immediately after exercise. He lost in weight and strength and frequently suffered with acidity. He would stay awake a large part of the night, tormented by eructation. It was found that he had some dilatation of the stomach, and on examination during an attack of eructation this was discovered to be spurious, the air being taken into the esophagus by a swallowing effort, with the muscles of the neck tightly fixed, and then regurgitated. It was explained to him that this eructation really did not come from the stomach and that he could control it by effort. He succeeded in this on the very first trial, and from this time rapidly improved until the habit was completely cured.

Boas,¹ in discussing **dyspeptic asthma**, alludes to 12 cases of his own. In some of these he found diseases of the lungs or heart, in others gastrointestinal disease, especially cases of excessive HCl with atony of the walls of the stomach. The nature of the attacks is obscure, but the author found in some of his cases that the diaphragm was elevated above its normal position. He opposes the theory of auto-intoxication, stating that his own examinations have not shown any evidence of this.

Rosenbach² contributes an elaborate paper on the **dyspepsia of emotion**. The symptoms in general are somewhat as follows: after a severe emotional disturbance, especially in nervous, anemic persons, either at once or in a short time, there are mild or severe digestive disturbances, complete loss of appetite, alternating attacks of increased salivary secretion and dryness, a feeling of constriction in the neck, and sense of pressure in the epigastrium and the abdomen. These patients, as a rule, are able voluntarily to distend their bellies. Dyspnea and sighing respiration with a feeling of constriction beneath the sternum are frequent, and eructation, often associated with air-swallowing, may be observed. Peristaltic activity and noisy borborygmi are frequent. Colicky pains and alternating constipation and nervous diarrhea are significant. The anorexia may be interrupted by periods of excessive appetite, the acid foods being specially craved. Insufficient food taken by these patients leads to exaggeration of the symptoms, and especially of the subjective sensations. The digestive process itself is normal, and examination of the stomach-contents or of the vomited matters discovers no evidences of organic disease. The prognosis depends upon the nature and removability of the cause. Under proper conditions the outlook is favorable. Warm applications, the drinking of moderate quantities of warm water, and the insistence upon a proper diet are important, and small doses of sedatives with small quantities of brandy are advisable.

Mathieu³ refers to a group of symptoms met with in **hysteria** suggesting genuine **hematemesis**. There is usually vomiting of bloody fluid at night, after a feeling of distress and burning beneath the sternum and in the epigastric region. The quantity is usually about 100 c.c. and the fluid presents the appearance of raspberry syrup. It does not contain clots, traces of food are seldom found, and it grows darker on standing. These attacks occur monthly in certain women, who show typical hysterical symptoms with vague dyspeptic manifestations. The vomiting is rarely preceded by nausea. The stomach is distended with gas, and a point of tenderness is found to the right of the middle line about the position of the pylorus. The attacks may occur daily, or may be longer in duration with intermissions of several days. The vomited matters tend to separate into layers, the lower being composed of mucus

¹ Berlin. klin. Woch., No. 39, 1896.

² Ibid., Jan. 25, 1897.

³ Gaz. des Hôpitaux, Nov. 16, 1896

and corpuscles with detritus, the upper of clear liquid. On testing it is found that saliva is present, the starchy digestion being demonstrable. The sources of blood in these cases is doubtful, though it could be traced to denuded mucous membrane in the mouth in several cases.

Treatment of Chronic Gastric Disease.—Sawyer¹ advocates the use of **arsenic** in the treatment of gastralgia. He accepts the classification of Romberg, who distinguished two forms, *gastrodynia neuralgica*, which he holds to be hyperesthesia of the gastric branches of the vagus, and *neuralgia coeliaca*, which he attributed to hyperesthesia of the solar plexus. Clinical experiences show that this distinction is of doubtful use, treatment being the same. He gives arsenic in pill-form (arsenious acid gr. $\frac{1}{24}$) with 2 or 3 gr. of a vegetable extract such as gentian, 3 times daily between meals. The medicine should be continued for some weeks. In severe cases he also uses counterirritation over the epigastrium. A full and varied diet is better than restricted food.

Storek² employs **formalin** as an irrigating solution of a strength of 1:1000 in chronic gastric disease with marked fermentation.

Max Einhorn³ contributes an experimental paper upon the **effect of electrical currents upon the contractions of the stomach**. Meltzer found that direct and indirect faradization of the stomach in animals demonstrated an inordinate resistance on the part of its mucous membrane to the passage of electrical currents. Einhorn found that by placing one electrode upon the serous coat and the other in the stomach contractions were readily elicited. The same occurred when one electrode was placed on an adjacent part of the body and the other in the stomach. Both poles being placed in the stomach, peristaltic contractions could be produced, though not active ones. He claims to have proved by direct experiment that the mucous membrane is a good conductor. In a patient with one electrode in the stomach and one upon the skin over the epigastrium the resistance measured by Wheatstone's apparatus was 6800 ohms. When the electrode was taken from within the stomach and placed upon the back the resistance became 22,000 ohms, proving the ready transmission through the mucous membrane. [While these experiments are somewhat crude the conclusions seem to us entirely justified.]

Salomon⁴ subjects **Rosenheim's stomach-sound** to a severe criticism, finding that it does not under ordinary pressure project fine streams laterally against the walls of the stomach. He suggests as improvements diminution in the size of the central hole and reduction of the number of side holes from 24 to 9, making the lumen slightly less and giving them an upward direction. With these changes he finds that it is a most satisfactory instrument.

Lauenstein⁵ reports a case of hour-glass deformity of the stomach, in which **gastroanastomosis** was performed. The patient, a woman of 43, had suffered with vomiting, cardialgia, constipation, hematemesis, and loss of flesh. Examination with the stomach-tube detected reduction in the size of the organ. Operation was undertaken and hour-glass deformity was discovered. The lesser curvature was adherent to the under surface of the liver and a constriction appeared at this point. Marked improvement followed the operation.

Gastric Ulcer.—F. Page,⁶ C. F. Dent,⁷ and R. F. Jowers⁸ each report a case of **perforated gastric ulcer**, in which **laparotomy** was performed

⁸ Ibid.

and recovery ensued. Further cases are reported by A. Thomson¹ and W. H. Bennett.² In all there were 6 cases, 5 of which recovered. The 6th case died of pneumonia on the seventh day. The patients were 3 women, between 19 and 27, and 3 men, between 32 and 44. The ulcer occupied the anterior wall of the stomach in each case, and there was generally considerable extravasation of the gastric contents into the peritoneal cavity at the time of the operation. The symptoms previous to the rupture were sometimes uncertain, as in the case of Bennett's, in which the clinical history was very indefinite for weeks, and at last resembled that of intestinal obstruction. Operation was undertaken in 5 of the cases between 3½ and 7 hours after severe pains indicated a rupture; in one case it was 24 hours after rupture. Thomson refers to the fact that hemorrhages into the gastrointestinal tract, without the external appearance of blood, in the course of gastric ulcer, may cause symptoms of perforation, and he refers to a case in which perforation of gastric ulcer was suspected and in which he made an incision, only to find a healthy peritoneal wall.

Küttner³ reports a case of gastric ulcer in which pain in the epigastrium came on acutely and was associated with obstinate constipation. Enemata of oil relieved both symptoms temporarily; but the pain recurring, associated with resistance in the epigastric region, operation was performed, and an abscess was found in the liver, through which gastric contents were discharged. At the autopsy an ulcer was found on the posterior wall of the stomach, perforating into the liver.

H. M. Lyman⁴ reports a case of gastric ulcer that presented subjective symptoms for 3 years. 6 months before admission the patient had vomited mucus streaked with blood. Finally, there was intense hemorrhage lasting for nearly 24 hours and causing a profound anemia.

Treatment.—Ratjen⁵ adopts **absolute withdrawal of all nourishment by the mouth** with absolute rest in bed for a period of 10 days for the cure of gastric ulcer. In 55 cases in which this was tried the cure seemed to be complete; for the purpose of quenching thirst water and a few indifferent teas were employed, and no drugs given excepting sometimes a little cognac.

Hirsch⁶ reports a case of gastric ulcer that for 2 years had not produced any symptoms and then, immediately after a severe fright, led to erosion of a vessel and fatal hemorrhage. He discusses the indications for **operative procedure** in such cases, and suggests that possibly it would be easier to discover the ulcer if the operation was performed during the hemorrhage; in general, he believes that operative interference is justifiable when, in spite of strictest rest and diet, there are continually recurring hemorrhages, which, by their quantity and severity, present a serious menace to the life of the patient.

Carcinoma of the Stomach.—Diagnosis.—Czygan⁷ believes that the presence of HCl and the condition of the ferments in the gastric juice are of great importance in the differential diagnosis between carcinoma of the pylorus and of the duodenum. In the latter condition he usually finds hyperacidity and sometimes, as in the case he reports, the absence of leucin, tyrosin, and bile from the stomach-contents. When bile is absent he considers that it indicates the location of the neoplasm between the pylorus and the ductus choledochus.

A. Hammerschlag¹ discusses the diagnosis of **cancer of the stomach**, based upon the examination of 42 cases. If there is absence of free HCl for a period of several weeks, if the albumin digestion is reduced below 15%, if much lactic acid is present and numerous long bacilli, and if no improvement occurs in the period of observation, cancer may be assumed with considerable likelihood even if cachexia and tumor are not developed. Neither deficient HCl, nor marked loss of peptonizing power is peculiar to cancer; nor is the presence of lactic acid distinctive. The demonstration of intense lactic-acid formation as a constant symptom warrants the belief that the peptic glands are largely atrophic, and that motor insufficiency of the organ exists. This combination is seen more frequently and earlier in carcinoma than in any other condition.

W. C. Weber² discusses the possibility of the early diagnosis of carcinoma of the stomach, and concludes that although it cannot be made positively, nevertheless the continued absence of HCl and the presence of lactic acid, and the condition of the blood, taken in connection with the symptoms of gastric disturbance, enable one to reach a conclusion with reasonable certainty, at least at a period when operative interference is still possible. [It must not be forgotten that all cases of gastric carcinoma are not amenable to operation even in the earliest stages.]

A. L. Benedict³ holds that the apparent **presence of a tumor** in the abdomen in the region of the pylorus is not always indicative of carcinoma, since the size of the tumor seems to increase with the thickness of the abdominal wall. He is not convinced that the slow absorption of KI is of much significance, having in a number of experiments found that in the same individual, under apparently similar conditions, the time at which it appeared in the saliva was exceedingly variable. Furthermore, he disputes the importance, as a sign of carcinoma, of the diminution of the daily quantity of urea excreted.

Huber⁴ reviews the subject of carcinoma of the stomach. Without the presence of a palpable tumor, the diagnosis can scarcely extend beyond a probability. The objective and subjective symptoms, particularly the vomiting of coffee-ground material, which is highly suggestive, are of some value. The absence of free HCl is usual, but the occurrence of this sign in other diseases robs it of value. The presence of lactic acid is of greater significance, and a specially high degree of lactic-acid reaction is highly suggestive. Another sign is the prolonged retention of food in the stomach, which occurs not only when the pylorus is affected, but also when the body of the organ is involved.

Reineboth⁵ refers to the **diagnosis of carcinoma** of the stomach **by examination of the fragments of the tissue** obtained in the vomita or in the washings after lavage. Cancer-cells cannot be recognized as such, and the diagnosis therefore rests upon the recognition of groups of cells; but even cancerous acini or cancer-nests cannot be distinguished offhand from similar aggregations of cells of noncancerous origin. In some cases it is necessary, in order to be certain, to discover other suspicious signs, such as the existence of tumor. If a distinct mass can be felt and then cell-nests are found, the diagnosis is fairly certain; but cells frequently show considerable alteration due to the action of the gastric juice and of necrosis. He has examined the washings of 28 cases for considerable periods of time. Four of these were cases of old ulcer; 10 were cases of chronic gastritis and nervous disorders; 6 were doubtful cases of chronic gastritis and old ulcer or

¹ Arch. f. Verdauungskrank., Bd. 2, H. 1 and 2. ² Jour. Am. Med. Assoc., July 11, 1896.

³ Internat. Med. Mag., Apr., 1897. ⁴ Correspondencebl. f. Schw. Aerzte Sept. 15, 1896.

⁵ Deutsch. Arch. f. klin. Med., Bd. 58, H. 1, 1896.

cancer; and 8 were cases of pyloric cancer. Of the latter 8, suspicious particles were found in 4, and the same occurred in 1 of the 6 cases in which the diagnosis was somewhat in doubt. The author then details briefly the clinical features of these 5 cases, and concludes that in the 1st the diagnosis was absolute; in the 2d almost so; in the 3d peculiar tubular formations were found in the tissue-particles, but without the existence of a distinct tumor it could not be positively asserted that the case was one of cancer; in the 4th case the diagnosis was negative; and in the 5th case doubtful. In the 5 cases in which fragments were found, 4 of which had pyloric stenosis, the microscopic examination established an undoubted diagnosis of cancer in 2. In 1 of these no cancer could be felt, while in the 2d the diagnosis was made in spite of temporary improvement (gained 15 pounds in 1½ weeks), such as is rarely seen in

FIG. 3.—Fragment of carcinomatous tissue found in stomach-washings (Deutsch. Arch. f. Klin. Med., Bd. 58, H. 1, 1896).

cancer. He reproduces some of the drawings made from the microscopic examinations. [It is gratifying to note the author's care in drawing deductions from the microscopic appearances, as contrasted with the reckless manner in which some observers have claimed to be able to distinguish various diseases and even stages of disease in this way.]

W. O'Neill¹ records a very interesting case of **hematemesis**, in which considerable quantities of **tumor-substance were vomited**. The patient, a man of 60, much emaciated and extremely anemic, was almost syncopal. There were pain and tenderness in the epigastric region and the stomach was found to be enlarged. The patient had vomited twice the morning he came under observation. The vomita consisted of blood, mucus, and numerous bits of carcinomatous tissue of the colloid kind. There were 3 portions of this so large that the man's wife said she had pulled them out of his throat to prevent

¹ Lancet, Oct. 3, 1896.

him choking. The quantity of vomited matter was from 8 to 10 oz. On careful examination there was found one portion in the shape of a ring and darker and harder than the remaining parts; this was apparently from the pyloric end of the organ. It is very likely from the appearance of the masses that the carcinoma was of polypoid character. The patient improved very much after he recovered from the immediate effects of the loss of blood.

Symptoms.—Brosch¹ reports a case with the symptoms of obstinate constipation and rending pains in the region of the stomach. There were melena and hematemesis, and a rough, hard, resistant surface apparently connected with the pylorus could be felt in the epigastrium. The stomach was not dilated and free HCl was present. At the operation metastases were found in the abdominal cavity. The autopsy showed a carcinoma upon the posterior surface of the stomach and two annular stenoses of the intestines produced by secondary carcinomata.

Powell² describes a case of **infiltrating carcinoma** of the stomach. The patient, a woman of 34, who had always been somewhat dyspeptic, said her illness dated from an attack of influenza 2 months previously. She first suffered with pain, and 5 months later vomiting, eructations, and constipation set in. There was no hematemesis. She discovered a lump in the epigastric region, which, however, remained about the same in size for 6 months, although it underwent temporary variations; she had lost some flesh, and on admission was thin but not emaciated. On physical examination an elongated, somewhat kidney-shaped swelling was found about $\frac{1}{3}$ of the way down below the ensiform cartilage toward the umbilicus. It was 3 in. in length and extended to the left cartilages, being lost beneath the costal margin on that side. On the right side it had a rounded border in the parasternal line. The tumor was movable to some extent, and from time to time it could be felt to harden as if by intrinsic contraction; it descended somewhat with inspiration. The stomach-outline was about normal. No splash could be elicited. It was clear that it was not connected with the liver. The spleen appeared normal, though a small mass felt on deep inspiration below the ribs, and more or less in touch with the tumor, might be either the spleen or an offshoot. Displaced kidney was excluded on account of its superficial position and location anterior to the transverse colon. The position and characteristics of the tumor were compatible with the diagnosis of an omental mass, but the peculiarity that the tumor varied in hardness led to the diagnosis that it was a thickened stomach. The duration of the symptoms and the absence of extension of the tumor or involvement of other organs were against the idea of malignancy. An exploratory incision was made, which showed that the mass was a hypertrophied wall of the stomach, the pylorus itself being healthy. The patient reacted well from the operation but subsequently died, and the autopsy showed the stomach contracted, pinkish-white in color, and opaque. The pylorus admitted the middle finger; the stomach-wall was greatly thickened; there was diffuse cartilaginous infiltration beneath the mucosa. The process was most marked in the pyloric third, although the whole stomach was involved. Accurate analyses of the stomach-contents had not been made, but the vomita did not react with congo paper. [Cases of this kind are of great interest from a diagnostic standpoint, and it is regrettable that accurate studies of the gastric secretions and functions were not attempted. In spite of these, however, a strong suspicion of malignancy was justified by the evident massive thickening of the walls of the stomach. It is to be remembered that many of the older cases in literature of cirrhosis of the stomach were probably instances of such infiltrating carcinoma.]

¹ Deutsch. Arch. f. klin. Med., Dec. 18, 1896.

² Practitioner, Feb., 1897.

Bouveret¹ describes a case of carcinoma of the pylorus in which a **fistula into the colon** was established. The existence of the latter could be determined by the following points: for 3 months there was permanent diarrhea, uninfluenced by medicines; the evacuations invariably followed 10 or 15 minutes after the patient took food; in spite of marked nausea and attempt at vomiting the patient was able to vomit only once, just before death. The vomited material showed the same constitution as the dejections, which had none of the fecal characteristics, but a marked odor of butyric acid; HCl was never found free or combined. The condition of the nutrition of the patient was such that there was evidence of communication with the ascending colon and therefore a moderate preservation of the digestive activity and absorption.

Septic Infection.—Herard² discusses the various forms of sepsis that may occur in cancer of the stomach. The principal entrance is through the portal system, giving rise to an adhesive or suppurative pylephlebitis, the latter being distinguished by a greater severity of the symptoms. Once the organisms have passed the portal capillaries they may produce all the characteristic symptoms of pyemia. These infections often have considerable influence upon the development of the cachexia.

De Besse³ has studied septic infection occurring in gastric carcinoma. This may remain localized either in the cancer or in its neighborhood, or may be transmitted by the lymph-channels to distant organs, such as the pleura or pericardium, or by the portal vein to the liver, or it may give rise to septiemia or even pyemia; these usually occurring as secondary to suppurative pylephlebitis. He believes that this septic infection has much to do with the development of the cachexia.

Geo. Doek⁴ reports a case of primary carcinoma of the stomach which developed in a farmer 18 years of age. At the autopsy, which occurred 2 years later; large masses of carcinomatous lymph-nodules were found surrounding the cardiac orifice, and there was metastasis to the mesentery and liver.

Boas⁵ discusses a case of **pyloric tumor** of unusual interest. The patient, a laborer of 56, had suffered with disturbances of the stomach since the latter end of 1895. He had suffered considerable loss of weight, but was not cachectic. No physical alterations could be observed in the stomach, but there were always remnants of food and an intensely acid reaction. There was no free HCl, but lactic acid; no sarcine, but long, thread-like bacilli. After these conditions had been determined a number of times a diagnosis of carcinoma was made and laparotomy was performed. A tumor was found compressing the pylorus and removed. On examination this proved to be an adenocarcinoma. The man subsequently improved sufficiently to return to work, and at the time of the report presented a healthy appearance.

Pyloric Stenosis.—A. S. Hotaling⁶ reports a case that had presented symptoms of gastric disturbance. Upon examination the stomach was found to be greatly dilated with a thickened mass at the pyloric end. At the autopsy an old ulcer was found situated on the posterior wall near the pylorus which had been involved in the cicatricial contraction.

Clay⁷ reports a case of obstruction of the pyloric end of the stomach, due to kinking brought about by adhesions following suppuration of the gall-bladder. The patient, aged 42, was admitted complaining of vomiting of 2 months' duration. Two years before he had a swelling in the right side, a

¹ Lyon méd., Nos. 9 and 10, 1896.

⁵ Berlin. klin. Woch., Jan. 18, 1897.

² Gaz. hebdom. de Méd. et Chir., Nov. 15, 1896.

⁴ Am. Jour. Med. Sci., June, 1897.

⁶ Med. Rec., Mar. 20, 1897.

⁷ Brit. Med. Jour., Jan. 23, 1897.

little below the region of the gall-bladder, that he was told was an abscess. It ruptured into the bowel and he was apparently cured. Two months before admission he began to vomit fluid of a brownish color, often as much as 2 quarts at a time. There was no pain. Operation was undertaken, but the patient died. At the autopsy the stomach was found to be dilated, and the pyloric end, the colon, and gall-bladder matted together by adhesions. The gall-bladder was full of stones and pus, and a band of adhesions passed between it and the pylorus, so that the latter was drawn up and produced a kink. There was a small opening from the pylorus into the gall-bladder and another sinus passed from the latter downward into the duodenum. There was no other cause of stenosis of the pylorus or of the dilatation of the stomach.

Hayem¹ believes that it is possible in some cases to distinguish between pyloric stenosis and partial subpyloric stenosis or stenosis of the duodenum below the ampulla of Vater. The chief symptom of either condition is the presence of liquid in the stomach in the morning before breakfast. If this liquid is abundant and contains masses of food, the stricture is at the pylorus; if it is scanty and contains bile with no masses of food that can be recognized without the aid of the microscope, it is probably subpyloric. The treatment is entirely surgical; but, as in some cases there is a tendency to spontaneous cure, operation should not be too hastily advised. In the discussion of this paper Robin² stated that a large number of the cases of apparent pyloric stenosis were due to pyloric spasm and yielded readily to medicinal treatment; reporting, in support of his statement, 5 cases, in all of which a diagnosis of Reichmann's disease had been made, that recovered without operation. [The differential diagnosis of the two conditions is not as easy as Hayem seems to imply. The number of cases that he studied was too small to establish general points of diagnosis. Neither the presence of considerable liquid, nor of fluid in large masses, is sufficient to exclude subpyloric conditions.]

Finkelstein³ describes the features of **congenital pyloric stenosis**. The condition was described by Landerer in 1879 and later by R. Maier, who constructed the clinical history from 31 cases. Finkelstein described 10 cases with postmortem examinations in 7. In the other 3 cases the patients survived. The fatal cases lasted from 30 days to 2 years, the symptoms in some of the cases not appearing until a short time after birth. Later, marked gastric symptoms (vomiting—the vomita being without bile—scanty stools, dilatation of the stomach with fermentation) made their appearance. In moderate cases of stenosis there may be merely the indications of a simple chronic gastritis. In one of his cases the thickened pylorus could be felt. This is due to hypertrophy of the longitudinal muscle-fibres and is strictly limited above and below the pylorus.

DISEASES OF THE INTESTINAL TRACT.

Hohigmann⁴ has studied the **absorptive power of the small intestine** in a case with a fistula in the lower ileum. Fat was almost completely absorbed, but albumin was only partially utilized; the amount of nitrogenous excretion, especially in the urine, was greatly diminished, as if the organism had endeavored to replace the nitrogen lost in the intestine by withholding that normally excreted, and the same was true of the calcium salts. Experiments were then made to test the amount of iron that could be absorbed by the in-

¹ Bull. de l'Acad. de Méd., May 13, 1897.

² Ibid., May 27, 1897.

³ Jahr. f. Kinderh., Bd. xliii., No. 1.

⁴ Arch. f. Verdauungskrank., Bd. 2, H. 3.

testinal tract, and it was found that 81.3% of a normal therapeutic dose of ferric citrate was absorbed in 2 days. The patient, however, was suffering from extreme anemia, which possibly favored this process. [The observation in regard to iron is strong proof of its value in anemic conditions, a fact that has been doubted by some modern clinicians.]

Schmidt¹ discusses the **excretion of mucus** from the bowel. The substance to which Hoppe-Seyler called attention that can be extracted with water or alkaline liquid, and precipitated by acetic acid, is not mucin; nor are the hyaline mucous particles and yellowish mucous bodies of Nothnagel mucin. The membranes of mucous or membranous colitis are mainly composed of true mucin, but they contain also a notable quantity of fat or soapy material. Fibrin has never been demonstrated. The degenerated cells observed with the microscope are epithelial or round cells impregnated with soap. The diagnosis of ulcerous process may be established more certainly by scanty mucus than by an abundance of round cells. To determine the origin of the mucus is difficult; at the most, we may say that the occurrence of cells partly digested points to the small intestine as the probable seat of origin. Unless there is rapid peristalsis the mucous particles of the small intestine never remain undissolved and are not, therefore, recognized in the stools.

Constipation and Fecal Impaction.—Gersuny² describes a new symptom that he believes is pathognomonic of fecal tumors. It consists in a peculiar feeling of separation of the intestinal wall from the tumor if one presses firmly upon it with the finger, and then, still keeping the finger in contact with the abdominal wall, relaxes the pressure. This he calls the *Klebesymptom*. The conditions that must exist before it can be elicited consist of a certain degree of dryness of the intestinal mucous membrane and of impressionability of the surface of the tumor. If the latter is too hard, it can only be elicited after some method has been used which serves to soften it, such as an oil clysm, and it is of course necessary that the intestine should be distended with gas. He reports the first case in which he was able to discover these symptoms. The diagnosis had been made of a tumor, probably of the adnexa, and laparotomy had been performed; it was while the enormously distended colon was exposed to view that palpation revealed this peculiar sign, and after the wound had healed it was readily elicited through the abdominal wall. He also gives briefly the histories of 2 similar cases in both of which it was also present.

Oliver³ records an interesting case of **obstinate constipation** with impaction lasting 2 months. The patient, a woman of 53, had suffered for 2 years with indigestion and flatulence, and for a year with constipation. During the first months of 1895, however, she had to take laxatives freely. Gradually the constipation grew worse, and during the last 8 weeks prior to her admission she had had no movement. She was emaciated, sharp-featured, mentally dull, melancholic, and very obstinate. Her emaciation suggested cancer, but no physical signs could be determined. The abdomen was flat and even, except in the iliac fossæ, where there was some bulging. Occasionally peristaltic waves could be seen, and masses could be felt along the descending colon that were easily recognized as fecal in character. Similar masses were observed in the cecum. The patient was etherized and with difficulty the impaction removed. Later copious enemata and purges cleared the bowel. Her mental stupor disappeared or improved greatly as soon as the bowel was relieved; she gained 6 pounds in 1 week, and was apparently entirely cured.

¹ Zeit. f. klin. Med., Bd. 32, H. 3 and 4.

² Wien. klin. Woch., Oct. 1, 1896.

³ Brit. Med. Jour., Sept. 26, 1896.

[We have recently seen 2 cases of very obstinate constipation in young men presenting the symptoms of lassitude and melancholia with a great desire to sleep, both of whom returned to their normal mental condition when the constipation was relieved.]

Max Einhorn¹ states that the most important prophylactic measure in the treatment of habitual constipation is to abstain from administering cathartics during slight transient disturbances of the digestion, and when constipation exists to employ careful hygienic measures, increasing the amount of the vegetables and fats, diminishing mental anxiety and establishing regular habits. Cathartics should be given only infrequently, and then as sparingly as possible.

Intestinal Obstruction.—Herz² reviews the subject of **stenosis of the duodenum** and reports 4 cases of his own. Stenosis above the papilla of the bile-duct is scarcely to be distinguished from pyloric stenosis. When the stenosis is below the papilla the symptoms of greater significance are the presence of bile in the stomach and, in some cases, the dilatation of this organ. The absence of dilatation in some cases is remarkable, and is probably ascribable to congenital peculiarities. Whether dilated or not, the stomach is rarely empty, but contains liquid with admixture of bile or saliva. [*Vide* Hayem, under Pyloric Stenosis.]

Wilkinson³ records a case of **intestinal obstruction due to impaction of a gall-stone**; the patient was a stout woman of 63. On the 4th day of her third attack of biliary colic she was seized with stercoraceous vomiting and general abdominal pain, with tympany and thready pulse. A diagnosis of impacted gall-stone was made and it was decided to use expectant measures. After various fluctuations the stone was discharged 11 weeks after the onset of the first symptoms. It was the size of a pigeon's egg, was faceted, and weighed 341½ gr. The patient recovered completely. [It is evident that, as the author states, the stone must have ulcerated its way from the biliary passages to the duodenum. A case of this kind came under our own observation a few years ago. The patient had never suffered from biliary colic, but died of intestinal obstruction. A large cholesterol stone was found blocking the small intestine. The gall-bladder and duodenum were closely united, and fibrous adhesions were found surrounding the junction of the two. There had evidently been a gradual ulceration of the biliary ducts and subsequently adhesive contraction.]

Aeria⁴ reports a case of **gall-stone impacted** in the bowel, causing complete intestinal obstruction. Upon admission the patient gave a history of having been vomiting for a few days; the vomita consisted of undigested food apparently mixed with blood and of rather a sour smell. There were frequent scanty liquid evacuations. Both liver and spleen were normal and there was no temperature, although the patient was in profound collapse. The diagnosis was made of cholera and appropriate treatment employed. The symptoms were progressive, however, and death occurred 9 days after admission. At the autopsy the gall-bladder was found adherent to the duodenum, and through the point of adhesion a perforation had occurred. In the ileum 3 feet from the ileocecal valve there was a large gall-stone, 2½ by 2 inches, which had apparently been broken.

Lundy⁵ recommends rapid distention of the colon with CO₂ in cases of suspected intussusception. He reports 3 cases in which the symptoms were not conclusive, but which presented all the signs of gastrointestinal obstruc-

¹ Post-graduate, Oct., 1896.

⁴ *Indian Med. Rec.*, Jan. 1, 1897.

⁵ *Lancet*, June 19, 1897.

tion, obstinate constipation, vomiting, and pain in the abdomen. In one case an elongated tumor could be felt. The patients during the inflation, which was sometimes repeated, felt a sudden, sharp pain followed by immediate relief. All appeared to be permanently cured.

Turck¹ holds that the presence of bacteria and a suitable soil for their development are indispensable to fermentative processes in the intestines. In the **treatment of chronic intestinal disease** he considers bran a most important element, the indigestible particles aiding in the mastication of food. He also advocates the use in the colon of his various forms of apparatus for hydrotherapy. Occasionally the gyromele will pass the sigmoid flexure and enable the physician to make topical applications to the descending colon. [Radical treatment of this kind is not free from the danger of aggravating the existing disease. The gyromele is capable of doing great damage.]

Enteroptosis.—Stiller² discusses the nature of enteroptosis, and concludes that it is a congenital anomaly. It is a descent of the atonic and dilated stomach, of the large intestine, particularly the transverse colon, of the right or both kidneys, and rarely of the liver or spleen, occurring in early life in consequence of generalized, congenital relaxation, particularly of the ligaments. It occurs in persons who have a dyspeptic neurasthenia of congenital origin, with soft muscles, small amount of fatty deposit, and delicate bony organization. One of the certain indications of this condition is **abnormal movability of the 10th rib**. Grasping the point of the 10th rib, which lies in the mammary line, it is easy to determine whether it is movable or not. This movability is due to fibrous instead of cartilaginous junction of the rib with the sternum.

Max Einhorn³ holds that enteroptosis begins with a prolapse of the intestines, particularly of the right part of the transverse colon, due to relaxation of the colico-hepatic ligament. Coincident with this descent the mesentery is relaxed, the small intestine with the stomach prolapses, and the liver and right kidney are dragged downward. The author describes the symptoms of the disease as first pointed out by Glénard, and then refers to his own experience. Among 57 male patients with gastric disturbance he found distinct enteroptosis and movable right kidney in 4; among 33 female patients of the same kind, 13 were thus affected. In another series there were 5 cases among 84 males and 19 among 59 females. Although it is his experience that pronounced enteroptosis may exist without symptoms of any kind, he believes with Glénard that it may as such produce distinct symptoms. [This condition undoubtedly occurs as a result of a variety of causes.]

Maragliano⁴ reports a case of **diaphragmatic hernia** in which the diagnosis was made during life. In but 7 of 266 cases reviewed by Laehner could a diagnosis be established *intra vitam*. The author succeeded in his own case by intestinal inflation. The patient was suffering with influenza, when, during a paroxysm of coughing, the hernia suddenly developed. After the ordinary measures of diagnosis had been considered the intestines were inflated with a pump per rectum, and it was found that the abdomen was not increased appreciably, nor the diaphragm displaced upward, but the thorax increased 1 cm. in volume. Simultaneously with each insufflation a sound was audible in the fifth intercostal space. He introduced a needle into the left thorax and introduced a certain amount of liquid. This could be made to bubble as the air entered the intestine. Finally distention of the intestine with liquid caused an area of dullness in the left thorax where it had been resonant before.

Appendicitis.—Goluboff¹ holds that appendicitis is a distinct infectious disease, which may occur as an epidemic. The lighter forms are often overlooked and diagnosed as some other condition, thus interfering with recognition of the epidemic character. He gives the following description of the clinical appearance. The cases occur in early adult life and commence with sudden pain in the region of the umbilicus. The tongue is coated; there are malaise and moderate local edema. The condition disappears in the course of 1 to 3 days. [The frequency of appendicitis has seemed to us to depend upon the greater prevalence of intestinal disorders due to influenza; but we cannot agree with the author that there is any epidemicity.]

Rotter,² in discussing 213 cases of appendicitis in the St. Hedwig Hospital of Berlin, states that the mortality is not as great as is often assumed, being only 8.9% of all the cases in his experience, and 2.5% of the cases of circumscribed character; among the localized cases 90% recovered spontaneously, and 84% of the total number of cases received during the first 6 days of the attack. The fever is an important basis of classification. He distinguishes: (1) Cases beginning with high fever (40° C.) and decreasing in 3 or 4 days with rapid convalescence. (2) Same onset, but more continuous fever; among 14 cases of this kind all recovered; 3 required operation. (3) Same onset, with temperature remaining elevated longer than the 5th day; these cases show virulent infection and the prognosis is unfavorable; among 11 there were 2 deaths. (4) The temperature declines at first, but rises again; these always indicate large accumulations of pus. (5) General peritonitis; temperature low and often subnormal in severe infection; higher in progressive cases; the pulse indicates the severity of the attack; recovery only after surgical interference.

Smith³ reports 2 cases of appendicitis. In the 1st the local symptoms were on the left side, and consisted of a swelling in the region of the sigmoid flexure. Subsequently there were marked tympanites and general peritonitis. Death occurred on the 16th day. At the autopsy considerable adhesive peritonitis was found, and the appendix was adherent to the anterior abdominal wall, showing a perforation communicating with an abscess-cavity. The 2d case commenced characteristically and a diagnosis of appendicitis was made. Apparent recovery took place under the influence of morphia. At the end of 3 weeks the parotid gland on the right side became acutely swollen and subsequently that of the left, both suppurating. After these had discharged signs of peritonitis again set in, and the patient died. At the autopsy there was a large collection of pus about the cœcum enclosed in adhesions. A small perforation was found at the base of the appendix. He believes that in the 1st case operation was not justifiable on account of the cachectic state of the patient, and in the 2d on account of the apparent recovery before the development of the parotiditis.

MacNaughton⁴ describes the case of a child of 11, which during the convalescence from scarlet fever complained of pain in the abdomen. There was constipation but no vomiting. The temperature was 37.8°. No resistance was detected on palpation; expectant treatment was instituted, and on the third day there was some relief. That night vomiting and diarrhea set in; 2 hours later repeated stercoraceous vomiting and collapse. There was no pain. The patient died, and at autopsy ulcer of the vermiform appendix with abscess-formation posteriorly was discovered. There was general peritonitis. There was no perforation of the appendix itself. [This irregularity of the

¹ Berlin. klin. Woch., Jan. 24, 1897.

³ Edinb. Med. Jour., Aug., 1896.

² Centralbl. f. Chir., Oct. 24, 1896.

⁴ Brit. Med. Jour., Oct. 24, 1896.

symptoms, and especially the insidiousness of onset, are often met with in appendicitis in childhood.]

Gill¹ reports 2 cases of appendicitis with supposed endocarditis of the pulmonary valve as a complication. There was no autopsy in the fatal case and the other recovered. Pulsation and murmur were detected over the pulmonary area. [These signs, however, are so uncertain that we feel they scarcely justify the deduction.]

Simon Flexner² reports the case of a man who had lived in a malarial district and who was suddenly attacked with chills and fever and severe diarrhea. In the blood malarial parasites were found, and in the evacuations a number of amebæ coli. At the autopsy peritonitis was found and cultures from the peritoneal exudate showed the presence of virulent diplococci and bacteria coli communis. The source of the peritonitis was apparently necrosis of the appendix. [The author urges that this extraordinary case demonstrates the importance of thorough bacteriologic and microscopic examination in all cases, both ante- and postmortem.]

Pick³ insists upon the occurrence of **stercoral typhlitis** as a clinical condition. In discussing appendicitis he states that the importance of colic of the vermiform process has been underestimated, and that it is mainly due to the presence of a foreign body, though it may be purely nervous and without any anatomic lesions. This form of colic resembles biliary, renal, and intestinal colics. The pain may be severe and may occur with great suddenness. It ceases with the discharge of the foreign body. If this result is not attained, the appendix after a time becomes quiescent from paresis; ulceration and perforation of the walls may then occur.

Cholera Morbus.—Pottien⁴ has studied the **bacteriology of cholera morbus** very carefully in 3 cases. In one he found the bacterium coli very virulent for mice, and also a capsulated bacillus resembling the bacillus pyocyaneus which produced a green coloring-matter, and which he calls the *bacillus fluorescens liquefaciens*. The same organism was found in the 2 other cases.

Mucous Colitis.—Franke⁵ reports a case of mucous colitis in which there were unbearable pain and great reduction of strength, and in which he performed a colotomy. There was remarkable relief; so much, indeed, that the patient refused to have the artificial fistula closed later. He believes the operation is justified in cases of great severity, such as the one he reported, although he would first try the effect of suggestion, as he regards the disease as hysteric in nature.

Mendelson⁶ reports 5 cases of mucous colitis. He believes that the disease presents 3 cardinal groups of symptoms: neurasthenia, mucous passages, and abdominal pain. The mucus is usually found lying upon the feces and not intimately mixed with them. Tenesmus is often agonizing. The cause of the disease seems to be exhaustion of the nervous system, and it usually occurs in women from the ages of 20 to 45 years. Treatment consists of the rest-cure and irrigation of the bowel. All of the 5 cases reported improved very much under this régime.

Dysentery.—Étiology.—Janowski,⁷ having had occasion to observe a number of cases of dysentery in none of which he was able to find the amebæ coli, undertook an investigation of the literature of this subject in

¹ Australas. M. Gaz., Sept. 21, 1896.

² Bull. Johns Hopkins Hosp., Sept.-Oct., 1896.

³ Wien. med. Woch., 15-17, 1896.

⁴ Zeit. f. Hyg. u. Infektionkr., Bd. xx., H. 1.

⁵ Mittheil. aus de Grenzgeb. der Med. u. Chir., 1-3, 1896.

⁶ Med. Rec., Jan. 30, 1897.

⁷ Centrabl. f. Bakt. Parasit. u. Inf.kr., Feb. 5, 1897, ff.

order to determine what relation this organism bore to the disease. He concludes that dysentery is etiologically not a simple disease, and in all probability is never produced by the action of a single parasite, but apparently by the combined action upon the organism of several varieties. The cause of the common dysentery of the temperate zones is some bacterial complex; a form exists, however, entirely different from this both clinically and pathologically, the so-called tropical dysentery, and this is apparently the result of association of bacteria with a certain species of ameba.

Celli¹ concludes from the literature concerning the etiology of dysentery that no peculiar bacillus can be cultivated from the fecal evacuations, but that among others the *Bacillus coli dysentericus* is usually found, and causes experimental dysentery in animals. The infection is due to the toxins produced by this bacteria, which may have a pyogenic, dysenteric action. It is possible to render animals resistant to the two latter actions, but not to the former action, by repeated doses of the toxin.

Galli-Valerio² studied a series of cases of epidemic tropical dysentery at Valentina. In addition to the ameba coli, he found in the stools great numbers of short bacilli varying in length from 1 to $2\frac{1}{2}$ μ with rounded ends. They were motile, and, with the exception of failing to give the indol reaction, presented many of the characteristics of the *bacterium coli communis*. They were also pathogenic, producing signs of general infection in guinea-pigs, and dysentery in dogs, which identifies them with the *bacilli coli dysenterica* of Celli. He found that it was possible to produce immunity in a dog by repeated inoculation of the bacilli, and that the serum of this dog was able to protect a guinea-pig from their pathogenic action. He therefore supposes that ere long it will be possible to apply serumtherapy to human dysentery.

Masterman³ reports a case of wandering edema and purpura that preceded an attack of dysentery. The parts affected by the edema were—first, the left leg, then the left arm, then the eyelids. Three days after the first attack purpuric patches appeared upon the edematous limbs. He regards the case as a sort of septic phlebitis, although the veins were not swollen nor tender.

Treatment.—Maberly⁴ reports 90 cases of acute and 10 of chronic dysentery, treated with tincture of **monsonia**, a plant indigenous to South Africa. It acted promptly in all cases, relieving tenesmus in a short time, and, in general, causing a prompt cure without any tendency to relapse. One patient died of cancerum oris after the dysentery was cured, and in one a relapse occurred, but this case had been treated with an old tincture. The author believes, after a careful trial of both in tropical countries, that the drug he has introduced is more certain than ipecac and much less dangerous.

Lockwood⁵ reports a case of amebic dysentery treated successfully with enemata of **quinin bisulphate**.

Diseases of the Peritoneum.—Alpago-Navello,⁶ in discussing the early **diagnosis of ascites**, suggests that the patient be put in the knee-elbow position, when the liquid accumulating anteriorly dulness can readily be detected about the umbilical region.

A. R. Edwards,⁷ after pointing out that the determination of the existence of abdominal effusion is merely a preliminary to the diagnosis of ascites, offers the following scheme: (a) Is the accumulation due to a mechanical agency (increased pressure)? Is it then a hypostatic transudate? (b) Is it due to

¹ Annali d'igiene sperimentale, vol. vi., p. 204, 1896.

² Centralbl. f. Bakt. Parasit. u. Inf'kr., Dec. 19, 1896. ³ Brit. Med. Jour., Apr. 3, 1897.

⁴ Lancet, Feb. 6, 1897.

⁵ Mathew's Quarterly Jour., Apr., 1897.

⁶ Gaz. Med. di Torino, No. 21, 1896.

⁷ Medicine, Oct., 1896.

increased permeation of the blood-vessel walls? Is it a cachectic hydrops? (c) Is it due to exudate—inflammation? (d) Is the cause some local peritoneal lesion other than inflammation? In the course of the further discussion he refers to the fact that in hepatic cirrhosis edema of the feet may antedate the ascites by an interval of months or even as much as a year and a half; and he cites a case in which there were swelling of the feet and dilated veins over the lower part of the abdomen and the legs without real jaundice, ascites, or splenic tumor. This has been explained by Thierfelder as only apparent, external edema being more easily discovered than the internal accumulation. Bamberger believes that the pars hepatica of the inferior cava is contracted by the shrinking of the liver. Other explanations are contraction of adhesions about the vena cava, pressure, etc. However, the author holds that, in the case cited by himself, none of these causes was operative, but that the great collateral circulation opened communications between the portal veins and the epigastric veins, by which the blood flowed from the liver to the crural veins and produced the edema of the limbs before marked ascites had developed.

Moneret has described an instance in which by the mechanism suggested an overfilled epigastric vein produced edema of the abdominal walls. Under the heading of cachectic ascites the author refers to 3 instances in which it existed in the convalescence of typhoid fever and in which peritonitis was excluded by the absence of all the usual indications. [He does not refer to the cachectic ascites sometimes seen in chronic malaria.] Under the heading of ascites due to diseases of the peritoneum other than peritonitis, he refers to new growths and to uterine fibromata and ovarian cysts.

Schramm¹ records a case of **chylous ascites** due to carcinoma of the thoracic duct. The patient, a woman of 53, came under observation early in Jan., 1896. She had begun to suffer with emaciation and weakness the previous summer; loss of appetite, with pressure after eating, appeared later. Pains in the back and abdomen and tympany developed shortly before her admission. There were great abdominal distention and liquid effusion, though the latter was apparently encysted, in the epigastric, umbilical, and hypogastric regions. The dulness was not movable. Incision into the abdomen showed the presence of marked whitish-yellow fluid, and the patient died within 48 hours. A hard nodular tumor the size of a fist was found at the head of the pancreas, and numerous secondary nodules were distributed in the neighborhood, involving the gall-bladder and liver. The thoracic duct throughout its entire course was thickened in places and at its upper termination was surrounded by enlarged lymphatic glands which compressed the adjacent veins. The duct was obliterated at various points, especially in the neighborhood of the nodules. No rupture was discovered, and the author concludes that the chyle escaped through the diseased walls. The only previously recorded case resembling this was one of Leidhecker's. This author, in addition, collected 5 instances of cancer of the duct without chylous ascites.

Codd² reports a case of chylous ascites that occurred in consequence of thrombosis of the left subclavian vein. The patient, a man of 35, suffered from a cardiac lesion and bronchitis. At the autopsy some 2.5 l. of a chyle-like liquid were found in the abdomen, and the upper portion of the ductus thoracicus was enormously dilated, its diameter being 7 mm. A partially organized thrombus was found in the subclavian vein.

Rotmann³ describes a case of chylous ascites due to gastric carcinoma with compression of the thoracic duct, another case due to carcinoma of the du-

¹ Berlin. klin. Woch., Oct. 26, 1896.

² Brit. Med. Jour., May 1, 1897.

³ Arch. f. Verdauungskrank., Bd. 1, p. 416.

odenum, and a case of chylous thorax due to tuberculosis. He has been able to collect 155 other cases from the literature, the majority of which occurred in the peritoneum. He does not regard the presence of sugar as of much value unless it exceeds 0.2%, as this amount may be present in other exudates.

Obolenski¹ describes a case of **intraperitoneal adhesions** and refers to 20 similar instances recorded in the literature. The cause of the adhesions was gall-stone in 10, ulcer of the stomach in 6, traumatism in 2, swallowing of caustics in 1, and unknown in 1. In his own case the patient, aged 50, had been injured in the region of the stomach 8 years previously; 2 years after this he had suffered with pains over the stomach and became unable to attend to his work. He then improved, but subsequently relapsed. When the pain occurred a tumor developed in the region of the stomach, which disappeared with the pain. He was constipated, but did not suffer with nausea or vomiting. Food increased the pain. The stomach was somewhat increased in size and showed active peristaltic movements. The stomach-contents seemed normal. The absence of a distinct tumor and the normal condition of the secretions of the stomach excluded the diagnosis of cancer or hypertrophy of the pylorus. Operation was undertaken and firm adhesions between the lesser curvature of the stomach and the liver were discovered. Gastroenterostomy was performed and the patient recovered. Finally, the author cites as characteristic features of adhesions of this kind: (1) marked pain; (2) dilatation of the stomach when the pylorus is involved; (3) fixation of the organ at the point of attachment, this being determined by distention with air, by lavage, etc.; (4) normal physiologic properties of the stomach; (5) absence of tumor; (6) the history, pointing to some recognized cause; (7) the fruitlessness of treatment.

Adami² discusses 2 interesting cases of **peritoneal and retroperitoneal lipoma**. The first patient, a man of 45, noticed abdominal swelling in Jan., 1892. General emaciation began, but there was no other symptom. Aspiration failed to discover fluid. In May an incision was made and a solid uniform growth was found filling the entire abdomen. It could not be removed, and some time later a softened area developed, and on aspiration 9 pints of pus were removed, and until his death in Feb., 1893, 60 pints were aspirated at various times. There was never any disturbance of bowels and never any pain. Postmortem a large lobulated fatty tumor was found springing from the left renal region and filling the abdomen. The intestines were for the most part to the right of and behind the growth, the descending and transverse colon, however, being front of it. The tumor was easily removed with the left kidney and the spleen, both more or less completely imbedded. Sections showed the features of lipoma with mucous degeneration, and the author regarded it as a retroperitoneal growth. It weighed 41 pounds.

The second specimen is preserved in the Army Medical Museum. It occurred in a man of 60. The abdominal growth was first noted in Feb., 1869, and it increased until Feb., 1871, when the patient died after exposure. There was great emaciation, and the autopsy revealed a mass of irregular character everywhere attached to the abdominal walls, which were infiltrated and distended with serum. The liver, the stomach, and the intestines were compressed. The tumor weighed 41.5 pounds, and sprang from the left renal region, the kidney being flattened and partly imbedded. The descending colon, as in the other case, passed in front of the tumor. Microscopically this was found to

¹ *Medicinskoje Obosrenje*, No. 9, 1895; *Centralbl. f. innere Med.*, Oct. 10, 1896.

² *Montreal Med. Jour.*, Jan. and Feb., 1897.

be a fatty growth with embryonal connective tissue. The author points out that such tumors are rare. He has collected 42 cases from the literature. A large number originated in the region of one or other kidney. The condition is more common in women, and is as frequent on one as the other side. In 1 case it occurred 14 days after birth, but the most frequent age is from 30 to 50. The growth is slow, the average duration being 2 or 3 years from the first appearance until removal or death. Clinically it is of interest to note that the fluid character of the tumor often leads to the suspicion of ascites, and aspiration with negative results has frequently been recorded. In 26 of 42 cases the tumor was removed in part or entirely, with 12 recoveries.

DISEASES OF THE LIVER.

Cirrhosis.—Van Henkelom¹ does not believe that **alcohol** is the immediate cause of cirrhosis of the liver, but rather that it produces a chronic gastritis, as a result of which much fermentation occurs in the stomach and various poisons, among others fat acids, are produced. The resorption of these may possibly give rise to cirrhosis, especially in those that are predisposed to it.

Kelynaek² found in 5053 pathologic cases 121 of pure hepatic cirrhosis, and of these 28 had also **tuberculous disease**. Doubtful or complicated cases, such as those of chronic heart-disease, were excluded; but it is not stated whether the subjects had been alcoholics or not.

Boix³ describes the enlargement of the liver that is frequently found in dyspeptics who have the so-called arthritic diathesis. He believes it to be due to the formation in the gastrointestinal tract of substances that are, to a certain extent, toxic, and irritate the liver. These give rise to frequently repeated congestion, that finally becomes permanent, and constitutes **dyspeptic cirrhosis**.

Letulle⁴ believes that alcoholic hypertrophic pigmentary cirrhosis should be classed with the similar forms occurring in diabetes, tuberculosis, malaria, etc.

Regaud⁵ does not believe that the presence of **hemosiderin** in the liver in cirrhotic conditions is sufficient to justify the creation of an independent morbid condition. He reports, in support of his contention, 3 cases of cirrhosis, due to malaria, alcoholism, and infection, with abundant visceral siderosis.

Gilbert and Grenet⁶ report a case of **pigmentary hypertrophic cirrhosis**, due to alcohol, occurring in a coachman of 49. Among the interesting symptoms were the dilatation of the cutaneous veins, frequent epistaxis, and purpuric blotches on the legs. The liver was greatly enlarged; the urine was slightly decreased in quantity, otherwise normal; but after urea had been used as a diuretic albumin appeared. There was moderate ascites, which in the later months of the sickness became very much augmented. At the autopsy the liver was found to weigh 2900 gm. It showed multiple lobular cirrhosis, the fibrous tissue originating from the periportal spaces and extraordinary proliferation of the biliary canals. The pigment was especially marked in the left lobe, and gave all the chemie reactions of iron.

Loeb⁷ reports a case of **hypertrophic cirrhosis with icterus**, in

⁷ Deutsch. Arch. f. klin. Med., June, 1897.

which there were all the classical symptoms and a loud systolic aortic murmur. Death occurred 10 days after the development of severe symptoms, and at the autopsy the liver and spleen were found enlarged, and the cystic duct was obstructed by a gall-stone. The author explains the heart-murmur by the dilatation of the ventricles as a result of alcoholic myocarditis.

Pussinelli¹ reports the case of a man who suffered with mild jaundice in 1887. The following year increase of thirst was noted, and 1.5 to 2% of sugar appeared in the urine. Up to 1892 an annual visit to Carlsbad was followed by cessation of the glycosuria for some months. In 1893, after a shock, swelling of the abdomen and jaundice appeared, and later pronounced ascites, swelling of the feet, and enlargement of the liver and spleen. The abdomen was tapped several times, when the ascites disappeared. The jaundice and enlargement of the liver and spleen gradually diminished, but did not entirely disappear. Sugar and albumin were found in the urine before the ascites, but during its existence disappeared, to reappear 2 weeks after the last tapping. After $2\frac{1}{2}$ years of fair health the patient died with anasarca and albuminuria. The autopsy showed widespread atheroma and sclerotic changes in the liver, especially in the portal areas. There were fresh tubercles in the peritoneum and pleura and recent tuberculosis of the lungs. The spleen was enlarged and the kidneys characteristic of diabetes. The author regards the liver-disease in such cases as a distinct affection. It is characterized by increase of size with little tendency to subsequent contraction, and accompanied by enlargement of the spleen and pigmentation of the skin.

J. M. DaCosta² reports a case of **acute yellow atrophy** of the liver. The patient, a young Italian of 16, was admitted to the hospital in a comatose condition, and died 2 hours later. He had lived an irregular life, was intemperate in alcohol and tobacco, and had recently acquired specific urethritis. He had attended the dispensary suffering with general abdominal distention and vomiting after food, constipation, and jaundice, the latter having appeared several days before his admission. On admission he was intensely jaundiced, and had severe dyspnea with convulsive movements and opisthotonos, and the pupils were dilated. The temperature was 102°, the urine was passed involuntarily, and some obtained postmortem was reddish in color, acid, and slightly albuminous. There were no tube-casts, but a crystal of tyrosin was found. The liver-dulness was diminished, though the margin could be felt below the ribs. The spleen was enlarged. There were some rales in the lungs. At the autopsy ecchymoses were found beneath the pericardium and in the mesentery, and small interstitial hemorrhages were found in the lungs. The gall-bladder was empty; the common duct patulous. The liver was small, weighing 28 ounces, and very flabby, its edge thin, and it exhibited yellow streaks, but the substance cut firmly. The brain was edematous, and a hemorrhage was found beneath the ependyma over the optic thalamus. The microscopic examination of the liver showed widespread fatty degeneration of advanced stage, apparently beginning in the periphery of the acini. The cells showed various forms of nuclear and protoplasmic destruction. In some places no traces of liver-substance remained, new connective tissue with round-cell infiltration taking the place. Miliary abscesses were found scattered throughout the connective tissue beneath the acini. There was a tendency to proliferation of the bile-ducts. The author states that he has found the disease rare in Philadelphia, this being the 5th case that he can recall. The disparity between the sexes is not so great as often stated. When persons have previously been addicted to alcohol the liver may be increased in size by ex-

¹ Berlin. klin. Woch., No. 33, 1896.

² Univ. Med. Mag., May, 1897.

cess of connective tissue, and thus show no appreciable diminution during the course of acute yellow atrophy, though there may actually be great destruction of liver-cells. Tyrosin is not a pathognomonic indication, but taken in connection with distinct symptoms of the disease it has great significance. Microbi and Rainaldi¹ have discovered virulent bacilli coli and streptococci in the liver and kidneys of a case of acute yellow atrophy of the liver. There were fresh inflammatory proliferations into the interlobular connective tissue, showing that the microorganisms had been present during life.

Clarede² reports an instance of **hepatic disease with great hyperthermia**. The patient had been exposed to the vapors of mineral acids. He was slightly icteric; the urine was diminished in quantity and contained albumin and an excess of nitrogenous matters. The stools were decolorized and glairy, and the liver was enlarged and tender. The patient was extremely weak, cyanosed, and cold. The temperature was found to be 33.8° C. (92.8° F.). Subsequently it rose to 40° C. (104° F.) and the general condition improved, the urine became more copious, albumin disappeared, and after two months the patient was dismissed cured. The author ascribes the condition to hepatic changes resulting from intoxication with mineral acids.

S. Flexner³ reports 2 cases of **perforation into the vena cava of amebic abscess of the liver**. The first patient (under the care of Osler) was a man of 51, admitted with chills, fever, and sweating. His illness began two months before, though he had experienced some chilly feelings and sweating 6 weeks previous to that. The liver was distinctly enlarged and tender. No amebæ were found in the stools. He was moderately anemic. An exploratory incision was made, but no abscess discovered. Later exploration through the lower intercostal spaces with needles discovered pus, and a second incision was made. The patient, however, died some days later. An abscess-cavity about 10 cm. in its greatest diameter was found in the liver, and communicated with the inferior cava, which contained a thrombus at the point of perforation. The intestines were free from ulceration, and only a suspicious, puckered area was discovered. The fresh abscess contained living amebæ and various bacteria. Small surrounding foci contained streptococci only. The second patient suffered with similar symptoms, but the liver was apparently not enlarged nor sensitive on deep pressure. The man, however, expectorated blood-tinged sputa of characteristic appearance, and on examination the breath-sounds in the right lung were impaired and there were rales. Amebæ were found in the sputa, as well as crystals supposed to be bilirubin. No amebæ could be discovered in the intestinal mucus. An incision was made into the lower part of the chest, and a large quantity of pus removed. Amebæ were found in the intestinal mucus, obtained with a tube several days after the operation, and 5 days later diarrhea set in and continued until death. At the autopsy a condition was discovered similar to that of the first case. The author calls attention to 2 points of interest: 1st, the existence of the amebic abscess of the liver without a distinct intestinal lesion; 2d, the probability that the intestinal lesion followed the disease of the liver in the second case rather than preceded it. [In the first case, if the intestines were not diseased, the mode of infection is obscure. The history of diarrhea during the previous summer was obtained from the patient after he had been in the hospital some time. It is true, no lesion was found in the second case, but it does not follow that the absence of symptoms excludes the existence of lesions prior to the discovery of the abscess. It is of more im-

¹ Arch. Ital. di Clin. Med., 1896, p. 1.

² Sem. méd., No. 35, 1896.

³ Am. Jour. Med. Sci., May, 1897.

portance that the intestinal lesion had the appearance of acute development, and there is no doubt that, if the ulcer existed previously, it suffered an exacerbation just before death.]

Rendu¹ reports 2 cases of **abscess of the liver following tropical dysentery**. The second presented difficulties of diagnosis on account of the absence of fever and the excellent health of the patient. In fact, the tumor was supposed to be a hydatid cyst, until after the operation. Both abscesses were opened and drained with excellent results.

Roger² reports a case of a woman of 30 who came under observation with high fever and pain in the region of the left part of the liver. After several weeks' illness a fluctuating tumor appeared in the epigastrium. An operation was performed, but the patient died 8 days later. On examination several other abscesses were found in the right lobe and an old inflammatory focus in the pelvis. In this region as well as in the pus of the hepatic abscesses pure cultures of streptococcus were found.

C. von Kahliden³ reports a case of **primary sarcoma** of the liver; the patient was a man 32 years of age, who 5 months before his death had noticed an increase in the size of the abdomen. This continued for 3 months without symptoms, when it was noticed that the feces were black and the urine dark. Later the abdomen increased still further in size and nodules could be felt that altered their position after eating. When admitted to the hospital he was found to have anasarca downward from the 8th rib and marked ascites. The skin showed a slight icteroid discoloration, the thorax was negative, the abdomen was enormously distended, and the hepatic dullness commenced at the upper border of the 5th rib; the lower edge of the liver was irregular and could be felt in the neighborhood of the umbilicus. The surface was rough, showing some hard and some rather soft elevations. Death occurred as a result of edema of the lungs. At the autopsy an enormously enlarged liver was found, that was covered with numerous small or confluent nodules, some white some yellowish in color. In the tissue that was still preserved the acini showed a retracted brown center and a swollen yellow periphery. Microscopically the tumor was found to be a round-celled sarcoma, that apparently sprang from the endothelium of the blood-vessels, although a number of small giant-cells were found with 4 or 5 nuclei. v. Kahliden does not care to call it a giant-cell sarcoma. He finds that the description he has given corresponds closely with the description given by Arnold of his 2 cases, although in these, as well as in the cases of Windrath, the color of the nodules was grayish-red and therefore more characteristic of sarcoma.

B. Bramwell and R. F. C. Leith⁴ describe a case of **primary sarcoma** of the liver. The patient was a woman of 25, and presented certain signs pointing to abscess of the liver. The enlargement was considerable, especially in an upward direction. The heart was displaced to the left and upward, and there was tenderness on pressure in the 6th interspace and in the anterior axillary line. At this point the chest was aspirated and bloody liquid removed. A week later incision was made, and 1500 c.c. of blood removed. Death occurred from secondary hemorrhage and exhaustion a month after the first puncture. The liver was considerably enlarged and contained a cystic tumor of angio-sarcomatous spindle-cell type. There were small cysts lined with endothelium. The growth had evidently sprung from the connective-tissue surrounding the perivascular lymphatic channels.

⁴ Edinb. Med. Jour., Oct., 1896.

Pickler¹ reports a case that had a large liver with pain in the abdomen and delirium. The urine was dark red in color and on standing became darker. It contained some sugar, and upon the addition of Fe_2Cl_6 became black. There was some leucocytosis, many of the leukocytes containing pigment, and there was also some free pigment in the blood. A diagnosis of **melanotic sarcoma of the liver** was confirmed by the autopsy.

Chauffard² reports a case presenting a large fluctuating tumor of the liver. This was punctured and 10 c.c. of liquid withdrawn, immediately after which the patient was seized with convulsions and finally died in asphyxia. At the autopsy a **hydatid cyst** was found, it and the liver weighing together 6500 gm.; the liver itself weighed 2600 gm., and histologically showed similarity with the structure of the fetal liver, being compensatorily hypertrophied. All the other organs were normal, and the author is obliged to assume a sort of relative toxicity on the part of the fluid of the cyst, which, in some way, had been excited by the puncture and served to produce death.

Stéfani³ records a case of **echinococcus cysts** of the liver, treated by the method of Baccelli. This consists of injection into the cyst of 20 c.c. of distilled water containing 0.02 gm. of corrosive sublimate after the withdrawal of 30 c.c. of the liquid. In his own case the volume of the tumor remained the same for about a week and there was moderate fever; then the temperature declined, and the tumor decreased in size, disappearing wholly within 25 or 28 days after the injection. Four months later there was no sign of the tumor or any other symptoms. The author refers to 7 similar cases. The successful results obtained by this method justify the belief that it should be practised in the treatment of echinococcus cysts before a formal operation is undertaken.

F. A. Packard⁴ reports an instance of **movable liver** occurring in a man of 40. The patient had had acute rheumatism and typhoid fever. Later he complained of pain in the abdomen, especially in the region of the liver and gall-bladder, which was paroxysmal, always worse in the evening, and sometimes very severe. Five days after its onset he was slightly jaundiced. The stools became light-colored and the urine contained bile-pigment. There were slight fever and distention of the abdomen, and, on physical examination, the liver was found to extend from the upper border of the sixth rib to a point 9 or 10 cm. below the ridge, where the edge could be distinctly felt. There was no splenic enlargement or ascites. The lungs were decidedly emphysematous. Dulness was discovered posteriorly at the base of the chest, and it was suspected that it was caused by subdiaphragmatic abscesses. Operation was contemplated, but the patient died shortly afterward. At the autopsy it was discovered that the right pleural sac contained $\frac{1}{2}$ pint of liquid without evidence of pleurisy. The liver weighed 610 gm., and was found in its normal position under the diaphragm, almost hidden by the costal cartilage; the discovery of a puncture in the convexity in the organ due to an attempt at aspiration during life, allowed it to be placed in the position occupied during life, and showed that this must have been abnormal. Unfortunately, the measurements of the ligaments of the liver, etc., were not obtained. The author cites cases in which the same condition was mistaken for hydronephrosis, typhlitis, and other conditions.

DISEASES OF THE BILIARY PASSAGES.

Wm. Osler¹ discusses the **ball-valve gall-stone** in the common duct. His attention was first called to this condition by a patient in the Philadelphia Hospital, who had been admitted a number of times with chills, fever, and jaundice. The attacks had recurred for a period of about 2 years and various diagnoses had been made, such as malaria, hepatic abscess, etc. Finally a diagnosis was made of Charcot's hepatic intermittent fever, probably due to a gall-stone lodged in the common duct. An operation was performed, but no gall-stone was found, and death occurred from peritonitis a few days later. Just beneath the mucous membrane of the duodenum and close to the orifice of the common bile-duct a gall-stone was found which could be pushed to one side. The author subsequently saw 2 similar cases, upon 1 of which he was able to perform an autopsy and to obtain a similar specimen. The other is still suffering from recurrent attacks. Osler lays stress upon the valve-like folds of mucous membrane in the cystic and common duct and upon the sphincter at the orifice of the latter. The fever must bear an important relation to the impaction of the stone, either by reflex irritation or by preventing the escape of toxic ingredients. Of course, in making a diagnosis of this condition it is first necessary to recognize the existence of a stone in the common duct. The exacerbations of jaundice and fever, associated with intense pain, are due to the fact that a gall-stone lodged in the common duct and producing the symptoms in greater or less intensity during the interval, is pushed against the orifice, causing total occlusion. The symptoms, then, of this variety may be given as follows: chronic jaundice, rarely deep and varying in intensity, at times almost or entirely disappearing, to deepen invariably after a paroxysm (the icterus may be of maximum grade and associated with intolerable itching); pain, often a constant sense of discomfort, sometimes only obscure gastric distress, and at others agonizing, griping, and like ordinary liver colic; fever occurring in paroxysms usually preceded by chills and followed by sweats. The chills may be quotidian or tertian in type, or they may recur for weeks on the same day. The spleen is usually enlarged during the febrile paroxysms. Though persisting for months or even years, the general health may be little or not at all affected, and in the intervals between the paroxysms the patient may be able to work as usual. The differential diagnosis is to be made from malaria, abscess of the liver, and suppurative cholangitis. He gives the records of 10 cases that he has personally seen. Of these, 5 made perfect recovery, 3 died, 1 disappeared, and 1 is still under observation. Treatment may be employed, but Osler does not believe that it is possible to dissolve the stone either with olive oil or sodium phosphate. Surgical interference may be employed and occasionally complete relief may be obtained. As the stone is usually just beneath the mucous membrane of the duodenum it could probably be reached more readily through this organ.

Raimond and Taitout² report the case of a patient who at the age of 30 was admitted to the hospital for repeated attacks of **biliary colic** that had commenced after an attack of typhoid fever, 6 years before. The Widal reaction was negative and operation was performed, at which 6 gall-stones were removed. Cultures from the pus of the gall-bladder were found to contain nothing but the bacillus of Eberth. The author did not attempt to explain the absence of the Widal reaction, but maintained that the lithiasis is probably due directly to infection of the biliary tract.

¹ Lancet, May 15, 1897.

² Compt. rend. de la Soc. de Biol., Jan. 1, 1896.

Vissering¹ describes a case in which a **gall-stone was discharged through the lung**. There was probably, in the first place, empyema of the gall-bladder following impaction of a stone in the cystic duct. Attachment to the diaphragm occurred and subsequently perforation in the right pleura, then perforation into the lung with abscess-formation, and finally discharge of pus, bile, and gall-stone through the bronchus.

Gilbert, Fournier, and Oudin² have skiagraphed biliary calculi and find that those composed of cholesterin produce very faint shadows; those rich in pigment appear darker; nevertheless the results obtained by this method are very doubtful. [Our own experiments coincide with those here referred to.]

Duin³ has employed **potassium iodid** in the treatment of biliary colic and has found it very useful in 100 cases. It acts most favorably in instances in which the frequency rather than the severity of the attacks is the important feature; it is especially useful, also, in subjects exhausted by loss of sleep, anorexia, and the use of narcotics. He advises the administration of KI and Carlsbad water. He is in doubt whether it favors the solution of the stone or relaxes the gall-duets and thus facilitate its expulsion.

Thompson⁴ suggests the regular administration of **sodium phosphate** during the intervals of cholelithiasis.

DISEASES OF THE SPLEEN.

Bonardi⁵ records the case of a woman in whom **splenectomy** was performed. The patient had been under observation 7 years previously with some enlargement of the spleen, but refused operation. Four years later she suffered with anemia, diarrhea, albuminuria, and had a mitral systolic murmur. There was no alteration in the liver and no ascites. She came under observation again in 1896, complaining of further swelling of the abdomen from ascites, and examination of the blood showed considerable anemia. The urine was highly colored, but contained little urea. The patient improved under a milk-diet and the administration of urea, but paracentesis was finally performed and repeated 12 times, the last fluid being milky, albuminous, sp. gr. 1021, and rich in disintegrated white blood-corpuscles. There was no history of malaria or syphilis, and no abuse of alcohol or food, but the woman had suffered for many years from pellagra.

J. Bland Sutton⁶ discusses **wandering spleens** and adds some remarks on splenectomy. Considering the effect of wandering spleen, he shows that the movable organ is liable to congestion, especially when the pedicle is rotated. Complete torsion may lead to atrophy. Traction of the organ upon surrounding structures may be injurious; and among the dangers to life he notices rupture of the stomach or duodenum, intestinal obstruction, and rupture of the spleen itself. He refers to 2 cases in which tumors springing from the pelvis were mistaken for this condition. He has failed to find any evil effect from splenectomy. Patients suffering with wandering spleen are apt to be thin and gaunt, and he has found that this condition persists after the operation.

In discussing the paper Ballance said that one of his cases became extremely emaciated after operation and the blood become considerably impoverished, the leukocytes at the same time being increased. In other cases, too, he has found deterioration of health.

DISEASES OF THE PANCREAS.

Simon¹ reports 3 cases of **acute pancreatitis**. The first 2 occurred in stout, middle-aged men, both of whom presented a picture of acute intestinal obstruction with severe abdominal pain. As there was slight icterus but no distention of the abdomen, diagnosis was made of gall-stone impacted in the jejunum. Laparotomy was performed, and at the autopsy both cases presented the signs of severe gastrointestinal catarrh. The head of the pancreas was swollen, softened, and contained fatty exudate. The third case occurred in an elderly woman who was brought into the hospital on the 5th day of the disease, with distention of the abdomen and vomiting. Laparotomy was performed without result, and at the autopsy severe duodenitis with swelling of the pancreas and hemorrhage into the tissues was found. In all 3 cases the bacilli coli communis and an unknown thread-like bacillus were found. As the pancreas was unaffected, the author believes that the infection must have reached it from the intestinal tract.

W. Cayley² lectured upon a case of acute pancreatitis. During the first 2 days there were epigastric pains and constipation, then vomiting, and on the 4th day death in collapse. At the autopsy there were fat-necrosis in the abdomen and some sanguinoserous liquid in the peritoneal cavity. The pancreas was enlarged, the lobuli pale red, and the cells in a condition of coagulation-necrosis.

Allina³ reports a case that was brought into the hospital suffering from severe cramp-like pains in the abdomen, which had been increasing for several days. There had been some vomiting and obstinate constipation. For over a year previous to admission the patient had suffered at frequent intervals from similar attacks. The abdomen was distended and tympanitic with some tenderness just below the umbilicus. In the urine neither sugar, indican, nor albumin was found. In the belief that the condition was one of typhlitis laparotomy was performed, but there were no symptoms whatever of inflammation. On the next day death occurred, and at the autopsy the pancreas was found to be necrosed and hemorrhagic, and there was slight diffuse hemorrhagic peritonitis.

A. C. Hovenden (1)⁴ and Stanley (3)⁵ report 4 cases of acute pancreatitis. The disease in all cases commenced with severe pain in the umbilical region, vomiting, obstinate constipation, and, toward the end, collapse. At the autopsy the pancreas was found to be increased in size, softened, and reddish, with more or less fat-necrosis in the neighborhood. [It is probable that this disease is much more common than mortality statistics would indicate, the majority of cases being diagnosed as acute intestinal obstruction. In a case that we observed an antemortem diagnosis was made from the fact that the feces were dark and contained a considerable amount of fat; unfortunately, however, the obstinate constipation usually renders this very suggestive symptom unavailable.]

M. MacIntosh⁶ reports a case of **glycosuria** for which no adequate cause could be found, but which was evidently associated with considerable gastrointestinal disturbance. At the autopsy it was found that the pancreas had been almost entirely destroyed by a large suppurating cyst.

Chiari⁷ discusses the **lesions discoverable postmortem** in the pan-

¹ Lancet, May 15, 1897.

³ Wien. klin. Woch., Nov. 5, 1896.

⁴ Lancet, Jan. 9, 1897.

⁶ Ibid., Oct. 24, 1896.

⁷ Zeit. f. Heilk., 1896, Bd. 16, p. 70.

creas. He observed 2 cases in which circumscribed necrotic foci were discovered that were not apparently dependent upon vascular disease or disseminated pancreatitis, and in which bacilli could not be found. In both there were evidences of reactive changes around the necrotic areas, showing that the process must have begun some time before death. He therefore examined the organ in 75 cases, and found in 11 total necrosis of connective tissue, the protoplasm of the cells being homogeneous and the nuclei staining poorly or not at all; in 29 cases there was disseminated necrosis of the acini and connective tissues; in the remaining cases (35) there was no necrosis. He assumes that the condition is one of auto-intoxication, as neither decomposition nor previous disease could be adduced as the cause.

E. R. Maxon¹ describes the symptoms of **pancreatic carcinoma** as follows: profound cachexia, anorexia, fatty alvine evacuations, and abdominal pains that may extend from the region of the pancreas to the right shoulder.

W. H. White² reports 2 cases of **carcinoma of the pancreas**. The first case was extremely cachectic and when examined under anesthesia a hard lump could be felt in the abdominal wall on the right side about on a level with the umbilicus. Secondary nodules rapidly developed and the patient died. At the autopsy a large scirrhus was found occupying almost the whole of the tail of the pancreas. The second patient was brought to the hospital in a state of collapse, vomited blood occasionally, and soon died. At the autopsy a hard, solid carcinomatous growth was found occupying the middle of the pancreas. Neither patient showed any traces of abdominal fat-necrosis.

Picoli³ reports 2 cases of **sarcoma of the pancreas**. The first patient was a peasant 54 years of age. He had had malaria and was an alcoholic. Four years before his death he was injured in the right hypochondriac region; this was followed by stabbing pains in the region of the liver that were repeated at intervals of 5 or 6 months; 2½ years after this injury he became slightly jaundiced, and this became more and more pronounced at the same time that the pains grew more severe and emaciation gradually developed. Upon admission he was found jaundiced and emaciated, but his digestive functions were apparently intact. The liver and spleen were both slightly enlarged, and there was general enlargement of the lymph-glands. The feces were clay-colored, offensive, and contained a considerable quantity of fat. The urine contained bile-pigment. The psychological functions appeared to be somewhat affected. Later there was some ascites. The cachexia progressed and ultimately terminated in death. At the autopsy a neoplasm was found, which seemed to invade the hilum of the liver, the head of the pancreas, and a portion of the duodenum. Upon section the surface appeared to be grayish, smooth, and homogeneous. Histologically, however, the tumor resembled in most of its characteristics a sarcoma rather than carcinoma. The jaundice was apparently explained by the metastatic mass that had invaded the papilla of Vater and partially occluded the opening of the common bile-duct. The second case was in a laborer, 48 years of age, who had been in excellent health until 3 months before his death, when he suddenly felt severe, stabbing pains in the region of the liver, had anorexia, obstinate constipation, and emaciation. Three weeks later he began to vomit everything, and from time to time there was severe hematemesis. Upon admission it was found that the liver and spleen were considerably enlarged, that there was ascites, and that the liver was exquisitely sensitive. The digestive functions of the stomach were very imperfect. The blood showed marked leukocytosis

¹ N. Y. Med. Jour., Jan. 16, 1897.

² Lancet, Sept. 26, 1896.

³ Ziegler's Beiträge, vol. 21, H. 1, 1897.

(25,000). The cachexia progressed steadily and finally terminated in death. At the autopsy the liver was found to be enlarged and to contain numerous round white nodules. In the pancreas were also several small nodules that appeared to be similar to those in the liver. Histologically it was found that the hepatic neoplasm consisted of a small round-celled sarcoma, and the pancreatic neoplasm, on the other hand, of a giant-celled sarcoma. The author is inclined to regard the growth in the liver as primary, although he admits that a definite decision upon the question is probably impossible. An interesting feature of the cases was the metastasis to the neighboring lymph-glands, particularly in the second case, where this metastasis evidently came from the pancreas on account of the presence of giant cells.

Linossier¹ has investigated the **effect of the presence of HCl upon pancreatic digestion**. He finds that pancreatin is destroyed in 20 seconds when exposed to a solution of 1 : 1000, and if the exposure is continued for a few seconds longer trypsin is also destroyed. As a result therefore of hyperacidity there is often rapid emaciation of the patients. This, however, may be prevented providing there is copious secretion of bile or the pancreatic juice itself is abnormally alkaline. There are therefore 2 classes of cases suffering from hyperacidity; those in which intestinal alkalinity is sufficient or but slightly affected; and those in which it is insufficient, causing disturbance of intestinal digestion and ultimately profound cachexia.

Zecluisen² has investigated the **digestive activity of various fluids** obtained from cysts or other sources. Among his results are the following: diastatic ferments could be determined in most cases; no trypsin action was found in the transudates, rich in albumin, in the exudates and cystic liquids, nor in any cyst-contents, poor in albumin, though these liquids easily underwent putrefaction on account of their alkaline reaction. The addition of a few drops of a one-half normal sodium hydrate solution causes no digestive power. Some specimens of urine showed trypsin action after addition of a little alkali, others peptic action after addition of HCl; still others were negative. Sterilization of the fibrin used to determine the digestive action influences the results very much. These experiments are of value mainly as showing that the discovery of digestive ferments in a liquid should not lead to hasty conclusions in regard to its source. The positive discovery of an emulsifying ferment is conclusive of a pancreatic cyst; but its absence does not exclude this condition, neither does the absence of trypsin exclude pancreatic cysts, though its presence supports the diagnosis. Diastatic activity is of no significance.

DISORDERS OF THE URINE AND KIDNEY.

Franz³ experimented on the urine and the urethral secretion in reference to the presence of **bacteria**. In 41 cases the urethral secretion was investigated; in 21 with positive results and in 13 with negative results. In 52 cases the urine was examined; in 21 with positive and in 31 with negative results. The patients were selected with reference to their health and general normal condition. The organisms found were chiefly cocci of various kinds, although in one case the bacterium coli was present and in another sarcina alba. His conclusion is that the urethra normally contains bacteria, and all the bacteria found in the urine originate from the urethra; and, therefore, that any method of bacteriologic investigation of the urine without catheter-

¹ Compt. rend. de la Soc. de Biol., May 7, 1897.

² Centralbl. f. innere Med., Oct. 3, 1896.

³ Wien. klin. Woch., July 9, 1896.

ization is absolutely worthless. In only 2 cases were organisms found in the urine that were not found in the urethral secretion; in 1 the bacterium coli, and in the other, a case of myocarditis with passive congestion, streptococci.

Chyostek¹ has utilized the suggestion of Franz and examined the urine bacteriologically in a number of cases, always using the catheter and taking every precaution to prevent accidental contamination. In general results were negative. Whenever, however, fever existed, no matter of what nature, microorganisms were found. In 2 cases the fever was malarial; in 4 others it was artificially produced by injection of tuberculin. The organism usually found was the staphylococcus albus. It does not seem reasonable to suppose that the fever had rendered the urethra a more favorable culture-bed, so that the possibility of its entrance into the bladder was more likely, but rather that in the febrile state microorganisms remaining latent in the system enter the blood and are excreted by the kidneys. As, however, the organisms found have nothing to do with the fever in any of these cases, it does not seem possible to utilize these investigations for the purpose of determining the etiology of a morbid condition, and that only the recognition of a specific organism, such as that of typhoid fever or tuberculosis, would render it possible to draw any conclusions regarding the nature of the disease, staphylococci appearing to be merely a temporary occurrence in the course of various infectious diseases.

Bunge and Trautenroth² have studied the **smegma-bacillus** with special reference to its occurrence in different parts of the body and its distinction from the tubercle-bacillus. Though the occupant particularly of the genito-urinary mucous membranes, it may occur on any part of the surface of the body, wherever sebaceous secretion exists, and has also been found in the mouth, nose, and other mucous cavities. The diagnosis of tuberculosis of these parts must therefore be made with knowledge of this fact, and only after the smegma-bacillus has been excluded. The method of staining they have found most useful is the following: the specimens are spread upon cover-glasses, fixed, and deprived of their fat by extraction with absolute alcohol for at least 3 hours; then placed in 5% chromic acid solution for 15 minutes; washed with water, stained in carbol-fuchsin, and decolorized with dilute sulphuric acid solution (3 minutes) and pure nitric acid (1 to 2 minutes) and further by concentrated alcoholic solution of methylen-blue for 5 minutes. This solution decolorizes and counterstains coincidentally. This method insures the decolorization of the smegma-bacilli and does not affect the tubercle-bacilli. [We have convinced ourselves that the smegma-bacillus is not always so readily decolorized as the authors contend. There is, however, even in well-stained specimens, a certain difference of appearance from the tubercle-bacillus (the smegma-bacillus is longer, narrower, and stained more yellowish) that may sometimes lead to a suspicion of its nature.]

May³ reports a case of transverse myelitis occurring in a boy of 16 years. Examination of the urine showed the presence of **dextrose**, and examination with the polarimeter led to the suspicion that **levulose** was also present. A careful chemical examination confirmed this idea, and May states that the following characteristics are sufficient to identify the substance: deviation of the light to the left; reduction of the metaloxids; fermentability with yeast-cultures with the formation of alcohol and carbon dioxid; and formation of phenyldextrosazon. Although dextrose and levulose were excreted by this patient, May is confident that both substances simply pass through the kidneys as such, and that one is not to be looked upon as a derivative of the

¹ Wien. klin. Woch., July 23, 1896.

² Fortschr. d. Med., Dec. 15, 1896.

³ Deutsch. Arch. f. klin. Med., vol. lvii., sec. 3 and 4.

other, either as a result of the action of the renal epithelium or of the micro-organisms that might be present in the course of a cystitis, such as existed in the present case.

F. W. Pavy¹ reports a case of **lactosuria** occurring in a woman suffering from slight digestive troubles, who was weaning her child without artificial removal of the milk. Within 2 months lactose had entirely disappeared from the urine even when the patient was given a diet particularly rich in carbohydrates.

McCann² has examined the urine of 100 nursing-women and found **lactose** present in all.

Rumpf³ found that in a series of cases of febrile infectious diseases the amount of **ammonia** was regularly excessive irrespective of the diet. The increased excretion does not come on suddenly, often, indeed, only after some time, and in some cases persists and is particularly notable during convalescence. He estimates the amount of ammonium nitrogen as compared to the total nitrogen in health at 4.87%, and in febrile conditions at 6.7%. Hallervorden⁴ also considers this subject, but entirely from a physiological and pathological point of view.

Pfeiffer⁵ mentions a patient with gout who, in the course of the disease, had a severe attack of colic, associated with the presence of an enormous quantity of **cystin** in the urine. This was interesting because Baumann was unable to find any diamine in the urine, and he believes that it indicates that they need not invariably occur simultaneously. Two brothers of the patient suffered frequently from renal colic. The urine of his son gave an abundant precipitate of cystin upon addition of acetic acid; the urine of his daughter was negative.

Stange⁶ reports a case of **alcaptonuria** that occurred in a young man of 18 years of age. It was noticed that his urine, upon standing, assumed a dark-brown color, and that it contained a substance that reduced copper, but did not ferment in the presence of yeast. The only subjective symptom was extreme dysuria during the period of this attack. His mother reported that when a child he had had a similar attack. The urine contained a small quantity of mucus, a few crystals of uric acid, and numerous crystals of calcium oxalate. Further investigations showed that the reducing substance corresponded very closely to the homogentisic acid, and it was found that the best method of obtaining it in a relatively pure state was to agitate the urine with an equal quantity of ether, which was then separated and distilled, leaving in the bottom of the beaker a dark-brown crystalline mass; this was then further purified, and, finally, a clear, white, needle-like substance obtained. The daily quantity was found to average 5.9 gr., with frequent periods of increase, which could be brought on by giving the patient an exclusive meat-diet. Purgatives had no effect in diminishing the quantity. Stange suggests, although, as he admits, without sufficient clinical warrant, that it is a case of intermittent alcaptonuria. The case differs from those previously reported in the fact that the urine always gave an acid reaction which did not disappear upon long exposure to the air.

Nakarai⁷ has examined 250 specimens of urine from 144 patients suffering from 39 different diseases, for the presence of **hematoporphyrin**, using the method of Salkowski. It was found in only 10 cases, 6 suffering from chronic

¹ Lancet, Apr. 17, 1897.

lead-poisoning, 2 from intestinal tuberculosis with hemorrhage, 1 from rheumatism, and 1 a case of empyema that had used sulphonal for a considerable time. He reaches the following conclusions: that hematorporphyrinuria is a constant symptom in various forms of lead-intoxication, and occurs also in poisoning with sulphonal and sometimes after intestinal hemorrhage, but is in general rare in other diseased conditions.

Strauss¹ finds that 50 gm. per day of Liebig's beef-extract, whilst not producing any subjective symptoms whatever, increase elimination of **uric acid and the alloxur bodies** very considerably, but this increase probably merely represents the excess contained in the extract itself.

Klein² reports a case of **fibrinuria** that occurred in a man 52 years of age suffering from nephritis. About a week after admission the urine presented an extraordinary appearance, being filled with white or whitish-gray coagula of various sizes from 1 to 10 cm. in length. In some specimens when the urine was allowed to stand it gradually coagulated, as if it were an ordinary serous fluid. These threads consisted of pure fibrin. The urine showed remarkable decrease in the phosphates, the presence of considerable albumin and globulin, and an alkaline reaction. Regarding the causation of the condition Klein has but little to suggest definitely, although he believes that the factors favoring it were the alkaline reaction of the urine, the large amount of albumin present, and perhaps the diminution of the phosphates during the period when fibrin was present. An interesting feature of the disease was the occurrence of chill and fever in several paroxysms of fibrinuria. After a period of improvement the chills recurred with increasing frequency. Edema and oliguria occurred, followed by death. At the autopsy the kidneys exhibited extreme amyloid degeneration, although it is not stated how this could have had anything to do with the fibrinuria. In addition there was an acute fibrous pericarditis and a tubercular ulcer in the ileum. In the same paper Klein also reports a case of cystitis in the course of which long, fibrous-like threads appeared in the urine which gave the xanthoprotein and biuret reactions, but were not digested by pepsin and free HCl, and were therefore regarded as consisting of a central coagulum of nucleo-albumin surrounded by mucin.

Klemperer³ distinguishes 2 groups of **renal hemorrhage**: (1) Acute hemorrhage following overexertion, first referred to by Leyden. Klemperer has observed 2 cases. The first was an officer of nearly 50, who had become fatigued by a long horseback-ride, and at the end of this had difficulty in passing urine, which was found to be of a dark-red or black color. The symptom disappeared the next day, and the patient has remained well ever since. The other case was of similar character. (2) Chronic renal hemorrhages, of which he distinguishes renal hemophilia and angioneurotic hemorrhages, constitute the second group. Of the first variety he states that no case has been reported since Senator's. He himself has observed 2 in the clinic of Leyden. The first occurred in a patient whose history pointed to undoubted hemophilia. After a period of several years of freedom the patient had an attack lasting 7 weeks. In the 2d case the hemorrhages had existed during 16 years, and the patient suffered with pain in the region of the right kidney of longer or shorter duration. The existence of casts showed that the hemorrhage was of renal origin in both cases. The use of tepid baths with cold effusions relieved both. Of the angioneurotic form the author has seen 2 cases, the first in a young man of 22, of neuropathic ten-

¹ Berlin. klin. Woch., Aug. 10, 1896.

² Wien. klin. Woch., July 30, 1896.

³ Berlin. klin. Woch., Dec. 7, 1896.

dency, in whom the hemorrhage was found, by cystoscopic examination, to come from the left kidney. After nephrectomy there was immediate recovery. The kidney was normal. During the last 7 months he has observed a second case in a nervous man of 37, who suffered with mitral regurgitation, without any evidence that this bore a distinct relation to the renal hemorrhage. For 8 weeks hemorrhage from the kidney had existed, and hydragric treatment carried on for 3 weeks led to recovery. In the discussion Leyden referred to a further case of hemorrhage after exertion. Mendelsohn referred to 3 cases, in 2 of which traumatism over the kidney was the cause, while in the 3d the excretion of abundant oxalates seemed to indicate another factor. Nitze spoke of 7 cases, all of which were operated on, 5 of them by himself. In 4 the kidney was removed, and in 3 merely an incision was made to the kidney. He holds that renal hemophilia must be carefully distinguished from essential hematuria. The former is only one expression of hemophilia; the latter is a local condition, and must be distinguished from tumors and other local diseases. Senator held that the condition described by him is not merely renal hemorrhage in the course of general hemophilia, but rather a condition of hematuria on the basis of hemophilia without other hemorrhages. He has observed a number of cases of hemorrhage after excessive exertion, and he suggests the following classification: 1, renal hemophilia; 2, essential hematuria; 3, nephralgie hématurique.

F. R. Eeles¹ reports 8 cases of **hematuria**. He states that if the bleeding is from the urethra it may ooze between the periods of micturition; if from the neck of the bladder, it is more particularly noticed at the end of micturition; if from the bladder, it is usually very abundant, persistent, and more likely to clot, and accompanied by bladder irritability; if from the kidney, the blood is generally mixed with the urine, although, if the quantity is large, characteristic urethral clots may be found. Of the cases he reports, he believes the 1st and 2d were malignant, the 3d certainly tuberculous, as the urine injected into a rabbit's eye produced characteristic tubercles, and the remainder malarial, although the blood was not examined for the parasite, because in all of these cases quinin produced complete cure. Krauss² reports a case of hematuria, at first paroxysmal and later more constant. Frequently fibrous clots were present, and often the first portion of the urine was more deeply colored than the later portion. An operation showed that the condition was caused by numerous small hemorrhoids in the prostatic portion of the urethra.

Klemperer³ reports 2 cases of **hemoglobinuria**. The first, a man of 28, became suddenly ill with jaundice and hemoglobinuria. The latter lasted 3 days, then the urine became normal. Jaundice and distinct swelling of the spleen continued for 7 days longer and the aspect of the case in general was that of an acute infection. No microorganisms could be found in the blood; but the patient had eaten blood-sausage the evening before his illness and it is not unlikely that intoxication occurred in this way. The second case occurred in the course of typhoid fever. The patient complained of heat and cold and presented an urticarial eruption.

A. E. Isaacs⁴ reports a case of recurrent icteric hemoglobinuria. The attacks commenced with a chill, then vomiting, and, finally, about 24 hours later the development of icterus and passage of dark urine. When the latter was examined by the spectroscope it showed the bands of oxyhemoglobin. Bile was not present. The urine contained a large amount of albumin. No cause is assigned. G. B.

⁴ Brit. Med. Jour., Nov. 14, 1896.

Sweet¹ reports a case of paroxysmal hemoglobinuria which was apparently caused by sudden exposure to cold water in bathing, and which subsequent examination showed, in his opinion, to be due to cold, as the blood of a ligated finger which had been exposed to freezing was greatly disintegrated and not unlike that found in the urine. The case, however, improved permanently upon the administration of 15 gr. of quinia combined with calcium chlorid, 3 times daily.

Gillespie² believes that **albumosuria** is to be explained by excessive production and correspondingly excessive destruction of leukocytes. He supports his theory by the results of his investigations of 2 cases suffering from gout.

Chyostek and Stromayer³ have extended the observations of Maixner regarding **albumoses in the urine** in cases of gastrointestinal disease. They administered a midday meal of 1 or 2 oz. of "peptone" or somatose, given in warm water or broth, to patients without albuminuria suspected of suffering from gastric or intestinal ulceration. The urine was examined at intervals of 2 or 3 hours for albumose by Devoto's method. In 6 of 9 cases albumosuria to a greater or less extent developed. In these cases, though the symptoms varied greatly, tuberculous ulcers of the intestines were found post-mortem. In 3 cases in which similar ulcers existed albumosuria could not be produced, perhaps on account of vomiting or other causes. In 20 individuals without disease of the alimentary tract the administration of these foods failed to cause albumosuria. They conclude that it is impossible in persons whose intestinal tract is normal to produce this symptom, but that a negative result of the test does not exclude ulceration.

Adolph Ott⁴ tested 270 specimens of urine in healthy and diseased persons for the presence of **nucleo-albumin**, and obtained cloudiness or precipitate in every case with Almen's solution of tannin. This reaction was not influenced by the degree of acidity of the urine; but in cases of fever, particularly when severe, the amount of these bodies seemed to be increased. At the commencement of febrile albuminurias he was able to note that only nucleo-albumin was present.

Arnozen⁵ discusses **cyclic albuminuria** and some allied forms of disease. The nature of the former he believes is that of mild nephritis, which may lead to chronic Bright's disease and uremia, or may terminate favorably, this being the more apt to occur. He then refers to the following: 1, minimal albuminuria—a form in which the quantity of albumin is very small—the nature of this may be very diverse, it has only a clinical importance, and is probably not a pathological entity; 2, the albuminuria of adolescence; 3, residual albuminuria, a form in which after an attack of nephritis a small amount of albumin may persist; 4, partial albuminuria (albuminurie parcellaire), in which it is assumed that only certain tubules are affected; 5, cicatricial albuminuria—a form described by Bard—in which epithelial desquamation is assumed to be replaced by tissue incapable of restraining the transudation of albumin from the blood; 6, phosphatic albuminuria, in which phosphaturia accompanies the albuminuria.

Kast and Weiss⁶ discuss cyclical albuminuria or Pavy's disease, which usually occurs in young subjects. A type somewhat similar to this, but actually very different, is intermittent albuminuria. It is frequently complicated with asthmatic or convulsive attacks, or else is due to malaria. Other types

¹ New Zealand Med. Jour., Oct., 1896.

³ Wien. klin. Woch., No. 47, 1896.

⁵ Gaz. hebdom. de Méd. et de Chir., Aug. 23, 1896.

⁴ Zeit. f. Heilk., Bd. 16, p. 177.

⁶ Berlin. klin. Woch., No. 28, 1896.

of albuminurias are those called albuminuriæ minimæ: of these there are 2 forms. In the first the albumin is constant—that is to say, it is not altered by diet. The other is easily altered by various conditions, such as cold and fatigue.

Albu¹ has invariably found albumin in the urine after long, severe bicycle tours. He is inclined to consider this condition as the result of toxemia rather than of venous congestion, and he is strengthened in this belief by the increased amount of uric acid in the urine and the presence of tube-casts. This albuminuria disappears usually very rapidly.

Halamon² discusses the **prognosis of albuminuria**, and considers that it is unfavorable when there is permanent polyuria with considerable albumin; when there is marked diminution in the quantity of urine excreted, whilst the quantity of albumin remains about the same; if the patient is young and shows cardiac hypertrophy and arterial sclerosis, the prognosis is also grave. Albuminuria occurring in the course of other diseases is not always of much significance. If in the course of heart-disease, it is only serious when it persists after compensation has been reestablished. In fever and diabetes, if transient, it is not of grave import.

Nephritis—Etiology.—Macaigne³ divides **nephritis** due to the **bacillus coli** into 2 groups: (1) that in which infection is from below, and (2) that in which the infection is through the blood, the kidney being affected by “descending nephritis.” From the latter he excludes cases in which the bacilli are in the urine merely as a sign of general coli infection, and not as a result of nephritis as the principal condition. He describes 3 cases of descending nephritis of this kind, and notes that autoinfection requires 2 conditions: (1) a breach in the alimentary canal; (2) increased virulence of the bacillus. Diarrhea causes both. The microorganism may enter through any part of the intestinal tract. In one of his cases sore throat was the preliminary lesion. There may be either signs of the ordinary epithelial nephritis with more or less grave symptoms, and with a tendency usually to recover, or suppurative nephritis with pyuria, fever, etc., and more grave prognosis. [The possibility of bacillus coli infection through the mouth would seem to require further proof.]

Pedenko⁴ reports a case of acute **nephritis following an infected wound**. The patient, a young man of 20, had a felon on one finger which was not opened until suppuration had extended to the bone. General edema, dyspnea, headache, and great weakness had occurred some days previously. Three weeks after the infection the staphylococcus albus was found in the urine, and the same organism with the aureus and bacilli was found in the pus. As the wound improved the condition of the urine grew better, and finally the bacteria disappeared.

Ebstein and Nicolaier⁵ have found that the administration to animals of uric acid, dissolved in alkalis or piperazin, caused severe parenchymatous changes in the kidneys, and a peculiar necrosis of the epithelium of the convoluted tubules and of Henle's loops. They found frequently spheroliths, which dissolved in acids with a production of urates and left an organic remnant. These are, no doubt, derived from cells; they become free when the cells undergo destruction, and are sometimes found abundantly in the urine of animals.

J. J. Thomas⁶ calls attention to the frequency with which blood or **albumin**

¹ Berlin. klin. Woch., Mar. 8, 1897.

³ Arch. gén. de Méd., Dec., 1896.

⁵ Virchow's Archiv, Bd. 43, H. 2.

² L'Union méd., No. 36, 1896.

⁴ Presse méd., Dec. 19, 1896.

⁶ Boston M. and S. Jour., Sept. 3, 1896.

or both have been found in the urine in cases of **infantile scurvy**. Sometimes the disease of the kidneys seems to be the principal disorder. The author then reports a case in which the kidney symptoms were the first and most marked indications. He concludes from his studies that the kidneys are affected in a large proportion of cases, and that the catarrhal nephritis is probably caused by the presence of an irritant in the blood which, by its effect upon the walls of the renal vessels, produces hemorrhages. This condition is interesting mainly as showing another of the conditions which may account for nephritis developing in early life and persisting subsequently.

Bohne¹ has reached the conclusion, after experiments upon mice and guinea-pigs and careful observation upon a number of patients suffering with various diseases, accompanied by coma or conditions similar to that of uremia, that this condition is not improbably due, at least in large part, to the **retention of chlorids in the body**. In the experiments doses of approximately 2 gm. per kg. of body-weight produced distinct motor disturbances, often unilateral, and a condition of stupor. In a patient suffering from carcinoma of the seminal vesicles, who exhibited typical uremic symptoms and finally died in a condition of coma with signs of dyspnea, the average daily excretion of NaCl was less than 3 gm. In other cases it was observed that where the excretion of NaCl was normal the uremic symptoms did not appear; where it was diminished headache, asthma, or edema was nearly always present. In 2 of these cases in which autopsy was obtained it was found that the quantity of chlorids in the liver was greatly increased; Bohne therefore draws the definite conclusion that retention of chlorids in the organism, if not the only cause for the origin of uremic and comatose conditions, is nevertheless the one principally concerned; and he also calls attention to the value of quantitative determination of the chlorids in the urine in order to control, in some measure, the treatment.

N. Tirard² discusses the **relation of indigestion to Bright's disease**. Gastric disturbances secondary to renal trouble are, he believes, perhaps a manifestation of the elimination. On the other hand, symptomatic albuminurias frequently occur as a result of errors in diet, or in cases where there is considerable disturbance of the digestive function. He concludes that it is important to test the urine in every case of dyspepsia occurring in middle life.

Pathology and Symptoms.—Pollaci³ has examined the **sweat-glands** in cases of nephritis in 16 cases, taking portions of the fresh and the hardened tissue from different parts of the body. In the edematous parts of the skin compression of the glands, even to complete atrophy of the lumen and necrosis, was found. In the other portions the lumen of the glands was larger than normal, and cystic formations with a flattened condition of the epithelium were discovered. In parts where the process was most advanced the protoplasm of the cells was granular, and the nuclei either disappeared or refused to take stains. The periglandular connective tissue showed signs of proliferation.

Wooten⁴ reports 5 cases of chronic nephritis in which, at some time during their course, albumin was absent from the urine, although the general symptoms of the disease were pronounced. In 2 of these cases casts disappeared as well as albumin.

C. C. Aitken⁵ reports a case of chronic **nephritis and uremia associated**

¹ Fortschr. d. Med., Feb. 15, 1897.

² Lancet, Aug., 1896.

³ Riforma Med., No. 92, 1896.

⁴ Texas Med. Jour., Mar., 1897.

⁵ Lancet, Sept. 26, 1896.

with Raynaud's disease. The patient, a man of 43, had well-marked gouty diathesis and albuminuria for more than 6 years. Chronic interstitial nephritis was recognized 5 years before. Two years previous to that time the symptoms of Raynaud's disease began and recurred at intervals. Mortification of the digits occurred. The urine frequently contained a small amount of hemoglobin with numerous epithelial and granular casts. The amount of urea was never above 320 gr. daily. Albuminuric retinitis was discovered in each eye, and there were some retinal hemorrhages. Between May 21 and July 2, 1895, there were 7 "uremic convulsive attacks," 5 of which had an apparent close relationship to the crises of the concurring attacks of severe vascular spasm. The patient died of uremic coma. [The author does not consider the possibility of the convulsions having been caused by vasomotor conditions of the brain. Such attacks have been described in pure Raynaud's disease, and must be considered in the present case.]

Haug¹ describes a case of **hemorrhage from the nose and into the ear** in the course of chronic Bright's disease. The patient, an alcoholic, had suffered from weakness of the heart for a year and a half, and 9 months previously had profuse epistaxis. The urine was then nonalbuminous, but recently he had more severe nasal hemorrhages and the urine was found to contain casts and albumin. Severe pains in the ears with deafness and tinnitus due to hemorrhages into the tympanum and membrane followed, and albuminuric retinitis with hemorrhage was discovered. The hemorrhagic manifestations in this case, the author believes, were largely the result of the cardiac condition, although their connection with Bright's disease was also of importance. He holds that blood escapes by diapedesis rather than by hemorrhage, and that the terms albuminuric tympanitis and myringitis are applicable. The condition is probably more common than is supposed.

A. R. Edwards² reports 4 cases in which the **differential diagnosis between uremia and meningitis** was extremely difficult. The 1st patient had paralysis of the muscles of the left eye and complete right hemiplegia, excepting the upper branch of the facial. At the autopsy there was some edema of the brain, but no lesions, and a diffuse pyelonephritis. The 2d case presented paralysis of the muscles of the left eye and the lower branch of the right facial. There were hyaline and granular casts, and considerable albumin in the urine. No cerebral lesion was found. The 3d case had no nervous symptoms excepting coma. The urine was heavily loaded with albumin; nevertheless the kidneys were negative, but a profuse, purulent infiltration was found over the base and convexity of the brain. The 4th case presented the symptoms of delirium tremens. The urine was albuminous. Suddenly focal palsies occurred in both eyes, but at the autopsy only the kidneys were diseased. [As a general rule, the focal symptoms of uremia are transient, those of meningitis more permanent; nevertheless we have recently seen a case of tubercular meningitis in which a marked hemiplegia disappeared in the course of a night.]

Clayton³ reports a case of uremia in which the attack was precipitated by the taking of an ounce of **laudanum** with suicidal intent and exposure to very high temperature. Upon admission the patient had slow respiration, pin-point pupils, and a temperature of 105°. The urine contained a large quantity of albumin and numerous casts. Recovery ensued after several convulsive attacks.

Treatment.—Bettmann⁴ has studied the action of **urea** as a diuretic.

¹ Deutsch. med. Woch., Nov. 5, 1896.

² Am. Jour. Med. Sci., Aug., 1896.

³ Med. News, July 25, 1896.

⁴ Berlin. klin. Woch., Dec. 7, 1896.

He treated 12 cases, including 3 of cirrhosis of the liver with marked ascites, 4 of unilateral pleurisy, and 5 of effusion into different serous cavities. He began with 10 gr. 3 times a day and increased this to 20 gr. He found a marked diuretic effect in only 3 instances. In the first of these the increase of urine occurred after aspiration and might have been ascribed to coincident improvement of the action of the heart. In the 2d and 3d cases there was also improvement after aspiration. The author is inclined to believe that urea may be given with hope of useful results after aspiration, but doubts its efficiency during the existence of ascites. He has never found the decidedly beneficial result claimed for the remedy by Klemperer.

Friedreich¹ has used urea in heart-disease, exudation, and transudation, and also in diseases of the liver. He found that where the kidneys were healthy it exercised a diuretic power. The number of cases is small and the results are not striking; but he attributes the latter fact to the small dose employed.

Lemoine² has employed **methylen-blue** in 8 cases of albuminuria. In 5 of these there was rapid diminution; in 3 complete disappearance of the albumin. The diseases represented were subacute and interstitial nephritis, sometimes complicated with renal congestion. All cases treated showed increased diuresis and increased elimination of urea. The doses employed varied from 0.025 to 0.050 gm. per day. No disagreeable result was noticed from its employment, excepting a slight cystitis when impurities were present in the drug. This, however, was readily amenable to treatment. Lemoine concludes that it modifies the functions of the kidneys and is also a diuretic.

Achard and Castaigne³ recommend methylen-blue for the purpose of testing the permeability of the kidneys. It may be administered either by the mouth, or, as they prefer, subcutaneously, in doses from $\frac{1}{4}$ –1 gm. In normal subjects it appears at the end of $\frac{1}{2}$ hour and persists for nearly 2 days. If, however, any lesion of the kidney exist, there is more or less retardation.

Tirard⁴ reports a case of dropsy occurring in connection with advanced kidney-disease, in which, other methods having failed, **diuretin** was employed with the result of inducing marked polyuria and reduction of the edema.

Myszinska⁵ has treated 10 cases of albuminuria with the tincture of **cantharides**. The first of these, a case of chronic malaria with abundant albumin in the urine, was completely cured. The second, a case of tuberculosis in the stage of cavity-formation, was also cured of the renal conditions. In 3 other cases there was some amelioration, but in 2 cases of saturnine arteriosclerosis the patients became rapidly worse. In 2 cases of parenchymatous nephritis there was no effect, and in 1 case of dormant tuberculosis there were an increase in the quantity of albumin and development of fever. Myszinska believes that cantharides is of some benefit, although admitting that the milk-diet which was enforced may also have had considerable influence. [It must be remembered that cantharides is capable of aggravating renal irritation even though given in minute doses.]

Julia⁶ reviews the treatment of nephritis by external applications of **pilocarpin**. This method, as employed by Mollière in 1894, consists in the application every morning of injections of nitrate of pilocarpin (0.75–1.5 gr.) in 3 oz. of vaselin in the dorso-lumbar region. The surface is subsequently covered with cotton and remains undisturbed during the day. The report embraces 80 cases, some of acute nephritis following cold, some chronic, and

¹ Berlin. klin. Woch., No. 17, 1896.

² Compt. rend. de la Soc. de Biol., May 7, 1897.

³ Gaz. hebdom. de Méd. et Chir., May 9, 1897.

⁴ Brit. Med. Jour., Mar. 20, 1897.

⁵ Gaz. heb. de Méd. et Chir., Feb. 11, 1897.

⁶ Lyon méd., Dec. 6, 1896.

some infectious nephritis. The acute cases were generally improved, albumin frequently disappearing from the urine during treatment. There were invariably diaphoresis and diuresis.

Richardière¹ advocates the use of **artificial serum** in uremia. He bleeds the patient 300 or 400 gm. and immediately introduces 800 gm. of aseptic Hayem's serum, at the temperature of the body, into the cellular tissue. His first case had intense dyspnea, mucous and subcrepitant rales over the chest, and great edema. Under ordinary treatment he grew worse and became distinctly uremic and finally comatose. Serum-injections were practised, and during a few days the patient greatly improved, but relapsed when the treatment was suspended. The treatment was again instituted and no further trouble occurred. In the second case injection was followed by improvement, but relapse occurred in 20 hours. A second injection was followed by profuse diarrhea and then permanent amelioration of the symptoms. The injections are harmless, though painful; they raise the temperature and cause a slowing of the pulse and breathing; the amount of urine increases and there seems to be a tendency to diarrhea, though it is of favorable omen. [This treatment is undoubtedly advisable in many cases. We have practised it in a few with good effect, and commend it from theoretic considerations as well as from practical experience.]

Carrien² prefers **hot-air baths** to vapor baths or hot-water baths in the treatment of nephritis. The hot-air bath relieves the kidney by abundant sweating and regulates the metabolic processes. The air is kept at a temperature of 40° C. for 20 minutes. This is repeated every 3 or 4 days. Profuse perspiration, with acceleration of the pulse and elevation of temperature from 1° to 2° C., is observed. The breathing is not embarrassed and, excepting for some palpitation and headache after the first bath, there are no unpleasant symptoms. The day following the bath the urine is usually reduced and the next day there is a marked but transient polyuria. The proportion of albumin decreases progressively. This treatment, he holds, is indicated in acute parenchymatous nephritis and contraindicated when there is coexisting arteriosclerosis, inflammatory skin diseases, or nervous conditions.

Bissman³ discusses **renal disturbances** occurring in connection with **gastrointestinal disorders**. Most of the patients excrete small quantities of highly concentrated acid urine, although some show the reverse condition. He believes that these conditions are frequently due to lodgement of scybala in the lower bowel, which not only irritate the mucous membrane, but form foci for the development of bacteria.

Auche and Carriere⁴ examined the urine in 2 cases of chronic enlargement of the lymphatic glands, one tubercular, the other leukemic, and found that the **urotoxic coefficient** was diminished in both, more markedly in the tubercular.

Ranglaret⁵ has studied the effect of **douches and massage** upon the general health. After 8 or 10 consecutive daily applications the body-weight is reduced, this being due to the effect on the general nutrition. The total quantity of urine is slightly diminished, the organic elements being increased. The urinary toxicity is increased even in healthy persons undergoing the treatment.

Cornell⁶ reports a case of **enuresis** of 20 years' duration. The only assignable cause was an attack of scarlet fever and a nervous disposition.

¹ L'Union méd., Dec. 5, 1896.

³ Med. News, Jan. 23, 1897.

⁵ Ann. d'Hydrologie, Nov., 1896.

² Sem. méd., Aug. 15, 1896.

⁴ Compt. rend. de la Soc. de Biol., July 3, 1896.

⁶ Physician and Surgeon, Dec., 1896.

Great improvement followed the administration of strychnin and the application of faradic electricity.

Francis¹ reports a case of anuria coming on suddenly in a man that had passed some **calculi**, but who was apparently in good health at the time of the attack. Death occurred on the 10th day from uremia, and at the autopsy calculi were found blocking up the commencement of both ureters. The kidneys showed advanced pyelonephritis.

Geo. Klemperer,² in discussing the **treatment of renal calculus**, points out in the first place that firm calculi cannot be dissolved because the uric acid is intimately combined with the organic basis. Stone-formation may, however, be prevented. The deposits of urates and uric acid may be obviated by increasing the amount of water, but, unfortunately, it is impossible to administer sufficient water to accomplish this purpose absolutely. It is necessary to avoid saline and other purges which decrease the amount of urine, and also excessive sweating and exercise. Milk, cheese, egg-albumin, and vegetables are useful, but meat, and particularly organs such as liver and pancreas, are deleterious, as they contain considerable nuclein, which is excreted, in part at least, in the form of uric acid. The acidity of the urine must further be reduced, and this may be accomplished by the administration of remedies like piperazin, lysidin, urotropin, etc., but just as thoroughly by administering sodium bicarbonate. He recommends alkaline waters containing this salt. Finally, he has studied the effect of urea clinically and experimentally, and believes it to be of very great value in the treatment: he prescribes a table-spoonful every 2d hour of a 5 or 10% solution. The remedy has no evil effects, and is useful both for its solvent action and for the increased diuresis which it induces. Mendelsohn³ believes that the lithium salts are too insoluble to be of much value in the treatment of renal calculi. He therefore prefers persistent but careful administration of the alkalies, with free ingestion of liquids.

CLINICAL INSTRUMENTS.

Egger⁴ has investigated the **phonendoscope** of Bianchi. He finds that some overtones are badly conducted or not at all. This explains the disappearance of the metallic sounds and the high tympanic sounds. He holds that Bianchi's contention that the quality of the sound is not altered is incorrect; moist sounds produced immediately beneath the chest-wall may sound metallic. He holds that the phonendoscope may be useful for differentiating murmurs and in distinguishing between endocardial and pericardial sounds. He is skeptical of the value of the instrument in mapping out organs, and with all its advantages does not believe it can replace the ordinary stethoscope. Schaposchnikoff⁵ has used the instrument in over 100 cases, and decides that it is very doubtful whether the internal organs can be correctly mapped out by its help, as suggested by the inventor; that the sounds and murmurs are greatly intensified, and therefore their correct interpretation is difficult; and that the sounds produced by the instrument itself interfere with the examination. Pribram⁶ finds that the delimitation of organs by stroking toward the staff does not always correspond to the contours obtained by percussion or palpation. He therefore regards the results obtained with that instrument as uncertain. He finds that amplification of the sound causes

¹ Boston M. and S. Jour., Apr. 8, 1897.

³ *Ibid.*, No. 14, 1897.

⁵ Ruskaja. Medzinsk. Gaz., No. 39, 1896.

² Berlin. klin. Woch., Aug. 17, 1896.

⁴ Münch. med. Woch., Nov. 10, 1896.

⁶ Prag. med. Woch., No. 33, 1896.

extreme fatigue to the ear. Litten,¹ in describing the phonendoscope constructed by Aufrecht, states that it is not specially advantageous, and in particular he has found that the method of delimiting organs, by drawing an instrument or finger over the skin near the border of the organ, is unsatisfactory. The changes of note detected by the instrument are due to vibrations in the skin and not in the deeper organs. [We have reached exactly the same conclusions.] Schwalbe² concludes that sounds which are ordinarily inaudible are readily appreciated by the phonendoscope, and even sounds not heard by other means, such as those of the muscles and joints, etc. Baruch³ also recommends it, mentioning that the sounds of the heart may be heard in cases of myocarditis, in which they are inaudible with the ordinary stethoscope, and that the patient may be examined thoroughly without disrobing. Manges⁴ gives a number of points at which the staff should be placed in order to utilize it to the greatest advantage for outlining organs. These are usually situated over the soft tissue, as the vibrations of bone interfere with the accuracy of the delimitation. However, he has been unable to map out the different ventricles and auricles of the heart, and has also been unable to do very accurate work in connection with the liver and spleen. In regard to the stomach, however, he has confirmed his results by all the other methods and found them to be very accurate. He holds the instrument to be a distinct improvement over the binaural stethoscope.

Chauveau⁵ describes a new form of **stethoscope** in which, as he says, the sounds are conveyed to the ear by aërial transmission. It is essentially an ordinary double stethoscope in which the bell is replaced by a heavy metal cup, the open surface of which is covered by a thin disk. Just beneath the point where the 2 branches meet a lateral branch is given off which communicates with the outer air. This, according to Chauveau, permits the sounds to be transmitted to the ear without any interference with their natural timbre.

Zieniec⁶ attaches a long tube to the ordinary single stethoscope, preferably of stiff rubber, such as is used for the esophageal sound, and to this an ear-piece. He claims that the sounds are clearer and, if the tube is long enough, it is possible to use the instrument in class demonstration. If, however, the distance of the students be considerable, the better method is to employ one of the so-called children's telephones, by which sounds can be transmitted for several meters.

Kingscote⁷ describes a **pleximeter** that he has devised, which overcomes the vibrations of the chest-wall and does not hurt the patient. It consists of a wooden cone to which a thick India-rubber ring is attached, so that when this is pressed firmly against the chest the apex of the cone touches a definite point on the skin. The base is struck with a hammer having a bulbous end and a flexible handle.

Max Herr⁸ has devised an instrument called the **onychograph**, by which he is able to record the variations in blood-pressure in the capillaries of the tips of the fingers. It consists essentially of the ordinary sphygmograph, which is so arranged that the pelotte can be brought against the finger resting upon a hard surface. The onychogram is extremely variable; it differs from the sphygmogram, the ordinary details being absent. The respiratory influence is best seen when the pulse is failing. Another phenomenon similar to this, but evidently due to nervous influence, is irregularity, variation in size

¹ Centralbl. f. innere Med., Feb. 20, 1897.

³ Jour. de Méd. de Paris, Oct. 4, 1896.

⁴ Lancet, Dec. 19, 1896.

⁵ Deut. med. Woch., No. 31, 1896.

⁶ N. Y. Med. Jour., Jan., 1897.

⁷ Wien. med. Woch., Apr., 1897.

⁸ Wien. klin. Woch., Aug. 15, 1896.

occurring several times in a minute. Cyclical conditions are readily observed; the pulse is much smaller when the attention is fixed. The greatest variation occurs in cases of cardiac insufficiency, the movements of the indicator sometimes being so great that they exceed the limits of the paper band. The influence of heat and cold is also very marked. The pulse seems to be increased in icterus, in fever excepting pneumonia, and in insufficiency of the aorta. It is decreased in mitral diseases. In emphysema of the lungs the respiratory variation is absent. In arteriosclerosis the curve is low and blunted. In those cases, however, where the radial is not sclerotic, although there is an atheromatous aorta, the curve is high and steep.

CLINICAL SKIAGRAPHS.

[The application of skiagraphy to internal medicine has been much greater than was at first anticipated, and the results have been very satisfactory, especially in cases of obscure intrathoracic disease.] William Pepper¹ has contributed a very interesting paper upon the diagnostic value of the Röntgen rays in internal medicine, confining his discussion in this paper to the diagnosis of intrathoracic aneurysm. He points out that in many cases this new agency only serves to confirm the diagnosis already established with great confidence by auscultation and percussion. Even in these cases, however, greater precision as to location, size, and form may be obtained with this assistance; and, on the other hand, intrathoracic aneurysms may be of such small size or so situated as to cause few symptoms and to be insusceptible of diagnosis by the ordinary methods, while they are demonstrable by the x -rays. Finally, this method serves at times to exclude aneurysm by failing to reveal any increase of the shaded form of the heart and aorta when the symptoms suggest the presence of aneurysm. In 3 cases of suspected aneurysm of the arch of the aorta, under his own care, his associate, Dr. Leonard, practised skiagraphy with surprisingly happy results, confirming the suspicion in two and removing it in the third. The first case was one of certain aneurysm, the physical signs being unequivocal. The patient had previously suffered with aneurysm of the popliteal artery, but after ligation this subsided. The signs of a large aneurysm of the chest were plainly marked. The skiagraph was taken with the patient lying on the plate. A double focusing tube was placed over the middle line of the chest, 18 in. from the plate; exposure was 15 minutes. An impenetrable area was seen in the upper part of the sternal region and to the right of the heart's shadow. The picture is indefinite, but the author states that this is unavoidable, as a longer exposure might cause penetration of the aneurysm by the rays. The second case was also one of marked aneurysm of the thoracic aorta, and the skiagraph fully confirmed this view. In the third case, in which symptoms pointing to aneurysm were present (dulness under the manubrium, paralysis of the vocal cords, tracheal tugging, inequality of pulse, and bruit), the skiagraph failed to show any abnormal opacity corresponding to the dulness on percussion; and the course of the case corresponded with this exclusion of aneurysm. A fourth case of aneurysm of the innominate artery is merely alluded to.

Thompson,² in discussing the practical application of Röntgen rays in diseases of the heart and great vessels, reports a case in which aneurysm was suspected, but physical signs were not sufficient for a positive diagnosis. Upon examination with the fluoroscope an indefinite shadow above the heart, to the left, was seen from the front, which, examined from the back, showed the

¹ Univ. Med. Mag., Jan., 1897.

² Lancet, Dec. 12, 1896.

outline of a large mass just above the heart. Subsequently the history of the case confirmed the diagnosis of aneurysm of the aorta.

Bergonic¹ has used the radioscope for the diagnosis of intrathoracic lesions and found that the coincidence between the shadow-changes and the lesions was always perfect. Dulness was represented by opacity and it was also possible to recognize exactly the limits of a hydatid cyst by this method.

Bouehard² has employed the Röntgen rays in the diagnosis of pulmonary diseases. He finds that pleural effusion produces darkness on the side in which it exists. Pulmonary infiltration or consolidation also causes the appearance of a shadow, the difference between the two being that one usually occurs at the apex and the other at the base of the heart. Cavities are indicated by lighter areas or clear spaces in the midst of the shadows. He reports several cases in which the diagnosis was doubtful until the fluoroscope had been employed.

Wasserman³ reports 2 cases in which the diagnosis was finally confirmed by means of the Röntgen rays. In the first there were symptoms of pulmonary infiltration, but it was only when the thorax was examined with the fluoroscope that attention was attracted to the lower part of the field, which was much darker than the upper part, to a very bright spot about 2 cm. to the right of the shadow of the sternum, and just above the shadow of the liver. Upon careful examination of the thorax anteriorly in the corresponding place it was possible to find signs of a cavity, but absolutely impossible posteriorly. The author concludes that in case of a central cavity not giving rise to signs, either anteriorly or posteriorly, it would be impossible to diagnose it except by this method. As the tubercle-bacilli had never been found in the sputum, the discovery of this cavity confirmed the otherwise doubtful diagnosis. In the 2d case there was some dulness in the first intercostal space to the right of the sternum, but no pulsation. When, however, the thorax was examined with the fluoroscope a large pulsating tumor was found in this situation that also reached considerably further to the left than percussion had indicated, and extended quite a distance downward along the descending aorta, rendering it very easy to make a plastic representation of the diseased artery. It is possible by this method to detect an aneurysm too small to give rise to symptoms, and also to make a differential diagnosis between aneurysm and tumor.

Von Basch⁴ has been able to recognize the condition of pulmonary swelling and inelasticity, that he has previously described, by means of the Röntgen rays.

Satterthwaite⁵ suggests the use of the fluoroscope in connection with percussion. He marks upon the chest-wall the outline as obtained by percussion, then places the Crookes tube at a point directly back of this in order that the rays casting the shadows shall pass perpendicularly through the chest. The important angles are all confirmed by this method and the result is then sketched.

Levy-Dorn⁶ records an observation of the intrathoracic conditions **during an attack of asthma** made with the aid of the **fluoroscope**. Before the attack nothing specially interesting was observed excepting the right-sided enlargement of the heart. During the attack he observed the following changes: the left half of the diaphragm sank repeatedly and then rose in a labored fashion, and again descended rapidly, and this continued, expiration

¹ Trib. Med. Jour., Feb. 3, 1897.

² Rev. de la Tuberculose, Dec., 1896; Gaz. des Hôp., Dec. 22, 1896; *ibid.*, Jan. 5, 1897.

³ Wien. klin. Woch., Jan. 28, 1897.

⁴ Wien. med. Woch., Jan. 30, 1897.

⁵ Med. Rec., Apr. 10, 1897.

⁶ Berlin. klin. Woch., Nov. 23, 1896.

being difficult and slow and inspiration sudden and complete. At the same time the right half of the diaphragm behaved in an entirely different manner, remaining stationary in both expiration and inspiration. When the patient was directed to take a deep breath the left side made somewhat greater excursions, but the right side still remained fixed. This continued some months, when a severe attack of coughing occurred and the paroxysm was ended. The author concludes from his observation that the position of the left side of the diaphragm was due to marked distention of the left lung, and holds that it furnishes disproof of the theory that bronchial asthma is dependent upon diaphragmatic cramp and confirmation of the view that asthmatic dyspnea may be dependent upon disturbances in the bronchi of one side only.

ANIMAL PARASITES.

Protozoa.—Mathieu and Soupault¹ discuss the pathogenic importance of *amebæ* in the intestines. They note that *amebæ* are found in large numbers in the liquid stools of healthy persons after salines; they are met with in large numbers in cases of dysentery, but are not always to be found in dysenteric stools, having been absent in certain epidemics with grave manifestations. They have frequently been found when patients presented diarrhea, but no dysenteric manifestations; in the last-named cases they are usually more numerous than in healthy persons, and disappear when the condition is relieved, although occasionally their disappearance bears no relation to the attack. They hold that no certain relation between the form of *amebæ* found and the clinical variety of diarrhea has been established, and they cast doubt upon the pathogenic significance of the organisms. Finally, as to the existence of certain pathogenic or virulent forms, and certain non-pathogenic forms, they hold that it is premature either to accept or reject this suggestion. Their own inclination is to believe that the *amebæ* in large number and with increased virulence may occasion grave diarrhea or certain dysenteric affections of the intestines, though they admit that this view is not established.

Wijnhoff² has reported the case of a woman of 30 years who suffered with attacks resembling renal colic, followed by bloody and purulent urine. Numerous colorless bodies, identical with the *amebæ coli*, appeared in the urine after each attack; but in the intervals only encysted bodies and ring-forms were present. In 3 other cases *ameburia* occurred during attacks of stranguary and vesical or renal colic; the urine was cloudy, and contained numerous pus-corpuscles, and the formation of daughter-cells out of the large *amebæ* could be observed. The author believes that the organisms bear an etiologic relation to the attacks. Zeehnisen, in abstracting the above report, mentions the case of a medical student who had an almost painless attack of hematuria with blood-casts in the urine and numerous *amebæ*; after the attack the ring-shaped *amebæ* were still present.

Leyden and Schaudinn³ have described a form of *amebæ* occurring in the liquid removed from patients suffering with ascites. This organism was first found by Leyden in a patient suffering with chronic heart-disease and ascites. Repeated tapping was practised, and the *amebæ* was always present. The organisms were gelatinous cells, often aggregated and presenting active amoeboid movements. Small nodes formed upon the processes at times, separated, and developed into new cells. The patient presented nodular masses in the abdomen (found after tapping), and it was believed that she had cancer. Similar

¹ Gaz. des Hôpitaux, Oct. 17, 1896.

² Centralbl. f. innere Med., No. 52, 1896.

³ Sitzungsbericht d. Kgl. Pr. Akad. d. Wiss., Berlin, July 30, 1896.

bodies were found in the fluid removed from a case of carcinoma of the stomach with ascites in a man of 63. Dr. Schaudinn made studies of the organisms, and declares them undoubtedly amebæ. [The opinion of the latter is of particular value, as he has been working upon the subject of protozoa for years.]

Janowski¹ has observed **flagellate protozoa** in the feces of 6 cases. In 2 the patients suffered from chronic dysentery; in 1 from typhoid fever; in the other 3 from indifferent diseases. He holds that the trichomonads are of no particular significance, but that they may occasionally give rise to diarrhea. He recommends for treatment calomel and quinin, the latter being also useful when given as a clyster.

Gurwitsch² reports 7 cases of **balantidium coli** that he has observed in human beings. The chief symptom of the disease is diarrhea, the stools containing mucus, undigested food, and occasionally blood. The subjective symptoms are those of colitis. In addition to the ordinary encysted ovoid form, he describes another two or three times as large as this which shows distinct traces of segmentation. He holds that this is probably a persistent form, brought about by an attempt to expel the parasite. From the fact that the number of parasites existing was usually proportionate to the severity of the symptoms, he concludes that they had a direct pathogenic action. One patient died of hemorrhage; 5 others harbored other parasites.

Vermes.—Thorpe³ has made some studies of the occurrence of **filariæ** in the blood of natives of the Fiji or Friendly Islands. In 24 cases seen in the hospital at Suva, Fiji, he found filariæ in 4 of 16 men having no form of elephantoid disease, and in 1 of 4 men having elephantiasis. The remaining 4 cases were women without elephantiasis, and of these 1 had filariæ. These results show that 25% of the Fiji natives have filariæ. Subsequently slides of blood from 100 cases came into his hands, and he found filariæ in 24, or about the same proportion as in his cases. He next studied the subject in the Friendly Islands. In examining the blood of the native Tangans he was struck by the fact that the parasites were quite as common in the daytime as at night. Ninety-six natives were examined both day and night, and in only 2 were the filariæ absent at one time and present at another. In 1 of these they were found during the day alone; in another during the night only. The filaria of the Tangans is in other respects like the *Filaria nocturna*, but is a little smaller than that found elsewhere. The author believes that the habit of waking frequently during the night to talk or eat is the cause of the loss of periodicity. Statistically he found on the 4 large islands of the group: among males: examined day and night 55, 27 affected; examined only during day 8, 1 affected; only at night 60, 23 affected; among females: examined day and night 41, 13 affected; during day 9, none affected; during night 41, 5 affected. The total was 214 cases examined, and 69 affected, or a proportion of 32.24%.

Manson⁴ refers to the frequency of filariasis in Samoa. Dr. Davies sent him blood-films of 56 adult Samoans, each of whom had some form of elephantoid disease, of which 27 contained filaria. In some cases the parasites were enormously abundant. The author states that the slides were in the majority of cases obtained from that part of the population least likely to show filaria in the blood—that is, from subjects of elephantiasis, in whom the filariæ are presumably blocked in the lymphatics. He believes, therefore, that

¹ Zeit. f. klin. Med., vol. xxxi., p. 442.

² Russ. Arch. f. Path., kl. Med. u. Bact., Sept., 1896.

³ Brit. Med. Jour., Oct. 3, 1896.

⁴ Ibid., Nov. 7, 1896.

examination might show that practically all adult Samoans harbor the *Filaria nocturna*.

Sellei¹ reports 19 cases of ***Filaria medinensis***, all of which were found in a negro colony that was on exhibition at Budapest. The disease commenced as a small fluctuating tumor, usually on the foot, which in the 3d or 4th week suppurated and opened, leaving a small abscess in which the head of the parasite was found. The longest that he obtained measured 52 cm.

Blanchard² reports a case in which a live, thread-like worm, 30 cm. long, which proved to be the ***Gordius tricuspidatis***, was vomited by a young man, who had apparently swallowed it in drinking-water about 2 weeks previously. The symptoms during that time had been simply slight discomfort in the hypogastric region.

Brown³ reports the results of a study of several cases of **trichinosis**. There was considerable leukocytosis, with increase in the number of eosinophile cells, reaching $62\frac{1}{2}\%$ of the leukocytes, and diminution of the polynuclear cells to 6.6%. There was no increase in the excretion of uric acid nor in the elimination of any of the nitrogenous constituents of the urine. The muscles showed great proliferation of the nuclei, the presence of parasites with disintegration of the fibers they inhabited, and extravascular eosinophile cells.

Brooks⁴ reports a case of ***Distoma hæmatobium***. The patient, who had spent a year in South Africa, did not notice the symptoms until his return to the United States. Toward the end of micturition the urine became bloody and upon examination was found to contain minute coagula imbedded in pus. Within these, or else free in the urine, were a large number of ovoid bodies, with one end drawn out into a sharp spine, which developed rapidly into embryos when placed in fresh water.

Souderm⁵ reports a very similar case. The patient had lived in South Africa, and also observed a small quantity of blood at the end of each micturition; examination of the urine showed, in addition to pus, the presence of the characteristic eggs. Gallie acid improved the symptoms without materially reducing the number of the ova.

Zinn and Jacoby⁶ have studied **the fauna of the intestinal tract** in negroes, and have found in 23 native Africans representing various parts of Africa, east and west, *Ancylostomum duodenale* 21 times, *Trichocephalus dispar* 8 times, *ascaris* 8 times, *teniae* 4 times, *Anguillula stercoralis* 4 times, and *amebæ* twice. None of the cases showed any sign of anemia. In some of the cases of anchylostomiasis the number of parasites was very great, and the authors ascribe the lack of symptoms to racial peculiarity.

Galgey⁷ has recently begun the investigation of the progressive pernicious anemia so common in the natives and especially the coolies of the island of St. Lucia, West Indies. The number of cases admitted to the Victoria Hospital was 209 in 1892, 277 in 1893, and 272 in 1894. Most of the cases were coolies, but the natives are also liable. The patient is weak and dejected, the skin is waxy and pale, and the breathing difficult. Finally, extreme weakness prevents his continuing at work. The author's attention having been called to the frequency of **anchylostomiasis**, he studied one of the fatal cases postmortem and discovered numbers of the worms in the intestine. He then adopted the thymol treatment, giving 40 gr. in 2 doses, and the fol-

lowing day a light diet and brisk purgation. The proof of the nature of the disease is determined by the examination of the evacuations. He appends the histories of 23 cases, all of which were improved under the treatment. Since then fully 60 other cases have undergone the same treatment with the most successful results. Geophragia or earth-eating is very prevalent among the coolies, both children and adults.

Mohlan¹ reports 5 cases of *Anchylostomum duodenale*; 2 were apparently imported from Italy and the other 3 seemed to have originated in America. The symptoms of the disease, as he observed them, are the marked anemia, the bronzing of the skin, and a peculiar sensation of warmth in the region of the intestines, which he ascribes to hemorrhage and which he finds always precedes the appearance of blood in the feces. Besides these, there is a peculiar pain, commencing very mildly and increasing in severity, irregular diarrhea, and sometimes a swelling nearly over the pancreas. The diagnosis is, of course, to be made by the discovery of eggs in the feces, and it is usually desirable to administer a cathartic before the examination. [The discovery of anchylostomiasis originating in North America is of considerable interest. We know of no previous case.] Moeller² also reports 2 cases occurring in slate-workers in the southern portion of Saxony. In both the diagnosis was made by the discovery of the eggs in the feces. Combination of hydrotherapy—that is, high rectal injections of salt water—and cold applications, and *caesarea sagrada*, produced permanent cure.

Sommer³ contributes a further paper on the occurrence of *Tænia echinococcus* in the United States. In his first paper⁴ he summarized 67 cases. He now adds 33 additional instances, making the whole number 100. Of these latter cases 1 occurred between the ages of 11 and 20, 5 between 21 and 30, 4 between 31 and 40, 6 between 41 and 50, 4 between 51 and 60, 2 between 61 and 70, and 3 between 71 and 80. There were males, 21; females, 11; not stated, 1. As to the organs affected, he finds in his present series: liver, 22 cases; lungs, 2; bladder, 2; pleura, 1; peritoneum and omentum, 1; mesentery and omentum, 1; abdomen, 2; omentum, 1; brain, 1; ventricles, 1. In 1 case the parasites were found in the vomita.

Hagelstan⁵ reports 2 cases of anemia caused by the *Bothriocephalus latus*. Both patients were Finns that had emigrated to the United States. He describes the symptoms of the disease as those of profound anemia with slight icterus, the blood showing poikilocytosis and leukocytosis. The diagnosis is made by microscopic examination of the feces.

Daniels⁶ states that 2 specimens of a tapeworm allied to the *Tænia Madagascariensis* were found in an adult male, aboriginal Indian at George Town, British Guiana. They were in the jejunum; both were dead and the heads were not found. One of the specimens was cut and the other uncut. The latter measured 9 in. (23 cm.) in length, and the segments increased in size and length from above downward. The first segment was 0.37 mm. in breadth and 0.07 mm. in length; whilst the 50th was 0.8 mm. in breadth and 0.2 mm. in length; at the 150th segment the breadth was 1.2 mm. and the length 0.4 mm.; but at the 250th segment the breadth and length were about the same, 1.7 mm. In the remaining segments the increase was almost entirely in length, the terminal segments (about the 320th) being slightly over 3 mm. in length and little more than half this in width. The most peculiar feature and the one in which it resembled the *Tænia Madagascariensis* is the

arrangement in the ripe segment of the eggs in masses or balls visible to the naked eye. The genital pores barely projected and were invariably found on the same side of the segments. The illustrations represent segments enlarged about 9 times, Fig. *d* being even more highly magnified.

Overton¹ reports 2 cases suffering from **tapeworm**. The first patient was given a powerful vermifuge and had passed some of the worm by the rectum, when a violent attack of vomiting came on, during which the rest of the

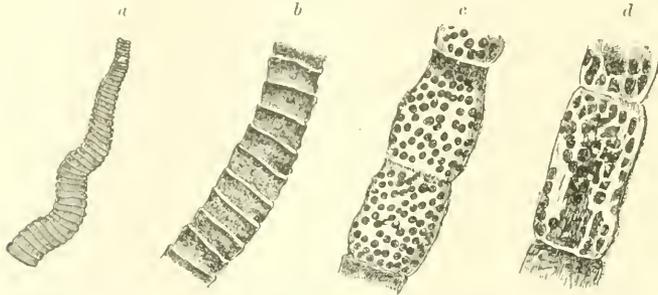

FIG. 1.—*a*, portion of worm just below the head; *b*, portion of worm at about 150th segment, showing genital pores; *c*, *d*, portions of worm between segments 300-320, showing egg masses (Lancet, Nov. 21, 1896).

worm was expelled by the mouth. He also reports another case, in which the patient, after a vermifuge, passed 2 tapeworms, in 1 of which the head was lacking. At intervals of 6 weeks the symptoms would recur, followed in each case by the expulsion of a headless tapeworm; after the 3d treatment, however, cure apparently took place.

Tretrop and Lambotte² found living parasites in the liver and mesentery glands of a native of the Congo, which were from 15 to 18 mm. in length and were recognized as **Pentastomum constrictum**.

Arthropoda.—Henschen³ reports a case in which the intestinal tract was infested with **maggots**. These had persisted for 7 years and gave rise to a chronic pseudomembranous enteritis. Treatment with filix mas would expel large numbers, but they invariably reappeared.

GENERAL SURGERY.

BY W. W. KEEN, M. D., AND J. CHALMERS DACOSTA, M. D.,

OF PHILADELPHIA.

General Review of the Year's Work.—The general trend of surgery during the past year has been in the direction of an enlightened conservatism. Destructive radicalism, recently so popular, is obviously waning. Startling novelties are not common, but laborious studies, careful investigations, and thorough reinvestigations of important subjects constitute the great bulk of the work of surgeons for the past twelve months. Among a host of important matters which have been discussed we may mention the following as of particular note: the real position of iodoform in surgery; formaldehyd as a disinfectant; the use of antistreptococcic serum and the doubts as to its genuine utility; the treatment of inoperable malignant tumors by the mixed toxins of the streptococcus of erysipelas and the micrococcus prodigiosus; orrhoterapy for malignant tumors; the possibility of retarding the growth of or of curing cancer of the female breast by the performance of oöphorectomy; the value of eucain as a local anesthetic and the method of employing it; the treatment of certain forms of neuralgia by intradural section of the spinal nerves; the lack of permanency in the operative cure of epilepsy; forcible correction of the deformity of Pott's disease of the spine; hypertrophy of the prostate gland and the various methods employed in treating it; partial nephrectomy as a substitute in certain cases for complete nephrectomy; the value of the cystoscope in diagnosing renal and vesical disease; treatment of albuminuria by incision or puncture of the kidney; the very important recent studies upon the immediate suture of divided blood-vessels; methods of draining and cleansing an infected abdominal cavity; the technic of appendicitis operations; the value of the intravenous injection of hot saline fluid in the treatment of shock and the collapse of hemorrhage; the ambulatory treatment of fractures; the treatment of certain fractures and dislocations by incision, and the employment of the Röntgen rays in surgical diagnosis.

ASEPSIS AND ANTISEPSIS.

N. Senn¹ discusses ideal **catgut sterilization**. He states that no other surgical procedure has ever enjoyed the confidence of the entire profession as thoroughly as has the catgut ligature. Nussbaum has appropriately said that catgut is without doubt Lister's greatest discovery. Lister's original method of rendering catgut aseptic has been variously modified during the last 25 years. The fact that so many methods have been used is proof positive that no one of them has proved absolutely perfect. Kocher abandoned juniper gut as unsafe after giving it a prolonged trial. Carbolized catgut, sublimated gut, and chromicized gut have been used extensively, but not

¹ Jour. Am. Med. Assoc., Dec. 12, 1896.

infrequently wound-infection could be traced to imperfect sterilization of the material. Dry sterilization has been largely used, but it cannot be relied upon. Catgut should be sterile, should be mildly antiseptic, and of unimpaired tensile strength. Senn says we have all been seeking for a method which would enable us to boil catgut without diminishing its strength, and such a method has recently been found. It has been shown that after catgut is immersed for 48 hours in a 2% solution of formalin it undergoes an unknown chemical change which alters its texture. It can now be boiled with impunity, and boiling actually increases its tensile strength. Hofmeister's method of preparation is as follows: the catgut is wound on a glass plate with projecting edges and the ends of the gut are fastened through holes in the plate. It is immersed in a 2 to 4% aqueous solution of formalin for from 12 to 48 hours. It is then immersed in flowing water at least 12 hours to free the gut from the formalin. It is boiled in water for from 10 to 30 minutes. It is preserved in absolute alcohol containing 5% of glycerin and $\frac{1}{10}$ of 1% of corrosive sublimate. In this method of preparation the gut must be wound tightly around the glass plate and cylinder. Formalin-catgut is absorbable in the tissues, but not so readily as catgut prepared by other methods. Inoculation-experiments prove the formalin-gut to be sterile. It is very strong, the knot is secure, and the material can be boiled and even reboiled any number of times without injuring its texture. Simple sterile catgut is not a safe material because as it lies in the tissues it can act as a culture-medium for microorganisms. Hence every catgut ligature should contain some antiseptic. Hofmeister, as noted above, keeps the gut in an alcoholic solution of corrosive sublimate; some surgeons immerse it in a carbolic solution; both these antiseptics are irritants, increase primary wound secretion, and thus interfere to some extent with healing by first intention.

Lauenstein has recently proved that it is impossible to render the field of operation absolutely aseptic by any known method of disinfection. Nearly every wound inflicted by the surgeon must contain some pathogenic microbes. Ewald has proved that sterile catgut often contains a toxic substance of unknown composition. This substance when present in sufficient amount has a destructive action upon the cells carrying on repair, transforms them into pus-corpuseles, and produces a limited aseptic suppuration and the formation of sterile pus. Many stitch-abscesses originate from this cause. Senn has come to the conclusion that catgut should not only be sterile, but should be made sufficiently antiseptic to inhibit the growth of pyogenic organisms which enter the wound at the time of operation or which are carried to it by the circulation. He has modified Hofmeister's plan by substituting iodoform for corrosive sublimate. Senn advises hospital authorities and surgeons to prepare their own catgut, and not depend upon the material put up by the manufacturers. Senn's method is as follows: the catgut is formalinized by the method of Hofmeister, being wound, however, upon glass test-tubes or glass drainage-tubes instead of plates. It is boiled for from 12 to 15 minutes, is cut into pieces and tied in bundles, when it is immersed and kept ready for use in the following mixture: 950 parts of absolute alcohol, 50 parts of glycerin, 100 parts of finely pulverized iodoform. The bottle is closed with a well-fitting glass stopper and should be shaken every few days. One of the valuable properties of the iodoform in a recent wound is that it diminishes the amount of primary wound secretion. It does not destroy pus-microbes, but it does inhibit their growth. [The opinion of Prof. Senn that hospitals should prepare their own catgut, is worthy of respectful attention. The formalin-iodoform catgut seems to be a satisfactory material. We have

never employed Senn's catgut, but have tried ordinary formalin-gut, and were not satisfied with it. At present we use with great satisfaction the palladium catgut of Johnston, the formula for which will be found in the *Year-Book* for 1896.]

Henry Jellett¹ presents a **modification of Fowler's method of sterilizing catgut.** The method of Fowler, as is well known, consists of sealing up strands of gut in a U-shaped glass tube containing alcohol, raising the temperature of the tube by placing it in a dry sterilizer, and immersing it in boiling water. Jellett calls attention to the fact that raw catgut must be septic because of its origin and its method of preparation. It is made by twisting into cords the prepared submucous tissue of the small intestine of the sheep. The process of twisting brings bacteria which were originally on the outside of the intestine into the centre of the threads. The fat present glues the strands firmly together and encases the bacteria in a sheath which forms an impassable barrier to ordinary means of sterilization. When catgut is introduced into the body the process of absorption serves to bring every particle of it, layer by layer, into contact with the surrounding tissue. Bacteria contained in silk or silkworm-gut may never come in contact with the tissue, but every bacterium present in catgut necessarily does so, and it is this property of being absorbed which makes the absolute asepsis of catgut imperative. In endeavoring to kill bacteria in gut chemical methods are very uncertain because the bacteria are surrounded by fat. The fat must be first removed by ether, but chemical disinfectants require frequent changes of liquid, are troublesome, expensive, and uncertain. Heat is the best antiseptic, but boiling water or steam causes catgut to swell into a shapeless mass and dry heat is likely to make it brittle. Alcohol is a medium in which catgut can be heated without diminution of the tensile strength of the gut. Alcohol boils at 173° F. This is not a great enough heat to sterilize the material, hence the alcohol must be superheated. The author's modification of Fowler's method enables anybody to quickly sterilize catgut. He tells us to roll gut on glass plates and place it in a brass box three-fourths full of alcohol. The box has a screw top provided with an India-rubber washer. This box is immersed in boiling water. It must be able to stand a pressure of 4 pounds to the square inch. Before placing the gut in the box it should be dehydrated by keeping it in absolute alcohol for 3 or 4 days. It must not be rolled tightly on the plate. A coil 90 in. long will lose from $\frac{1}{2}$ to 1 in. in length in preparation, so if rolled too tightly at first it will be greatly weakened after the process is completed. The brass box is placed in a saucepan of cold water, the water is raised to boiling and is boiled for 15 minutes. Do not place the box directly in boiling water. If this is done, it will take some time to heat the box and its contents and the material might be removed before sterilization is complete. The plates of catgut are kept in a mixture of alcohol and glycerin—from 5 to 20% glycerin.

Edebohls'² **method of sterilizing catgut** is as follows: he buys the raw material from an importer of jeweler's supplies, raw gut 0 and 100, in coils 5 meters long. He tells us not to buy the smooth white gut; this has been made smooth and white by the use of sandpaper, and it is weak and unreliable. Take away from each coil the fine strand used to fasten it, place the coils in ether to remove fat, and chromicize by placing for 30 hours in the following solution: 1½ gm. of potassium bichromate, 10 gm. of carbolic acid, 10 gm. of glycerin, 480 gm. of water. Dissolve the potassium bichromate in the water, then add the carbolic acid and glycerin. After 30 hours remove the

¹ *Lancet*, Aug. 8, 1896.

² *Boston M. and S. Jour.*, Sept. 24, 1896.

catgut with and upon the core and wind it upon frames in lengths of 1 meter. This prevents kinking. The catgut is dried for several days at a temperature not exceeding 40° to 50° C. Higher temperatures might make the moist gut gelatinous, and hence brittle and useless. The drying must be perfect, because if any moisture remains in the gut when high temperatures are applied it will become gelatinous and brittle. After the gut is absolutely dry cut it into pieces 1 meter long, roll the pieces into small coils, pack into 1-ounce glycerin-jelly jars, 20 coils to a jar, pour absolute alcohol into each jar until it is full, and screw down the metal cap. Place the glycerin-jelly jars into a large anatomic jar which contains from 2 to 4 ounces of absolute alcohol; screw down the cover of the anatomic jar, place the whole in an Arnold sterilizer, boil for 5 hours, and then allow it to cool. The firm closure of the jar secures boiling under pressure. This gut is not changed by alcohol. Gut thus chromicized and sterilized remains strong, sterile, and unimpaired in quality for years.

The question of a **cheap and efficient surgical suture-material** is discussed by A. V. Gubaroff.¹ He maintains that hemp and linen thread are worthy of more attention as suture-materials than is usually assigned them. The objection commonly made is that they are difficult to thread and liable to roll up and tangle. He suggests a method of preparation which prevents these difficulties—namely, take linen thread, boil it in soda solution to remove fat, wash it in water and dry; sterilize it in steam and keep it in alcohol for several days. Dip it into 5% solution of celloidin, in alcohol and ether, and dry by stretching upon frames. The threads shrink, become smooth, are threaded with great ease, and do not become tangled when placed in aqueous solutions. They can be sterilized by boiling or by putting them in a steam apparatus, but should not be placed in alcoholic solutions. They keep best dry. We can add 1:1000 of corrosive sublimate to the celloidin solution; but if we do so, the thread must be subsequently boiled to remove the superfluous sublimate.

Carl S. Haegeler² discusses **airol and other substitutes for iodoform**. He tells us that the three chief objections to the employment of iodoform are its occasional poisonous action, its irritant effects, and its offensive odor. The exact action of iodoform is not known. We are not sure whether it is or is not an antiseptic, and we are not certain that wounds can be infected by the use of unsterilized iodoform. Unquestionably, it produces decomposition-products on which its activity largely depends, the chief one of these being iodine. It is disputed whether it acts upon the organisms, the toxins, or the tissues. In an area of putrefaction the iodoform is decomposed with great rapidity. There can be no question that it has strong antitubercular power. A substitute for iodoform should not be toxic, should not be irritant, should not have a disagreeable odor, and should contain an effective antiseptic material. He tells us that neither iodol nor aristol can be esteemed as substitutes, and dermatol has a very weak antiseptic action. The combination of gallic acid and bismuth with iodine has been recommended by Lüdy. This agent gives off iodine early when introduced into wounds and is called airol. It is not toxic, it acts upon microorganisms like iodoform, it is a valuable drying-powder, it is not at all irritant, and has no disagreeable odor. Haegeler says that it is of no value in erysipelas, because iodine is not set free with sufficient rapidity to keep up with the movement of microorganisms in the lymph-vessels. He thinks it of great value in phlegmonous staphylococcal inflam-

¹ Centralbl. f. Chir., p. 1025, 1896.

² Beiträge z. klin. Chir., Bd. 15, H. 1, p. 266, 1896; Ann. of Surg., Mar., 1897.

mations, and likes it very much in recent wounds. It is an efficient stimulant to granulation. We can inject tubercular joints with a 10% emulsion.

P. F. Lomry¹ discusses the **antiseptic value of iodoform**. He considers that wounds which have been infected with staphylococci or streptococci heal better when treated with iodoform than when not so treated. He tells us that laboratory reports on the absence of antiseptic value in iodoform are not to be trusted because the observers have used nutrient material which does not dissolve iodoform. When we place iodoform in living tissues it is found to have a powerful action upon microorganisms. It greatly weakens the power of staphylococci and streptococci pyogenes. It neutralizes the products of many microorganisms; it does not interfere in any degree with the phagocytic power of the white blood-cells—in fact, it actually seems to increase it. In view of the fact that iodoform is probably not germicidal, the sterilized drug should be employed and the dressings changed every day.

E. Hues² recommends **tribromophenol bismuth** as a valuable antiseptic. It has very slight poisonous power. It antagonizes suppuration, lessens pain in the wound, and stimulates healing. It greatly quiets pain in burns, decomposes very slowly in the wound, and keeps up a constant action, the tribromophenol attacking the microorganisms, the bismuth serving to dry the parts and to prevent fermentation. This remedy does not promote granulation as strongly as iodoform. It does decidedly promote epithelial growth, is unaltered by light, and possesses some advantages over iodoform.

C. Longard³ discusses the value of **amyloform**, which is a white powder produced by the chemical combination of starch with formaldehyd. This powder is odorless and non-poisonous, entirely insoluble, and not decomposed even by great heat. Gauze impregnated with amyloform can be subjected to steam without producing any change in the drug. It is a powerful antiseptic, deodorizer, and absorbent. It is unirritant and extremely cheap.

Von Leignek⁴ calls attention to the interesting fact that when **catgut ligatures are kept in solutions of corrosive sublimate** the corrosive sublimate is precipitated after a time and the supposed antiseptic solution will not contain a single trace of mercury, it having changed to calomel and been thrown down to the bottom of the vessel. A rubber drainage-tube has the same effect on a corrosive sublimate solution after a time.

Hofmeister⁵ recommends formalin for the **sterilization of syringes**. His experiments to determine the effect of formalin upon catgut led him to investigate its action upon leather. He found that ordinary leather after it had been placed for 24 hours in a 2 to 4% solution of formalin could be boiled in water without damaging it to any degree, but if it is boiled without such previous treatment it becomes after boiling a hardened mass which can be easily ground up. He tells us that syringes which consist of glass, metal, and leather are the only ones to which his method of sterilization can be applied. The syringe must be fastened by screws and not by cement. He takes out the piston and places it in ether to remove the fat. He then places it for 24 to 48 hours in a 2 to 4% solution of formalin; after the formalin is washed out the piston is put back, the air is removed, the barrel is filled with water, and the instrument is placed in cold water, the temperature of which is gradually raised to boiling. From time to time this method of treatment must be repeated. The principle of Hofmeister's method is that leather can be boiled in plain water without detriment if previously treated with formalin.

⁴ Wien. klin. Woch., ix., No. 39, 1896.

⁵ Centralbl. f. Chir., p. 641, 1896.

H. C. Wood¹ writes upon **formaldehyd**, telling us that the article known commercially as formalin is a 40% aqueous solution of formaldehyd. The germicidal powers of formaldehyd were discovered by Trillot, in 1888. Not only is it a germicide, but it renders innocuous the toxins of tetanus, diphtheria, and many other organisms. It is of great value for disinfection of rooms. A 1% solution deodorizes feces (Walter). It is a far safer agent than corrosive sublimate, because it is not actively poisonous, and if a person started to swallow it by mistake it would be at once detected because of its taste and irritant properties. It will satisfactorily disinfect the hands, will disinfect instruments without dulling them, and is a valuable agent in the sterilization of catgut. Wood thinks its use may do away with many of "the tedious procedures at present connected" with the preparation of dressings. He says we should place the dressings in a receptacle of copper or tin, and attach the nozzle of a formaldehyd-forming lamp to the vessel so that the vapor will pass freely through. To wash wounds use a 2% solution; to irrigate use a $\frac{1}{4}$ % solution (Willard). Such strengths are not irritant. Strong solutions are irritant even to sound tissues, and are used when we wish a caustic effect, as in chancreoids or poisoned wounds. Vaginal gonorrhoea is benefited by irrigation with a solution of a strength of 1:1000, and the cervix can be painted with a 4% solution (Von Winckel). Wood suggests to surgeons to try the immediate disinfection of wounds by the vapor of formaldehyd on the ground that this vapor will more thoroughly disinfect recesses and pouches than will any fluid. He further advises the introduction of the vapor into the abdomen after incision in cases of peritonitis.

[The chief use of this agent until lately was as a fixing-material for the laboratory. Mosso and Parletti² made a careful study of the properties of formalin, and determined that it almost equals corrosive sublimate as a germicide, but is far less toxic. Laboratory experiments show that a 3% solution kills the organisms of anthrax in 15 minutes and all other pathogenic organisms in 1 minute. A strong solution is very irritant and produces sloughing of tissue. In the Jefferson Medical College Hospital formalin has been used extensively for irrigation of foul ulcers, abscess-cavities, and sinuses, and for washing infected wounds, and has given much satisfaction. A 2% solution is the best strength for wounds. Irrigate sinuses or abscess-cavities with a solution of a strength of $\frac{1}{4}$ to $\frac{1}{2}$ %. Formalin vapor is used for the purpose of sterilizing catheters by R. W. Frank and others. A study of the antiseptic value of formaldehyd has been made by F. C. J. Bird.³]

Fürbringer and Freyhan⁴ discuss the question of **how to disinfect the hands**. They maintain that it has been demonstrated with certainty that the hands cannot be completely sterilized by the use of soap and water even when associated with the use of antiseptics. Alcohol must be used, and the more alcohol employed the greater the cleanliness. They advise surgeons to place the hands in warm water and scrub them with a brush and soap for at least 5 minutes, rinse them off in sterile water, wash in alcohol for 5 minutes, and, finally, wash in sterile water. They hold that the alcohol is germicidal; that it helps to remove grease and fat and so opens up the way for the action of a germicide, and that it removes the epiderm itself, which structure always contains bacteria.

Robt. F. Weir,⁵ as regards the disinfection of the hands, thinks the weak

¹ Univ. Med. Mag., June, 1897.

² Arch. Ital. de Biol., xxiv., 3; Brit. Med. Jour., Feb. 8, 1896.

⁴ Deutsch. med. Woch., Feb. 4, 1897.

⁵ Med. Rec., Apr. 3, 1897.

spot in aseptic surgery has been in obtaining sterilization of the hands of the surgeon and the skin of the patient. Geppert proved a number of years ago that the hands could not be thoroughly disinfected by corrosive sublimate solutions, and Abbott in 1891 confirmed the views of Geppert. Kocher proved over 15 years ago that carbolic acid was unreliable. Fürbringer advised the employment of alcohol in addition to the mercurial solution. Weir has found that even this plan does not invariably sterilize. He agrees with Reinecke that Kelley's method is not always reliable (washing in a saturated solution of potassium permanganate, then in a saturated solution of oxalic acid, then in sterile water). Weir now employs with great satisfaction chlorin, obtained by a plan which was suggested to him by Wm. Rauschenberger, apothecary of the New York Hospital—that is, mixing in the hands chlorinated lime and washing-soda and adding a little water. Chlorin is evolved when this mixture is rubbed over the hands. It helps to remove a portion of the epiderm and also saponifies fat.

The plan in full is as follows: thoroughly scrub the hands in running hot water with a brush and green soap, cleansing under and around the nails with a piece of soft wool. Something less than a tablespoonful of the lime material is passed into the palm, a piece of washing-soda is placed upon the chlorinated lime, enough water is added to make a cream-like mixture, and this material is rubbed into the hands and arms until the rough granules of soda can be no longer detected and until the material forms a thick paste (will need from 3 to 5 minutes). The next step is to rub the paste under the nails and around their edges by means of a piece of sterile cotton. The hands are now cleaned in sterile water. [We have used this method with entire satisfaction in numerous cases, and we are persuaded of its value. It leaves the hands smooth and soft, and beyond a temporary sensation of heat occasionally felt during its application produces no trouble or annoyance which is at all persistent. We have used it in a clinic 3 times within 2 hours without causing dermatitis.]

L. A. Stimson writes to the *Medical Record* (Apr. 10, 1897) in criticism of R. Weir's statement about the introduction of the method into the New York Hospital. Stimson says that Mr. Rauschenberger suggested the method to him and that he used it as long ago as 1893. Its use by Stimson and Hartley in the Hudson Street Hospital was alluded to in the *Ann. of Surg.* for May, 1896.]

The value of **nosophen** and its salts has been a subject of some discussion during the year. Nosophen is obtained by adding iodine to a solution of phenolphthalein. It is a powder, light yellow in color, and free from odor, insoluble in water but freely soluble in an alkaline solution. The technical name of this drug is tetra-iodo-phenol-phthalein. Antinosin is the sodium salt of nosophen and eudoxin is the bismuth salt. A. L. Rix¹ has reported a cure of lupus brought about by nosophen. H. H. Duke² looks upon it as a true substitute for iodoform. Howard Lillianthal³ has reported a case of tuberculous skin disease cured by this drug. Among other interesting articles upon this drug we would mention those of Müller,⁴ Sprecher,⁵ and Robin.⁶ [We have tried this agent extensively and find it very useful. It is free from the odor of iodoform, is not toxic, is not irritant, and does not form cakes like aristol. We agree with Sands that it does not cause dermatitis around the wound. It prevents putrefaction, favors granulation, tends to arrest bleeding,

and has analgesic properties. Nosophen is not efficient when applied to a sloughing or suppurating wound unless the dead materials are first washed away; to be efficient it must come into contact with living tissue. In the treatment of chaneroids it has not proved as satisfactory as iodoform. We have never used nosophen-gauze and have had no experience with antinosin and eudoxin.]

For a consideration of Schleich's formalin-gelatin in wound-treatment, see Wounds, p. 441.

SUPPURATION, GANGRENE, ETC.

Hentschel¹ contributes a study of **pyemia and sepsis**. He classifies the various conditions under the heads of pyemia, septicemia, sapremia, and sepsis. He says that pyemia is exclusively produced by the microorganisms of suppuration. Septicemia is an extremely rare condition in man, and in it the organisms multiply in the blood. Sepsis and sapremia are conditions of intoxication due to the absorption of toxins from local areas of infection. He quotes one case of pyemia in which the diplococcus lanceolatus was found and another case due to the staphylococcus citreus. He quotes as a typical case of sepsis an instance in which toxic absorption took place from a gangrenous focus. In a case of compound fracture of the leg followed by sepsis the blood was found absolutely free from microorganisms. In another case due to another cause the sepsis was produced by a focus of ischiorectal suppuration. There were no bacteria found in the blood.

E. Blondel² considers the question of **stitch-abscesses** and how to prevent them. He has returned to the ancient idea which commended the use of alcohol in wounds. He uses as few stitches as possible, and just before tying them wets them and also the wound-edges with alcohol of the strength of 90% and sponges out the wound itself with alcohol. After the suturing is complete the line of suture is covered with iodoform. He says that alcohol causes dryness, removes the grease, coagulates the serum, and promotes cicatrization. [It will be remembered that Le Dran occasionally washed wounds with brandy and that Baron Larrey believed that alcohol improved the condition of a wound. The practice is old and comes up anew from time to time, and we believe has much to commend it.]

The *Indian Med. Rec.* for Mar., 1897, quotes from the *Brit. Med. Jour.* on the proper treatment of inflammation from vaccination when running to excess. If it is found on the 12th or 14th day that the vaccination pustules are becoming confluent and are surrounded by a spreading inflammatory zone, with involvement of the axillary glands and probably with edema of the arm, the area of trouble should be dusted with iodoform and dressed with a dry pad of sterile gauze. The advance of the process will be completely arrested in 24 hours. The fistule will dry, the redness pass away, the glands diminish in size, and the edema disappear. This method is greatly to be preferred to the use of hot fomentations or moist antiseptic appliances, which are difficult to use upon an infant and involve the healing of an open wound.

Hugenschmidt³ considers the **antiseptic properties of saliva**. He undertook the investigation in order to determine why mouth-operations are rarely followed by infection. He found that ordinary microorganisms grow rapidly in the saliva, but that nevertheless this fluid does have a tendency to

¹ Centralbl. f. Chir., No. 40, 1896.

² Jour. de Méd.; Jour. Am. Med. Assoc., Jan. 30, 1897.

³ Ann. d. l'Inst. Pasteur, Oct., 1896.

keep down infection. It is alkaline and thus prevents fermentation. It washes away considerable portions of food which tend to lodge on the mucous membrane and dilutes that which remains. Hügenschmidt maintains that saliva stimulates the diapedesis of the white blood-corpuscles in the lymphatics. Even normal saliva contains microbial products, and, therefore, because of its attractive power toward microbes favors phagocytic action, the phagocytosis being due to rapid migration of the leukocytes.

Trenite¹ advises the use of **methylen-blue in the treatment of boils and anthrax**. The methylen is injected into the boil. A solution of the strength of 2 : 1000 is made and about 15 minims of this are injected. He maintains that by this method a boil can be cured in 48 hours. This same treatment is advised in anthrax. In true carbuncle Trenite incises the area of necrosis and removes sloughing material and after this makes the injection. When an injection has been given the wound is packed with iodoform-gauze which has been soaked in a hot solution of common salt.

W. W. Russell² calls attention to the possibility of a mistake being made in the diagnosis between **malarial and surgical fever**. In view of the fact that the diagnosis of malaria can be certainly made by the discovery of the hematozoa, in every doubtful case the blood should be examined. He cites a case in which through neglect of this precaution the patient was subjected to an oöphorectomy when nothing was wrong but malaria. The author cites several other cases of mistake to prove his contention. [More often sepsis is mistaken for malaria than malaria for sepsis.]

Jurinky³ presents a report of 3 cases from Wölfler's clinic in Prague, which exhibit the curative effect of **potassium iodid in actinomycosis**. In 2 cases the head and neck were the seat of disease. Abscesses were incised and from 15 to 30 gr. doses given. Both were cured. In a case of actinomycosis of the appendix the abscess was incised and the iodid was given for several months. The case was cured, but subsequently a small abscess appeared in the scar. It is not known how the drug acts, but it very rapidly stops the pain, and its administration should be continued for some time after all fistulæ have closed. Colvin B. M. Smith⁴ records a case of actinomycosis of the cheek which was cured in 2 months by the administration of potassium iodid. Smith recalls the fact that 3 cases were recently successfully treated in the Bristol Royal Infirmary by the same method. He says that in his cases the cure was either spontaneous or resulted from the exhibition of the iodid. It is very improbable that the cure was spontaneous, because it took place coincidentally with the exhibition of the iodid after months of no improvement. The patient refused to permit surgical treatment. Herbert B. McIntire,⁵ of Cambridge, Mass., records a case of actinomycosis of the chest-wall and lung in which infection was by the bronchial tubes and in which the iodid failed to cure. Parker Syms,⁶ of New York, records a case of intraabdominal actinomycosis in which there were discharging fistulæ surrounded by indurated masses. A large swelling over the groin was opened and scraped out, but the woman refused any thorough operative treatment. She was placed under the charge of Dr. Van Arsdale, who administered potassium iodid, and has somewhat improved, but the writer does not think that this case tends to show that iodid has any curative effect.

⁶ Ann. of Surg., Feb., 1897.

H. Vincent¹ has made a study of the etiology and lesions of **hospital gangrene**. He describes a bacillus which he has found on the false membrane of the surface of the ulcers. He has found this bacillus in every case, and considers it to be the cause of the disease. In some cases it is the only bacillus found, but it is present in greater numbers even when pus cocci and spirilli also exist. He gives a careful description of this bacillus and its properties. An examination of tissue which is attacked by the gangrene exhibits two zones: the superficial, consisting of a false membrane, and a deeper zone, formed of necrotic tissue infiltrated with blood and altered by the action of the organisms. In the neighborhood of the abiding-place of the microbes embryonic tissue exists as a barrier against systemic invasion. The organism is not met with in the blood, and the writer has failed in his attempts to cultivate it on artificial media. From the fact that inoculations in the lower animals have not produced the disease he is inclined to think that the gangrene is limited to the human species. He inoculated several healthy rabbits without any result, and this leads him to infer that many factors are necessary to permit the bacilli to live and multiply. When animals which were the victims of tuberculosis were inoculated with the false membrane they developed typical cases of the disease. [The failure to inoculate animals may mean, as the author suggests, that these animals are not subject to the disease, and may also mean that his bacillus is not really the cause of hospital gangrene.]

Ernest A. T. Steele² records a case of acute **spreading gangrene treated with antistreptococcic serum**. The patient was a child $1\frac{1}{2}$ years of age; 3 weeks before admission to the hospital she had been burned on the calf of the left leg with a red-hot poker. The wound did not heal; 16 days after this injury she was sick and fretful, and the mother discovered a red spot on the center of the forehead and a small abscess on the lower lip. By the next day the spot had increased to the size of a shilling and had become black in the center. The child was feverish, and there was offensive discharge from the left nostril. She was admitted to the hospital 20 days after the accident to the leg and 4 days after the appearance of the red spot on the forehead. On admission there was a gangrenous spot on the forehead the size of a five-shilling piece; around the edges of this area the skin was inflamed and undermined. The tissues crepitated from the presence of gas; the general condition was excessively bad. The pulse was 120, the temperature 101.8° , and she had had a shivering attack before admission. Furthermore, she was drowsy and irritable. The edge of the left lower eyelid was covered with sloughing granulations and there was an offensive seropurulent discharge from both nostrils. On the left leg was an ulcer $1\frac{1}{2}$ in. long and 1 in. broad, which was covered with gray sloughs and showed here and there depressions where the ulcerations had passed into the deeper structures. The child was anesthetized, the edges of the gangrenous area on the forehead were clipped away, and all unhealthy tissue was removed. The part was mopped with nitric acid and the ulcers on the lip and leg were scraped with Volkmann's spoon and cauterized with the acid. The child became temporarily better, but six days afterward it was again necessary to repeat this scraping process. The child was extremely ill and in grave danger. It was decided to administer the antistreptococcic serum. An injection of 5 c.c. was given, and brandy and strychnin were administered internally; no other local treatment was admitted. The next day the morning temperature was 100.8° . There was a marked change in the appearance of the wounds and ulcers. The gangrene had ceased to spread and the phage-

¹ Ann. de l'Inst. Pasteur, Sept. 25, 1896.

² Brit. Med. Jour., Dec. 19, 1896.

denic process in the ulcers had stopped. In the evening the temperature rose to 103.2°, and another injection of 5 c.c. was given. From this date the child steadily improved, although 5 days later suppuration took place in the right elbow-joint which required incision and drainage. Complete recovery ensued.

Obalinski¹ discusses the operative treatment of **suppuration of the posterior mediastinum**, and reports 5 cases. He practises rib-resection near the articulation with the spine. He separates the costal pleura from the ribs and from the thoracic vertebra, thus permitting him to gain ready access to the posterior mediastinum. In 2 cases the pleura was torn, and traumatic pneumothorax arose. The wound was at once packed with gauze; no infection took place, and the pneumothorax passed away in 2 days. The author advocates this method of procedure when a cervical abscess passes down into the mediastinum, when an abscess takes origin near the spine, when it has caused a fistula in the thoracic region, or when it has followed perforation of the wall of the esophagus.

Samuel Broke² reports a case of **blood-poisoning treated by anti-streptococcic serum**. The patient had a whitlow of the thumb which resulted in widespread suppurative cellulitis of the forearm. Free incisions were made. Several days after the incision antistreptococcic serum was administered. Up to the time the serum was used the swelling was rapidly extending, but a notable decrease took place in the swelling as soon as the serum was employed. The author says it is "difficult to decide" if this improvement was produced by the serum or the incisions. It became necessary in this case to amputate the arm because of threatened gangrene. The patient died 10 days after operation. A. H. Cook and A. R. Cook³ report 2 cases of blood-poisoning in which antistreptococcic serum was used. One patient suffered from suppurative cellulitis of leg following upon a lacerated wound, the other patient had infection following a punctured wound of the thumb. In case 1 the injections seemed to be followed by great benefit. In case 2 the value of the serum was doubtful.

T. J. Bokenham⁴ writes upon the orrthotherapy of blood-poisoning, and makes a plea for exactitude in the use of antistreptococcic serum. He reports a case of erysipelas of head, which was treated by Alfred R. Friel, and which rapidly recovered under serum-treatment. Serum from one of the bullæ showed a pure culture of streptococci. Then follows a report of 2 cases treated by Mr. Stephen Paget. The first case was lymphangitis due to inoculation from a case of septic peritonitis. This case was promptly cured by the use of the serum, which agent prevented the headache and great depression which we expect to accompany septic infection. The second case labored under lymphangitis from mixed infection, and the patient died in spite of the use of serum. Blood examination made during life proved that mixed infection existed, and the prognosis in mixed infection is always worse than in pure streptococcus infection. The author concludes that this death from mixed infection does not indicate that the serum is useless.

In a case of infection by staphylococci serum injections had been given without result. Bokenham examined the exudate, found that staphylococci only were present, and advised the surgeons in charge that serum-treatment would probably prove useless.

The author holds that the serum is harmless, that laboratory experiments offer much presumptive evidence that the material is valuable, and that its

¹ Wien. klin. Woch., Dec. 10, 1896.

² Brit. Med. Jour., Feb. 27, 1897.

³ Ibid., Oct. 31, 1896.

⁴ Ibid., May 22, 1897.

use does not debar us from employing at the same time other methods of treatment. The serum is obtained from horses, which are immune or very resistant to streptococci, the animals having been rendered resistant by repeated injections of streptococci, or of the germ-free filtered culture-medium in which streptococci have grown, or by a combination of these materials. Bacterial examination should be made to confirm a clinical diagnosis of septic infection.

[The value of antistreptococcic serum is still in doubt. It is an agent which does not appear to act by simply antagonizing toxins, but acts by killing streptococci, and dead streptococci may be virulently poisonous. As Primrose, of Canada, puts it, "We know that there are bacteria which, when killed off, are capable of producing more virulent toxins in their death than during their life." It does not seem proper to say that this agent is absolutely harmless. It may kill large numbers of cocci, and by liberating large amounts of poison may do great harm.]

CYSTS AND TUMORS.

W. Joseph Hearn¹ reports a case of **congenital multilocular cyst of the omentum** in the male. Hearn reviews the literature and tells us that these cases are extremely rare. The patient was 8 years of age. The family physician observed the distended abdomen when the child was born. At the age of 6 weeks the distention had decidedly lessened and remained stationary for the next 6 years. When 6 years of age the abdomen began to increase in size. Aspiration was twice employed, a small amount of brown fluid being drawn off each time. On admission to hospital the abdomen was found greatly distended: greatest circumference was 44 in. The distance between the sternal notch and the pubes was 25 in. Weight was 93½ pounds. There were practically no symptoms except a frequency of micturition and a sense of weight. The abdomen was opened, the cyst incised, and the several compartments drawn out of the wound as they were emptied. The entire cyst was finally delivered, and the point of origin was found to be in the folds of the great omentum, below the margin of the transverse colon. The patient made an excellent recovery, and two weeks after the operation weighed 49 pounds. The weight of the cyst with its contents must have been almost 50 pounds.

Dr. Jacob Frank² writes upon **hydatids of the liver**. After considering the etiology and pathology, he discusses the diagnosis and reports 2 cases. The first was that of a woman of 32, born in Russia. The diagnosis made in her case was cyst of the gall-bladder due to obstruction of the common duct. Operation disclosed a hydatid cyst of the liver. The cyst was incised, and as the wall became relaxed it was pulled out and emptied. The peritoneum was sewed about the cyst-wall by a continuous suture, 2 in. of sac were removed, and a drainage-tube and packing were introduced. The patient made a good recovery. The second patient was a man of 28, born in Germany. The diagnosis was biliary calculus. Operation disclosed a hydatid cyst. The peritoneum was stitched around the border of the mass, thus forming a circular surface about the size of a silver dollar closed off from the abdominal cavity; the aspirator drew off the typical fluid. Gauze was packed over the puncture, the wound dressed, and 4 days later the cyst was incised. The cavity was irrigated with sterile water, the inner surface was curetted, a drainage-tube was introduced, and the wound was dressed. This patient also made a good recovery.

¹ Ann. of Surg., June, 1897.

² Am. Jour. Med. Sci., Oct., 1896.

Dr. Frank offers the following conclusions in regard to the treatment of hydatids of the liver: an incision over the most prominent part of the mass should be made, if a mass can be detected; but if no tumor is obvious, the guide to incision is the area of hardening and of dulness on percussion. The surgeon should always examine for adhesions, and, if adhesions do not exist, he should produce them by suturing the peritoneum around the mass, thus shutting off the abdominal cavity. The aspirator is used to prove the diagnosis, always bearing in mind the possibility that typical fluid will not appear, as it may be too thick to enter the needle. When it has been found necessary to produce adhesions artificially the surgeon waits for several days before opening the cyst. The opening made in the cyst-wall should be of sufficient size to admit a large-sized drainage-tube. The dressing must be conducted with the strictest antiseptic care. For the first week after operation the cyst-cavity should be washed out with sterile water, after this with carbolic solution, iodin solution, or any of the antiseptic solutions. Frank says in cases in which no adhesions exist it is possible to perform an operation with success in one sitting if great care be employed; but it is wiser to sew the peritoneum to produce adhesions, and when the adhesions become firm to open the cyst. [It will be observed in a later article that all surgeons do not agree with Frank as to the advisability of suturing the peritoneum to the cyst-wall, at least before the cyst is partially emptied. John O'Connor,¹ of Buenos Ayres, speaks of such a proceeding as "dangerous and useless," and says that the cyst-wall is so thin and tense that sutures will enter the cyst-cavity unless the cyst is previously partially emptied. If needles do enter the cyst-cavity, hydatid fluid will squirt from the punctures and may enter the peritoneal cavity and thus cause the formation of new cysts or the onset of hydatid toxemia. O'Connor surrounds the cyst with sponges, empties the cyst through a cannula, and when the tension is lessened seizes the cyst and draws it to the surface, enlarges the opening in the cyst-wall, removes the sponges, and then sutures the cyst to the parietal wound, suturing to the peritoneum only at the upper and lower angles of the wound.]

E. S. Jackson,² of Queensland, furnishes the notes of a case of hydatid cyst of the liver presenting several unusual features. One peculiarity about this cyst was that no endocyst was discovered at the operation or subsequent to the operation. The small cysts numbered many hundreds. No hooklets were discovered in the fluid and there were no daughter-cysts. Since the operation it has been necessary many times to tap cysts which have become prominent; none of the cysts tapped have been larger than a hen's egg. The case is published in the hope that someone may have seen something similar, and almost with the suspicion that the diagnosis was incorrect. It is possible that it was a form of hydatid or some hitherto undescribed parasite.

John O'Connor,³ of Buenos Ayres, furnishes a valuable clinical contribution to the surgery of the liver, and in this paper reports 9 interesting cases of hydatid cyst. One case was a hydatid of the liver in a schoolboy of 10. This case recovered. O'Connor, in commenting upon this case, calls attention to what he designates the dangerous and useless practice of introducing sutures through parietes and cyst-wall before the cyst is at least partially emptied. The cyst-walls are so tense and thin that it is impossible to pass sutures without invading the cyst-cavity. He tried to do it in this case, but from each needle-puncture there was a flow of fluid. Some of this fluid entered the peritoneal cavity, but fortunately no ill result followed. In cases in which

¹ Ann. of Surg., May, 1897.

² Intercol. Med. Jour. Austral., Sept. 20, 1896.

³ Ann. of Surg., May, 1897.

hydatid toxemia follows the operation the condition is due to the escape of hydatid fluid into the peritoneal cavity, from which point the poison enters into the system. Such cysts should always be emptied through a medium-sized trocar and cannula, the peritoneal cavity being walled off with sponges. The tension is thus relieved, and the cyst can be grasped with hooks and drawn to the abdominal incision. The trocar-opening is then enlarged, the sponges removed, and the cyst sutured to the abdominal wound. In this last step the peritoneum at the upper and lower ends of the wound is sutured to the cyst, but throughout the rest of the wound the cyst is sutured to the fibrous surface of the incision. The next case was a hydatid tumor of the liver in a patient of 25, in which a transthoracic operation was performed and the patient recovered. An aspirator-needle was introduced into the 4th intercostal space anterior to the axillary line and a few drops of clear liquid were drawn off. A portion of the 4th rib was resected, the costal pleura was opened, and a large cyst was felt beneath the diaphragm. An incision was made through the diaphragm and diaphragmatic pleura, a trocar was inserted into the cyst, and after the cyst had relaxed a portion of it was pulled through the diaphragm and sewed to the wound in the chest-wall. There was no endocyst that appeared. The cavity was irrigated with Condy's fluid, and a large drainage-tube was inserted. Seven weeks after operation during irrigation the endocyst appeared and was removed with forceps. The patient made a good recovery. O'Connor comments on this case, and says that it taught him the valuable fact that if an endocyst is not removed at the time of operation profuse and prolonged suppuration will inevitably occur. Now he always continues the primary irrigation until the endocyst is evacuated. The next case was a hydatid tumor of the liver operated upon by abdominal section. This patient recovered after profuse suppuration and prolonged urticaria from hydatid toxic poisoning. He performed Bond's operation upon this case. That is, after opening the cyst the hand was introduced, the endocyst was removed, the cavity was irrigated with corrosive sublimate solution, the interior of the cyst was dried with sponges and dusted with iodoform-gauze, the opening in the cyst was closed with a continuous silk suture, the mass was returned within the peritoneal cavity, and the external wound was closed. He says that he will never repeat Bond's operation. He considers marsupialization a thoroughly safe procedure, but does not think Bond's operation is safe. He believes that in the ordinary operation very large abdominal incisions should be made, in order to expose the cyst thoroughly and permit of removal of a large portion of the cyst-wall and suture of the remainder of the cyst in folds to the wound. The next case was a hydatid tumor of the liver occurring in a woman of 51 years. The abdomen was opened, the peritoneal cavity was blocked off with sponges, the trocar and cannula were inserted into the liver, and the cyst was struck at a depth of 1 in. Some clear fluid escaped. The trocar was at once reinserted in the cannula in order to prevent collapse of the cyst-wall. A blunt bistoury was passed along the trocar, and an incision $\frac{1}{2}$ in. long was made through the liver-tissue. Violent hemorrhage occurred which was arrested by pressure. A pair of forceps were inserted and opened, when a furious hemorrhage took place. Pressure failed to arrest it, and it was found necessary to insert sutures deep in the liver-substance and apply pressure in association with it. Unfortunately the sutures cut out, and the only hope was to remove the cyst-wall at once. The cyst was at once opened. O'Connor grasped the edges with forceps, and forward traction controlled the hemorrhage. He introduced silk sutures through the parietal wall and no more bleeding occurred. The patient died the next day but one after the

operation. He considers that in this case he made some vital mistakes. The first was the introduction of a knife to cut through the healthy liver-substance. Even after he had done this he might have saved the patient had he emptied the cyst through a cannula and closed the external wound. The most lamentable error was the attempt to make an opening into the liver by the use of the forceps. This was a procedure which rendered it impossible for him to retrace his steps, and as the hemorrhage had to be arrested his finger was the only instrument left him with which to reach the cyst. He states that he read¹ with interest a case of **transthoracic hepatotomy**, in which the surgeons strongly advised what they called the *simple method* of pushing a knife into the cyst alongside the trocar, and following this up with a dressing-forceps to dilate the opening. After his experience he is not certain whether to envy or pity the surgeon who has the courage to advance such an opinion. O'Connor says that if in future he should encounter an inch of healthy liver over the hydatid cyst he will do the operation in two stages. In order that sponge-pressure may be successful in arresting hemorrhage it is necessary to have a firm basis of support; but a torn liver recedes and affords no basis of support, and sutures are unreliable for they tear out. If firm pressure is to be made, the only hope is to have firm adhesion with the parietal wound, and then if hemorrhage does occur we have something solid to press against. The first stage of the operation is to obtain adhesion between the parietal and visceral peritoneum. In the second stage the trocar should be introduced as a guide, but the cautery should be employed to open the cyst.

He reports another case in which suppuration occurred in a hydatid cyst of the liver, and abdominal section was performed by the usual method. The patient made a good recovery. This is the only case of primary suppurating hydatid cyst that he has ever met with, and it is an interesting fact that although the endocyst was gangrenous no constitutional symptoms accompanied the suppuration.

He reports another case of collapsed hydatid cyst of the liver in which abdominal section was performed. This patient had a series of symptoms which suggested congestion of the liver. The physicians had inserted an aspirating-needle a month previously because they suspected hydatids. O'Connor's diagnosis was suppuration in a hydatid following puncture. On opening the abdomen a collapsed cyst was found. It was drawn to the surface, and the collapsed endocyst and a bucketful of fluid were removed. There was no suppuration and no peritonitis. The patient recovered in 67 days. The fever which had followed the tapping a month before was due to hydatid toxic poisoning. He reports another case in which there was a hydatid tumor of the liver treated by transthoracic hepatotomy. The patient recovered. In another case a patient with a hydatid of the liver recovered after a celiotomy. O'Connor states that never in his experience has he been able to detect hydatid fremitus.

J. Bland Sutton² writes on **myelomata or myeloid sarcomata**. He has come to the conclusion that it is an error to include myeloid tumors in the genus sarcoma. He holds they should rank as a separate genus under the term myelomata, because red marrow is as distinct a tissue as fat, myomatous, or fibrous tissue. Myelomata arise in the red marrow in the cancellous portions of bones, and the tissue composing them is histologically identical with the red marrow of young bone. When a tumor is cut fresh its surface looks like a piece of fresh liver. The microscope shows us that such growths abound in giant cells imbedded among round and spindle cells, the greater

¹ Lancet, Sept. 12, 1896.

² Edinb. Med. Jour., Feb., 1897.

mass of the tumor being composed of giant cells. Such tumors are especially apt to appear in certain bones, notably the tibia and the radius. They are most common in the upper part of the tibia and in the lower end of the radius. Myelomata prefer the head of the fibula rather than the part below, and the lower end of the ulna rather than the part above. Some cases have been reported as occurring in the clavicle, the sternal end being the favorite seat. In the humerus the head of the bone is the usual site, but in the femur the condyloid end is the area most prone to invasion. The patella is a very rare situation for myeloid tumors. As regards the bones of the head, myelomata are peculiar to the jaws. The clinical features are tolerably characteristic. The patients are rarely over 25. The tumor grows slowly and expands the bone equally. As the bony tissue expands it thins until the shell becomes so attenuated that it crepitates under pressure. Here and there the tissue perforates the bony shell, and at the points of perforation there is marked pulsation. Myelomata do not disseminate and do not infect the lymph-glands. If a patient comes under the surgeon's care before the osseous capsule has been perforated, the growth may be extirpated without fear of return. The manner of extirpation varies with the situation of the tumor. Enucleation should not be attempted in the tibia, and in the femur amputation should be performed at some distance above the growth. In the upper limb the lower end of the radius and of the ulna and the upper end of the radius have been excised, with the result that cure has been obtained with the retention of a useful hand. Excision has been practised upon the head of the humerus, the sternal end of the clavicle, and the acromial end of the clavicle, with cure as the result. In the upper jaw the premaxillæ have been removed, this operation sparing the removal of both maxillæ. If the patient does not consult the surgeon until a tumor of the maxilla has fungated, the soft parts will be so invaded that even complete extirpation offers a very slender chance of permanent cure. These tumors are rare, and differ histologically, pathologically, and clinically from the sarcomata.

Dr. Denissenko¹ discovered the fact that **warts** could be **cured by application of the juice of chelidonium majus**. He was led to employ this remedy in the treatment of epithelioma, and he claims that it is of extreme value. He uses it externally and gives it internally to the amount of even 75 gr. a day in an aqueous solution. Locally it is used by hypodermic injection into and about the tumor. The solution employed consists of the extract of chelidonium, glycerin, and distilled water. Denissenko claims that the cancerous cachexia rapidly abates under the influence of this agent and that the tumor greatly diminishes and tends to separate from the sound tissues.

Herbert Snow² speaks anew of the value of **opium and cocain in the treatment of cancer**. He tells us that these two drugs possess in a notable degree the power of inhibiting tissue-metabolism—that is to say, that they powerfully sustain the bodily powers. He has long been in the habit of giving opium in cancer with the most beneficial results. Cancer of the female breast produces sooner or later and in every case deposit in the bone-marrow, and this deposit eventually infects the blood-stream. When operations are done, and even when bone-marrow infection exists, we may, by the use of opium, retard recurrence for a long period of time, the patient being apparently in perfect health. For the past three years Snow has been in the habit of combining cocain with the opium. Cocain is of value in sustaining vitality, and its anesthetic powers contribute greatly to the comfort of the indi-

¹ Deutsch. med. Zeit., Sept. 24, 1896.

² Brit. Med. Jour., Sept. 19, 1896.

vidual, especially of one who labors under cancer of the tongue or mouth. In gastric and intestinal cancer this drug is of great value because of its property of preventing vomiting. When Snow has operated on a case in which he anticipates recurrence he places the patient on an opium regimen as soon as convalescence is attained. In this article he reports a number of typical cases to exhibit the great value of these drugs. He tells us that under the opium treatment alone a woman who had been operated on in June, 1877, for advanced mammary cancer with marrow-deposit had no recurrence until December, 1893. One patient remained entirely free from January, 1881, to February, 1885, and 3 from July, 1886, to June, 1893; 3 cases of breast scirrhus operated on in 1891, 2 in 1892, and 2 in 1893, with well-marked marrow-infection, as yet show no evidence of recurrence. A man was admitted in April with a tumor in the abdomen, enlarged liver, extreme emaciation, and a history of persistent vomiting for six months. He evidently labored under cancer of the pylorus. He was placed under cocaine and opium, and since beginning this régime has not vomited at all and has gained much in strength and comfort. Other cases equally striking are cited by this author.

J. Collins Warren,¹ of Harvard, presents the results of **operations for the cure of cancer of the breast.** He tells us that the old idea was that this condition was incurable, and this idea was true under the circumstances then existing, and the fact that the condition was incurable was due to inadequate operation. Sir James Paget stated that he was not aware of a single instance of recovery. This opinion, however, has been entirely overthrown, although a number of surgeons are still unconvinced. About 15 years ago Volkmann called attention to the necessity of clearing out the axilla. Heidenhain also asserted that it was necessary to remove the fascia of the great pectoral muscle. Mitchell Banks and the younger Gross were among the pioneers in advocating a more radical breast-operation. Halsted's recent work gives convincing evidence of the advantage of removing the pectoral muscles and clearing out the infraclavicular and supraclavicular regions. A frequent source of recurrence is the flaps of skin which are left, and a wide sweep should always be made around this organ in order to remove any infected area. The point to aim at is, not to obtain union by first intention, but rather to remove all of the disease. A clean dissection of the axilla is entirely effectual against a return of the disease in that locality. Warren then discusses certain important points about the anatomy of this region which bear upon the operation necessary to be performed. The operation which he performs now has been developed from the so-called completed operation. By the term completed operation was meant the removal of the mammary gland with a considerable amount of integument and the free dissection of the axilla, the gland and paramammary tissue and integument being removed sufficiently extensively to include the superficial lymphatic vessels which spring from the various breast quadrants and run toward the margin of the pectoralis major muscle. The operation comprises in all cases the removal of the sternal portion of the pectoralis major muscle, division of the pectoralis minor muscle, and occasionally removal of this muscle; dissection of the axilla and the infraclavicular space, and exploration in many cases of the supraclavicular region.

Warren then describes his operation in detail. In 92 consecutive cases in which this operation was performed there were but 2 deaths, 1 from erysipelas and 1 from Bright's disease. The death from erysipelas occurred many years ago. This shows a mortality of but little over 2%. The com-

¹ Boston M. and S. Jour., Nov. 2, 1896.

pleted operation is absolutely essential, as proved by the fact that in only 3 of these cases was it shown by the microscope that the lymphatic glands were not infected. The tables Warren publishes include only the cases in which it was possible to obtain a subsequent history. Taking 3 years as the period which it is considered generally necessary to elapse to pronounce the case as cured, and with 42 cases whose subsequent history he knows, 11 of them are living and well, or 26%. These 42 cases include the 2 fatal cases. If we do not calculate with them included, we have 40 cases with 11 cures, or 27%. There are 15 without recurrence at the end of 2 years. In a series of 28 consecutive cases in his practice there are 14 alive at the present time. Billroth asserts that a patient who has lived one year after operation and shows no sign of recurrence when examined by a competent surgeon may be pronounced cured. In very many cases in which recurrence is said to have occurred at a later date the truth of the matter is that the nodule existed at the time of operation but was not removed. In 33 cases in which the date of recurrence was noted it was found that the disease appeared on an average in 14 months after the operation. The average duration of life in 28 cases in which death was due to recurrence was 32 months. In only 2 of these cases did the disease arise from a benign tumor. There were 2 cases of cancer of the axillary border, a term which Warren has applied to a growth which begins as a nodule of the skin at the point mentioned, and remains localized for a considerable time, but eventually involves all the axilla and breast. Warren then presents his case-records in detail. [Warren insists that, as renewed growth is often encountered in the flaps of skin which are allowed to remain, a large area of skin should be removed. Halsted believes this and removes a very large piece of skin and closes the gap with Thiersch grafts. The younger Gross invariably removed all of the skin over the breast, leaving a considerable gap to heal by granulation. Tansini has recently written upon the necessity of removing considerable skin, and he advises the removal of all the skin covering the breast and also a strip of skin about 4 in. wide from the breast into the axilla, and the partial closure of the gap by dissecting a flap from the back and sliding it forward into the wound. It seems to us that the skin is a dangerous tissue to leave, but that the subcutaneous tissues are much more dangerous. It is necessary to remove a large area of subcutaneous tissue, and with this the skin can be taken, or only a portion of the skin is removed.]

Herbert Snow¹ discusses the insidious **marrow-infection of mammary carcinoma**. He tells us that secondary deposit in the bone-marrow was definitely present in considerable amounts in 80% of the cases of mammary cancer which died. It is very doubtful if the remaining 20% were free from infection of marrow to the end. Out of 150 patients seen in the Out-Patient Service who had cancer of the breast averaging in duration from 10 to 12 months, 90 on their first visit showed well-marked evidences of this condition, 22 showed slighter evidences, and 8 developed them subsequently; total, 120 or 80%. As a rule, when a scirrhous cancer exists in the breast of a woman the lymph-glands of the corresponding axilla are infected in from 6 to 12 weeks. The cancer-cells block up the lymph-channel and the lymph-current regurgitates and passes in abnormal directions. The axillary glands receive lymph from the area of the tumors and from the head of the humerus. When these glands become cancerous the lymph containing cancer-cells regurgitates into the marrow of the humerus. The humerus is, as a rule, the first bone infected. From the edge of the mammary gland some lymphatics pene-

¹ Lancet, Jan. 9, 1897.

trate the thoracic wall and carry the lymph to the mediastinal lymph-glands and the thymus gland. The cells which enter into the thymus gland proliferate and directly invade the sternum. After bone-invasion has existed for a considerable length of time fragments of cell-protoplasm pass from the marrow into the circulation, and thus enter into the opposite breast, other bones, or the viscera. The physical signs of marrow-infection are often not positively evident until the disease has existed 18 months, and they may even be delayed until a much later period. The upper $\frac{1}{3}$ of the humerus becomes tender on pressure and the bone feels thicker than its companion of the opposite side. The sternum gradually bulges forward at the junction of the upper and middle portions and the lump is painless. There are very frequently pains in the loins and the scapula which are mistaken for rheumatism. These pains are on the same side as the lesion. Unlike rheumatism they do not affect the articulations. The sternal prominence might be simulated by a natural conformation of the part. It is only when sternal prominence is associated with the gnawing lumbar and scapular pains, and especially when a gradual development has taken place under observation, that entire reliance can be placed upon it as absolute evidence of infection. When infection of the bone-marrow occurs white marrow is formed—a firm material as white as note-paper. When in making a postmortem we find this firm white marrow we can be assured there is cancerous infection even if a microscopic examination is not made.

Snow then records 5 typical cases to illustrate his views, and states that only 5 or 6 times has he seen the sternal protrusion advance to actual tumor-formation with subsequent ulceration. He tells us in conclusion that deposits in the bone-marrow are peculiarly chronic and latent. They may grow unnoticed for 4 or 5 years or even more. They cause hardly any appreciable impairment of health until general blood-diffusion takes place. The marrow is rarely examined at an autopsy unless some palpable bone-lesion exists, and these investigations invite closer attention to it. Many cases which are regarded as osteomyelitis and osteitis deformans have been reported as associated with malignant growths somewhere in the osseous system, and it seems likely that more will eventually pass into the same classification. As a routine symptom marrow-infection for mechanic and anatomic reasons is shown only by cancer of the female breast, but it may follow any form of malignant growth which directly implicates the marrow, as in primary sarcoma of bone or in rectal cylindroma adherent to the sacrum, but under none of these conditions is it insidious. In view of these observations it is impossible to pronounce a patient cured 3 years after the removal of the breast cancer, even when there has been no recurrence, unless we can confidently pronounce that marrow-deposits are absent.

Herbert Snow¹ reports 300 cases of **breast-excision for malignant disease**. He considers these cases carefully and comes to certain definite conclusions. He concludes that infection of bone-marrow is a great obstacle to radical cure. This, as a general rule, occurs within six months of the beginning of the disease and frequently earlier, although the symptoms of it are rarely detected until the second year. In atrophic scirrhus the condition may be delayed for years. Immunity from recurrence for 3 years affords no basis on which to pronounce the disease cured unless insidious marrow-symptoms are absent or unless we have reason to believe that the disease was extirpated before marrow-infection occurred. The most important point in the excision of the female breast is extensive dissection of the subcutaneous connective tissue around the mammary gland from the sternum to the axilla

¹ Brit. Med. Jour., Oct. 17, 1896.

and from the subclavian fossa to the cartilage of the 7th rib. This tissue is the most dangerous tract in which recurrence is apt to appear. It can always be satisfactorily removed by dissecting off a flap of healthy skin, and after its removal we can bring the edges of the skin together and obtain immediate union. Snow asserts that there is absolutely no advantage in destroying an extensive area of skin, and in every single case that he has operated on he has been persuaded that the utmost benefit that surgery could offer was compatible with union of the greater part of the wound by first intention. If the skin is infiltrated, we may be sure that the bone-marrow is infected, and no amount of skin removal will save the patient. He tells us that a startling novelty, which is to be mentioned with incredulous surprise, is amputation at the shoulder-joint in order to secure a covering-flap from the deltoid. If we encounter instances of scirrhus, or even encephaloid, of but 2 or 3 months' duration, the surgeon should endeavor to eradicate the disease permanently by

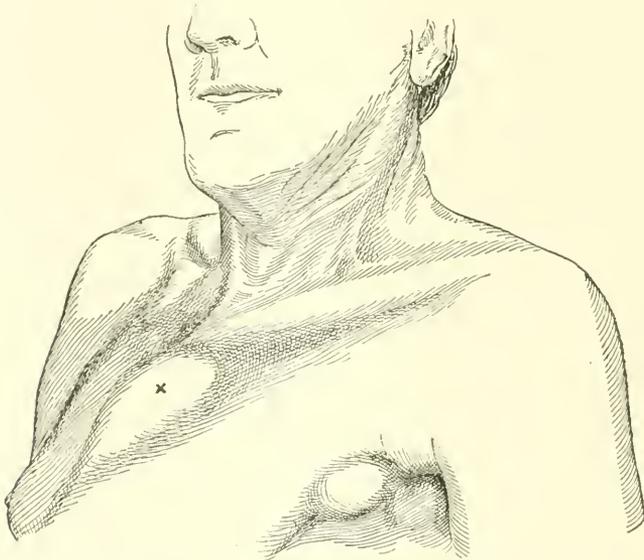

FIG. 5.—The "sternal symptom" of marrow-infection: the characteristic prominence marked X (from photograph by Dr. Johnston English).

removing the mammary gland and a wide area of subcutaneous tissue from around this gland and also the contents of the axilla; but in advanced cases it is futile to risk life by prolonged and heroic measures when we know that there is a deep-seated nidus which we cannot touch. The utmost that we can do in these latter cases is to remove the gross lesions, obtain prompt union of the wound, and by after-treatment with opium and cocain retard the progress of the disease or possibly cause it to remain stationary for years. Partial amputation of the breast for cancer is of course undesirable, excepting for mere purposes of palliation; for even the smallest scirrhus extirpation should be performed. There are 3 exceptions Snow notes to the very just rule that the axillary contents should always be removed. They should not be removed in intracystic cancer-growths, in fairly recent atrophic cases, and in scirrhus appearing close to the sternum, whence the axilla is much more slowly infected than are other regions of the organ, the lymph-current flowing to the thymus and the mediastinal lymph-glands.

George Thomas Beatson,¹ of Glasgow, presents a very remarkable article on **the treatment of inoperable cases of carcinoma of the mamma** and suggests a **new method of treatment**, with illustrative cases. The author says that he has seen a considerable number of cases in which it was obvious that ordinary surgical methods could not be applied with any hope of benefit. In considering these cases he has worked out a plan of treatment which he thinks has not as yet been tried by others. This plan is founded on a conception of the etiology and nature of carcinoma which is radically opposed to the local parasitic theory of the disease. Inoperable cases of cancer may be placed into 2 groups: those which have recurred after an operation has been done, and those in which, although no operation has been done, the disease has advanced too far to permit of thorough removal. He reports 3 cases, one of which illustrates the first group and the other 2 the second. The first case was a woman of 33; the left breast had been removed and the axilla cleared out for cancer, but the growth quickly recurred. It was very evident that the case should be classified as inoperable according to our ordinary conceptions of the limits of operation, and the question had to be decided whether anything at all could be done. Beatson asked himself the question: Can the disease be attacked in any other way than by local removal? He tells us that some 20 years ago he made a study of lactation and gathered a considerable amount of practical information from farmers and shepherds. Certain points struck him as of great interest. He discovered that the secretion of milk, though affected by the general nervous system, had no special nervous supply of its own to control it. Division of the sympathetic and of other nerves produced no result whatever on the secretion of milk. It was clear that the changes that occur in the mammary gland during lactation are almost identical up to a certain point with what occurs in the cancerous breast. In both of these conditions the epithelial cells proliferate, occlude the ducts, and fill the acini of the gland; but in lactation these cells become vacuolated, undergo fatty degeneration, and form milk, while in carcinoma they stop short of that process, penetrate the walls of the ducts and acini, and invade the surrounding tissue. He discovered the remarkable fact that in some countries it is the custom to splay the cow after calving if it is the wish to keep up the supply of milk, for when this is done the cow will go on giving milk indefinitely. This fact seemed to point to one organ holding the control over the secretion of another and separate organ. The fact that struck Beatson most strongly was the local proliferation of epithelium in lactation, the very thing most characteristic of cancer of the breast and of cancer everywhere, differing from it only in the fact that it was held in control by another organ and could either be arrested by that organ or be continued to a further stage where the cells became fatty and passed out of the system as milk. After these observations the author frequently asked himself, Is cancer of the breast due to ovarian irritation, as from some defective step in the cycle of ovarian changes? and if it is due to ovarian irritation, Can proliferation be arrested, or can the cells be forced to go on to fatty degeneration by removal of the ovaries? After trying some experiments upon rabbits and considering much upon these points, he felt that the position of matters was that our present state of knowledge has nothing better to offer than the surgeon's knife when the tumor is limited and can be thoroughly removed, but in the inoperable cases it might be that the administration of thyroid extract would improve the case or work a cure. If this failed, the surgeon should endeavor to arrest the progress of the growth by performing oöphorectomy. He placed the

¹ Lancet, July 11, 1896.

patient upon thyroid tablets pushed until physiologic action was manifest, but at the end of a month there was no obvious change in the growth. He then removed the tubes and ovaries. The right ovary was healthy, the left one a little cystic. The patient made a good recovery; no local application was used on the cancer itself. Two weeks after the operation the administration of thyroid tablets was resumed, the idea being that thyroid extract would be useful as a lymphatic stimulant. Five weeks after operation examination of the diseased area showed a marked change for the better. The large mass of tissue was far less vascular; it was smaller, flatter, and less prominent. Seven weeks after the operation the improvement was still more notable, and 4 months after the operation it was more manifest, while 8 months after operation all traces of cancerous disease had disappeared. Beatson showed the patient to the Society, and it was seen that there were a sound cicatrix and healthy tissues. The patient was apparently in excellent health. It should be stated that microscopic examination by a most competent pathologist proved this growth to have been carcinoma.

The next case Beatson records was a woman of 42 who had had a large tumor of the right breast for $5\frac{1}{2}$ years which had not as yet been operated on. It was evident that the case was inoperable. He placed her in the hospital and watched the progress of the case for a month. In this time the patient grew distinctly worse. Beatson decided to remove the tubes and ovaries. Within 10 days after their removal the pain, which had been very severe, had almost entirely disappeared; the neck which had been stiff and painful moved more freely, and the skin became decidedly less vascular. It may be stated that the uterine adnexa were thick, adherent, and altered in both size and situation. After the operation the patient was placed upon thyroid as was the previous case. She left the hospital, but subsequently became worse because she did not take care of her health, and possibly also because she did not take the thyroid tablets. She returned within 2 months of leaving the hospital, was kept in bed and given her medicine regularly. Under these measures improvement again set in. He exhibited this patient not as a case of cure, but as illustrating the fact that definite changes for the better had taken place in the tumor.

The third case was a woman of 49; she had a large sore on the left breast and the mammary gland was almost entirely destroyed, as if it had been removed by operation. The disease had existed for about 7 years. There were no evidences of any secondary deposits. Examination by a pathologist proved that this ulcer was typically cancerous and not tuberculous. He placed the patient on thyroid tablets, pushing them to their full physiologic effect. During the 3 months they have been taken he has not observed any marked effect on the sore. By itself thyroid extract seems to have little effect on cancerous processes. The question in this case is whether, in the light of what has been observed in the other 2 cases, the removal of the tubes and ovaries would be of any service. The benefit would be very problematical in view of the fact that the woman has passed the menopause, but he is not sure that it would not be right, even though the menopause has set in, to try the effect of removing all the uterine appendages.

The conclusion Beatson draws from the 2 cases he has brought under notice is that we must look in the female to the ovaries as the seat of the exciting cause of carcinoma, certainly of carcinoma of the mamma, in all probability of cancer of the female generative organs generally, and possibly the rest of the body. He has long felt that the parasitic theory is unsatisfactory, and that in concentrating all our energies upon it we are simply losing time. He

is satisfied that in the ovary of the female and the testicle of the male we have organs that send out influences more subtle and mysterious than those which come from the nervous system. It may be said that in many cases of cancerous disease there is no change manifest in the ovaries. This statement may arise in the fact that changes have not been looked for, or because the changes are of a delicate nature and require special methods of investigation to detect them, or because the changes are so subtle as to elude detection.

Prof. A. Simpson stated some years ago that removal of both ovaries predisposed to cancer. If this is so, then the theory of the ovarian origin of cancer falls to the ground; but the point that Simpson has overlooked is this: in the cases he refers to the ovaries were removed because they were diseased, and thus these very cases really support the view that cancer in the female is probably due to altered condition of the ovary. If cases can be shown that have had both healthy ovaries removed and have subsequently become the victims of cancer, then the entire theory falls. In recapitulation the author urges the following points: 1. There seems evidence of the ovary and testicle having the control in the human body over local proliferations of epithelium; 2. The removal of the tubes and ovaries has effect on the local proliferation of epithelium which is found in cancer of the breast and aids the tendency which carcinoma naturally possesses to pass into fatty degeneration; 3. This effect is best seen in cases of cancer in young people—the class of cases where removal of the disease by the knife is often very unsatisfactory. [The cases recorded by Beatson are very striking and important. In spite of the fact that Sir Spencer Wells states that he has seen many victims of cancer from which the tubes and ovaries had been previously removed, it seems to be the duty of surgeons to give this novel theory a thorough test. Stanley Boyd, in a recent number of the *Brit. Med. Jour.* (Oct. 2, 1897), reports some cases which seem to confirm the theory that oöphorectomy can cause atrophy of mammary cancer. Boyd suggests that the ovaries may furnish a secretion which in some cases favors the growth of cancer, and that removal of the ovaries in such cases permits the tissues to combat successfully parasitic cells. If a dozen leading surgeons make careful collective investigation, the truth of the matter will be certainly determined.]

Peterson¹ makes a study of the literature of **bacterial treatment of malignant diseases** and of the cases studied in Czerny's clinic, and comes to the conclusion that the treatment is not of the slightest use in cancer; that in very exceptional cases sarcoma disappears under its influence; and that the treatment itself possesses many elements of danger.

Hughes Reid Davies² reports a case of a woman aged 53, who had a hard, clearly defined, and movable mass at the axillary border of the right mammary gland distinct from the gland-tissue. There was an adherent, infiltrated mass in the axilla extending into the muscles. Davies advised operation, but the patient's family refused to permit it. As a consequence of this he decided to employ subcutaneous **injections of Coley's fluid**. The patient presented distinct reactions after these injections, but after they had been continued for about a month she became unconscious and died. The usual Jewish objections were interposed in regard to making a postmortem, but external examination showed there was extreme enlargement of the liver. The result of treatment in this case was manifestly *nil*. In the early stage Davies fancied that the rate of growth was checked and the fetor lessened, but the reactions were terribly alarming and induced him to suspend the injections after a few had been given.

¹ Therap. Monatsh., Jan., 1897.

² Lancet, Feb. 13, 1897.

George B. Beale¹ reports a case of a woman, aged 67, who had had the left breast removed for cancer and who presented herself with a scirrhus carcinoma of the right breast. Some glands in the left side of the neck were enlarged and painful. The arm was edematous. He tried the treatment of Coley. He gave injections on alternate days from March 22d to May 1st. She gained flesh, had a return of appetite, and became able to sleep well. The glands in the neck shrunk to one-quarter their former size, the tumor in the breast disappeared, the pain disappeared, and the edema almost passed away. It was now considered that the case could be operated upon; the glands of the neck were removed, but did not present any evidence of cancer.

Marmaduke Sheild² makes some remarks on a case of recurrent sarcoma of the mammary gland treated by Coley's fluid, with a fatal result. The patient was 44 years of age. Mr. Piek had previously removed the left breast for a myeloid sarcoma; the axilla was at that time apparently free. Within six weeks of the operation, the wound having healed, the disease appeared in the scar, in the axilla, and beneath the clavicle. When Mr. Sheild saw her there were two masses of disease in the centre of the scar. One was the size of a walnut, was of a livid hue, and was crossed by large veins; the other was of smaller size, but was on the point of evacuating through a large mass of disease into the pectoral muscle. The general health was good and there were no evidences of metastasis. The patient was treated with injections of Coley's fluid. There seemed to be no question that the masses were influenced most favorably by the injections. The injections were commenced on the 3d of April. On the 22d a rigor occurred and the temperature rose to 103°. The next two days the symptoms became worse. On the 23d the temperature was 105°, pustules appeared on the legs, with petechial spots on the abdomen, the patient became comatose and drowsy, and died on the 24th.

Sheild sums up the symptoms observed as follows: sharp reaction from the first two injections; after that three injections failed to produce a reaction. After a week's interval severe reaction again followed injection. The effect on the growth was unquestionably very marked and favorable. The injections caused undoubted shrinking and apparent disappearance, this result seeming to be due to inflammatory action rather than any specific effect of the fluid. The postmortem examination showed the evidences of general pyemia. The secondary abscesses contained staphylococcus aureus. This is important, as the original fluid was prepared from streptococci. Sheild has recorded this case because it illustrates both the difficulty and danger that attend methods of treatment the effects of which may easily spread beyond control. In this case the grave nature of the malady justified a perilous mode of treatment. Life was unquestionably shortened by the treatment, but nevertheless so marked was the effect produced upon the growth that he would advise this treatment in cases of sarcoma which appear hopeless when less risky methods are employed. It is interesting to note that this same fluid in the same dose was used for another patient suffering from cancer, and that little or no reaction resulted. The injections were always made with scrupulous care with an aseptic syringe. The fluid was found to be sterile, hence the fatal organisms probably developed in the necrosing tissues of the growths. The mistake in this case was possibly the imperfect disinfection of the skin. Sheild says that the most conflicting testimony exists in regard to the value of this treatment. Prof. Semm has reported 9 failures and says that the method is of no value.

Coley has reported some truly remarkably successful results. It seems to Sheild undoubted that remarkable results have occasionally been brought about

¹ Brit. Med. Jour., July 4, 1896.

² Ibid., Jan. 23, 1897.

in the treatment of sarcoma. He says the method is worthy of more extensive trial; the case he has related shows the great importance of making every attempt to prevent the entrance of dangerous organisms into the inflamed tumor.

William B. Coley¹ considers the **therapeutic value of the mixed toxins** of the streptococcus erysipelas and bacillus prodigiosus in the treatment of inoperable malignant tumors. He tells us that a considerable number of cases have been reported by competent observers in which undoubted malignant growths have been permanently cured by an attack of erysipelas. Czerny has reported 2 most important cases. Fehleisen produced erysipelas by inoculation in 7 cases; nearly all the cases showed improvement and in 1 of them the tumor disappeared. The case that led Coley to take up these investigations was one of small round-celled sarcoma of the neck. It had been operated on 5 times by William T. Bull. At the last operation in 1884 it was found impossible to remove the growth entirely and the case was considered hopeless. A few days after this an attack of erysipelas occurred, quickly followed by a second attack. The tumor entirely disappeared. Coley traced the case and found him alive and free from recurrence in 1891. The author then relates the steps of his investigations and how he was led to make the fluid which he now advises for injection. He tells us that the value of all preparations of the toxins depends largely upon the virulence of the original cultures. In most of the successful cases the cultures were obtained from fatal cases of erysipelas. Much larger quantities can be tolerated when injected subcutaneously than when injected directly into a vascular tumor. We should begin with a very small dose, 1 minim of the filtrate or $\frac{1}{2}$ minim of the unfiltered toxins. This dose should be increased each day until the reaction-temperature reaches 103° or 104°. The temperature should be the guide in estimating the dose, and very little benefit will accrue if no reaction is obtained. Usually the injections are given daily, and he aims to get 2 or 3 well-developed reactions every week. If well borne, the treatment may be continued from 2 to 3 weeks. If there is no decided improvement at the end of that time, it might as well be abandoned. In some of the successful cases it has been kept up for three or four months, occasionally an interval of a few days being taken for a rest. By a careful study of the cases which have been treated by this method we are able to answer three important questions: 1. Have these toxins an antagonistic influence upon malignant tumors? 2. In what variety of tumors is the influence most marked? 3. Is this action permanent in character?

The cases include 94 sarcomata and 63 carcinomata. Besides the cases of malignant tumors 8 other cases have been treated with the toxins—2 cases of tuberculosis, 1 of keloid, 2 goiters, 1 recurrent fibro-angioma, 1 fibroma, and 1 mycosis fungoides. Of the sarcomata 45, or more than half, show some improvement. Spindle-cell sarcoma is most apt to show improvement. Melanotic sarcoma is less apt to show it. Osteosarcoma shows little effect. In 1 case of round-cell sarcoma of the neck of very rapid growth the tumor decreased from the size of an orange to the size of a hen's egg in 1 week after 3 injections. The spindle-cell variety forms a large proportion of the successful cases. The results in carcinoma are far from ideal, but are such as to lead us to believe we are working in the right line. The fact that cases of undoubted carcinoma have been cured by incidental erysipelas gives weight to this view.

In a considerable number of cases of inoperable carcinoma Coley has seen

¹ Am. Jour. Med. Sci., Sept., 1896.

improvement follow the injections. In 2 cases the tumor disappeared and the patients are well, one 1 year and 9 months after treatment and the other a year. In a case of recurrent carcinoma of the breast there was very marked benefit under the influence of the toxins. Coley thinks that the chief value of the toxins in carcinoma will be to lessen the chances of recurrence after the primary operation. Coley turns to a consideration of the question, Is the action of the toxins permanent? One case which would remain well for a considerable time can be considered as answering this question. Four cases, all pronounced inoperable by well-known surgeons, in every one of which the diagnosis was confirmed by microscopic examination, are free from recurrence $2\frac{1}{2}$ to $4\frac{1}{2}$ years after treatment. It is proper to regard these cases as permanently cured. The author then records in full 18 cases in which this treatment was employed, and the result in many of them is extraordinary.

AMPUTATIONS.

The **amputation-statistics** at the London Temperance Hospital are presented by W. J. Collins.¹ The table was prepared by Dr. Leonard Wilde, the registrar of the London Temperance Hospital, and includes all amputations performed since Mr. Pearce Gould's retirement in 1888.

Table showing Amputation-mortality from July 1, 1888, to December 31, 1896.

	For disease.		For accident.	
	Cases.	Deaths.	Cases.	Deaths.
At hip	4
Of thigh	9	1	2	..
Of leg	7	..	5	..
Of foot	6
Of toes	12
Of arm	2	..
Of forearm	2
Of hand	1	..
Of fingers	19	..	6	..
Total	59	1	16	..

The total number of cases is 75, with 1 death. In only 2 of the above cases was any alcohol administered: one a case of sarcoma of the thigh, which died, the other a case of embolic gangrene with heart-disease, which recovered. Full details of all cases in which alcohol was used are put forth in the annual report of the hospital in accordance with the rule. [These statistics are remarkably favorable, but no limited series of observations can prove that alcohol should not be used. We have never seen harm result from the therapeutic use of alcohol. We consider this agent a drug of great value when properly used. It is worthy of note that the London Temperance Hospital has an unusual mortality in typhoid fever; Osler says the death-rate is 15-16%.]

A. Primrose² contributes a note upon **amputation at the hip-joint in advanced tuberculous disease**. He tells us that upon the question of the advisability of amputation in advanced tuberculous disease of the hip-

¹ Lancet, Jan. 9, 1897.

² Canad. Pract., Nov., 1896.

joint there is a great divergence of opinion. The very conditions which some authorities maintain contraindicate operation, other authorities hold render it necessary. The association of profuse suppuration with amyloid changes, albuminuria, tuberculous disease in organs, and the extension of the process into the pelvis, has been mentioned in a recent text-book as calling for its performance in order to save life, and yet most of these conditions have been set forth by writers as precluding the possibility of performing a successful amputation. Primrose says that one cannot narrate a train of symptoms either for or against the operation; that numerous considerations must be carefully weighed in each case, and no two patients will present the same identical association of symptoms. The immediate danger from the operation is not as great as has been formerly imagined; but, unfortunately, the prospect of curing the patient is not the best. Primrose then cites a case of tuberculosis of the hip-joint which was first treated by fixation, and next by excision, without the eradication of the disease, and he thinks in such a case as this the question of amputation should be considered. He tells us that Mr. Knaggs has reported an equally severe case which was cured by amputation, and he then relates a case of his own similar to it in which amputation by Furneaux Jordan's method was performed, with the cure of the case. He thinks that the rate of mortality is usually placed far too high, because we do not separate in our statistical tables cases operated upon for tuberculous disease from cases operated upon for other causes. The usual estimated mortality in text-books after amputation at the hip is 60%. The mortality after amputation for injury is 80 or 90%, and, according to Ashhurst, after amputation for disease is 40.2%. Of recent years, however, the mortality after amputation for disease has been very greatly reduced by improvement in technic. Primrose thinks the mortality is in the neighborhood of 10% in amputation for tuberculosis in children.

The operation that he advocates is that of Furneaux Jordan, and is never performed unless excision has previously been done. A primary amputation is never justifiable in tuberculous disease of the hip-joint. The prevention of hemorrhage is a matter of the greatest possible importance. He disbelieves in the use of Wyeth's method when operating upon children. He thinks the method is admirable when applied to an adult with a healthy hip-joint. The method that Primrose advocates is digital compression of the main artery. The femoral artery can be compressed over the pubis. When this is done the amount of blood lost will be very slight and there will be very little subsequent oozing. Digital compression is always possible in children. He thinks that the method suggested by Mr. Howse of removing the limb by successive segments has much to recommend it. In tuberculous disease of the hip demanding amputation Mr. Howse first amputates at the knee and later at the hip-joint, claiming that this method secures to a greater extent freedom from pain; that in many instances the first amputation improves the hip disease; and that in any case the severity of amputation at the hip is very much lessened by the antecedent operation. It is needless to say that the operation of amputation at the hip-joint should only be performed in cases otherwise hopeless, and should be reserved for cases in which excision has previously been performed. Neither amyloid disease nor perforation of the acetabulum is any contraindication to the operation. [Excision of the hip for tuberculosis is decidedly dangerous. The mortality is from 25 to 48%, which is far higher than the mortality of amputation. In not a few cases excision is followed by dissemination of the tuberculosis. Barker and Wright believe in early excision when caseation occurs. Howard Marsh and many others disbelieve in it. We

agree with Primrose that mechanical treatment should be given a thorough trial in hip tuberculosis. If mechanical treatment fails, excision is admissible, recognizing its dangers but believing it is justifiable to incur those dangers in preference to sacrificing a limb at once. We disagree with the assertion that amputation is never to be performed unless excision has been previously practised, and we hold that in more severe cases and in very much debilitated cases amputation should be done at once.]

Charles Greene Cumston¹ writes on **amputation of the foot with a dorsal flap**. He tells us that Baudens was the first to perform this operation, having done it in 1839. The 2 cases of this amputation performed by Poncet, of Lyons, show that the dorsal flap makes an excellent stump. The indications for the performance of this operation are the impossibility of finding enough tissue in good condition on the sole of the foot to make a trustworthy flap. In such conditions as perforating ulcer of the sole of the foot and in various atrophic conditions this amputation is useful. Tumors of the heel may require disarticulation of the dorsal flap. The contraindications are loss of vitality of the skin on the dorsal aspect of the body, advanced age of

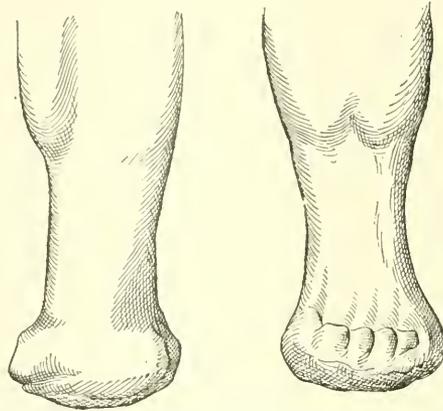

FIG. 6.—Anterior and posterior aspects of the stump after amputation of the foot with a dorsal flap (Charles Greene Cumston, in *Ann. of Surg.*, Dec., 1896).

the patient, and poor general health. In the latter case the question of life is to be more considered than the functional result of the operation. The dorsal flap is composed of the skin, the subcutaneous tissue, the dorsal aponeurosis, the tendons and layer of fibrous tissue, and, lastly, the pediosus muscle with the artery and nerve. This skin, it is true, is thin and elastic, but later it becomes thick and hard because of friction. The cellular tissue contains veins and nerves. The superficial aponeurosis is decidedly dense. The amputation is divided into four steps. In the first the flap is marked out and the soft parts incised. The incision begins in the tendo Achillis below and behind one of the malleoli. The incision is made to follow the dividing-line between the plantar and dorsal aspects. The point of the knife is made to move closely to the bone. It rounds off in the shape of a gaiter over the interdigital groove. The second step is dissecting up the flap. We remember that the flap is to include all the soft parts of the dorsum, and must be particularly careful not to injure the tarsal artery. The dissection is carried up to the tibiotarsal articulation, the surgeon exercising precaution not to lacerate the tissues. The third step is the opening of the tibiotarsal articula-

¹ *Ann. of Surg.*, Dec., 1896.

tion and the disarticulation of the foot. Disarticulation is effected by the ordinary method. The soft parts of the back of the foot are divided if necessary and the insertion of the tendo Achillis is cut off from the os calcis. The fourth step is the sawing of the malleoli and the toilet of the tissues. The malleoli are sawn just above the articulation, care being taken to obtain an even surface. Tendons are trimmed off and nerves are pulled down and cut. The tendo Achillis is sutured to the extensor tendons of the toes. Blood-vessels are sutured, the flap is sutured, and a drainage-tube introduced. Poncet cautions us to mark out the flap as high as possible. Retraction of the skin in this region is very great, and *be sure* to have enough flap. The cicatrix is on the posterior aspect of the heel and is not pressed upon by walking. Three months after operation the patient can use an artificial foot.

Durant, of Lyons, has invented a boot to be worn after this operation.

Charles McBurney¹ advocates **direct intra-abdominal finger-compression** of the common iliac artery during amputation of the hip-joint

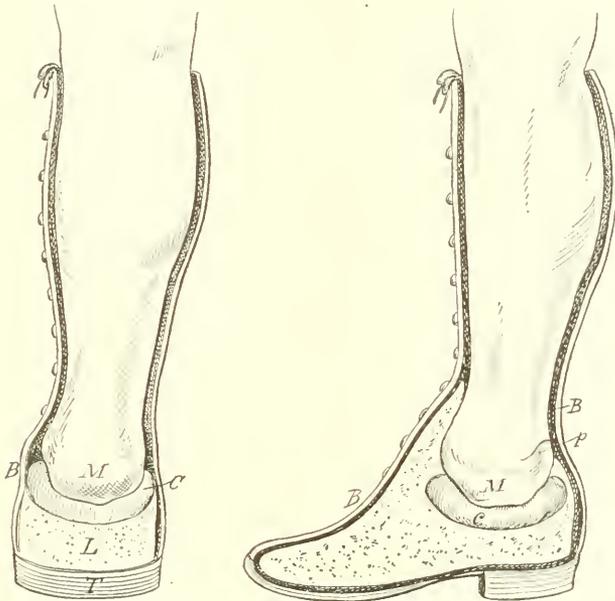

FIG. 7.—Shoe to be worn after amputation of foot with a dorsal flap: M, stump; L, cork foot; C, hair pad; B, boot; T, heel of boot (Charles Greene Cumston, in *Ann. of Surg.*, Dec., 1896).

as a means of preventing hemorrhage. He has adopted the method in several cases, and he has found it easy and effectual. In the reported cases as much blood as could be safely returned to the body by means of position or the Esmarch bandage was so returned. An incision was then made over the abdominal wall $1\frac{1}{2}$ in. internal to the anterior spine of the ilium, and through this incision an assistant passed his index finger and compressed the common iliac artery. The blood-current beyond the point of compression was arrested and the field of operation was entirely free from a bandage or an appliance of any sort. In his last two cases McBurney made the incision by separating the muscular and aponeurotic fibers according to the plan he devised for the removal of the appendix in interval-cases. [McBurney first described this plan in the *Annals of Surgery*, Aug., 1894. Macewen uses surface abdominal

¹ *Ann. of Surg.*, May, 1897.

pressure, made by the hand of an assistant, to prevent hemorrhage (for details of method see *Annals of Surgery*, vol. i., p. 1, 1894, or *Jacobson's Operations of Surgery*, p. 1134, 3d ed.)]

John A. Wyeth¹ makes a report of 69 cases of **amputation of the hip** done by the author's method; 56 of the patients were males and 13 were females; there were 11 deaths, a mortality-rate of 15.9%. In the 40 cases of sarcoma in which amputation was performed there was a mortality of 10%. In the 22 cases of bone-disease there was a mortality of 13.6%. An analysis

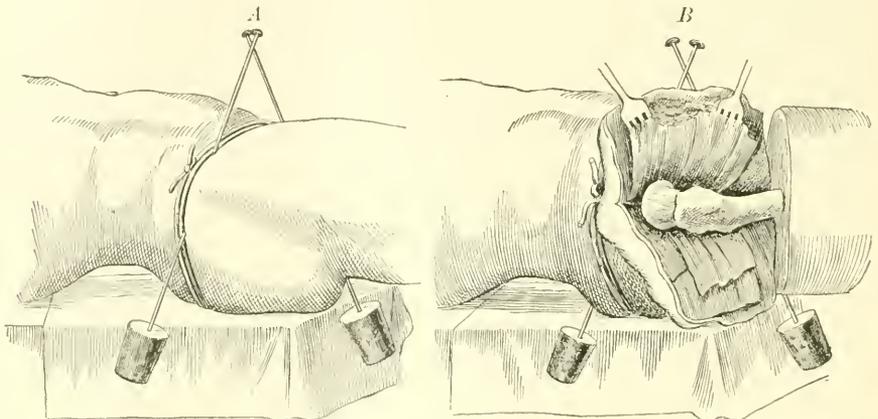

FIG. 8.—Hip-joint amputation: A, pins and rubber-tube tourniquet in position; the Esmarch bandage has been removed. B, the same, showing the soft parts dissected from the bone and the capsule exposed (John A. Wyeth, *Ann. of Surg.*, Feb., 1897).

of these cases shows that the method of controlling hemorrhage was satisfactory in every case but two. In one case the first incision showed that the constriction was not tight enough. In another case the pins yielded to the pressure, not being sufficiently strong. This operation Wyeth first applied in

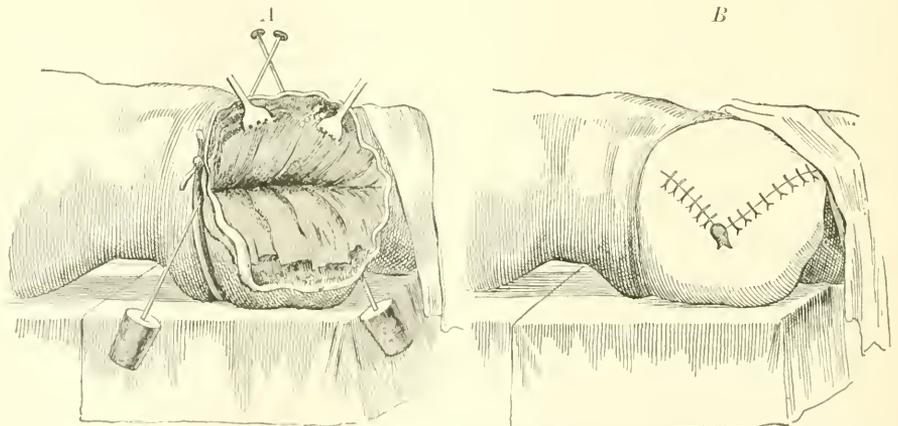

FIG. 9.—A, the same, with the disarticulation complete, constrictor still in position. B, the operation completed (John A. Wyeth, *Ann. of Surg.*, Feb., 1897).

1890. He had used the same method in arresting hemorrhage at the shoulder-joint more than a year before. Wyeth then describes the operation, the

¹ *Ann. of Surg.*, Feb., 1897.

steps of which are well known. He says in his first operation he divided the femur on a line with the incision through the muscles, tied the vessels, removed the bone, and then dissected loose the upper fragment. Finding disarticulation by this method difficult he adopted the suggestion of the late Dr. Murdoch, of Pittsburg, and left the femur intact to facilitate disarticulation.

[We have found the pins and band perfectly satisfactory in controlling hemorrhage. Jacobson thinks it is an objection to the method that it requires a special apparatus which may not be at hand. This distinguished surgeon uses elastic compression by the method of Jordon Lloyd.]

E. T. Elliot¹ reports a case of recurrent myxosarcoma of the scapula in a patient aged 76, who first consulted him when she was 71 years of age. There was a sarcoma of the right scapula. The growth was removed, but recurred in 2 weeks. The growth was again removed by free incisions and the wound was left open and packed with iodoform-gauze. The patient recovered, but the growth again recurred. Since the second operation Elliot has operated 12 times (14 operations in all). He finally removed the entire upper extremity (15th operation). The patient made a good recovery from this serious procedure.

ANESTHESIA AND ANESTHETICS.

Frederic W. Hewitt,² the anesthetist of the London Hospital, discusses the **past, present, and future** of anesthesia. He sets forth what anesthesia has done, analyzes the work of Snow and Clover, and shows the value of having a specialist administer the anesthetic. He contrasts the deductions from physiology and the beliefs obtained by practical experience, and thinks that the subject suffers at the hands of certain physicians and physiologists. The giving of an anesthetic is a purely practical matter, and no one is competent to express an opinion upon how it should be given who has not himself had personal experience in the operating-room. Many of the theories that are put forth so freely by physicians would be quickly modified or abandoned were these gentlemen to take a position for a short time as anesthetist in a large hospital. They would realize the important fact that in anesthetizing the human being factors come into play which are not met with in the lower animals. Not long since, Hewitt visited a physiological laboratory where an experiment was being conducted in which the question arose as to whether an animal had ceased to breathe. To his astonishment he saw that respiration was looked upon as existing as long as feeble and occasional muscular contractions about the chest and abdomen persisted, contractions which were without the slightest influence in causing ingress or egress of air. This shows that what the physiologist regards as respiration the anesthetist does not so regard, and that practical experience in giving anesthetics to human beings would greatly assist the physiologist in his investigations. The practice of administering the same anesthetic without regarding the nature of the operation or the type of the subject is a thing of the past. Successful administrators vary their anesthetics and their ways of giving them according to the circumstances of each particular case. Modern surgery requires that all the patients shall be saved, but it may be required that one patient be absolutely immobile, that another be less deeply anesthetized, and that a third be very slightly under the influence of the anesthetic. A very important development in the modern knowledge of the subject is the recognition of the advantage of profound anesthesia over light anesthesia in most instances. It

¹ Lancet, Nov. 7, 1896.

² Practitioner, Oct., 1866.

is also a fact learned in comparatively recent times that during the anesthetic state the respiration is apt to be obstructed mechanically, and there is good ground for the belief that this period of obstruction has been the initial factor in most of the cases spoken of as chloroform-syncope. Experience has taught us that within certain limits the state of the patient's heart may be entirely disregarded. It used to be the custom to determine whether or not a patient were fit to take an anesthetic by listening to his heart. The truth of the matter is that patients with strong hearts are more liable to pass into suddenly dangerous condition than those with feebler circulation. A postmortem study of deaths from chloroform will show that in most instances the heart has been perfectly normal. Hewitt does not mean to imply that people with advanced heart-disease or in a condition of extreme asthenia are the best subjects for anesthetics. Another recent addition to our knowledge is the fact that it is a good plan when chloroform-anesthesia is wished for to give the patient first a short course of ether and then continue with chloroform, and this is most readily effected by beginning the administration with gas and ether, or A.-C.-E. mixture and ether, and then after a time giving chloroform. This form of anesthesia is safer than that obtained by giving chloroform from the start. We are now able to obtain anesthesia from nitrous oxid without any of the evidences of asphyxia. It has also been pointed out in giving anesthetics that certain postures are inadvisable and others are of advantage. [There is a world of wisdom in Hewitt's statements that "the responsibilities involved in administering anesthetics are not yet fully realized," and that "the administration is too often placed in the hands of comparatively unskilled men." We have frequently been impressed with the truth of the above assertions. Not a few surgeons pick out the most competent person present to act as personal assistant and let any one at all give the anesthetic, and the "any one" may prove to be unfit for the task. There can be no doubt of the usefulness of one who makes a specialty of giving anesthetics. Every hospital worker realizes the difference between a specialist and an "any body" when he goes away to operate and does not take his assistants. It is absurd to suppose that a person can give ether well by instinct. The post of anesthetist should be regarded as one of trust and responsibility, the duties of which are second in importance only to those of the operator. To ask a person to give an anesthetic should be considered an evidence of confidence, not of disdain.]

Treves¹ publishes an article with the title of "Anesthetics in Operative Surgery." He states his conviction of the great importance and responsibility of the position of anesthetist. A man to meet successfully the many demands that are made upon him must have had large opportunities; must be possessed of the power of patient observation, tact, and judgment. The anesthetist is made and not born. This is not the belief of very many. There is a widespread belief that the giving of an anesthetic is a trivial act, and that the power to give it comes with the granting of his diploma. A man cannot give chloroform well unless he has extended practice. He will fail utterly if he follows some method of his own, or if he watches the operation, or attends to anything else excepting the giving of the chloroform. He tells us there are those who think the giving of chloroform a trivial affair, where there is often a stage of struggling when the patient is forced down upon the table as though he were a piece of mechanism possessed of a hardly controllable power to spring into the air. In this state he shrieks and yells and has occasional outbursts of speech which pain the sense of propriety of the relatives. Then comes pouring on large quantities of chloroform and beginning the operation

¹ Practitioner, Oct., 1866.

before the patient is unconscious. Then more pouring on of chloroform in a hasty, irritable, and even vindictive manner; then comes suspended animation, artificial respiration, and rushings to and fro, and after these things operation may or may not be completed. It is a true assertion that most patients look upon the anesthetic with far more dread than they do the operation. The patient is but ill prepared for this ordeal by an administrator who solemnly displays an apparatus which he manipulates with the stolid ostentation of an executioner, and he is not to be comforted by the jaunty anesthetist who calls for a handkerchief and after placing it over the patient's face chatters of his summer holiday. The anesthetist must appreciate the patient's condition of mind and must sympathize with it.

Regarding the choice of an anesthetic, other things being equal, more depends upon the one who gives it than upon the one which is given. Equally good results are attained by different administrators with different agents. Those who are especially adept in giving ether may not succeed so well with chloroform, and *vice versa*. An anesthetist of experience should be allowed to give that agent with which he is most familiar or which he regards as best suited to the case. Mr. Treves is convinced, in general, that ether is to be preferred to chloroform. Certain qualities are demanded of the anesthetic. It should be safe, it should not be very disagreeable to inhale, it should produce muscular relaxation, it should not be succeeded by ill effects, it should not lead to the production of hemorrhage. In regard to the safety of anesthetics, as stated before, Treves is assured that ether is infinitely safer than chloroform. In the hands of a thoroughly experienced man there may be no more danger with chloroform than with ether, but in making our estimates as to risk we judge from the success attained by the average administrators and not by the specialists. Chloroform is certainly not suited for indiscriminate use, nor should it be used by people of small experience. There are certainly some cases in which any anesthetic is dangerous. For instance, in intestinal obstruction with great distention of the abdomen and a weak and failing pulse. In cases of this variety, as soon as the anesthetic abolishes the reflexes there is often a torrent of vomit from the mouth and nose and death may immediately ensue. In some cases the pulse and respiration cease and the thorax becomes rigid, the great distention of the abdomen rendering artificial respiration almost impossible. These results are as common with ether as chloroform. In such cases no anesthetic should be given. The patient's capacity to appreciate pain is blunted, and we can often do a formidable operation with little evidence of suffering. After-sickness is much less common after ether has been given than after chloroform has been given, and this is a matter of great importance in abdominal operations. It occasionally happens that vomiting of a most persistent character arises because of some peculiarity due to the patient and the anesthetic, and the same remark applies to hiccough. Occasionally vomiting after an operation is due to iodoform-poisoning. Ether has another disadvantage which chloroform is free from—it is irritant to the respiratory mucous membrane, this irritant effect being especially pronounced when some inflammation of the air-vessels already exists; hence in operations upon the respiratory passages or the pleura chloroform is used instead of ether, and chloroform is preferable in cases in which tracheal or bronchial catarrh exists. It has been stated that one fault in ether is that it produces extreme venous engorgement and leads to much oozing from the field of operation. Mr. Treves does not think the objection well founded. The question is one of administration. When an anesthetic is given by a skilful man the difference between the vascular condition when the patient is under ether and under

chloroform is hardly detectable. It is quite true that some administrators who are not skilful in giving ether may put the patient in a state of asphyxia which may impress the operator. Mr. Treves has never noticed that more points require ligature when ether is employed than when chloroform is used, and he thinks that the after-oozing is greater with chloroform than with ether.

Marmaduke Sheild¹ makes a strong plea for the need of better **instruction in the administration of anesthetics**. He thinks the teaching of anesthetics is greatly neglected in most institutions. It is possible for a man to obtain the right to practise without any practical knowledge of giving anesthetics. In order to show the degree of incapacity which exists in this most responsible duty which falls to the lot of medical men, Sheild mentions an actual experience which he had in a remote district, and he thinks that such experiences are too frequently duplicated in private practice. The patient had been given a full meal and some alcohol. The administration of chloroform was begun without examining the mouth for foreign bodies or false teeth and without undoing the corset. The operator noticed that the administrator had no tongue-forceps and no tracheotomy-tube. We know, as a matter of fact, that by careful watching on the part of the operator and considerable good fortune these cases do well; but we simply court disaster and may barely rescue the individual from the jaws of death. A piece of vomited matter may be hooked out of the larynx just in time to prevent death, and other exciting adventures are liable to occur which impress an operator who is already too busy. We hear much of deaths from anesthetics, but we do not hear of the narrow escapes. We should always remember that no anesthetic is without risk, and we should endeavor to reduce this risk to infinitesimal proportions by great care in administration and by a theoretical as well as a practical knowledge of the subject. Instruction in anesthetics should be compulsory. There is ample opportunity for instruction in the London hospitals, as the amount of material is very large and the number of operations very great.

Sheild thinks the tendency to examine into difficult and obscure subjects to the neglect of common and ordinary ones is a most serious defect in modern medical education. He would establish examinations in anesthetics. He would not expect every medical man to be a highly skilled administrator, but he should know enough to be able to select an appropriate anesthetic for a certain case, and he should be competent to give the common agents with confidence. He should have a thorough knowledge of the preliminary measures necessary for the safety of the patient and of the remedial measures to be employed in case of sudden danger. In remote districts the general practitioner will be forced to administer anesthetics himself in cases which, if treated in the city, would be anesthetized by a skilled assistant. The administration of an anesthetic in such a condition as empyema, for instance, is extremely perilous. The patient's safety can only be insured by long experience and cautious and skilful administration. We, of course, cannot educate all medical men to such a point of excellence, but we should at least instruct them to the degree where they will be fit to estimate the limit of their own capacities and be able to know when a certain case is difficult and dangerous. [The advice in the above article is eminently sound and timely. We ourselves have seen many narrow escapes and have felt several times that peril would have been avoided if the administrator had possessed a little more knowledge. Sheild's criticism of the tendency of modern medical education is true. Examiners multiply subjects, ask many profound questions, and in quest of the deep

¹ Practitioner, Oct., 1896.

and theoretical lose sight of the obvious and practical. The tendency is most deplorable.]

J. Milne Bramwell¹ revives the subject of **hypnotic anesthesia**. He tells us that Esdaile's first mesmeric operation was performed in 1845, and at the end of that year he had reported 100 successful cases. A committee of medical men investigated Esdaile's work and reported in his favor. In 1851 he reported 261 painless capital operations, and many thousand minor ones, and reduced the mortality in the removal of the great tumors of elephantiasis from 50 to 5%. The author tells us that when he began hypnotic practice 7 years ago he found he could often produce anesthesia. In view of the fact that we already possess reliable anesthetics he looked upon this chiefly as useful in showing that hypnotic phenomena were genuine. Nevertheless, hypnotic anesthesia is not valueless. He reports several cases operated upon without pain by this means: one of double strabismus, one of ankylosis, one of excision of exostosis of the great toe, and many cases of teeth-extraction. Numerous other operations during hypnotic anesthesia have been reported of late, and Bramwell appends a list of the results of other practitioners. The chief objections to hypnotism are the difficulty and uncertainty in inducing primary hypnosis, because of the widely varying susceptibility of different individuals. 94% of people can be hypnotized, but many preliminary attempts are often necessary, and sometimes hypnosis never becomes deep enough for operative measures. The nervous and hysterical are the most difficult to hypnotize, the healthiest and well-balanced are the easiest. Hypnosis possesses many advantages. When deep hypnosis with anesthesia has been once induced it can be repeated at any time desirable—it not being necessary to reproduce the hypnotic process, a verbal order to sleep being sufficient. The hypnotizer's presence even is not necessary, as the patient can be put to sleep by a written order or by other means suggested during hypnosis. The patient is not obliged to abstain from food or to make any other preparation. The nervous apprehension can be removed by suggestion. The process is pleasant, is free from danger, can be kept up indefinitely, can be stopped immediately; during it the patient can be placed in any position without risk, and will alter that position as the operator commands; gags and other apparatus are not required; analgesia alone can be suggested with great advantage in throat operations. The influence of the muscles can be increased or diminished by suggestion, which is of value in labor cases. There is no tendency to sickness during or after the operation; pain after the operation or during subsequent dressings can be prevented, and the rapidity of the healing process is frequently very marked. [The author makes the assertion that the nervous and hysterical are the most difficult persons to hypnotize and the healthy and well-balanced are the easiest subjects. This view is in direct antagonism to the teachings of Charcot. Charcot asserted that nervous patients, and particularly those laboring under hysteria, are predisposed to the hypnotic state. The absolute safety of the hypnotic state is doubtful. Binet and Ferré specifically state that death may occur during hypnosis. The process can never be generally used, because of the difficulty of inducing the hypnotic condition in many individuals. The fact that after a person has been hypnotized it may be possible to hypnotize him easily on another occasion, *even against his own will*, is an objection, as most persons would be unwilling thus to endanger their own liberty in the future. That perfect anesthesia can be obtained by hypnotism is beyond doubt. The experience of Esdaile proves this fact. Guérineau, of Poitiers, amputated a leg successfully under hypnotic anesthesia, and Cloquet am-

¹ Practitioner, Oct., 1896.

puted the breast of a woman who was hypnotized. Cloquet performed his operation in 1829, and Esdaile did not operate under hypnotism until 1845. Binet and Ferré,¹ Chareot's pupils, state that the hypnotic sleep cannot be induced in all subjects; that even susceptible subjects must be subjected to a series of daily hypnotizations before operation; and that sometimes hyperesthesia is produced instead of anesthesia.]

Fränkel² sets forth a method of **preventing the disagreeable after-effects** of ether-anesthesia and chloroform-anesthesia. Quarter of an hour before giving the anesthetic Fränkel administers 1¼ c.c. hypodermically of the following solution: morphin hydrochlorate, 0.15 gm.; atropin sulfate, 0.015 gm.; chloral hydrate, 0.25 gm.; distilled water, 15 gm. The patients after taking this injection are very easily influenced by chloroform, and pass into unconsciousness after the administration of a small amount of an anesthetic. This mixture was not given to people who had lesions of the heart. [The elder Gross was a believer in the administration of morphin before giving the anesthetic, and for many years was accustomed to give it to patients who were found to be nervous and very apprehensive. It has been asserted that atropin given before the administration of ether tends to prevent vomiting in the stage of reaction, but we have never been persuaded of the truth of the statement. It will be observed in the next article that Silk opposes the use of morphin, because he believes that this drug may mask the symptoms of a fatal narcosis from the anesthetic.]

J. W. Silk,³ anesthetist of King's College Hospital, presents some notes upon the **preparatory treatment** of patients who are subjected to anesthesia. He says that nitrous oxid should not be given directly after a meal, nor should it be given with the head in a position which permits the tongue to fall back over the glottis, but beyond this no previous preparation is required. In regard to ether and chloroform, attention to preliminaries will not only give comfort to the patient, the anesthetist, and operator, but will sometimes save a patient's life. As a general fact, it may be stated that an anesthetic is taken better if the patient has been subjected to what may be called hospital *régime*—that is, rest of body and mind, regulation of the evacuations, the use of a bland and easily digestible diet, and the abandonment of alcohol. We every now and then hear someone suggest that a particular drug given before the anesthetic is administered may prevent the dangers and the troubles which occasionally arise, but there is no drug which has a specific action in the matter. The gastrointestinal system should always be placed in good condition before giving an anesthetic. Purgatives should be given the evening before the operation. The stomach should be empty when the anesthetic is administered. This last direction does not mean to carry starvation to the verge of weakening the patient. Of course, the power of digestion will be lessened because of the nervousness of the patient, and yet the operation may be so severe as to prohibit the withholding of food for many hours. The best plan in most cases is to give a cup of hot broth or beef-tea 3 or 4 hours before the operation. Milk and other foods which digest slowly are not suitable. In patients who are very weak, or on whom a severe operation is to be done, it will be found useful to give a nutritive enema half an hour before operation. The enema that Silk recommends consists of the yolk of an egg, an ounce of beef-tea, an ounce of milk, and an ounce of brandy, the food elements being peptonized. As a general rule, it is not wise to give

¹ Animal Magnetism, by Binet and Ferré.

² Zeit. f. prak. Aerzte, 1896; quoted by Bull. gén. de Thérap., Sept. 26, 1896.

³ Treatment, Mar. 25, 1897.

brandy before operation, although in some instances it may be necessary when the patient is in danger of syncope from fright. The hypodermic use of morphin before operation is deprecated. It has no real advantages, and is apt to mask the symptoms of dangerous narcosis and hence lead to fatal results. Strychnin is a valuable agent in obviating and lessening shock, and some think the tendency to after-sickness is abated by its employment. The position to anesthetize in is, as a rule, the position the patient assumes himself as most comfortable. Chloroform should never be given to a person in the sitting posture. Everything in the shape of belts and stays, which tend to restrict respiratory movement, must be removed.

Clement Lucas¹ thinks that the occurrence of **pneumonia after the administration of an anesthetic** is too common to be explained by antecedent infection or by the effects of cold. He maintains that pneumonia is invariably a germ-disease, and thinks it quite possible that the germs may come from septic secretions. In this connection he quotes the remarks of James Bell, made over 12 years ago in the *Montreal Med. Jour.* Bell maintained that the Clover inhaler possessed every possible disadvantage; that it could not be cleansed, and that patient after patient respired through the same dirty mask in the same dirty rubber bag, each one adding his quota of mouth-secretions, which are possibly specific, cancerous, or tubercular. Lucas says that it would be a good thing to appoint an instrument destruction committee to have absolute power to destroy all out-of-date instruments and relieve hospital surgeons of being obliged to operate with useless tools and appliances. [Prescott has asserted that out of 40,000 etherizations only 3 persons developed lobar pneumonia. The same observer says that broncho-pneumonia and inhalation-pneumonia are more common (*Year-Book*, 1897). Nevertheless we believe profoundly in the use of a clean inhaler.]

Dudley P. Allen² has made a study of the effects of anesthesia upon temperature and blood-pressure. His experiments have been made from the standpoint of the clinician rather than that of the physiologist. His conclusions are that animals lose heat in a marked degree under prolonged anesthesia. This loss of heat may be to a great extent prevented by carefully covering up the animal. When an animal is carefully covered up and surrounded with hot bottles the temperature may be actually increased under anesthesia. That these temperature-changes are due to anesthesia is proved by certain facts: (a) that temperature-changes in dogs without anesthesia are very slight; (b) that temperature-changes in dogs under anesthesia depend on whether the dog was covered or uncovered and whether he was or was not surrounded by hot bottles. Allen found that the temperature after anesthesia ceased tended to return to normal no matter whether it had been above normal or below normal. This loss of heat is somewhat retarded by the administration of ergot or of atropin. The lower temperature quickly returns to normal after the cessation of the giving of ether; but if the anesthetic be chloroform or the A.-C.-E. mixture, the temperature continues to fall for some time after the administration has ceased. Loss of blood-pressure corresponds closely with loss of heat. The administration of enemata of alcohol tends to bring back the blood-pressure, but renders the return to the normal temperature slower. In a room having a high temperature (93° to 96°) the administration of an anesthetic causes an increase of temperature to a considerable amount, but at the same time a decrease of blood-pressure. These observations seem to indicate that operations in rooms at a high temperature cause the patient more distress and are more perilous than operations in a room of moderate

¹ Lancet, Apr. 3, 1897.

² Am. Jour. Med. Sci., Mar., 1897.

temperature with the patient thoroughly protected. Slow operations with loss of blood produce a much greater fall of blood-pressure than operations of much greater severity performed quickly when care is taken to prevent hemorrhage. Allen maintains that in every prolonged operation the patient should be carefully covered to prevent loss of heat, and if he had already lost heat because of injury or exposure artificial heat should invariably be applied. Every care should be taken to limit the loss of blood. In his studies upon human beings he observed 80 patients. During operation there was a temperature-loss varying from 0.2° to 2° ; the average loss was about 0.6° , but in some cases there was no loss whatever. [All practical surgeons have long been in agreement as to the absolute necessity of keeping the patient well covered. The theoretical objections against operating in very hot rooms are sustained by experience. We have seen deaths occur which we believe resulted purely from the exhaustion induced by the excessive heat of the operating-room. A year ago one of the editors (DaCosta) was operating for appendicitis. The temperature outside was 98° . The operating-room contained a steam sterilizer, and what the temperature of the room was is purely conjectural. The patient developed thermic fever during operation. The other editor (Keen) had a patient die of thermic fever a few hours after operation. It was midsummer, the temperature outside was 96° , and the room contained a steam sterilizer.]

A. E. Bridger¹ considers **disorders** which are **favoured** or produced by **anesthesia**. He reported a case of acute mania which followed directly on the giving of nitrous oxid gas. He also reported cases in which an aortic aneurysm came on very suddenly after the administration of ether, the patient having struggled with considerable violence. The individual had labored under a specific disease and was a drinker, 53 years of age. He reported a case of pneumonia following the administration of ether and also one in which during the administration of chloroform to a morphin *habitué* it was noticed that the stage of excitement was very greatly prolonged.

Gilbert Geoffrey Cottam² advocates the administration of **spartein sulphate** in surgical anesthesia. This is given before the administration of an anesthetic, in doses of $\frac{1}{10}$ gr. hypodermically. During the progress of the operation $\frac{1}{5}$ gr. additional can be administered if necessary. He maintains that it strongly antagonizes the depressing influence of chloroform upon the circulation.

Kirk³ writes on **auscultation of the heart** during chloroform-narcosis. He has made a study of 200 cases. He decides that the effect produced by chloroform on the heart can be assigned to one or both of two causes—either the susceptibility of the patient or the method employed. The following indications show dangerous idiosyncrasy: 1, a very forcible impulse with accentuation of one or both sounds; 2, irregularity before the administration is begun; 3, tachycardia or irregularity during the administration. Victims of syphilis are especially liable to bad results.

Henry J. Garrigues⁴ writes on **anesthesia-paralysis**. He tells us that it has been noted after the administration of an anesthetic that in some cases the extensor muscles of the forearm and hand were paralyzed. This phenomenon was explained by the arm having been permitted to roll out and hang over the table-edge so that pressure was brought to bear upon the musculospiral nerve, the paralysis being exactly analogous to that seen in a man who sleeps with the arm hanging over the back of a chair. But there are other

¹ Proc. Soc. of Anesthetists, Jan. 21, 1897.

³ Brit. Med. Jour., Dec. 12, 1896.

² Therap. Gaz., Nov. 16, 1896.

⁴ Am. Jour. Med. Sci., Jan., 1897.

kinds of disturbance in the nervous system which may follow or be associated with the administration of anesthetics and which have received but little attention. Dr. Garrigues reports several interesting cases. One of them, a woman, was found to have paralysis of the right arm after recovery from ether, there having been no kind of pressure of the extremity against the table. In another case a left arm was paralyzed, without pressure. Garrigues quotes the well-known article by Budlinger, an assistant of the late Prof. Billroth, in which 9 cases of this sort are described. He also quotes the reports of Placzek of Berlin, Franke of Elberfeld, and Vautrin of Nancy.

In regard to the etiology of anesthesia-paralysis the cases may be divided into two groups, those which are of central origin and those which are of peripheral origin, the latter being by far the most common. These cases may happen it matters not what anesthetic is employed. Many of the cases have occurred after prolonged operations; others have occurred after short operations. Loss of blood may have some effect in predisposing to the paralysis. Children and emaciated individuals are more apt to suffer from it. The related cause of the peripheral cases is pressure, not of necessity pressure against the table, but pressure which is exercised upon the nerve by some position in which the extremity has been placed. When the arm is elevated alongside of the head or when it is brought out strongly from the body, pressure may take place between the clavicle and the first rib. Braun maintains that in such positions the head of the humerus presses upon the brachial plexus. Kron has shown by studies upon the cadaver that by lifting the arm backward and outward when it is in external rotation the median nerve is stretched across the head of the humerus, and that when the forearm is flexed and supinated the ulnar nerve is stretched. But unquestionably in most cases the pressure takes place between the collar-bone and the first rib. The plexus is especially likely to be injured if the nerves are stretched, which stretching is brought about when the head is drawn to the side opposite to that on which the arm is being elevated or when the head is permitted to fall back. Paralysis of the arm, it will be noted, is the most common; but paralysis has also been observed in the extremities and in the face. When the brachial plexus is pressed upon, the 5th and 6th cervical nerves are more apt to be caught than the 7th and 8th cervical and 1st dorsal are. In such a condition we find the deltoid, brachialis anticus, the biceps, and the supinator longus paralyzed, the other muscles having escaped. In some cases the muscles of the shoulder are implicated. If the lower roots are also compressed, the forearm and hand are involved. In some reported cases there was visual disturbance, the palpebral fissure was lessened in size, and there were contracted pupil, amaurosis, and double vision. These conditions are due to trouble with the communicating branch from the first dorsal nerve. There is more or less disturbance of sensation. There may be numbness, there may be absolute insensibility, there may be pain or tenderness on pressure, and sensitive points may be found over the nerves. It has been noted that even when the muscles supplied by the circumflex nerve, the deltoid, and the teres minor are paralyzed the skin over this region is not anesthetic. In some cases the extremities swell. Anesthesia-paralysis of central origin may be due to apoplexy or embolism. People who violently resist the anesthetic and old people with degenerated arteries are most liable to such a condition. It may also be produced in rare instances by primary softening of the brain, brought on by the direct action of the drug on nerve-tissue. The paralysis of central origin may appear as hemiplegia or hemiparesis. It seems likely that the so-called anesthetic death in some cases is due to apoplexy. The prognosis of the lighter cases of peripheral palsy is good, complete recovery being usually

soon brought about. In severe cases of plexus-paralysis it may take months or even years to effect a cure. In a central paralysis the prognosis is extremely grave. In giving an anesthetic we should avoid pressure upon special nerves. We should not permit the arms to be raised above the head, but should have them resting easily pressed upon the chest. When leg-holders are employed the parts which are subjected to special pressure should be carefully padded with cotton. The head should rest on a pillow, and if vomiting occur and it is necessary to raise the arm, the head must be bent toward the arm and not away from it. In regard to the prophylaxis of central paralysis, abstain as far as possible from operating on very old persons and shorten the duration of the anesthesia as much as possible. In treating the peripheral paralysis electricity is of the utmost value. Its application shortly after the operation will be found to be very painful, and it is better to wait a week before applying it. A faradic current is the proper one to use, although Krumm recommends galvanism. Massage and hydrotherapy may be associated with the electricity. Strychnin is given internally, and we may also give iron, quinin, arsenic, extract of red marrow, and a nonriching diet.

George H. Bailey¹ considers the **principles of ether-administration**. He prefers to use Clover's gas and ether apparatus. He thinks, in preparing the patient for anesthetization, that we are often inclined to give too little food to old people and possibly to make the interval too long between taking food and operating. A small amount of stimulant just before the operation is in many cases valuable. His own practice is not to examine the patient before operation. As we know little of the causes of death, and the most healthy people are the ones who give the most anxiety, we had better consider every person as apt to succumb to the anesthetic than to lean upon the reed that would most likely fail to give support. In every reported death the statement is made that the patient was examined and found healthy. The attention of the anesthetizer should be centered upon the pulse, the respiration, and the condition of the pupil. Each will point out some special danger if not performing its function in a rhythmic manner. The golden rule as to the position of the patient is, first, make the patient comfortable and then yourself. As a rule, the best position for the patient at the beginning is recumbent with the head and shoulders slightly raised. Bailey stands on the left side, with his left thumb on the superficial temporal as it passes from the zygomatic process and holds the head. After the patient is anesthetized place him in any position required, even if it is necessary to suspend him by the feet. If mucous secretion gathers, sponge out the throat. If the jaws become fixed, employ a Mason's gag to open the mouth. In 2 cases of Bailey's laryngotomy was necessary. The indications for laryngotomy are perfect blueness with fixation of the chest-walls. Bailey is a strong disbeliever in warming the ether. He thinks ether if warmed is liable to produce dangerous symptoms. The pupils may vary from so trivial a cause as sickness with a tendency to slight syncope or the turning of the head on one side to give free exit to the vomit. If with dilated pupils and failing pulse and respiration there is flaccid eyeball, the case is very alarming. We should at once suddenly compress and as suddenly relax the chest-walls in order to expel the poisonous vapor from the lungs. After doing this two or three times it will usually be found that the patient's condition again becomes satisfactory. Time is lost by pulling out the tongue and by applying the stethoscope. If a rally does not come very quickly, artificial respiration must be used. He thinks there is no distinction in complete anesthetic

¹ Practitioner, Oct., 1896.

effects between ether and chloroform, and that either agent can be used efficiently in operations upon the abdomen, the brain, the chest, or eye. Ether given correctly can be used in the same cases as chloroform. In operations about the mouth chloroform is better than ether because ether cannot be as well kept up. He does not agree with the statement that the very young and the very old should not be etherized. He would just as soon give ether in the extremes of life. He says that certainly the young may die under chloroform and that the stimulation of ether benefits the aged. Neither agent is used in organic disease, but then we do not operate in such conditions. In this, the 50th year of the use of ether, we find it in far greater and increasing favor than some time ago.

The administration of ether is considered by F. Woodhouse Braine.¹ He maintains that ether should rank *facile princeps* amongst anesthetics. If he were limited to the use of one agent out of all the anesthetics that have ever been brought forward, he would choose ether. He totally disbelieves the statement that ether should not be given to patients who are below the age of 5 or above the age of 60. He gives it to infants when a few days old as well as to patients over 80. Infants are readily brought under its influence without any cyanosis. It is often a question with an inexperienced anesthetist as to when an infant has reached a proper degree of anesthesia. The writer's method is as follows: place the index finger in the infant's hand and it will be found that during the early part of the administration the finger is tightly grasped, but as insensibility approaches the infant's fingers gradually relax. As soon as the fingers are entirely lissome the operation may be begun. In the adult our guide is the conjunctival reflex. In the infant our guide is the amount of palmar and digital reflex. This method in an infant is greatly preferable to making the conjunctival test, because the conjunctiva loses its sensitiveness very quickly after being touched but a few times with the finger, hence an infant may seem to be thoroughly insensible by the conjunctival test when in reality it is not so. The writer has never seen bronchitis produced in an infant by the administration of ether, but he is very careful to guard against the breathing of cold air for some hours after operation. He does not allow a window to be open, and when possible keeps the child in the room in which the operation was performed for at least six hours. This care not only prevents bronchitis, but antagonizes vomiting, and these results he attributes to the non-stimulation by cold air of the nerves of the lungs with a consequent reflex action on the stomach. After the age of 3 years it is wise to precede the ether by the administration of nitrous oxid. Nitrous oxid is given until the patient is insensible and then the Ormsby inhaler, into which about 2 ounces of ether have been poured, is quickly applied without permitting a single inspiration of air in the interval of transference. With nervous individuals and drinkers the gas should be given until the patient is completely insensible before the change is made to ether. Always bear in mind that we cannot get the patient too quickly under the influence of ether. The pulse may be disregarded, for the circulation will always outlast the respiration. It is the respiration which especially requires the etherizer's attention. When ether is being given a slight duskiess of the face is not of any moment at all in fleshy, thick-necked people, especially with people who breathe through the nostrils with the lips closed lividity is apt to become marked. This can usually be prevented by placing a probe between the teeth. It is the absence of oxygen rather than the presence of ether which causes the lividity. If the wedging of the mouth apart by a probe does not cause the return of the

¹ Practitioner, Oct., 1896.

healthy color to the face, let the patient have a few inspirations of pure air, and if these do not produce the desired effect, it becomes the imperative duty of the administrator to get fresh air into the lungs of his patient by the means he is most accustomed to. The patient's life is in his hands and in his hands only. It occasionally happens during artificial respiration when the tongue is drawn forward and the air-passage freed from any foreign body that pressure on the thorax seems to drive air out of the chest, but none enters in to replace it. The obstruction in such a case depends upon the lax vocal chords being forced together by atmospheric pressure. This condition is overcome by the anesthetist placing his lips within those of the patient, closing the patient's nostrils, and making forcible inspiration. The atmospheric pressure is thus removed, the air left in the patient's lungs expands and forces the glottis open and permits air to enter. The after-effects of ether may be summed up in four words—nausea occasionally, sickness seldom.

J. B. Blake¹ furnishes some notes upon the use of **oxygen after ether**. His conclusions are that oxygen administered after ether abridges the time of returning to consciousness and diminishes unpleasant after-effects. It is a valuable cardiac and respiratory stimulant. It is indicated in threatened collapse and is appropriate in private cases, but in hospital practice its effects are not sufficiently beneficial to justify the expense which its routine use would entail.

Sydney Ringer² advocates the use of the tincture of **belladonna** for the prevention and cure of ether-bronchitis.

Newman and Ramsay³ have made some studies upon the **decomposition of chloroform**. They show that chloroform tends to decompose with the formation of hydrochloric acid and the chlorid of carbonyl, and that the chlorid of carbonyl is an agent that is mainly responsible for the after-sickness. This tendency to decomposition can be prevented by keeping a little slacked lime in the bottle of chloroform.

Alexander MacLennan⁴ records some cases of **stoppage of respiration** during chloroform-anesthesia which were treated by **tracheotomy**. This operation was done in 3 cases with a successful result in each. He says that obstruction to breathing may be due to tenacious secretion in the larynx or trachea, spasm of the chords, edema of the larynx, vomited matter in the air-passages, or a combination of some of the above conditions.

Waterhouse and Gibbs⁵ record an extremely interesting case of arrest of the heart's action and of respiration during chloroform-anesthesia in which **bleeding from the internal jugular vein** was practised, after which the patient recovered. The operation was for the removal of tuberculous glands of the right side of the neck. Just as the diseased glands had been enucleated the patient made several violent attempts at retching, and in about 30 seconds became deadly pale, the lips became blue, the pupils dilated widely, the respiration stopped, and the pulse ceased. There is no doubt whatever that the action of the heart ceased some seconds before the respiration failed. The patient's mouth was gagged open, the tongue was drawn forward, the foot of the table was raised, and artificial respiration was performed by compression of the chest. Brandy was injected by the nurse. This proceeding of artificial respiration was kept up for 3 minutes. It had no effect. The ear to the chest could detect no sound from the heart or lungs. Everyone in the room considered the patient to be dead. The jugular vein had been cut

¹ Boston M. and S. Jour., Nov. 12, 1896.

⁴ Brit. Med. Jour., Nov. 21, 1896.

⁵ Ibid., July 18, 1896.

during the operation and clamped. The forceps were now removed and the opening in the vein was enlarged by tearing its margins. A stream of dark blood poured out. The chest was now forcibly compressed and this produced a great flow of blood. Several ounces of blood escaped and after the internal jugular had been clamped artificial respiration was renewed. In less than half a minute the patient began to breathe. Soon the heart was heard and the patient was out of danger. The question which vein surgeons should open in such conditions depends upon the site of operation, but the vessel selected should be as large and as near the heart as possible. This proceeding relieves the distended right ventricle rapidly and thoroughly.

Mollison¹ furnishes postmortem notes of 11 cases of **death during the administration of chloroform**. In the first case it seems likely that chloroform had little if anything to do with the fatal result. The heart was found dilated and flabby and the muscular substance soft, and the kidneys large and congested. The lower lobe of the right lung was collapsed.

Cases II. and X. represent a class of cases in which it is inadvisable to give an anesthetic because of the increased shock and danger of insuflation of vomited matter. This latter accident happened in Case X. Case II. was a man laboring under cancer of the sigmoid flexure; the body was emaciated and the intestines greatly distended. Both sides of the heart were relaxed and flabby and the coronary arteries were tortuous. The tricuspid orifice admitted six fingers and the mitral orifice four fingers. Both lungs were congested. Case X. had also a cancer of the sigmoid, and when placed on the operating-table had fecal vomiting. The intestines were greatly distended with fluid feces, and the autopsy showed that death was due to asphyxia arising from the entry of vomited matter into the air-passages. Excluding cases I., II., and X., we have 8 persons who died because they were put under the influence of chloroform. In only one of these cases was there any evidence that primary cardiac failure was the mode of death; in all the others the evidences of asphyxia were more or less marked. In all of them the heart was abnormal, being either dilated or fatty. The study of these cases seems to Mollison to bear out the conclusion advanced many years ago by Syme, of Edinburgh, that it is necessary to watch the breathing and not the heart. It is not sufficient to watch a heaving abdomen or chest and fondly imagine that the patient is respiring perfectly. There can be no doubt that cases of sudden cardiac failure do occur, but this is much rarer than death by asphyxia, and when it does occur it is a question whether the chloroform is always to blame, as people with feeble hearts may die of shock and fright when an anesthetic is not given. Information as to the mode of death in the absence of a carefully conducted autopsy is absolutely unreliable. In several of these cases Mollison had been assured that the heart failed first, but the postmortem examination did not bear out this assertion.

Mollison here quotes a sentence from Hewitt, who wrote the article upon anesthetics in Treves' *System of Surgery*. Hewitt says: "Errors have been frequently committed in regarding the circulatory depression as the primary factor, the observers having overlooked the initial respiratory symptoms." Further, Hewitt says that "circulatory failure during anesthesia is in the great majority of cases connected with or dependent upon embarrassed or suspended breathing."

Mollison has further reported² upon the postmortem findings in 2 cases of death under chloroform. In 1 case the death was due to cardiac failure, although the slight congestion of the lungs and trachea suggests an element of

¹ Intercol. Med. Jour. Austral., Aug. 20, 1896.

² Ibid., Feb. 20, 1897.

asphyxia. In the other case death was due to partial asphyxia overcoming cardiac power in a heart dilated and degenerated from a continued fever. This mode of death, Mollison says, been called asphyxial syncope.

R. Hamilton Russell,¹ of Melbourne, endorses Mollison's views, and advises us to "watch the breathing and let the pulse alone."

Leonard Hill² contributes a most important article on the **causation of chloroform-syncope**. This article should be read with care. Space does not permit us to do more than present his conclusions, which are of the highest practical importance to the surgeon. He maintains: 1. That chloroform causes primary failure of the circulation and secondary failure of the respiratory center. The respiratory center fails to act partly because of anemia produced by the great fall in arterial tension. This statement is proved by the fact that the activity of the respiratory center can be restored by raising the arterial tension. The depth of anesthesia depends upon the primary fall of the arterial tension, and so does the paralysis of the respiratory center. 2. Chloroform more than any agent known rapidly abolishes the mechanisms of the vascular system which compensate for the hydrostatic effects of gravity. 3. Chloroform abolishes these mechanisms by paralyzing the splanchnic vasomotor tone and by diminishing the power of the respiratory pump. When these mechanisms are entirely destroyed circulation is impossible if the patient is in the feet-down position. 4. Chloroform produces paralytic dilatation of the heart, acting like nitrite of amyl on the musculature of the entire vascular system. 5. There are two forms of chloroform-syncope—that occurring during primary anesthesia and that occurring during prolonged anesthesia. In the syncope which occurs during primary anesthesia the patient struggles, holds his breath, raises the pressure within the chest, congests the venous system greatly, lowers the arterial tension, and finally makes several deep inspirations and thus charges the lungs with chloroform vapor. In the first stage the left heart becomes impoverished, and in the second stage it suddenly fills with blood. This blood is drawn from the lungs and is saturated with chloroform. The chloroform enters into the coronary arteries and the heart is quickly thrown into paralytic dilatation. Respiration and the pulse cease simultaneously or the pulse ceases before respiration. The syncope which happens during prolonged anesthesia arises from gradually giving chloroform to too great an extent. The arterial pressure diminishes more and more and the respiration ceases secondarily because of anemia of the respiratory center. The heart is not paralyzed by chloroform in these cases because the drug is taken in gradually by the shallow respirations and is distributed slowly by the feeble circulation. 6. A patient can be resuscitated from the second form of syncope by artificial respiration and placing him in a horizontal posture. 7. Artificial respiration carried out while the patient is in a horizontal position is the treatment indicated primarily in the first form of syncope. The heart must be rhythmically compressed by squeezing the chest. If these maneuvers do not quickly cause the pulse to appear, the patient should be placed in a vertical position with the feet down. The dilated right heart is thus completely emptied of blood, artificial respiration is kept up during this change of position, and the patient is brought again into the horizontal posture. By rhythmic compression of the chest circulation is maintained through the coronary arteries. If this maneuver fails in the first trial, it is repeated. 8. Placing the patient in the feet-up position or compressing the abdomen will simply increase paralytic dilatation of the heart. In other words, in syncope

¹ Intercol. Med. Jour. Austral., Nov. 20, 1896.

² Brit. Med. Jour., Apr. 17, 1897.

occurring during primary anesthesia both of these methods of treatment do harm rather than good. 9. Shock or fear acts like chloroform in tending to abolish the compensatory mechanism for the hydrostatic effects of gravity, and giving the patient chloroform may be the last straw which completely paralyzes the circulation. 10. Pneumogastric inhibition of the heart is of no importance as an agent in the causation of chloroform-syncope. 11. Ether is a vastly safer agent for anesthesia than chloroform. According to Ringer, it is 50 times less dangerous than chloroform. 12. Hill is in entire agreement with the conclusion of the Hyderabad Commission that the inhaler should be removed when the patient struggles or when the respirations are of irregular depth. Hill, in conclusion, says that the work of physiologists and the tracings of the Hyderabad Commission when carefully studied and rightly interpreted prove that paralysis of the circulatory mechanism, and not of the respiratory center, is what the anesthetist must dread. [The chloroform controversy still continues as it has for many years. Syme always taught that chloroform caused death by inducing respiratory failure. The London school has always taught that chloroform causes death by inducing cardiac failure. The followers of Syme watch the respiration for danger-signals, while the adherents of the London school watch the pulse. Hill succeeds in clearing up some disputed points and shows there are two varieties of chloroform-syncope. Hare maintains that while chloroform is a powerful depressant of the respiratory center and heart when given in excess, when properly given, if it produces death, it does so in the same manner as hemorrhage causes death, failure of the respiratory center occurring because it is deprived of blood, and the pulse-failure being due to vasomotor palsy and the heart having no blood to pump. Hare believes in abdominal compression, inversion, bandaging of limbs, and artificial respiration when chloroform-syncope occurs. Leonard Hill's book upon *The Physiology and Pathology of the Cerebral Circulation* is an important contribution to the chloroform discussion.]

Local Anesthesia.—Prof. Ceci,¹ of Pisa, gives a list of operations which he has performed under the influence of **cocain** or cocain and morphin. Some of these operations are of considerable magnitude. For instance, the radical cure of hernia, laparotomy, vaginal hysterectomy, and extirpation of goitre. He thinks that the addition of morphin for its general effect is a very valuable expedient. In old people he injects a maximum dose of 2 cgm. quarter of an hour before operating. In young people he injects 1 cgm., but he never uses such an injection when a person is under 20 years of age. The cocain he prefers is Merck's, of the strength of 2% dissolved in boric acid. He has a strong solution of a strength of 1:100 and a weak solution of the strength of 1:200. He warms these solutions to make them more active. He believes in making deep injections, the fluid being thrown in for some distance along the nerve-trunks. Local anesthesia he holds is indicated in operations where we can accurately determine beforehand what procedure must be carried out and where the field of operation is not too extensive. He does not believe in this method for children or for excitable or intractable individuals. The anesthesia by morphin and cocain lasts from 30 to 50 minutes. This observer has never seen poisoning, but has frequently met with thirst and dryness of the mouth and in some few cases with excitement and loquacity.

Prof. Karl Stoerk² discusses the question of cocain-anesthesia and particularly considers the toxic influence of the drug. He agrees with Wölfler that injections of cocain made about the head are more dangerous than injections

¹ Brit. Med. Jour., No. 1877.

² Wien. med. Woch., No. 44, 1896.

given into the trunk or in the limbs. The amount of $\frac{1}{3}$ of a gr. should never be exceeded in one injection in the mucous membrane of the mouth. Stoerk applies a 20% solution to the larynx, and has met with only four cases of poisoning as a result of this procedure. He holds that cocaine is absorbed much less readily from the larynx than it is from either the pharynx or the esophagus. He states that nervous people are far more apt to be affected unfavorably with cocaine than are others. In the milder cases of poisoning the condition resembles hysteria. In the more severe cases the face becomes deadly pale, the pulse becomes rapid, and the respirations shallow. In the very bad cases there is faintness which passes on to collapse or muscular jactitation, with sudden movements, hallucinations, and a feeling of great apprehension. After the acute symptoms have passed away the patient is prostrated and weak for many hours, and is apt to suffer from violent headache. There is no real antidote to cocaine. The patient should be placed in a horizontal position and should be given coffee or ether or camphor or injections of musk or inhalations of nitrite of amyl. This writer quotes Doufournier to the effect that the reason toxic symptoms have so often followed applications of cocaine to the throat and nose is because the patient in most of these procedures is placed in a sitting posture. He quotes Baracz to the effect that cocaine must be used with extreme care in epileptics. [A great many people show slight evidences of cocaine-poisoning after the drug is injected, and severe cases of poisoning are not unusual. In the slighter cases the symptoms are often attributed erroneously to fear. Among the symptoms of these slight cases are pallor, incoordination, dimness of vision, tinnitus aurium, headache, tremor, and subsequent sleeplessness for many hours. Cocaine is a dangerous drug, and many persons possess pronounced idiosyncrasy toward it. Nervous persons, the insane, epileptics, and drunkards are particularly apt to develop dangerous symptoms. Idiosyncrasy may run in family lines and may exist in even the most stolid and robust individuals. Cocaine is often used with a recklessness which is appalling. When first used in an individual very small amounts should be introduced, and if these produce no signs of trouble larger amounts can be given. The urethral use of cocaine not rarely produces toxic symptoms.]

John A. Wyeth,¹ in a paper upon cocaine-anesthesia, maintains that it is useless to throw cocaine into the subcutaneous areolar tissue or even into the deeper corium, such a procedure failing to produce satisfactory anesthesia and carrying with it a certain amount of danger. Injection into the subcutaneous areolar tissue is especially apt to be followed by rapid absorption and by toxic symptoms. The injections should be made into the Malpighian layer, where there is a network of sensory end-organs that are certain to come in contact with the cocaine solution. Injection into the Malpighian layer will produce rapid, certain, and safe anesthesia. Dr. Wyeth says that if we wish to inject portions of the body where it is impossible to impede the circulation by the use of the elastic bandage, we should proceed as follows: the needle is carried obliquely through the epiderm until the point is in the Malpighian layer. Arriving at this point about half a minim of a 4% solution is forced out. This causes whitening of the epiderm. With the needle still in position an incision from a quarter to half an inch in length is made as far as the anesthesia has spread. The needle is then withdrawn, is reinserted a quarter of an inch from the first point, and another half minim or minim of the solution is forced out at the same level and the incision is extended. From 2 to 4 minims of the solution will enable us to make an incision 1 inch long through the skin and corium and into the subcutaneous areolar tissue. After

¹ Med. News, Dec. 12, 1896.

opening the subcutaneous tissue, if it becomes necessary to prolong the operation, a weaker solution may now be used with advantage. In operating upon an extremity Wyeth uses a 2% solution for the skin. After the completion of the operation the tourniquet is loosened for three or four seconds and then readjusted for several minutes, and this procedure is repeated two or three times. In this way a small quantity of cocain is admitted into the circulation at one time, and this small quantity distributed over a large area produces no ill results. [We have followed a similar method and can endorse its efficiency and safety.]

The use of **eucain** has attracted much interest and attention during the year. This drug was studied by Prof. Charteris, assisted by Dr. McLennan.¹ These observers proved that eucain is far less toxic than cocain. Further, that eucain is slower in onset and of less intensity, but that it is thoroughly efficient as an anesthetic. Dr. George W. Spencer² made a careful study of the use of eucain in 20 cases of surgical operation, and he considers that this agent produces the most complete local anesthesia of any drug so far used. It does not lose its strength when kept in solution, and it does not decompose even when boiled. The fact that we can boil the solution without impairing its utility is of great advantage, for we are thus enabled to render it satisfactorily sterile. The amount of eucain used depends upon the severity of the operation. He has usually employed a 2% solution. In one case a dose of 15 grains was injected. In some cases he has used 2 drams of a 5% solution. In no case have any symptoms of poisoning been noted. The time necessary to obtain complete anesthesia varies. In 11 cases the anesthesia was complete within 5 minutes. In 7 cases it was complete in 3 minutes. In 1 case it was complete in 2 minutes. In 1 case in which the tissues were infiltrated with inflammatory exudate the anesthesia was not complete for 10 minutes. When we wish to remove a toenail we should wait at least 5 minutes for the anesthesia to become complete. The duration of the anesthesia varies between 20 minutes and 1 hour. In some of the cases slight local effect followed the use of this drug. Spencer disagrees with the statement of Arthur L. Fuller that eucain hardens the tissues to such a degree that it is difficult to introduce sutures. He has never seen this condition produced by it. [That eucain not usually causes sloughing is certain. We have noted this occurrence many times, and it constitutes a serious objection to its extensive use. We first thought sloughing might be due to the preliminary use of ethyl chlorid to produce an anesthetic area through which to insert the needle, but we have seen the same accident since the use of ethyl chlorid was abandoned. It has happened when no carbolic acid was used in the solution or in the tissues, and when the fluid was rendered sterile by boiling. We do not mean to say that it always happens, but it frequently does, producing a dry, semi-elastic, tough, and very adherent slough. Sloughing is most apt to occur after operations in fatty tissue, upon the fingers and toes, the prepuce, bursæ, and tendon-sheaths. In a few cases also it has produced constitutional symptoms of considerable danger.]

Eucain in surgery is the title of an article by Drs. Leguen and Lihou.³ They hold that in physiological action eucain is analogous to cocain, but it has very slight action upon the heart. Cocain slows the pulse and elevates the arterial pressure. Eucain slows the pulse very slightly and has no effect on the arterial pressure. Arterial pressure can be reduced by eucain only when extremely large doses are given. An animal can be killed by very large doses

¹ Brit. Med. Jour., Mar. 27, 1897.

² Univ. Med. Mag., Nov., 1896.

³ Gaz. des Hôpitaux, Nos. 19 and 20, 1897.

of eucain, death being due to respiratory paralysis and not to cardiac failure. Experiments show that eucain is far less toxic than cocain. These observers have used cocain in a large number of cases, including amputation of the fingers, opening of abscesses, etc. They use a solution of the strength of 1%, and rarely administer over 1½ grains of the drug. In the examination of the bladder by the cystoscope they use a solution in the strength of ½ of 1%, employing from 4 to 8 ounces of solution. They have never noticed any toxic symptoms. One patient who had previously been operated upon under cocain and had presented toxic symptoms was not affected at all by the eucain. The anesthetic effects have been as thoroughly good as those obtained with cocain. Hemorrhage is more abundant when eucain is used than when cocain is employed, because of the hyperemia induced by the eucain. This hemorrhage, however, always stops readily. It is a great advantage that eucain can be sterilized readily by boiling. Cocain is decomposed when boiled. The anesthetic effects of eucain are more rapidly obtained than those of cocain. The injection is a little more painful than the injection of cocain. [Eucain is sometimes irritant to the urethra. Görl's advice is sound: "Do not use eucain in the urethra if anesthesia is required oftener than once a day." Eucain causes a hyperemic condition, and should never be introduced into a bladder which tends to bleed.]

Dr. Spencer¹ presents a further investigation of eucain hydrochlorat as an anesthetic, with a report of 24 cases, and these additional studies have served to convince him of the great value of the drug. In this latter list of cases are included 3 tracheotomies, the removal of a large nevus, of a fatty tumor, of a portion of the lower lip, and of a melanotic sarcoma, operation for empyema, fistula in ano, thyroid cyst, traumatic gangrene of the finger, phimosis, hydrocele, needle in the hand, Alibert's disease, and dermoid cyst of the ovary; the operators having been Keen, Hearn, Brinton, Jones, DaCosta, Spencer, and others.

Among other articles upon eucain we would call attention to the papers of the following authors: T. J. Yarrow,² Martin H. Williams,³ W. J. Howe and Macleod Yearsley,⁴ Joseph S. Gibb,⁵ Gaetano Vinci,⁶ and E. Vogt.⁷

THE ESOPHAGUS.

[During the past year it has been found that the location of foreign bodies in the esophagus is made certain and easy by the employment of the x-rays. This application of the x-rays will be discussed in a special article devoted to them.]

William T. Bull and John B. Walker⁸ report a case of extreme interest in which a **foreign body** was successfully **removed from the esophagus** by external esophagotomy after a lodgement of 22 months. The patient had a fainting attack, and recovering found that she had swallowed a tooth-plate holding two teeth. The physician who was called in could only pass a probang 6 inches. The next day the patient was able to swallow liquids and at the end of 6 weeks could take solids. She remained in good health for about 18 months, when she began to suffer from dysphagia and hoarseness and loss of flesh became apparent. External esophagotomy was performed on the left side. Even when the esophagus was reached the body could not be felt. The tube was opened just above the sternum upon a bougie; 1 in.

below the incision and back of the first part of the sternum instruments were arrested. Eventually a whalebone bougie was passed into the stomach along the anterior wall of the gullet. A probe inserted alongside of the whalebone entered a pouch on the posterior esophageal wall and came in contact with the plate. The mucous membrane in front of the plate was nicked with scissors and the plate was removed by means of curved artery-forceps. A rubber catheter was inserted through the wound into the esophagus and was passed 4 in. below the point where the tooth-plate had been lodged. The wound was lightly stuffed with gauze about the cavity. For the first 24 hours the patient was fed purely by rectum, but after this period rectal feeding was supplemented by other methods. At this time fluids were first introduced through the catheter. The tube was withdrawn on the 13th day. In 48 hours after removing the tube the patient was fed by means of a stomach-tube, and a day or two later swallowing was permitted and rectal feeding was discontinued. The patient was out of bed 1 week after the operation and the wound was healed in 7 weeks. The length of time intervening between lodgement of the foreign body and its removal by operation makes this case especially noteworthy.

M. Péan¹ records a case in which a **coin lodged in the esophagus was located by means of a skiagraph.** Péan decided to perform external esophagotomy. After exposing the esophagus he concluded to endeavor to move the body upward by manipulation without opening the tube. By this means the coin was pressed upward until it was extracted from the mouth by means of alligator mouth-forceps. Péan tells us that children can swallow foreign bodies of at least 1 in. in diameter, these bodies lodging at the narrowest point of the esophagus, and the child still continuing to take liquids with ease and not complaining of pain. For this reason it is often thought that the foreign body is not in the tube. Both Broca and the author have reported cases in which death resulted from foreign body lodged in the esophagus, the cause of death not having been suspected until postmortem made it evident. It is a great advantage, if possible, to remove bodies without opening the esophagus, because this operation is dangerous and requires prolonged subsequent treatment which entails much discomfort.

The first case in which the skiagraph was used to detect and locate a foreign body in the esophagus was recorded by J. William White in the *Annals of Surgery* for August, 1896. The patient was a child 2 years and 5 months of age, and was brought to White 13 days after having swallowed a jackstone. The patient was able to swallow liquids but refused to swallow solids. A skiagraph was taken and the jackstone was distinctly recognized as it lay a little to the left of the middle line, somewhat above the bifurcation of the trachea. Attempts to reach the body with esophageal forceps failed and gastrotomy was performed. A slender and flexible esophageal explorer, which had fastened to it a stout silk thread 3 feet in length, was passed downward through the pharynx and into the stomach. One end of the thread was brought out of the wound in the stomach and the explorer was withdrawn, leaving the other end of the thread emerging from the mouth. Pieces of gauze of different shapes and various sizes were tied to this string, which thread was drawn up and down until finally a piece of gauze entangled the foreign body and brought it into the stomach, from which viscus it was easily extracted. The stomach-wound was closed and the child made a rapid and complete recovery. White dwells on the great improvement the Röntgen process of diagnosis is over the old method, in which the sur-

¹ Bull. de l'Acad. de Méd., No. 48, 1896.

geon came to a conclusion from a study of the history, the subjective symptoms, and the recognition of the presence of the foreign body by instruments. He shows how the Röntgen process enables us to determine the exact location of the foreign body, and hence to choose a suitable method for its removal. At first, on studying the skiagraph, he thought of performing esophagotomy, but on examining the short, fat neck of the patient he concluded that, if the body were at all fixed, it would be very difficult to dislodge it through the largest wound which could be safely made in the neck. In view of the fact that this foreign body was firmly lodged in the canal and was irregular in shape he thought it better to open the stomach and try to remove it, and thus dispense with attacking an inflamed and possibly ulcerated esophagus. The situation of this foreign body rendered any attempt to push it downward extremely hazardous. Such an effort would probably have resulted in perforation of the aorta or the bronchus. The fact that it was impossible to move the jackstone upward by the means employed in the operation vindicated the choice of the stomach-route. White thought of the possibility of keeping the foreign body in view with the fluoroscope while an endeavor was made to remove it by the use of forceps from above, but he did not employ this procedure because the general condition of the patient demanded haste and because the probable inflammation and ulceration of the esophagus contraindicated prolonged instrumentation. He thinks that in cases seen earlier this method might be employed. [Strange to say, within a short time of the performance by White of the above-reported operation Keen recognized a jackstone in the esophagus by the x -rays and removed it by esophagotomy, and A. C. Wood had a similar case, which he treated according to the method suggested by White.]

H. Beeckman Delatour¹ records a case in which a child 4 years of age swallowed an iron washer $\frac{9}{16}$ in. in diameter; 4 days after the accident the boy was brought to the hospital and the fluoroscope was applied. The foreign body was distinctly visible and a skiagraph was taken. Delatour was greatly impressed with the distinctness of the shadow obtained by looking through the fluoroscope, and he decided to attempt removal of the foreign body with a pair of esophageal forceps while he used the fluoroscope. Two days after admission the patient was chloroformed and the foreign body was successfully extracted with the esophageal forceps. Delatour thinks that this proceeding is especially valuable in children with short and thick necks in which external esophagotomy is extremely difficult. [The removal of the foreign body while looking at it with the fluoroscope was suggested by White in the report of his case (previous article).]

Two cases of a halfpenny in the esophagus are reported by Francis Johnston and C. Thurstan Holland.² The first case was a child $2\frac{1}{2}$ years of age, who had swallowed a halfpenny 2 days before admission into the hospital. The skiagraph showed the coin in the gullet, and it was easily removed with a coin-catcher. The second case was a child $2\frac{1}{2}$ years of age with a doubtful history of having swallowed a halfpenny. The child came to the hospital 5 months after the alleged accident, laboring under bronchopneumonia. At this time laryngeal stertor and inspiratory dyspnea were noted. These symptoms became constant and involuntary. It was evident that the pneumogastric or recurrent laryngeal nerve was subjected to pressure, but the laryngoscope threw no light upon the question; 13 months after the swallowing of the penny the Röntgen rays were applied and the coin was found. It was removed by means of a coin-catcher.

THE STOMACH.

Péan¹ discusses **gastrectomy**. He has performed 12 pylorectomies with 8 recoveries, and 3 gastroenterostomies with 2 recoveries. He thinks that pylorotomy is applicable in young people who are still in fair health and in cases in which the tumor is small, movable, and unassociated with lymphatic deposits or disseminations. The only cases in which operations should be done are those in which it is possible to leave a portion of the cardiac end. The cut portion of the duodenum should not be attached to this large gap in the stomach. The stomach-opening is sutured and the duodenum attached by means of a Murphy button to the nearest portion of the stomach. When the lymph-glands are involved or when visceral metastases exist pylorotomy should not be attempted, the preferable operation in such cases being gastroenterostomy by means of a Murphy button.

Willy Meyer² presented a patient to the New York Surgical Society on whom he had done **gastroenterostomy for cancer**. He used a Murphy button. The operation had been performed some 3 months before, and the button had not since appeared in the stools. The patient has gained largely in weight since the operation and is free from pain. In 6 previous cases the button has also remained in the stomach.

Emanuel J. Senn,³ of Chicago, proposes a **new method of gastrotomy** by the formation of a circular valve. He maintains that a gastrotomy should prevent leakage by making a valve of the stomach-wall itself, instead of utilizing other structures for that purpose; should minimize shock by putting but little strain upon the stomach; should leave a fistula which is closed during digestion and can be opened when we desire to administer food. He found a prototype of the ideal mechanism in the valves of the veins. These valves permit the blood to flow in one direction only. The author's operation consists in making an abdominal incision in any situation which is desirable, as no muscular structures are required for sphincter-action. The stomach is seized near the great curvature and an assistant forms a cone of this viscus and holds the apex with his fingers or with forceps. Two puck-

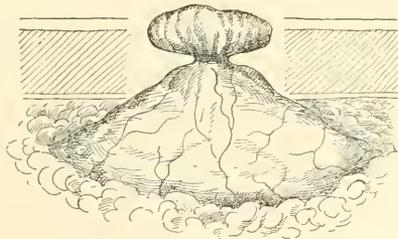

FIG. 11.—Puckering-strings tied, forming a constriction (E. J. Senn, in Jour. Amer. Med. Assoc., Nov. 28, 1896).

ering-strings of chromicized catgut are placed parallel to each other $2\frac{1}{2}$ in. below the apex of the cone, the sutures including the serous and muscular coats (Fig. 10). These sutures are drawn tight and thus form a neck (Fig. 11); a portion of the gastrocolic omentum is lifted up, and a cuff is sutured over the

¹ Rev. de Chir., Nov. 10, 1896.

² Ann. of Surg., Mar., 1897.

³ Jour. Am. Med. Assoc., Nov. 28, 1896.

constriction by means of silk (Fig. 12). The stomach is fastened to the parietal wall with silk sutures, which include the upper portion of the cuff of omentum, the serous and muscular coats of the stomach, and all the abdominal wall except the skin. The skin is closed with silkworm-gut sutures, leaving visible the portion of the stomach which is to form the valve. The stomach can be opened at this time or later, whichever is desired. The opening is made in the center of the portion exposed and should be $1\frac{1}{2}$ in. in

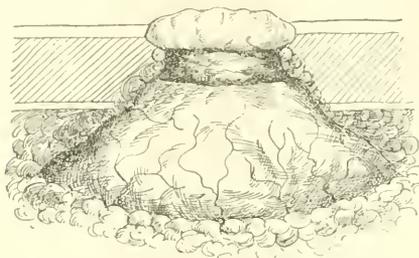

FIG. 12.—Omental cuff covering constriction, and stomach sutured to abdominal-wall (E. J. Senn, in Jour. Am. Med. Assoc., Nov. 28, 1896).

length. A rubber tube is passed into the stomach; the stomach-wall is now inverted, forming a circular valve, and the inversion is maintained by Lembert sutures (Fig. 13). The tube is now withdrawn. The author then records a case in which he performed this operation. The result was most satisfactory. The tube was removed every time after the patient was fed and

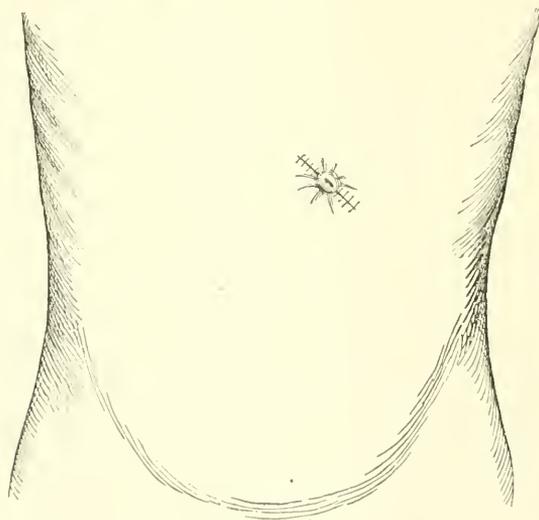

FIG. 11.—Operation completed (E. J. Senn, in Jour. Am. Med. Assoc., Nov. 28, 1896).

there was never the slightest leakage from the fistula. The valve and the constriction were easily passed by the tube, and when the tube was withdrawn the valve would close like a trap-door. Even when the stomach was filled with milk and the patient was told to cough and to move about violently there was not the slightest leakage. [Abbe has performed Senn's operation, and reports that the plan is very satisfactory.]

Fontan¹ describes a new method of performing gastrostomy. This method prevents the escape of gastric juice and is very simple in its performance. It is called by Fontan a valve operation. The ordinary abdominal incision is made, the stomach is grasped with forceps and a portion of it pulled outward, and this protruding portion is sutured to the edge of the wound. This hernia is invaginated while the forceps still retain their hold, and the serous surfaces at the ends of the wound are sutured together. The stomach is then incised and a cannula inserted. The author tells us that the cannula lies in a valvular canal, which is shaped like an inverted mitre of a bishop, the gastric surface being formed of the walls of the stomach and the serous surfaces being opposite each other.

Willy Meyer² records a case of gastrostomy performed according to the method of Kader (first described by Kader in the *Centralbl. f. Chir.*,

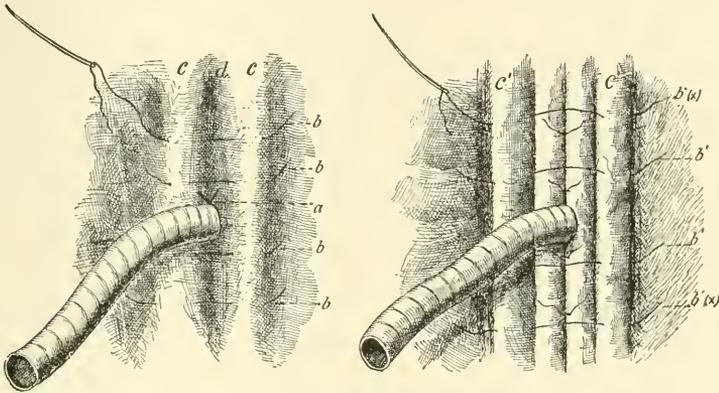

FIG. 15.—Kader's method of gastrostomy (Willy Meyer, in N. Y. Med. Jour., Nov. 7, 1896).

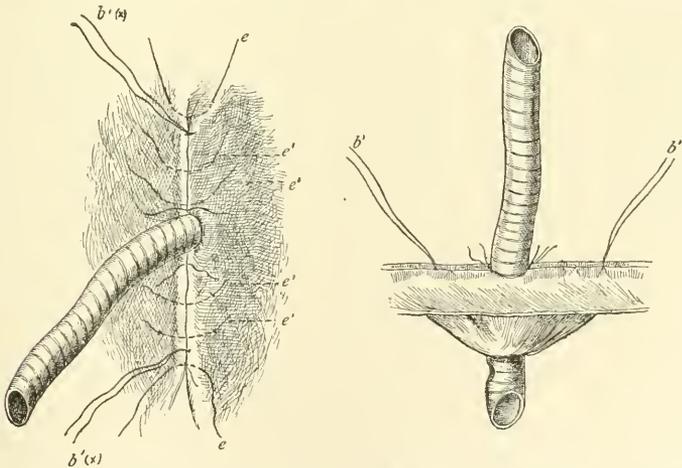

FIG. 16.—Kader's method of gastrostomy (Willy Meyer, in N. Y. Med. Jour., Nov. 7, 1896).

July 11, 1896). Kader stated that he had a case of cicatricial stenosis of the pylorus and esophagus. The abdomen was opened and a long incision was made through the anterior wall of the stomach to perform digital exploration.

¹ Rev. de Chir., Nov. 10, 1896.

² N. Y. Med. Jour., Nov. 7, 1896.

The stomach was very small and so slightly movable that it was found impossible to perform any of the ordinary methods of gastrostomy. Kader therefore modified Witzel's method and found the result admirable. His operation, which differs considerably from the Witzel operation, can be performed upon the most difficult cases, and is carried out as follows: an incision 3 or 4 in. long is made parallel with the borders of the ribs and two fingers' breadth distant from them. Kader states, however, that the simple vertical incision can be used, and Meyer thinks it should be used. The rectus muscle is divided by blunt dissection and the posterior sheath of the rectus and the peritoneum are cut. A fold of the stomach is pulled forward in the usual way. If the stomach is movable, the fold is drawn in front of the abdominal wall, the surrounding field being packed with gauze. A small incision is made and a drainage-tube the size of a pencil is introduced into the stomach for a distance of about 2 in. Bleeding is arrested. The drainage-tube is fastened to the stomach by a catgut suture (Fig. 15, A). Two Lembert sutures (Fig. 15, B) are put on either side of the tube so that they catch and unite a portion of the stomach about $\frac{1}{2}$ in. wide, leaving between a groove $\frac{3}{4}$ in. wide. These sutures are about $\frac{1}{2}$ in. apart. These sutures catch the serous coat and the muscular coat. By tying them two longitudinal folds are formed (Fig. 15, C). The stomach-wall is thus turned inward in the neighborhood of the tube and caused to surround the tube. The drainage-tube is thus surrounded by serous membrane and the canal in which it lies does not pass the stomach-wall obliquely, but enters it perpendicularly. This canal is lengthened by stitching two more folds of the stomach-wall over the first ones (Fig. 16, C). These threads are not cut off, but are left long in order to give the surgeon control of the stomach during the rest of the operation. The stomach is now stitched to the peritoneal wound and the posterior sheath of the rectus muscle, the seat of operation thus becoming extraperitoneal. The rectus muscle is sutured with a few stitches, the anterior portion of the sheath is sutured, and the skin closed on either side of the tube. In the case in which the stomach cannot be pulled forward into the wound Kader tells us to apply the deep occlusion-sutures and use them to draw the stomach up against the abdominal wall and thus close off the peritoneal cavity. In the case in which Meyer operated even this procedure could not be carried out, and he was forced to open the stomach within the abdominal cavity. If we wish to establish a permanent fistula, the folds should be made in the perpendicular direction; therefore in cancerous stricture make the folds perpendicular, in cicatricial stricture make them transverse. This operation has been carried out ten times in the clinic of Prof. Mikulicz; three times it was done under the influence of Schleich's infiltration-anesthesia. All ten patients recovered and in all the result was satisfactory.

Meyer then reports his case, in which the operation was performed for cancerous stricture of the esophagus. It gave a most satisfactory result.

Page and Clay¹ report a case of great interest which was seen at the Royal Infirmary, Newcastle-on-Tyne. There was **obstruction** at the pyloric end of the stomach **due to** kinking produced by the adhesion of a **suppurating gall-bladder**. This condition was confirmed postmortem.

Rutherford Morison,² of Newcastle-on-Tyne, publishes his notes on 4 cases of **pyloroplasty**. He says that Loreta's operation is seldom heard of now. It has to be performed in the dark, and is of necessity dangerous. The Heineke-Mikulicz operation has attained a prominent place in surgery. Morison says the diagnosis between cicatricial and malignant stenosis of the pylorus is often one of extreme difficulty, and is in fact frequently impossible.

¹ Brit. Med. Jour., Jan. 23, 1897.

² Lancet, Oct. 24, 1896.

In cases in which he has had the pylorus outside of the abdomen he has been unable to say whether an induration were due to malignant disease or inflammatory exudation. The most important element in the diagnosis is probably a long history, as this points strongly against malignant disease. If there is considerable scarring of the stomach-wall and adhesions, the indications are in favor of the non-malignant condition. Morison reports 4 cases in which he performed the Heineke-Mikulicz operation. All of these cases recovered and each of the patients greatly improved in health.

Von Bungner,¹ of Hanau, advises the **combination of gastroenterostomy with enteroanastomosis**. This procedure was originally recommended by Braun. Von Bungner operated upon a case by means of gastroenterostomy, but the operation failed to relieve the pain and vomiting still continued. A week after this operation he performed an enteroanastomosis between the afferent and efferent coils. The symptoms at once passed away and the patient made a good recovery.

Fricke² reports a very remarkable case in which a **large number of foreign bodies** were successfully removed from the stomach by **gastrotomy**. The patient, suffering from melancholia, had swallowed with suicidal intent a great number of bodies. The stomach was opened over the most prominent part of the distinct projection; just beneath the muscles an abscess was entered and was found to contain a crochet-needle $4\frac{1}{2}$ in. in length. The needle lay at the posterior portion of the abscess-cavity and adhered to the parietal peritoneum. No perforation was discovered in the stomach. The stomach was opened above the level of the abscess and Fricke removed from the viscus a door-key, a fork, a couple of teaspoons, two nails, two hairpins, a dozen bits of glass, a steel pen, several needles, a window-fastener, and a number of other materials. The total number of foreign objects was 37. The patient made a good recovery.

William F. Haslam³ writes on **gastrojejuno-stomy for pyloric obstruction**. He reports a case in which he performed this operation by means of a Murphy button. The button was passed 140 days after the operation. The patient was very greatly relieved by the operation and gained much in weight and strength. He died 10 months later. The second case was in a woman on whom he performed gastrojejuno-stomy with a Murphy button. The patient recovered well from the operation and gained in health and strength. A year after the operation the button had not passed. Haslam says that though we divide obstructions of the pylorus pathologically into those due to carcinoma and those due to a fibrous overgrowth, from a clinical point of view they are all worthy of the term malignant, for they tend to cause death, first by obstructing the entry of food into the intestines and secondly by exhaustion produced by repeated attacks of prolonged vomiting; they differ only in the length of time necessary to kill. A diagnosis before opening the abdomen is very frequently impossible. Even when the abdomen is opened and the growth is handled it may be impossible to tell whether we are dealing with a hard carcinoma or a fibrous stricture. If the patient recovers from the operation, improves rapidly, gains in flesh notably, and is able to return to work, we may hope that cancer was not the cause. There is no great advantage gained by attempting to diagnosticate the exact pathological nature of a growth before operation. If we feel sure there is a growth of the pylorus, we must feel equally sure that the patient will waste and eventually die if the surgeon does not interfere, and it is our duty to interfere. The rapid im-

¹ Verhandl. der deutsch. Gesell. f. Chir., XXVth Congress, 1896.

² Deutsch. med. Woch., No. 4, 1897.

³ Birmingham Med. Rev., Apr., 1897.

provement which often follows operation, even when cancer exists, is due to the fact that the growth is of the hard and fibrous type, and as soon as the patient can get a proper supply of food he is able to withstand the slow growth of the tumor. Haslam reminds us that the healthy stomach is always in a state of contraction. If undistended with gas, there is no appreciable cavity; if full, its walls are contracting on the varying amounts of food; but if the walls of the stomach have lost their tonicity and become dilated, as they must do after a pyloric obstruction, they are no longer able to contract and obliterate the cavity of the stomach and are no longer capable of emptying this viscus. As a consequence, after the performance of the operation of gastrojejunostomy vomiting may occur for a time because the contents of the jejunum are being forced into the stomach through the artificial opening. When we examine the abdomen with the flat hand we can often detect a pyloric growth, but not in the normal situation of the pylorus. The growth brings the pylorus down from beneath the liver, and when there are no adhesions the pyloric end of the stomach may even wander about the upper portion of the abdomen. It occasionally happens that we think a growth is freely movable and yet find on opening the abdomen that it had adhesions at the upper part, the growth having spread downward from the pylorus along the anterior wall of the stomach. Haslam believes in opening the abdomen early, and opposes waiting until the patient is worn out by vomiting and starvation and the effects of a distended stomach. An operation to be of real value should be done before the stomach is hopelessly distended and before there is great emaciation. Rapid operation is essential because these patients are weak and emaciated. Regarding the immediate result of operation there is much to be said in favor of **the Murphy button**. It is easy to apply and the operation may be quickly completed, whereas the use of sutures, the favorite type of operation with many, necessitates a prolonged operation. Some object to the Murphy button on the ground that it produces death of tissue, but there is no particular danger in this ring of necrosed tissue, as there are peritoneal adhesions around which effectually shut off the general peritoneal cavity. Another objection is that the opening is too small. This can be obviated by using a large-size button or an oval button. Another objection is that the opening has a tendency to contract; it is probable that some contraction does take place, but even then the opening may be large enough. Another objection is that a foreign body has been left and must be discharged before the patient is out of danger. Haslam says that there is no doubt that the chances seem in favor of the button dropping into the stomach rather than into the intestine. Even if it passes into the intestine it may possibly cause impaction or ulceration or damage of the intestinal wall. Nevertheless a study of the records would not lead us to believe that the chances of serious trouble are very great. If we open the stomach on the posterior wall, the best chance for drainage is afforded, but in order to reach the posterior wall we must perform a difficult and prolonged operation. Those who advocate this route state that the posterior opening facilitates the exit of food, lessens the chances of regurgitation when the patient is supine, and by preventing the accumulation of food in the stomach prevents distention. Haslam says that if the stomach is a mere passive bag, the posterior opening will facilitate the passage of food; but if it has the power of contraction, it will not. The pylorus, it will be remembered, is not situated at the lowest part of the stomach. With the anterior opening and a large and atonic stomach there is risk for a time that the stomach will not get rid of its contents, but when we know that this atonic condition exists we can take particular care not to overload the viscus. It occasionally

happens in this operation that there is obstruction in the transverse colon by pressure of a piece of jejunum, or pieces in front of it. This, however, is a very unusual condition, and results when the portion of the jejunum selected was very near the commencement, so that the tension of its mesentery obstructed the colon. We should select a piece of jejunum from its upper end, but not so high up as to have to drag it into position.

[There have been many interesting articles published during the year in relation to gastric ulcer and perforating gastric ulcer. We have selected some of the more striking reports.]

E. Claude Taylor¹ reports a case in which he believes that **perforation of a gastric ulcer** occurred and yet there was recovery without operation. The man had vague symptoms of gastritis for some time. He ate a hearty meal and went to work lifting barrels. He was seized with violent pain and vomited bile-stained material. Five hours afterward he had great pain, collapse, and rigid abdomen. He had passed urine and had had a bowel-movement. He was simply fed by the rectum and got well. Taylor inquires, Should we be in a hurry to operate in such cases, or should we wait as long as the patient is improving? E. A. Seale² reports a similar case in which there was recovery after symptoms of perforation. William H. Bennett³ reports a case of perforating gastric ulcer in which a large opening in the stomach was closed by means of an omental plug. The patient recovered. The procedure was a modification of Senn's original method. The patient was a man who had been seized with the signs of rupture of the stomach 5 hours before admission; a median section was performed and general peritonitis was found to exist. A perforation was discovered 2 in. from the pylorus on the upper aspect. The parts were very adherent. The opening was $\frac{1}{2}$ in. in its longest diameter and was surrounded by a zone of induration 3 in. in diameter. The extent of the induration prevented inversion of the peritoneum by the ordinary method. The trial was made, but the stitches cut out. Bennett turned up a portion of the omentum and pushed as much as was necessary into the perforation, completely closing it just as a cork closes a bottle. This omental plug was fixed in position by a single suture passing through the whole thickness of the plug and of the stomach-walls at the point of perforation and by several other sutures which after transfixing the base of the plug brought the peritoneum on each side into contact with it. These sutures were put in by the Lembert method in order to cause the peritoneum to overlap as much as possible. The abdominal cavity was washed and sponged and the wound was brought together in the usual way. The patient made an excellent recovery.

T. H. Morse⁴ reports 3 cases of **perforated gastric ulcer treated by laparotomy**; 2 of these patients recovered and 1 died. The first case was operated on 5 hours after the onset of the symptoms and the second case $4\frac{1}{2}$ hours after the onset of the symptoms, and they both recovered. The third case was operated on 24 hours after the onset of the symptoms, and died of shock. If a case of perforating ulcer is not operated upon, the patient will probably live for about 24 hours. This statement shows how necessary are diagnosis and early operation.

Mr. Arthur E. Barker⁵ reported in a clinical lecture 7 cases of perforated gastric ulcer treated by operation, with 3 recoveries. In all of these cases the perforation was on the anterior wall of the stomach. In no instance was there any evidence of a second perforation. In all of the cases excepting one the

⁵ Lancet, Dec. 5, 1896.

operations were similar. A median incision was made in all. In 3 of them it was necessary to add a transverse cut through the left rectus muscle. In one of them an inguinal incision had been made previously, and this materially facilitated the cleansing of the peritoneal cavity. In all of the cases the peritoneal cavity was cleansed by means of dry sponging rather than irrigation. Great care was taken in 6 of the cases to carry the sponge between the liver and diaphragm, a point in which material is very apt to collect. This procedure was omitted in Case 4 and a subphrenic abscess resulted. Barker has been surprised at the large amount of matter which he has been enabled to dislodge by sponging from between the liver and diaphragm. Great care must be taken to cleanse around and behind the gall-bladder, in the flanks, and in the pelvis. In 2 cases a drainage-tube was inserted through an incision in the flank, but it seemed to be of little benefit. In 4 cases the anterior wound was drained with iodoform-gauze with good results. A portion of gauze was carried down deeply between the liver and diaphragm on each side, another was carried down to the suture-line in the stomach, another was carried behind the gall-bladder. The pieces of gauze were removed on the 5th or 6th day. In no case was the ulcer cut out. The edges were inverted, and the silk stitches were inserted deeply in one or two rows by means of round sewing-needles. In after-treatment Barker advocates feeding by the mouth. He gives small amounts, frequently repeated, of egg-albumin and water, brandy, beef-tea, and chicken-broth, and begins to give them as soon as the patient recovers from the anesthetic. In addition to this he uses peptonized suppositories in the rectum, alternating every 2 hours with an injection of 5 ounces of hot water. Barker thinks the most important element in success in these cases is early operation. The prognosis is profoundly affected for the worse when it is found that the contents of the stomach have escaped among the intestines. If a solid meal has been taken shortly before perforation and large fragments of food have passed into the peritoneal cavity, profound shock and great distention result. Barker thinks that we should operate early, even in collapse. We had better operate when collapse is present than to take the chance of death involved in waiting for it to pass away. In all of his cases it was necessary to empty the stomach by pressure. This is better done by hand than by washing out. The author does not see how early feeding can injure while the stitches hold firmly. He would feel more anxious as to the consequences of mouth-feeding after 2 or 3 days than at first, because at the later period the stitches might cut out. Great benefit attends early feeding; it rouses the patient from collapse and thus overweighs the risk. Barker says he has been careful in the two patients that recovered to keep them for a long period in bed under strict treatment for the gastric ulcer, as this condition takes a long time to repair thoroughly.

Andrew J. McCosh¹ records a case of perforating gastric ulcer in which recovery followed operation. In this case perforation had occurred gradually and some time before and a limited abscess had formed. When the abdomen was opened it was found that the peritoneum was adherent to the structures beneath. The stomach and liver agglutinated together formed the upper wall of the abscess. At a depth of 2 in. beneath the stomach and liver the abscess-cavity was evacuated. At the bottom of this cavity the finger detected the opening in the stomach. The edges of the stomach-opening were scraped and trimmed and the opening was closed by two rows of sutures. A piece of gauze was brought into contact with the suture-line and was caused to emerge

¹ Med. News, Jan. 16, 1897.

through the abdominal wound; the rest of the wound was closed with sutures. The patient recovered from the operation and did well.

H. Littlewood,¹ of Leeds, reported 2 cases of perforated gastric ulcer successfully treated by operation. He affirms that the most important factor contributing to a successful result is early diagnosis, so that the operation can be performed within 8 or 10 hours of the period of rupture. In these cases Littlewood excised the ulcer. This was done quickly and easily. He thinks it is an advantage to remove the edges of the ulcer, especially if they are indurated. He believes, however, that there are a number of cases in which excision is not practicable and in which inversion merely should be practised. Littlewood says that the treatment of the peritoneum when there is purulent peritonitis is still an unsettled question. Some wash out, some wipe out. He believes that it is a physical impossibility to cleanse the peritoneum thoroughly by either method. The peritoneum can unquestionably deal successfully with a certain amount of septic material.

J. St. Thomas Clarke,² of Leicester, records a case of perforated gastric ulcer in which operation was followed by recovery. After opening the abdomen and inverting the perforation the abdominal opening was covered temporarily with hot sponges, and a second incision was made in the mid-line just above the pubis so as to explore Douglas's pouch. This pouch was found filled with the same turbid fluid which had been noted in the abdomen higher up. The abdominal cavity was irrigated with water at a temperature of 105°, the glass tube being passed between the coils of intestine above the liver, under the liver, and in different regions until the fluid emerged clear. A drainage-tube was inserted into Douglas's pouch and the wound closed, and a drainage-tube passed into the upper opening so as to reach the line of sutures about the ulcer. Dr. Clarke is a firm believer in free irrigation. He does not think that sponging alone can possibly remove all traces of the septic fluid. He believes the second incision a most important factor contributing to the good result.

Herbert P. Hawkins and C. S. Wallace³ report two cases of operation for perforation of gastric ulcer followed by recovery. In the first case the ulcer was inverted. Another incision was made below the umbilicus and several ounces of turbid fluid were removed from the pelvis. The abdomen was flushed out and each wound was drained. The second case was under the care of Makins and S. G. Toller. The margins of the rupture were freshened by scraping with a Volkmann's spoon and the rupture was inverted. There was no free fluid in the peritoneal cavity and no trace of solid food, and irrigation was not employed. In this second case the perforation had occurred 26 hours previous to operation, but the stomach contained little food at the time of injury. The opening was very small and no solid contents had escaped.

Van Noorden⁴ discusses the operative treatment of some **sequelæ of gastric ulcer**. The first case reported was that of a woman who when young had been supposed to have gastric cancer. At the age of 52 she was subjected to operation. A portion of omentum was found adherent to the stomach near the pylorus. The adhesions were cut; there was a spear-shaped depression on the serous coat of the stomach which was not interfered with. The patient improved very much after operation, but in three months the symptoms returned. They were believed to be due to nervous dyspepsia and disappeared under treatment. In the second case the patient had a gastric ulcer and developed the signs of peritonitis. The abdomen was opened, the

¹ Lancet, Nov. 21, 1896.

² Ibid., Mar. 20, 1897.

³ Brit. Med. Jour., Apr. 10, 1897.

⁴ Münch. med. Woch., Sept. 1, 1896.

omentum was found adherent to the stomach, and it was evident that protective adhesions had been formed, but that in spite of them there was perforated peritonitis. An opening was made between the stomach and the transverse colon. Lymph was met with but no pus. The site of perforation was discovered by observing an air-bubble. While preparing to resect a large tear was inflicted upon the stomach and some of the contents of the viscus escaped. The peritoneum was sponged cleaned and the stomach was surrounded with gauze pads. No resection was performed and it was decided to make a fistula. At a later period 4 attempts to close the fistula failed. The patient died some 8 weeks after operation. Postmortem disclosed the fact that there was a small opening on the anterior wall of the stomach near its lower border and passing over to the posterior wall. The stomach was the shape of an hour-glass. [A very able review of the varying views upon the treatment of gastric ulcer will be found in the *Annals of Surgery*, Nov., 1896.]

DISEASES OF THE PERITONEUM AND OF THE INTESTINES.

O'Connor¹ records a **chyle-cyst of the mesentery**. The swelling was distinct in outline, smooth and tense, fluctuating, distinctly movable, and about as large as a cocoanut. Pressure caused a considerable amount of pain. Percussion elicited a dull note. There was no thrill. When the abdomen was opened a greenish-colored cyst was met with. It was covered with large veins and looked much like sarcoma. The adhesions were so dense that removal was found impossible. The tumor was incised and the edges sutured to the abdominal wound, the interior being packed with gauze. The patient made a satisfactory recovery.

Theodore A. Magraw² discusses the utility of **omental splints in intestinal surgery**. He presents the records of some cases in which this method was applied with great advantage. He thinks that the omentum should be applied with little disturbance of its blood-vessels. It is a tissue that is well supplied with blood, and it is probable that its power to resist the ill effects produced by feces or pus arises chiefly from its ample blood-supply. It is an error to cut a flap of omentum, because doing so alters profoundly the blood-supply, as some blood-vessels would require to be tied and cut. Omental grafts are valuable purely because of their capacity for rapid adhesion. If this does not take place, their vitality fails. It is not likely that an omental graft, even when it unites quickly to the raw surface, will resist for any great length of time the pressure of feces if the suture gives way. The detachment of the flap from the omentum and its suture to the bowel produce a cord-like band under which strangulation may occur. Magraw is a believer in the application of uncut omentum. He says it should be drawn over the bowels like a sheet, and its extremity must be wrapped about the wounded intestine in order to cover the suture. In this way we can secure admirable support to the bowel, a support which is amply supplied with blood and which does not cause danger of intestinal strangulation. Omental flaps or omental grafts, or the use of neighboring coils of intestine as splints, are to be employed only in cases in which atrophy or disease renders it impossible to draw the omentum down to the wounded surface.

Gilbert Barling³ furnishes some valuable and practical considerations on **peritonitis due to perforation**. He states that peritonitis from perforation may be due to perforation of the vermiform appendix, bursting of a

¹ Brit. Med. Jour., Feb. 13, 1897.

² Physician and Surgeon, Oct., 1896.

³ Birmingham Med. Rev., Dec., 1896.

circumscribed abscess about the appendix, perforation of a gastric ulcer, a duodenal ulcer, or an ulcer of some other part of the intestine, sloughing of a typhoid ulcer, or the rupture of a distended gall-bladder, or a pyosalpinx. The onset is very acute and the progress of inflammation is extremely rapid, and early recognition is of the first importance. The course of perforative peritonitis is for several reasons not always the same: the simple cases are frequently not typical, variations being due partly to the nature of the material which is extravasated and the amount of this material, partly to the position which the damaged part occupies in the abdominal cavity, and partly to the vital resistance possessed by the patient. For instance, rupture of a gall-bladder with extravasation of mucus and bile only is not nearly so dangerous an accident as rupture of a gall-bladder containing pus. If perforation occurs in the stomach, widespread abdominal extravasation is apt to ensue. If perforation occurs in the appendix well behind the cecum, or in the pelvis, the extravasation does not at once spread widely through the abdomen, and the inflammatory process may for a time be limited. The danger of the stomach perforation varies according as to whether the stomach was empty or full and as to whether the person was in a vertical or horizontal position at the time of the accident. Nevertheless, it is usually possible to diagnose perforative peritonitis and to determine the seat of primary trouble. The onset is generally marked by very acute pain which may be accompanied by faintness. This symptom is especially prominent in perforation of the stomach. In some cases the pain is widespread at the start; but, as a rule, it is first local and subsequently becomes general, the locality of the initial pain pointing to the seat of perforation. Local tenderness early in the case corresponds to the seat of perforation; later in the case it becomes widespread. Soon after perforation the abdomen is not distended; in fact, it is rather concave from muscular rigidity, and this rigidity may be extreme. In spite of rigid muscles distention eventually becomes prominent. Distention may be due to paralytic distention of the stomach and bowels associated with a large peritoneal effusion. It may sometimes be due to free gas in the belly-cavity which has escaped through the perforation. If there is complete abolition of liver-dulness, it is almost certain that perforation has occurred, from the gas having entered between the front of the liver and the diaphragm. Mere diminution of liver-dulness is not of great diagnostic consequence. If at any part of the abdomen there is a circumscribed area of tympanitic resonance surrounded with comparative dulness and other symptoms indicative of perforation exist, this tympanitic area almost positively points to a collection of free gas which has escaped from the perforation. Vomiting is not very pronounced at the beginning. The patient often vomits once or twice and then the sickness passes away. There may even be no vomiting, only a feeling of nausea existing. As peritonitis finally begins vomiting is very apt to come on, but its frequency and persistence are much influenced by the manner in which the patient is fed. If the patient is fed by the mouth, there will be persistent vomiting; and if the stomach is kept empty, there will be very little vomiting. Obstruction of the bowel is a very common associate of peritonitis whether the peritonitis arises from perforation or not; but obstruction does not of necessity occur. There may be actual diarrhea or occasional passage of flatus. A case with complete constipation offers a worse prognosis than where there is not complete constipation. The fact that the bowel can act spontaneously or can be emptied by the use of purgatives is an important point in the differential diagnosis between perforative peritonitis and acute intestinal strangulation. The temperature of peritonitis varies extremely and it is very difficult to draw

useful conclusions from it, but in perforation a study of the temperature may give the most useful information. Right after the perforation there is either a subnormal temperature, or, if fever has existed before, there is at least a great abatement in the febrile temperature. The worse the shock the more positive is the drop in temperature. After this depression there is apt to be a decided rise, but this rise does not certainly follow. If at the time of perforation there is considerable shock, the pulse will be found to be small, fluttering, and of varying frequency. Whether shock has been pronounced or not some little time after the perforation there will be noted a quickening of the pulse, until in three or four hours it amounts to between 100 and 130. It may become of the hard, wiry character which is supposed to indicate peritonitis, but more often it is the soft pulse met with in septicemia. In making a diagnosis of a case of perforative peritonitis the age and sex should always be considered. In a child the most likely seat of perforation is the vermiform appendix, and in a young, anemic woman it is the stomach; in the young or middle-aged male we should first suspect the vermiform appendix, and after that the existence of duodenal ulcer.

The history of any previous illness is of great importance. If there is a possibility of typhoid fever, this may clear up the diagnosis. If there is a history of stomach indigestion, perforation of gastric ulcer should be considered. If the patient is a married woman who has been sterile for some time, or has been completely sterile and who presents a history of pelvic inflammation and purulent vaginitis, rupture of pyosalpinx is suspected. The history of previous attacks of hepatic colic would suggest ruptured gall-bladder. In perforation of the vermiform appendix there is often a history of previous attacks of so-called appendicular colic followed by tenderness and possible swelling in the right iliac fossa. In some cases we will obtain additional light by giving an anesthetic and palpating the abdomen to discover any thickening, a procedure, however, which is only undertaken if operative measures are in contemplation. The treatment of perforative peritonitis apart from operation is that of acute peritonitis in general, and does not call for a full description here. Barling, however, dwells upon a few points, especially the question of feeding and the necessity of rest. He restricts what is taken by the mouth to the very smallest quantity, thus keeping vomiting in subjection by having the stomach empty. Vomiting, if allowed to continue, greatly aggravates the distressing thirst. Nourishment is administered by the rectum and thirst is allayed by enemata of plain water. Occasionally fluids, in teaspoonful amounts, are given by the mouth, the amount being gradually increased if vomiting is not excited by their ingestion. If perforation of the stomach is suspected, absolutely nothing should be given by the mouth. If perforation is suspected, absolute rest is imperative because extravasated materials are capable of being localized to one portion of the abdominal cavity, where they may be retained and shut off by adhesions from the other portion. The slightest movement may serve to widely disseminate extravasation. Great harm is done by moving the patient from place to place.

Barling then discusses the use of opium. He says that one of the chief elements in the production of shock is the severe pain these patients suffer from, and he thinks it is cruel to withhold opium. A sufficient amount should be given to assuage the violent pain and tide the patient over until shock is passed, when the question of operation will be considered. If it is evident that an operation is to be performed, the less opium given the better for the patient, unless the condition is considered almost hopeless, when anything is justifiable which diminishes the patient's suffering. Opium after operation is

not desirable. If operation is not resorted to because the indications are not clear, opium should be avoided. It lulls the patient into deceptive calm and misleads the doctor into a sense of fancied security. When perforation is diagnosed and operation is refused give opium freely. Barling says the influence of aperients in peritonitis has been inculcated in modern times by Mr. Lawson Tait, and our gratitude is due to him for the discovery. The great value of aperients, however, is prophylactic rather than curative. If after an abdominal operation there are any signs of peritonitis, purging does the patient much good; but when once peritonitis has been thoroughly established purging is commonly difficult to bring about, and although still useful is not nearly so valuable as in the early stage. There is a tendency at present to give aperients freely whenever severe abdominal pain is complained of without special investigation into the cause of the pain. Such a proceeding may do great harm in perforation of the stomach and vermiform appendix. The use of aperients in appendicitis is a remnant of the old idea that fecal impaction exists in the cecum. Now that we know that the appendix itself is the seat of trouble and that it may be perforated or gangrenous, the use of any plan of treatment which disturbs the intestines and omentum about the damaged part can do great injury in the acute stage. If the parts are left at rest, adhesions can form a barrier around the diseased appendix. Although aperients may do harm, opium may do more harm by quieting symptoms of the patient and causing us to misjudge the gravity of his condition.

Barling lays it down as a rule that perforative peritonitis is fatal without surgical interference. It is quite true that cases have been recorded in which perforation of the stomach by round ulcers has been followed by recovery without operation, and occasionally recovery has followed typhoid perforation and perforation of the appendix; but these recoveries are so few that they may be disregarded. If perforation has been diagnosed and the condition of the patient and the surrounding circumstances admit of operation, the abdomen should be opened. If the patient is profoundly shocked or if peritonitis has advanced so far as to render the patient moribund, a wise surgeon will not operate. So, too, a surgeon may be without assistants or nurses, and the quarters occupied by the patient may be so miserable as to contraindicate operation. Otherwise invariably operate. If the diagnosis as to the seat of perforation is not certain and an operation is at first exploratory, do median section above the pubis. If it is possible to diagnose the site of perforation, the incision should be over that region. Barling says in perforation of the vermiform appendix there is one lesson he has well learned: that is, not to do too much in the very acute condition. The wisest course is to evacuate any extravasation or inflammatory material and introduce drainage. If the appendix is easily found, remove it; and if it is not easily found, leave it alone and remove it later in the interval if the patient recovers. A lengthened search for the appendix may break down the circumscribed inflammatory products and spread infection. Another reason for caution is that patients in this condition will rarely bear prolonged anesthesia or protracted manipulation. In not a few cases where perforation of the appendix has occurred and where general peritonitis is supposed to exist, in reality the condition is a circumscribed peritonitis occupying the lower half of the abdomen, but not involving the peritoneum above the transverse colon. For this reason Barling hesitates to use irrigation for fear it will tear away limiting adhesions and spread infection to regions that are free from it. In perforation of the stomach and duodenum it is absolutely necessary to close or in some way shut off the perforation from the belly-cavity and to clean the peritoneum by irrigation or sponging. The operation

must be done at the earliest possible moment. Every hour which passes adds 5% to the risk of death. The reader will understand, however, that operation is not undertaken during the primary collapse, but is done immediately after this collapse passes away, the period of collapse having been tided over by the use of morphin and stimulants. The abdomen is opened in the mid-line above the umbilicus, in some cases a transverse incision being added to the vertical incision. If on opening the abdomen no evidence of anything wrong is noted, the extravasation is limited, and the surgeon must try to keep it so. Search should be made between the liver and the stomach, where extravasation is most apt to be found. If nothing is detected there, follow along the pylorus and examine the duodenum. When stomach or intestinal contents are found they are carefully sponged away and the perforation is sought for. This is usually on the anterior wall of the stomach or on the lesser curvature; but it may be on the posterior wall, in which case it will be necessary to tear through the lesser omentum or the gastrocolic layer to reach it. It is unnecessary to excise a perforation. It is closed by interrupted Lembert sutures with a wide turning in of the edge. Excision is of no benefit; it consumes time and adds to the risk of the operation. If the perforation cannot be closed, a glass drainage-tube is passed down to it, and gauze is packed about the tube and brought out of the incision. If the stomach-contents have been widely extravasated or if general peritonitis exists, the abdominal cavity should be irrigated with large amounts of hot water or hot normal salt solution. This can only be done thoroughly when a second opening is made above the pubis; the fluid is introduced in the first incision; the surgeon's hand moves constantly among the intestines, along the colon, between the liver and diaphragm, and in the pelvis, and the fluid is made to emerge from the second incision. If the extravasation is limited and general peritonitis does not exist, irrigation is harmful, as it may break down adhesions and spread infection. In such cases cleansing is effected by sponging the infected area. After cleansing the abdomen drainage should be applied, and if two incisions have been employed drainage is maintained in each. Typhoid perforation is a not very unusual cause of death. The Birmingham general register shows 29 deaths from this cause in the last 20 years; 27 of these perforations were in the small intestine and 2 in the large bowel. In 20 cases in which the exact place of perforation is described in the post-mortem notes 17 were within 12 in. and 9 within 6 in. of the ileocecal valve. In these cases there is practically a choice only between operation and certain death, and the mortality from the operation is extremely heavy. Most operators in such cases have opened the abdomen in the middle line, but the post-mortem records above quoted suggest the advisability of opening it in the right semilunar line. When the perforation is small and the tissues around are not extensively sloughed invert the edges of the perforation with Lembert sutures. If the conditions are not favorable for this proceeding, Keith's drainage-tube should be passed down to the perforation, gauze-packing should be inserted around the tube, and the incision should be partly closed.

Dienlafaoy¹ writes upon **surgical intervention in the peritonitis of typhoid fever**. He says that in typhoid fever it is held that appendicitis can occur, one form due to typhoid, the other form associated with it, and either form can cause perforation. In the first form the lymphatic structure of the appendix becomes the seat of typhoid ulceration and perforation ensues. In the second form true appendicitis complicates typhoid fever. He considers also the other causes of perforative appendicitis, and strongly advocates surgical intervention as the only alternative to death. Dienlafaoy

¹ Bull. de l'Acad. de Méd., Oct. 27, 1896.

concludes that in typhoidal appendicitis and appendicular typhoidal peritonitis operation can be performed if the condition of the patient is good. In typhoidal peritonitis operation gives a chance of recovery.

John N. T. Finney¹ discusses the surgical treatment of perforative typhoid ulcer. In this paper we find an elaborate discussion of the history of the surgical treatment of typhoid perforation, the consideration of the conditions under which perforation occurs, an analysis of the symptoms in the reported cases, and a thorough study of all accessible statistics. The author says, if we include all cases that have been reported as operations for perforating typhoid ulcer, together with the six cases which he has collected, we have 52 cases with 17 recoveries, 32.68%. Excluding all doubtful cases we have left 45 cases, of which 11 recovered, a percentage of 26.22. Finney believes that Mikulicz's first case and Dandridge's case should be admitted; this would make a final and, as he thinks, a correct estimate of 47 cases with 13 recoveries, a percentage of 27.65. In 8 of the reported cases a wrong diagnosis was made; 3 were thought to be appendicitis, in 2 a diagnosis of ileus had been made, in 2 the symptoms were supposed to be due to internal obstruction of unknown cause. One was undiagnosed at the time of operation. The effect upon the mortality of the time of operation is uncertain. Some of the cases operated on earliest died the soonest, and *vice versa*. It would, however, seem reasonable to suppose that the earlier the operation is performed after the patient has undergone some reaction from the primary shock, the more favorable ought the result to be. The statistics throw but little light upon the disputed question of the respective merits of irrigation and wiping the peritoneum; 8 of the 10 cases in which general peritonitis existed recovered after irrigation. In only 4 cases was wiping practised, and 2 of these recovered. Because all but 2 of the fatal cases were irrigated it would not be fair to say that the irrigation caused death any more than other circumstances. Finney thinks in cases when the inflammatory process has gone beyond circumscribed points, but has not invaded the entire peritoneum, irrigating fluid may possibly disseminate infection. We must of necessity use a fluid so bland as to be practically without antiseptic power. Excision of the ulcer is entirely unnecessary and needlessly prolongs the operation. If the intestinal wall is so damaged that sutures will not hold, it would be unwise to excise the perforation, and it would be far better to pull the damaged loop outside of the abdomen and leave it there for a subsequent resection and anastomosis. Autopsy-records show that the peritoneal surfaces united just as thoroughly in cases when the edges of the ulcer had not been excised as when they had been. The mattress-suture of Halsted possesses great advantages over other sutures and should be used by preference. It is immaterial whether the line of sutures is parallel with the axis of the bowel or at right angles to it. The condition of the bowel-wall and other circumstances determine whether it is necessary to apply more than one row of sutures. The surgeon should always be careful to avoid encroaching upon the lumen of the gut more than necessary. Drainage should invariably be employed. If there is general septic peritonitis, the abdomen is practically an abscess-cavity, and the contents of this abscess-cavity should be thoroughly evacuated and effective drainage should be established. The best drainage is obtained by wicks of bismuth- or iodoform-gauze placed in different parts of the abdominal cavity, the ends being brought out through the abdominal wound, the rest of the wound being sutured. Drainage in the most dependent portion of the abdominal cavity is of great value. The signs which are of most value in recognizing typhoid perforation are sudden, acute abdominal

¹ Ann. of Surg., Mar., 1897.

pain, collapse, and abrupt and decided fall of temperature. Vomiting is often present. The obliteration of liver-dulness, the gurgling sound on respiration, hiccough, etc., are very valuable signs when present. No pathognomonic sign of perforation has yet been put forth. There is one point which promises to be of great aid in doubtful cases; that is, the examination of the blood. Thayer tells us that during typhoid fever there is no increase in the proportion of colorless corpuscles, but there is a tendency toward a diminution in particular at the height of the disease. Finney says in typhoid fever at the beginning the white corpuscles are about normal, the number gradually sinking during the progress of the fever, reaching the lowest point at about the end of the febrile period, at which time they vary from 2000 to 6000 per cubic millimetre. If an inflammatory complication arises, there is immediately a marked increase in the number of leucocytes. We must recall that a slight and temporary leucocytosis has been observed under certain methods of treatment and following a cold bath, but this is too slight and of too short duration to be mistaken for the leucocytosis that follows perforation. Cabot in his recent work on the clinical examination of the blood alludes to the marked leucocytosis which occurs at the time of perforation. So few observations of this sort have been made that systematic study of the blood from the beginning should be made in every case of typhoid fever, as the knowledge of any sudden change may be of great importance if an obscure complication arises. As a rule, perforation is quickly followed by symptoms of peritonitis, the intensity of the symptoms depending largely upon the nature of the infecting agent, the dimensions of the opening, and the area of surface involved. Pyogenic cocci are rarely absent from the intestine. The streptococcus pyogenes is usually found in numbers in the exudate of perforative peritonitis. The autopsy-records of the Johns Hopkins Hospital show 7 deaths from perforating typhoid ulcers. In 6 of these bacteriologic examinations were made of the peritoneal exudate. In 4 of the cases there was mixed infection with the streptococcus pyogenes and bacillus coli commune. In 1 there was found the streptococcus alone, in another the colon-bacillus alone. The length of incision should be sufficient to permit the operator to examine the parts thoroughly, to explore completely, and to cleanse satisfactorily. A long incision will heal just as quickly as a short one. When we deal with a case of fully established general peritonitis from perforation of a typhoid ulcer the chances of recovery from operation are somewhat better than 1 in 4. In the treatment of the cases of perforating ulcer 3 things are to be done: 1. Find and close the perforation; 2. Empty and cleanse the peritoneal cavity; 3. Establish and maintain efficient drainage. Finney says that in most cases we should make an oblique incision in the right iliac region, find the cecum, locate the ileum, and draw out coils of ileum through the wound. All the infected intestine is drawn out of the peritoneal cavity—if necessary, the entire small intestine. The peritoneal cavity is carefully wiped out with gauze pads and sponges wrung out of hot salt solution. It is not necessary to irrigate with salt solution; the intestines, which have been covered with hot pads, are next uncovered and irrigated while outside the abdomen with hot salt solution. They are then replaced in the inverse order from that in which they were withdrawn, being wiped dry before replacement. The worst coil is replaced last. The sutured portion is replaced next, and the abdominal wound is packed around with strips of bismuth-gauze, and if necessary a strip of gauze is carried into the pelvis; the abdominal wound is closed tightly, excepting where the gauze drain emerges. If there is much distention, the bowels are

moved early by calomel in broken doses, followed by salts and, if necessary, a high enema of turpentine and soap-suds.

Finney sums up his conclusions as follows: 1. Of the so-called diagnostic signs of perforation most reliance is to be placed upon an attack of severe, persistent abdominal pain, associated with nausea and vomiting and marked leukocytosis. 2. The surgical treatment is the only rational one. 3. The only contraindication to surgical operation is a moribund condition of the patient.

Finney then records 3 cases upon which he operated. The first died in 7, the second in 26 hours after operation, and the third recovered. At the end of this useful, thorough, and scientific article is a *résumé* of the cases collected from literature. [Finney is an advocate of operation in these cases, and we think proves his case. The choice is between death and operation. The question whether or not to irrigate is still in debate. It seems possible to cleanse the abdomen thoroughly by wiping if we eviscerate. Irrigation with saline fluid possesses certain merits. The saline fluid is in part absorbed, lessens shock, allays subsequent thirst, aids diuresis, and helps to expel toxins from the blood. The statement that "it is needless to excise an ulcer" voices the opinion of most surgeons. In cases of perforative peritonitis suprapubic and posterior drainage are of value. If a stab is made through the kidney pouch after the plan of Mayo Robson excellent drainage can be established. The increase of leukocytes after perforation seems to offer us a valuable diagnostic point. It is well to remember that leukocytosis occurs after hemorrhage, otherwise the value of the finding of leukocytosis will be overestimated. The blood ought to be regularly studied in every case of typhoid.]

W. G. Spencer¹ reports a remarkable occurrence in the progress of a neglected typhoid fever. This patient was supposed to be suffering from **influenza**, and had had a rupture in the left inguinal region for nine years. When he was admitted into hospital the left half of the scrotum was very much distended, the swelling extending to the inguinal region and the skin being dusky and edematous. The swelling was tympanitic on percussion and opaque to light, fluctuation was present, and the inguinal ring was filled by a firm mass which exhibited succussion on coughing. The temperature was 102.6°. Spencer made a diagnosis of ruptured hernia and made an incision. There was an escape of pus, gas, and flatus, and a mass of sloughing omentum was cut away. There was no bowel found in the sac. The adhesions separating the abdominal cavity were not disturbed. The sloughing hernial sac was treated antiseptically, the sloughs which subsequently formed being removed. For a few days the patient did well, but he soon began to waste with great rapidity, and died 17 days after admission. The postmortem examination disclosed the fact that the **perforation** had been **due to typhoid ulcer**. The oldest perforation was just above the ileocecal valve. There was no question that the patient's illness was due to typhoid fever.

Shattuck² reports the case of a Harvard student, 19 years of age, who had typhoid fever with perforation. The perforation occurred within 10 days of the time he took to bed, and was recognized at a consultation which was held 12 hours after the first symptom appeared. The operation was performed by Dr. C. B. Porter. On opening the abdomen there was an escape of turbid serum. No fecal matter was seen, although the odor was somewhat fecal. A coil of intestine bulged from the wound; the intestines were carefully examined, being gradually drawn out and replaced as fast as inspected. The duodenum was reached without finding a perforation. With

¹ Lancet, Apr. 10, 1897.

² Boston M. and S. Jour., Apr. 15, 1897.

the duodenum as a starting-point the entire small intestine was examined. The perforation was found in the cecum. Intestinal sutures were inserted in a diamond-shaped area, the line of sutures being transverse to the bowel-axis; a second row of these inversion sutures was placed over the first. The abdomen was cleansed by wiping and a drainage-wick was placed in each side of the pelvis. The patient died 61 hours after the operation.

E. B. Steel,¹ surgeon-lieutenant of the army medical staff, reports a case of typhoid fever which was complicated by perforation, peritonitis, and relapse, and followed by perityphlitic abscess. This individual had been attacked suddenly with violent abdominal pain; the abdomen was rigid and tender, the temperature was 103.6°, and the pulse was 130. Tenderness was most marked in the right iliac fossa. There was neither a tumor nor dulness on percussion. The previous history suggested walking typhoid fever. For several days the patient showed all the symptoms of acute peritonitis, and on the third day went suddenly into collapse, and it was necessary to administer considerable amounts of opium and morphin. Reaction took place, and for several days the patient presented the usual symptoms of peritonitis. Nine days afterward a crop of well-defined typhoid spots appeared on the abdomen. The condition grew progressively better, the temperature dropping and the symptoms abating, until about 16 days after the case was first seen the temperature began to rise again, and fresh spots appeared indicating relapse; still improvement took place. While the patient was becoming apparently better the pain returned in the right iliac fossa. This pain became very violent, and soon a swelling was detected and a diagnosis was made of suppurating appendicitis. Chloroform was administered and an incision made. Four ounces of pus were evacuated and a drainage-tube inserted. The patient made an excellent recovery.

Armstrong² reports the cases in which he operated for typhoid perforation. Three died and 1 recovered. He states that in 23 reported cases in which operation was done and in which the diagnosis was certain only 4 recovered. In spite of the excessive mortality operation is the only thing that offers the slightest chance for life. Even when the patient is in excessively bad condition, overwhelmed with the poison of typhoid fever, operation should still be undertaken, as it is the only chance. If the clinical evidence points to the fact that the perforation has been in the large intestine, or that it is likely to remain local, it is justifiable to wait for abscess-formation; but if the indications are that the perforation has taken place into the general peritoneal cavity, the only chance is laparotomy, inversion of the area, irrigation of the belly with hot saline solution, and free drainage. This operation should, of course, not be performed until reaction from the primary collapse is attained, and it should not be undertaken if the individual be obviously moribund. If a perforation occurs during convalescence, the chances of success from operation are greatly increased. Armstrong uses 2 or 3 rows of inversion sutures and passes them in the long axis of the bowel.

Joseph Price³ reports 3 cases in which he operated for typhoid perforation, with recovery. The first patient had a typical history of typhoid fever. There were symptoms of perforation, and he could make out an ill-defined tumor on the right side. Two perforating ulcers were discovered in the region of the ileocecal valve. In the second case the character of the ulceration was doubtful, as there was tuberculous trouble in the lungs. In the third case the patient was so far gone that she was unconscious at the time of operation. Dr. Price says that he never attempted to close a filthy peritoneal

¹ Brit. Med. Jour., Jan. 2, 1897.

² Ibid., Dec. 5, 1896.

³ Phila. Polyclinic, Nov. 14, 1896.

cavity, and yet recovery followed. He maintains that every case of perforation demands operation, and that operation is the only possible chance that the patient has of life.

L. S. Pilcher¹ presented at a meeting of the New York Surgical Society a specimen of **cancer of the splenic flexure of the colon** which he had removed from a woman 57 years of age. This tumor was as large as a man's fist and yet had produced no symptoms of obstruction. He united the ends of the bowel by the method recently described by Ullmann, which is really a modification of Maunsell's method. The suggestion made by Ullmann was that after the approximation of both the distal and proximal ends a spool of raw vegetable should be inserted and the ends tied about it with an encircling thread of catgut or silk and that then it should be placed within the bowel. Dr. Pilcher used potato; Ullmann used carrot. The potato placed within the bowel carried with it 2 ends brought into close apposition with a considerable surface. The serous surfaces thus brought together remain held together as long as the core remains in place or until the separation of that portion of the intestine which was strangulated by the cord. Pilcher believes this procedure is a very useful one. This patient died on the 12th day after operation of lockjaw despite the use of antitoxin.

A. J. Bodine² presents a new method of performing intestinal anastomosis with special reference to its adaptability to inguinal colostomy and subsequent restoration of the fecal current. He states that intestinal anastomosis when we do not use mechanical aids is an operation of extreme difficulty. Mechanical aids render the operation easier, but they are not absolutely reliable or entirely harmless. The method which he suggests is the outcome of studies made with the idea of improving the spur in inguinal colostomy. It is quite evident that if the spur is level with the skin-surface no fecal matter can enter the lower portion of the colon. The spur, which is formed by suspending the gut over a supporting rod, has neither thickness nor rigidity, and the dragging weight of the intestines pulls its upper border below the level of the skin, and when this happens fecal matter does pass into the lower portion of the intestine. Bodine thought that the mesentery might be folded so that it would stiffen the spur by stitching together both sides of the two limbs of the bend. He tried this on a dog and found it satisfactory. Acute flexion of the gut upon itself forms a septum fully an inch wide, which septum is between 2 rows of sutures. It will at once be seen that simple incision of the center of this spur removes the obstacle to the flow of feces. We therefore have a very simple method of restoring the continuity of the intestine. He has operated upon 5 dogs. He has done enterostomy as advised for intestinal anastomosis, making a temporary anus by excluding the mesentery from between the 2 rows of sutures. He has done colostomy as recommended for permanent anus by folding the mesentery between the 2 limbs of the flexure. The method of anastomosis he now proposes is as follows: the abdomen is opened, a pad is introduced to protect the intestines, and the parietal peritoneum is stitched to the skin with a continuous catgut suture. The lesion which has necessitated operation is sought for and is drawn through the incision until 6 in. of healthy gut protrude on each side of the lesions and beyond the incision. The limbs of this loop are laid side by side, the lesion being the apex. A stitch of fine silk, beginning at the points where excision is desired, is inserted, uniting the portions of intestine close to the mesenteric border and parallel with it for a distance of 6 in. The sutured loop is then passed into the abdomen until the point where the suturing commenced is on a level with the skin, where it is stitched into the ab-

¹ Ann. of Surg., Apr., 1897.

² N. Y. Polyclinic, Feb. 15, 1897.

dominal wound with a continuous suture of catgut. This leaves the lesion protruding outside of the abdominal cavity. If it is possible to wait, wait 12 hours, at which time apply cocain and cut off the protruding intestine, including the lesion. This establishes an artificial anus, and we may wait any length of time before attempting to reestablish the continuity of the intestine. When we wish to establish the continuity a finger is passed into the opening of each portion of intestine to define the spur and guide the cutting instrument; the septum is divided with scissors along the median line, the instrument employed being either a pair of scissors or Grant's clamp; the abdominal wound may be closed by any method which the surgeon prefers. Bodine prefers closure by the plan of Szymanowski or Byrd.

Czerny¹ states that he has used **the Murphy button** in 13 cases, with 3 fatalities. In 1 of the cases he used too large a button gangrene occurred and perforation took place. The other 2 cases in which death followed were very unfavorable, the operation being for gangrene of strangulated hernia. Czerny says the button, as a rule, is found in the stools in from 2 to 3 weeks after operation. In a case in which he used the button for gastroenterostomy it had not been found 24 days after operation. Czerny thinks that in the majority of cases the best method for closing intestinal wounds is to double suture. He says that the use of the Murphy button, although it requires practice to become dextrous, can be learned more easily than can the use of the double suture. He remains somewhat anxious for the patient until the button has been discharged. He thinks that this button is a positive advance in the methods of intestinal suture.

Frank,² of Chicago, has set forth **a new device for anastomosis**. He uses 2 collars of decalcified bone, with 6 nail-hole perforations at the shoulder of each collar; also a piece of ordinary rubber tube $\frac{7}{8}$ in. in length and $\frac{5}{16}$ in. in diameter. A bone collar is slipped over the rubber tube and is sewed to the tube, the material used to sew with being silk. The other collar is then fitted over the tube and fastened and the instrument is ready for use. The rubber tube over which the collars are fastened being hollow, permits the passage of intestinal contents after it has been placed *in situ*. When the appliance is introduced the intestinal ends are brought over each collar and crowded between the ends of the collar. The 2 collars are forced apart, the rubber tubing is stretched, and the intestinal ends are held in contact by the elasticity of the rubber. This process is sufficient to bring about necrosis of the interposed intestine. The collars after a time dissolve and only a small bit of rubber tube is left in the intestine to pass with the feces.

M. L. Harris³ has devised a method of **circular enterorrhaphy**. In this method he divides the intestine transversely, being careful to retain the mesentery up to the edge. He now removes the mucous membrane from the distal end of the gut for about $1\frac{1}{2}$ cm. This is readily done with a sharp curette. All of the mucosa ought to be removed. The proximal end is invaginated into the distal end. Three sewing-needles are threaded with fine silk; the first needle transfixes the thickness of the denuded end of the bowel just to one side of the mesentery and at the inner limit of the denudation. It is not pulled all the way through, but the point projects from the caliber of the bowel a little beyond its free edge. A point of this needle picks up a portion of the other end of the bowel transversely just to one side of its mesentery and close to its edge. By drawing the needle back a little it can be used as a lever, and by turning round its point of transfixion in the lower end it will invaginate the upper

¹ Centrallbl. f. Chir., No. 31, 1896.

² Medicine, Jan., 1897.

³ Chicago Med. Rec., Jan., 1897.

end into the lower end, as far as the part is denuded of its mucosa. The same process is repeated with the second needle, at a corresponding point of the bowel on the opposite side of the mesentery, while the third needle is used at the part of the bowel opposite to the mesenteric attachment. The needles are then drawn all the way through and the stitches tied, and thus permanent fixation is secured. By a united or continuous suture the exposed end of the bowel is stitched all round to the invaginated part, the surgeon being careful not to penetrate into the lumen of the gut. If the continuous suture is used, it should be broken at least once, so that when tightened it will not narrow the caliber of the bowel. Two or three stitches are taken on either side of the mesentery. It will be observed when the operation is completed that there are two rows of sutures around the bowel, one at either end, thus keeping the surfaces in accurate apposition regardless of the varying caliber of the bowel. This operation Harris performed on a boy of 8 years, who had a gunshot-wound of the intestine. The boy died in a few hours from shock. Death occurred at too early a period to permit of any conclusions as to the success of any particular method of suture. However, it became evident that the operation could be performed with great facility. The 2d case in which he performed it was a boy of 5 years, who had a large mesenteric tumor. It was found necessary to remove 51 cm. of small intestine. Resection and suture by this method required less than 15 minutes. The boy made a complete recovery and it is now more than 10 months since operation. This operation was tried first upon dogs before being applied to human beings.

Mitchell Banks¹ presented his experiences with the **Murphy button**. He says that in the operation for obstruction rapidity is of the greatest possible importance. The Murphy button is still upon trial; although it has received the approval of a large number of eminent surgeons, some few record serious consequences as the result of its use. Banks records 7 cases in which he used the button. One case of obstruction due to fibrous stricture of the small intestine: excision and death. One case of intussusception of the ileum: excision, end-to-end approximation, and recovery. One case of cancerous stricture of the descending colon: recovery from right lumbar colotomy; death after subsequent excision. One case of typhlitis followed by suppuration and fecal fistula: end-to-side approximation of the ileum and ascending colon; death from tubercular disease 11 months afterward. One case of intestinal fistula resulting from strangulated hernia in which a portion of the ileum was removed: the patient recovered from the operation, and died some months after from pelvic abscess. One case of tuberculous matting of the ileum, adhesion having taken place to the bladder and a fistula having formed between the bladder and ileum: end-to-side approximation of ileum to ascending colon was performed; the patient recovered from the operation and died some months later from tuberculous disease. One case of tuberculous disease of the cecum; end-to-side insertion of ileum into ascending colon; the patient recovered, but the operation is of too recent date to be sure of what is going to happen. The patient with intussusception remains fat and well 21 months after operation, showing that the union effected by the button is perfect.

Banks believes that the use of the button will supersede all other methods in intussusception. So far he has not met with any accident from the button, although he knows that others have. Cases have been reported in which buttons were never found again, but the patients have apparently been none the worse. Banks is sure that, if the surgeon and his assistants use the button

¹ Brit. Med. Jour., Oct. 24, 1896.

skilfully, they can complete the operation far more quickly than can be done by any other method.

[In endeavoring to estimate the value of various plans of anastomosis we should bear in mind the recent experiments of Ballance and Edmunds.¹ An epitome of these studies will be found in the *Practitioner* (May, 1897). They come to some interesting conclusions—viz., Halsted is right in his statement that intestinal sutures should invariably pass through the tough submucous coat. Lateral anastomosis is, as a rule, easier and less dangerous than end-to-end union. The best method of lateral anastomosis is that of Halsted, and to employ it we do not need mechanical aids. This method gives large openings. End-to-end anastomosis should be performed by suturing. If a mechanical device is used, we should employ one which does not require fastening to the bowel (the button of Murphy). Maunsell's method gives a very perfect union without the formation of an obstructing diaphragm. In using Paul's tubes it is found impossible to invaginate the intestine satisfactorily. The Czerny-Lembert suture obtains solid union, but leads to the formation of a ridge which is practically a diaphragm lessening the calibre of the bowel. The bobbin of Mayo Robson leaves a very small opening. The experiments of Ballance and Edmunds were made upon dogs.]

John Wheelock Elliot² furnishes a contribution to the **surgery of the large intestine**. He states that he recently resected a cancer of the ascending colon through the lumbar incision. He found the operation very satisfactory, and believes it to be a new proceeding. The incision was made at the outer border of the quadratus lumborum muscle and curved forward toward the anterior superior iliac spine. The bowel was drawn out and resected with the greatest ease. The divided ends were entirely outside of the body, so that there was absolutely no fear of infecting the peritoneal contents. When the bowel was returned it was in a perfect condition for drainage. This patient recovered. Elliot also records a case of bullet-wound of the colon and a stab-wound of the colon, both of which recovered.

W. A. Garrard³ reports a case of **carcinoma of the colon** occurring in a child of 12. He states that sarcomatous growths are common in early life, but epithelial carcinoma is excessively rare. In a large number of cases reported by Mr. Cripps in 1890 there was only 1 case of cancer of the colon in an individual under 30. Cancer of the rectum is known to be not very uncommon in young adults, and Garrard is inclined to think that younger people become affected with it more often than was formerly thought to be the case. This patient had labored under constipation for some time, and finally had complete obstruction. The abdomen was opened, the colon was found to be twisted, and the trouble was found to be a stricture in the sigmoid flexure. Colotomy was done, and the bowel was at once opened with a trocar and cannula. The boy recovered without trouble. An examination was then made of the lower end of the colon and rectum when the patient was under an anesthetic. A stricture could be felt under the artificial anus, but not per rectum. Six months after operation he presented himself again, complaining of pain in the artificial anus. There was a hard mass of skin about the colotomy opening, which was ulcerated. The spur was thickened and infiltrated. The naked-eye appearances strongly indicated cancer. During the next few weeks he grew worse and died. Postmortem demonstrated the fact that he labored under colloid columnar-celled carcinoma of the sigmoid flexure. [The above, we believe, is the only case upon record of cancer of the colon at

¹ Med.-Chir. Trans., 78th vol.

² Ann. of Surg., Mar., 1897.

³ Quart. Med. Jour., Apr., 1897.

such an early age. Sendler reported a case in a man of 22, and Powell reported a case in a man of 23. Czerny¹ reported a case of only 13 years.]

Archibald Cuff² reports an interesting case in which **intestinal obstruction** was caused by an **enterolith**. The patient was a woman 59 years of age. She had the symptoms of obstruction; the abdomen was opened and a hard mass was felt within the bowel about 3 ft. from the ileocecal valve. The bowel was occluded on each side of the obstruction by the fingers of assistants, an incision was made opposite the mesenteric attachment, and a stone removed. The wound in the bowel and the abdominal incision were then closed. The patient died of exhaustion. The stone is oval, brown in color, and weighs about $\frac{1}{2}$ an ounce—its long diameter is $1\frac{1}{2}$, its short diameter 1 in. Chemically, it is composed of carbonates and phosphates of lime and magnesia. [The collection of such a mass in the ileum so as to cause obstruction is a rare event. Enteroliths are far more common in the large than in the small bowel.]

Francis B. Harrington³ reports a case of intestinal obstruction due to a large **gall-stone**. When first seen it was supposed that the obstruction was due to malignant disease. The abdomen was opened, a mass was found within the small intestine, the intestine was opened, and a large gall-stone removed. The patient made a good recovery. The stone is cylindrical, has a circumference of $3\frac{1}{2}$ in., a diameter of $1\frac{1}{8}$ in., and a length of 1 in. It weighs 170 gr. Robert Wilkinson⁴ records a case of acute intestinal obstruction from impacted gall-stone. The patient was not operated upon, and although an unfavorable prognosis had been given gradually improved. Eleven weeks after the onset of the symptoms of obstruction the patient felt a great deal of pain, and examination detected a mass blocking the lower fourth of the rectum. By pressure through the posterior vaginal wall a foreign body was extruded, and found to be a gall-stone the size of a pigeon's egg, faceted, and weighing 5 drams, $41\frac{1}{2}$ gr. The patient became perfectly well. Wilkinson says that this case supports the view of his old teacher, Mr. Mayo Robson, that if we can be reasonably certain that obstruction is due to gall-stone, a palliative line of treatment will probably end in the passage of the foreign body, although many believe that the risk of waiting is greater than is the risk of operative treatment.

F. Kammerer⁵ had a patient on whom he had performed unilateral and finally total **exclusion of a part of the intestine for fecal fistula**. The patient was a man who had been operated on three times for appendicitis. After the last operation a fecal fistula developed from which all of the fecal matter passed. After an extensive operation to close the fistula Kammerer implanted the proximal end of the divided ileum into the transverse colon and closed the distal end. Six months later a little fecal matter still escaped from the fistula, and after another attempt at closure by resecting the bowel at the seat of closure he reopened the abdomen and divided the transverse colon immediately before the implantation, thus absolutely excluding from the fecal circulation a portion of the ileum, the weakened colon, and a part of the transverse colon.

Heydenreich⁶ states that in the large intestine exclusion with complete closure of the portion excluded produces no ill-effect, but partial exclusion with the formation of a fistula is a better operation. A patient may be relieved of a troublesome fistula by a total exclusion, but it may be necessary at

¹ Münch. med. Woch., No. 11, 1896.

³ Boston M. and S. Jour., Aug. 27, 1896.

⁵ Ann. of Surg., Apr., 1897.

⁴ Brit. Med. Jour., Feb. 13, 1897.

⁶ Sem. med., Mar., 1897.

any time to operate and make a new fistula. When there is profuse secretion in the portion we contemplate excluding total exclusion must not be brought about. A fistula must be made, and this fistula may close if the secretion becomes slight. The operation of exclusion is really only a palliative procedure, but is very useful in cases in which resection is excessively dangerous. The small intestine is not a suitable field for the operation of exclusion.

F. Kammerer¹ reports 2 cases of fecal fistula treated by total exclusion of a portion of the intestine. He thinks that it is remarkable that unilateral exclusion with implantation into the transverse colon should not be used more frequently for the cure of fecal fistula in the cecum. In malignant tumors of the cecum which are inoperable he does not advise unilateral exclusion, because in such cases there are apt to be ulceration and discharge into the lumen of the bowel. In this article Kammerer reviews extensively the literature dealing with fecal fistula.

D'Arcy Power² delivered the Hunterian Lectures for 1897 and discussed the pathology and surgery of **intussusception**. The ileocecal varieties are particularly apt to occur in children. He is a believer in the value of hydrostatic pressure in treatment. The patient should be anesthetized and the large intestine should be gradually filled with hot saline solution, the reservoir being raised not higher than 3 ft. for a child, all the fluid being permitted to remain in the intestines for 10 minutes. As a rule, when this fails the abdomen ought to be opened and an attempt be made to reduce the intussusception by manipulation. When the end of the intussusceptum is gangrenous, when the intussusception is very short, and when it is irreducible because of adhesions of its neck, because of the polypoid tumor or of the bulging of the end of the intussusceptum, the method devised by Barker and Greig Smith should be employed. This method consists in suturing the intestines with the intussusceptum at the neck of the tumor, opening the intestine, removing the portion of the intussusception which lies free, arresting the bleeding, and closing the wound in the intestine. If gangrene exists in the neck of the intussusception or when the intussusception is associated with malignant disease of the gut, it will be necessary to resect the intestine. Mr. Power believes that the Murphy button or the bobbin is most likely to give good results when intestinal resection has been done for intussusception in the small bowel, while Mammell's operation is indicated for ileocecal and colocolic forms of intussusception.

T. Pickering Pick,³ after discussing the causation and the symptomatology of acute intussusception in children, takes up the treatment. There are 2 chief plans of treatment: the one seeks to reduce the intussusception by distending the bowel with air or water aided by abdominal manipulation; the other seeks reduction after abdominal section. We should regard an intussusception in the same light as a hernia. No one would think of treating a strangulated hernia with purgatives or enemata, or rest, or opium, or abstinence from food. We ought not to adopt a like plan in intussusception. In a strangulated hernia we apply taxis, and if this fails operate at once, and this is the exact plan which should be employed in intussusception. First, try by introducing air to reduce the invagination. If this fails, promptly open the abdomen and relieve the obstruction. No surgeon would ever think of such a thing as waiting a day or two, or even a few hours, in a case of strangulated hernia before attempting reduction. Yet, strange to say, some surgeons still delay in cases of intussusception. Never delay, but take

¹ Med. Rec., Feb. 20, 1897.

² Treatment, Mar. 25, 1897.

³ Quart. Med. Jour., Jan., 1897.

active measures at once. Cases of intussusception are on record in which the gut has become gangrenous within 24 hours of the onset of the attack. The plan of distending the bowel with air is safer than distending with water. It is very important to keep the child warm. It should, therefore, be dressed in a woollen jacket and the legs and arms should be covered with woollen bandages. An anesthetic is given and an enema-pipe is introduced into the rectum. This pipe is connected by a piece of rubber tube to a pair of common bellows. The outside of the tube around the anus is carefully packed with wool, which is held in position by an assistant; the child is inverted and held by a nurse, and the bellows are slowly worked. The surgeon has his hand on the child's abdomen so that he can feel the tumor. As the intestine distends the surgeon's hand feels the colon bulge, and he can tell when the colon is distended as far as is safe. If this plan succeeds, the tumor will suddenly disappear from under the hand and the air will become diffused over the entire abdomen, causing a uniform abdominal distention instead of distention of the colon alone. The disappearance of the tumor from under the hand is no proof that the intussusception has been reduced; but the onset of uniform abdominal distention is proof. It happens often on inflating the intestine that the air causes a change in the position of the tumor, so that it slides from beneath the hand, and yet the intussusception is not reduced. Some surgeons have inflated the intestines with carbonic acid gas, generating the gas in the rectum by injecting first citric acid solution and then sodium bicarbonate, the catheter being quickly withdrawn and the nates held together to prevent escape of the gas. This method is not altogether safe; the gas is evolved suddenly and may produce serious symptoms, and we are unable to regulate the amount of the distention.

Senn used inflation with hydrogen gas, but Pick has had no experience with it. It is probable that inflation is useless when the intussusception is beyond the ileocecal valve, but in infants the vast majority of cases are of the ileocecal variety. In introducing fluid into the bowel it will be necessary to proceed with great caution otherwise serious injury may be done.

Forrest has shown that there is little danger of injuring healthy intestines in a young child by injecting water at a pressure of 6 pounds to the inch; but bowel which has been subjected to constriction is not healthy, and is liable to give way under pressure which would inflict no harm on a sound bowel. Fluid should never be injected by means of a syringe, but only by a method of irrigation. The reservoir containing the fluid is placed not more than 3 ft. above the bed. In an infant under 1 year of age $1\frac{1}{2}$ pints of fluid would be used. This amount will completely distend the infantile colon, and the injection of a greater amount will be dangerous. The best fluid to employ is boiled water at a temperature of 100°, containing a dram of salt to the quart. The child is prepared as for inflation. The fluid will be felt to distend the colon gradually. It is allowed to escape after a few minutes. The abdomen is now examined, and if the tumor has disappeared the patient is returned to bed and kept warm. No opiates should be given. If the injection fails, we should not resort to a second attempt. There is a third method of reducing an intussusception, without operation, although it is rarely successful. The method consists in thoroughly anesthetizing the child so that the abdominal muscles are relaxed, seizing the gut between the forefinger and thumb immediately below the tumor, and attempting to push the tumor backward along the course of the colon by a kneading movement. This method can only be applied to the ileocecal or ileocolic varieties.

There is no question that operation in infants is a very severe procedure.

Some surgeons profoundly believe that a section on an infant less than 12 months of age is almost certainly fatal, but this is not so. Many cases are on record in which laparotomy has been successful on very young children. Howard Marsh reported a case of a child under 6 months old. Wiggan has collected 64 cases which have been operated on by laparotomy for intussusception in infants under 1 year of age; 21 of these cases recovered.

Pick says that when the plans of treatment which he has mentioned have been tried and have failed, it is the surgeon's duty to operate. Incision had best be made in the median line, as we are thus enabled to deal readily with all portions of the abdominal cavity. After opening the abdomen care should be taken to prevent the escape of the intestines. If they are permitted to escape, they at once become distended and there is much difficulty in returning them, and the necessary manipulation may burst the intestine and increase the difficulty. The incision in the abdomen should be just large enough to admit 2 fingers. As soon as the peritoneum is opened a flat sponge is introduced to prevent bulging of the intestine. The finger is passed down by the side of the sponge to explore the abdomen. When a tumor is found the finger is carried around it until the lowest limit of it is reached. When this is done the intestine is grasped just below the tumor, and by working along the colon and grasping successive portions of the gut the intussusception is pushed backward and finally reduced. This is all done within the abdomen. If the intussusception has existed for a time and adhesions have formed, or if it is very acute, so that there is much swelling and congestion, the invagination cannot be reduced. In such a case it will be necessary to enlarge the incision and bring the tumor up to the surface of the wound. An attempt is then made to reduce it. On no account should any attempt be made to reduce the invagination by traction on the entering tube. Occasionally it will be found that the invagination is irreducible or the intussusception may be gangrenous. Under these circumstances there are 3 possible methods of procedure: 1. Longitudinal incision into the intussusciptum, drawing out the intussuscepted part, cutting it off and suturing the intussusceptum to the ends; 2. Resection of the invaginated gut and end-to-end anastomosis; 3. The formation of an artificial anus. The first proceeding is best carried out by Maunsell's method. It is seldom necessary to make an artificial anus. In these days, when we can do an end-to-end anastomosis as rapidly as we can make an artificial anus, there seems to be no justification for doing the latter imperfect operation.

Frederick Treves¹ reviews the **surgery of the peritoneum**. He maintains that the Continental operators have indulged in many extravagances in the performance of abdominal operations. Those who come after us will read with interest of operating-rooms built like a diving-tank, of glass tables, "of the ceremonial of washing on the part of the operator, of the rites attending the ostentatious cleansing of the patient, of the surgeon in his robes of white mackintosh and his India-rubber fishing-boots, of the onlookers beyond the pale who are excluded with infinite solicitude from the sacred circle as septic outlaws." Such an exhibition is not a part of surgery, it is rather "a fervent and idolatrous ritual." The people who follow these methods appeal to the infallible test of the bacteriologic laboratory; but most intelligent surgeons are content to appeal to the test of the patient and to show records of results. What is done in the surgical theatre can be judged by one solitary test, the future of the patient. The results obtained by English surgeons will contrast favorably with those obtained elsewhere in spite of the fact that they do not employ the elaborate ritual above alluded to. These characteristic preparations for operation are

¹ Brit. Med. Jour., Oct. 31, 1896.

unnecessary, and when they are employed no better results are obtained than are gotten from simpler methods. The prolonged exposure and washing of the patient after he is placed on the operating-table are harmful. Treves believes that a simple method, such as the following, is sufficient to secure antiseptic results. The operating-room should be clean and free from dust, the table can be of wood. Some time before the patient enters the operating-room the skin of the abdomen is shaved, is washed with soap and water and then with ether and a solution of corrosive sublimate, and is covered with a compress soaked in a 1:20 carbolic solution. This compress should be in position at least five hours before operation. The surgeon is clean, but he does not parade his cleanliness. The macintosh and blankets are clean in a domestic sense; the towels are sterilized; the instruments are sterilized by boiling and are kept in a tray containing 1:20 carbolic acid solution. Before the operation is begun the solution is largely diluted with boiled water so as to destroy its irritant properties. The sponges are made of Gamgee tissue and are soaked for 24 hours in a 5% solution of carbolic acid. Before operation the carbolic acid is washed out by sterilized water and each sponge is passed through a clean sponge-washer. Any onlookers can approach the operation just so they neither touch the patient, the sponges, nor the instruments. As to whether these simple precautions are enough, Treves takes as a test the operation of removing the vermiform appendix in the interval. He has performed this 150 times with one death, and he does not think this one case would have been saved if he had adopted the skin-washing and rubber boot ritual. In securing primary union after amputation and after excision of the breast the results obtained cannot be surpassed by any school of the advanced ceremonial. The dressings used are a matter of little moment. The wound is dried, is dusted with iodoform, and is dressed by a pad of wool and a binder. The selection of the dressing used to be a matter of the greatest possible importance. It is now known to be of not the least consequence. A great many wounds do not need any dressing, but are dried, dusted with iodoform, and left exposed to the air under the protection of a cradle. The fact that the iodoform is filled with microorganisms may disturb the bacteriologically minded surgeon, but it disturbs neither the wound nor the patient.

In discussing peritonitis Treves says there can be no doubt that all forms are septic and are due to microorganisms. It is very doubtful if there is such a thing as a rheumatic form of peritonitis. The form due to the pneumococcus has not yet established itself. There is no such thing as idiopathic peritonitis. The constitutional symptoms of peritonitis are the same as those of septicemia, and the patient dies from blood-poisoning and not from inflammation. When peritonitis is developed away from the small intestinal area it is apt to be localized. This is shown by the course of peritonitis in the iliac fossa, in the subphrenic region, and in the pelvis. We have made great advances in the treatment of localized peritonitis, but we have made but little progress in the treatment of diffuse peritonitis. We can open the abdomen, wash it out, and drain it; but the results are by no means brilliant. The results obtained in the treatment of tuberculous peritonitis have been most admirable. Abdominal section will cure over 60% of cases, and in 33% of those who recover the cure is permanent. It is not necessary to indulge in any elaborate preparations for opening an abdomen for tuberculous peritonitis. Simple incision with evacuation is the most successful of all plans of treatment. Treves says that that unfortunate term "toilet of the peritoneum" has wrought infinite harm in abdominal operations. This serous membrane has a wonderful capacity of protecting itself against microorgan-

isms. If the membrane is irritated, this power is diminished and extensive effusion may be brought about by rough manipulation. The surgeon who is infatuated by the term toilet of the peritoneum, who is indifferent to the nature and amount of effusion and seeks to remove it even when it is quite sterile by sponging, rubbing, and flushing, may cause results often disastrous in the extreme. Treves does not counsel us always to leave an extravasation in the abdomen, but he would prefer to leave a few ounces of sterile cyst-fluid than he would to damage the peritoneum beyond hope of recovery by persistent sponging. If the extravasation is both extensive and noxious, it must be removed, and this result is best accomplished by flooding with sterile water with very little handling of the intestines. If drainage of the abdomen is necessary, use the gauze tampon and not the glass drainage-tube. Primary cancer of the peritoneum does not exist. The peritoneum is, however, liable to sarcoma, and this growth is most common from the omentum. The victims of this malady are usually adults of about middle age, although occasionally it is met with in young people. They usually exhibit loss of strength, loss of weight, and loss of color. An omental tumor moves about the front surface, is flat, it may feel hobnailed or quite smooth. The swelling is dull on slight percussion, but may be resonant on deep percussion. After the growth has been pressed down it seems to float up again. There is usually some ascites and more than one lump may be felt. This form of growth is identical pathologically with retroperitoneal sarcoma. Treves has frequently observed diminution in the size of retroperitoneal growths after exploratory laparotomy. In the London Hospital, when a case of ascites needs tapping, puncture is never employed, but a small exploratory incision is used.

In discussing perityphlitis Treves says there is not one bit of evidence that such a condition as appendicular colic exists. The muscular tissue of the appendix is very feeble; the so-called muscular coat, in fact, is composed chiefly of fibrous tissue. In some appendices it is a question whether there is any muscle at all; in any case it is but a thin layer of denuded fibers. Again, the nerve-supply of the appendix is very small. Of course, the great majority of cases of perityphlitis are due to trouble in the appendix, but occasionally the peritonitis is started by trouble in the cecum itself, the appendix itself being sound. He does not allude to cases of cancer or actinomycosis of the cecum, nor even to tuberculous disease of that organ, but to examples of non-malignant, non-parasitic ulceration of the bowel. It is true that when the cecum is found perforated at the bottom of the perityphlitic abscess the perforation has usually come from without and the appendix is the cause. He is aware that an attack of perityphlitis may be brought about by changes in the appendix so slight as to be difficult of recognition. Nevertheless, it occasionally happens that true peritonitis is due to primary ulceration of the cecum. The etiology of perityphlitis is simple. The causal condition is a catarrhal inflammation going on to ulceration, and it is this condition which produces the stricture of the appendix which is so often found. The concretions which may be found in the appendix are formed just as the rhinoliths met with in the nasal passages are formed. Seeds have nothing to do with the production of appendicitis. In very rare cases foreign bodies have been reported found in the appendix, but Treves has never found a genuine foreign body within this structure. It is quite true that the concretions often look like seeds and stones, but a careful examination will show that they are not. The general death-rate in perityphlitis is about 5%. If an abscess form, the mortality may run up to 30 or 40%. If the patient survives an abscess, he is cured of his appendicitis. Treves first proposed interval operation in 1888. The risk of remov-

ing the appendix in the period of quiescence is less than 1%. In dealing with cases of appendicitis during an attack operation is rarely necessary before the 5th day. We should condemn in the strongest terms those who operate as soon as the diagnosis is made. There is no sound basis for such a procedure. It is quite true that a fatal attack may commence mildly, but the course of perityphlitis is by no means as erratic as many would have us believe. Very careful observation affords, as a rule, a sound basis for treatment. Violent cases which produce death in 48 hours are exceedingly rare and readily recognized. Of course, in extreme cases an operation cannot be done at too early a period. We are not encouraged to operate by the assurance that simple incision is attended by a death-rate of 18.18%. If there is a strong suspicion of pus, operation should be at once undertaken, and if swelling continues to increase without abatement of the fever, operation should be undertaken. There are few inflammatory conditions in which leeching acts more favorably than in perityphlitis. The application of 5 or 6 leeches in a case where operation seems immediately indicated occasionally appears to arrest the condition. The most active organism in the production of this disease is the bacterium coli commune, and it has pyogenic powers. When an abscess is evident or is suspected the site of incision is determined by mapping out the area of dulness and resistance. If a wound is made too far to the inner side, thus missing the pus and opening the peritoneal cavity, this incision should be sewed up and a fresh one made at the point where the effusion of pus can be reached within the area of adhesion. After incision the abscess-cavity is examined as to its size and shape and diverticula are carefully opened with the finger. No prolonged search is ever made for the appendix. A prolonged search may break down a weak abscess-wall and tear up adhesions which limit the pus from the peritoneal cavity. If any concretion is felt, it should be removed. If the diseased appendix presents itself, it is ligated and taken away. The high mortality accredited to this operation depends upon a blind resolve to excise the vermiform appendix at all hazards. We should evacuate the abscess and remember that the cases in which the least is done do the best. The cavity should not be squeezed out, should not be scraped, should not be sponged, and should not be irrigated. It should be drained by means of iodoform-gauze.

Egbert H. Grandin¹ makes some remarks on **septic peritonitis**, with special reference to the use of the antistreptococcus serum. A few years ago he read a paper upon suppurative peritonitis, and drew the deduction that local suppurative peritonitis will invariably recover after free incision is made and proper drainage inserted, if operation is performed before there has been positive general systemic infection. He also came to the conclusion that general suppurative peritonitis was invariably fatal no matter what treatment was employed. In the present paper he discusses the subject anew on the basis of personal experience. He says that septic peritonitis in the male differs from the same disease in the female only in the absence of certain elements of causation in the first. Of course, in the female there is a useful route for drainage which the male does not possess. His studies have enabled him to be more hopeful in the prognosis of general suppurative peritonitis than was formerly the case. His records for the past 6 years contain 40 cases of local and general suppurative peritonitis. These cases do not include instances of pus deep in the pelvis and accessible by vaginal operation. There were 9 cases of general suppurative peritonitis and 31 cases of local suppurative peritonitis; 31 cases arose from appendicitis, 8 cases from puerperal infection, 1 case from rupture

¹ Med. Rec., Apr. 3, 1897.

of a suppurating ovarian cyst. All of the 31 cases of local suppurative peritonitis recovered after incision and drainage. Out of the 9 cases of general suppurative peritonitis only 1 recovered. In 5 of these cases multiple incisions were made, points of counter-drainage were established, and the peritoneal cavity was freely flushed out. In 3 cases a median incision with flushing of the cavity was the treatment. In the 1 case which recovered multiple incisions were made, copious flushing was practised, drainage was maintained through the incisions, and antistreptococcus serum was injected. This case recovered. The patient was a woman who developed peritonitis, which was apparently secondary to perforative appendicitis. An exploratory incision in the appendix region showed that the appendix was gangrenous and perforated and that the free peritoneal cavity contained foul pus. The appendix was ligated and cut off. Irrigation was practised with hot salt solution and drainage was maintained by strips of gauze. In a few days intense pain developed in the left iliac region; a free incision was made in the left side, opening a cavity containing a pint of pus. This cavity was irrigated and counter-drainage was made into the vagina. The next day an area of dulness was detected in the left side of the abdomen above the level of the umbilicus. A free incision was made here, pus was evacuated, irrigation with saline solution was practised, and gauze was inserted. The patient was given $12\frac{1}{2}$ c.c. of antistreptococcus serum. The next morning the same dose of antistreptococcus serum was administered, and in the afternoon of the same day the two incisions on the left side were joined by another incision. The administration of antistreptococcus serum was kept up and the patient gradually became convalescent and recovered. After the administration of the serum the temperature invariably fell and the pulse-rate became less. The action of the kidneys was powerfully stimulated and the production of pus was greatly limited. The author is not absolutely certain that the serum brought about a cure, but he thinks it so highly probable that in future he will use it, believing that it may do good, and can do no harm.

Bishop¹ discusses **drainage in abdominal surgery**. He thinks that in operations upon the Fallopian tubes drainage is invariably necessary; that it should be employed in any septic operation and in every case where there is any doubt about the asepsis. When the tubes are not involved and when the case is absolutely aseptic drainage does nothing but harm. He then discusses the various materials used for drainage. The fact that a collection of blood exists in the peritoneal cavity is not in itself enough to demand drainage. A small amount of blood will be absorbed and will do no harm. A larger amount will simply serve to block up the drain by clots. Lymph does not require drainage. The only reason for drainage is pus. Drainage of an abscess can be carried out most readily by a gauze drain after the plan of Mikulicz. If we have to drain bile, rubber tubes should be employed. Glass tubes drain bile very well, but the hard inner extremity of the tube produces irritation and the tube is liable to be broken. If we have to drain urine in the region of the kidney, we should use a rubber tube. Tube-drainage should be employed for 48 hours after a lumbar nephrectomy. The action of the diaphragm sucks air into the tissues, and if a tube is not introduced the air is not forced out again. If we drain this region of the body, cover the tube carefully with aseptic cotton-wool or gauze. Drainage-tubes of decalcified bone are not satisfactory and strands of catgut drain very poorly. Horsehair drains should not be used because of the arrangement of the epidermic scales upon the hair, which may cause it to travel into the wound.

¹ Med. Press and Circ., Oct. 28, 1896.

Silkworm-gut is the best material for capillary drainage, but capillary drainage will not remove pus. It will only remove blood-serum or lymph. In the abdomen the best canal of drainage after all is the intestine, which is a natural suction-pump. Action of the bowels at an early period after laparotomy in most instances prevents peritonitis. This is not only because the lower bowel is emptied. The small intestine is practically a long sponge, and when it is in vermicular motion it draws into the lymph-vessels of its walls large amounts of fluid from the peritoneal cavity, forcing this fluid into the blood-current, from which stream it can be excreted. The rhythmic motion of the intestines forces the fecal contents into the rectum and sucks up fluids from the peritoneal cavity, and the removal of these fluids disposes of what might be a culture-medium for bacteria. The bowels should be made to move soon after the operation, because a delay may permit so large an amount of fluid to collect that it cannot be readily disposed of. Bishop believes that we should not wait for signs of peritonitis to give salines, but that we should give them in order to prevent peritonitis. Calomel does very well, but saline purgatives are better. If we place saline fluid in the intestines, that fluid is of a higher sp. gr. than the fluid outside and dialysis takes place. Sodium tartrate produces excellent effects and rarely causes vomiting. It is well to associate the use of salines with the administration of enemata. Some use turpentine enemata, but the most useful enema is soap and water with $\frac{1}{2}$ oz. of castor oil. This is given after two or three doses of the sodium tartrate have been taken.

The **treatment of tuberculous peritonitis** is discussed in the *Jour. des Praticiens*, Sept. 15, 1896. In certain cases a surgical operation is advisable. If ascites exists, operation is of much benefit. In a considerable number of young people the disease can be cured by placing the patient under proper hygienic conditions, by the use of tonics, and by abdominal counterirritation. Some cases are improved by placing iodoform upon the skin of the belly and keeping the drug in place by means of collodion. In some cases puncture of the abdomen does good; in others rectal injections of creasote are of use. Creasote can be given by the rectum mixed with cod-liver oil. In some cases inunctions of ichthyol can be used. [Casassoriei and Ligalea apply to the skin of the abdomen tincture of iodine mixed with guaiacol. It is applied in the afternoon during the highest temperature (about 2 gm. of guaiacol to 8 gm. of tincture of iodine). After the material has been applied the abdomen is covered with waterproof and cotton-wool. If the iodine irritates the skin, a mixture of guaiacol and oil can be used.]

G. Lenthal Cheate¹ writes on a **method of uniting divided intestine**. After a portion of the bowel has been resected, a V-shaped piece of mesentery is removed, and a longitudinal incision is made through all the coats in each end of the divided bowel opposite the mesenteric attachment (Fig. 17, A). The length of this incision is equal to the diameter of the bowel at the point of operation. The ends of the intestine are spread out like two fans and the serous surfaces are held against each other (Fig. 17, B). The first suture fixes the mesenteric attachments and the two next unite the extremities of the fan-shaped ends. Stitches are now inserted with exactness, all coats being transfixed. When ends are joined it is necessary to suture the longitudinal incision by any method the operator wishes (Fig. 17, C).

J. Greig Smith² pointed out the proper method of treating a case of **grave abdominal disease before a diagnosis** is made. Suppose a case in which we are in doubt whether a patient has colic (intestinal, biliary, or renal),

¹ Lancet, May 22, 1897.

² Treatment, Mar. 25, 1897.

obstruction, perforation, or effusion of blood. Give an enema of an ounce of brandy or whiskey in 3 ounces of milk. Before giving the enema explore the rectum with the finger for diagnostic purposes. Wrap the patient in hot blankets and surround him with hot bottles. The abdomen is left to be covered separately by a light woollen wrap, which can be easily removed. The surgeon sits by the bedside and watches the patient. The beneficial effects of the alcohol soon become obvious. The surgeon watches the evolution of signs and uses palpation, percussion, and auscultation. The patient's behavior is of much moment. In spasmodic colic the patient makes a tremendous fuss. In visceral perforation the patient makes but little disturbance; he keeps his body rigid, moving his arms and rolling his head. The behavior of the patient in strangulation is between these extremes. Note the condition of the parietes as to tension, distention, spasm, or relaxation, and whether the intestines are moving or quiescent. When peristalsis is active perforation does not exist, because this condition is soon attended with intestinal paresis. In perforation auscultation discovers no sounds in the abdomen except over the seat of trouble, where blowing or rushing sounds are audible. If there is not much distention, abolition of liver-dulness on percussion almost surely means perforation

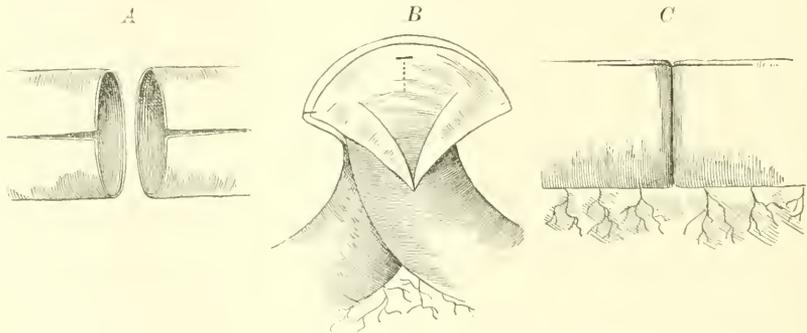

FIG. 17.—A method of uniting divided intestine (G. Lenthal Cheatle, in the *Lancet*, May 22, 1897).

of a hollow viscus or rupture of an abscess which contains gas. If much distention exists, the sign loses its importance, because it may be due to the bowels having gotten between the liver and abdominal parietes. The phonendoscope is used for auscultation. In colic there are diffuse sounds; in obstruction accentuated local sounds and rushing noises; in perforation general silence with "rare and remote noises." We can decide whether we are dealing with colic or a dangerous malady. Final diagnosis may be made with the aid of anesthesia. If the patient has simple colic, he "greedily inhales" chloroform, and in a few minutes his condition is seen to be greatly improved. In perforation or strangulation the anesthetic is not taken greedily, the nausea often increases, and the condition is not markedly improved. If we decide that the trouble is only colic, give a full dose of morphia and begin appropriate treatment. At the end of half an hour the diagnosis will have been so far made that the surgeon will have decided whether or not to operate. When operation is decided upon, try to locate the seat of trouble in order to determine the proper place for the incision.

Smith says he places in the front rank these "items of advice": avoid morphia; give nothing by the mouth; give an enema containing alcohol; apply external heat; sit by the patient and watch. As shock passes off the evolution of special signs takes place and we observe these signs.

W. H. Battle¹ describes a case of peritonitis in which **symmetrical edema** of the subcutaneous tissue was noted in both groins. It did not pass into the thighs, being limited by the deep layer of the superficial fascia, but passed outward to the iliac spines and slightly into the flanks. The area of edema was tender and somewhat flushed; the scrotum was edematous. The patient died, and the necrosy showed the existence of acute peritonitis of the pelvic cavity, the cause of which was not discovered.

Robt. Abbe² presents a paper upon the prognosis and treatment of **acute general peritonitis**, saying that most infections which originate in the pelvis, in the fossæ about the colon, and in a less degree in the area about the liver and stomach and above to the colon become localized by walls of lymph in the course of a few hours. An infection at a more central point among the coils of the small intestine is rarely limited by lymph. The grave form of acute general peritonitis is almost invariably due to rupture of a hollow viscus (stomach, intestine, appendix, or bladder). Its origin is certainly bacterial, and septicemic infection overwhelms the patient. It is unconfined by any barrier of lymph. The area invaded depends on the stage in which the case is seen. Surgeons who report from 30 to 60% of cures following operation have included cases which were not true unlimited peritonitis. If infectious material is introduced into the abdominal cavity, the peritoneum endeavors to free itself of this. The most common cause of the disease is appendicitis; next, perforating gastric ulcer; and after this intestinal traumatism, rupture of a pelvic abscess, rupture of urinary bladder, and rupture of gall-bladder. The virulence of the attack varies with the nature of the material introduced. Material from the appendix is more actively poisonous than material from the stomach, or normal urine.

Most perforations of gastric ulcer occur after eating. Weir has collected 97 operations for gastric perforation, with 22 recoveries. Abbe has collected 20 cases, 3 of which are his own. In this series 18 cases labored under general extravasation; 12 of them recovered and 6 died. Abbe believes that future studies will further prove the necessity for operating early after the accident. In gunshot and penetrating wounds of the abdomen operate at the earliest possible minute. It is impossible to be sure that an organ is not injured or that extravasation is not beginning without looking at the "invaded part." If the wound is slight or the shock profound, the wound can be enlarged under cocaine, and if perforation or hemorrhage is discovered the flow is arrested temporarily until the patient recovers from shock, when an appropriate operation is performed. Of 39 cases of gunshot-wound operated on within 12 hours 18 recovered; of 22 cases operated on after 12 hours 5 recovered. If cystitis exists, the chance of grave peritonitis arising is increased. If an inflamed gall-bladder be injured, septic peritonitis will soon arise unless operation is quickly performed, because the bile of an inflamed bladder is filled with bacteria, especially the coli commune. The peritoneum is able to dispose of normal bile fairly well.

Acute general peritonitis from typhoid ulcer differs but little in course and treatment from that due to ulceration of other parts of the alimentary canal.

Finney shows that operation is successful in 26% of cases. Operation must be performed early. Sharp pain associated with nausea is a signal of perforation. In general peritonitis from appendicitis early operation is of the most urgent importance. In cases which recover albumin and casts are absent from the urine. When the kidneys are choked with bacteria operation is useless. When only the lower segment of the abdomen has been invaded, there

¹ Lancet, Mar. 27, 1897.

² Med. News, May 29, 1897.

is but one opinion in regard to cleansing the abdominal cavity. The minute septic material appears it is sponged away before it can be diffused. The bowels which present are mopped with sponges, soaked in hot salt solution, and are dried before other coils are drawn up for inspection. When parts are reached which are not much inflamed, a gauze tamponade is pushed among the bowels far from the field of work, a tape is sewed to the tamponade, and a clamp which projects externally is fixed to the tape. One or more tamponades are thrust up and across the abdomen before the pelvis is cleansed. The pelvis is mopped out thoroughly, a packing of iodoform-gauze is placed in the pelvis, the gauze tamponades are withdrawn, and if they are wet from absorbed effusion, pieces of iodoform-gauze are carried in several directions among the coils of bowel. The wound should not be closed.

In the grave cases a long median incision or two lateral cuts are required. A cut for lumbar drainage is only required when the median incision is used. Gauze-packing is far better for drainage than tubes of glass or rubber. When infection is widespread irrigation must be practised. Flush systematically with saline solution as hot as the hand can bear (over 105°). Irrigation with hot saline fluid stimulates the patient and diminishes the power of the endothelium to absorb toxins. If the intestines are distended with gas and fluid, let them emerge from the abdomen, cover them with hot towels, prick them in one or two places with a knife, evacuate gas and fluid feces, and wash away in a stream of hot water. Through one of the openings inject a syringe of saturated solution of Epsom salt and then close the punctures.

McCosh says that in every bad case we should pass a dose of salts into the bowel through an aspirating-needle and close the puncture with one suture. Salts so introduced cannot be vomited and cause downward peristalsis. If regurgitation exists, lavage of stomach is done before operation, after operation, and whenever regurgitation is renewed. A rectal tube is used to remove gas, and is of great value in promoting downward peristalsis. An ice-coil or light ice-bags upon the abdomen do good and are grateful to the patient. Strychnin is often needed. When the patient is well out of ether and complains of severe pain morphin hypodermically is useful rather than harmful.

George Ryerson Fowler,¹ as to **septic peritonitis from the clinical standpoint**, says that a clinical classification of septic peritonitis is useful to the practitioner. The term diffuse septic peritonitis is preferable to that of general peritonitis, because it is impossible in any case to be sure that every portion of the peritoneum has been attacked. The term perforative peritonitis is useful, and so is the designation circumscribed or local peritonitis. Hematogenous peritonitis is a rare condition. The name is better than cryptogenic septico-pyemia, which some apply to this state. The term puerperal peritonitis is warranted by the frequent occurrence of peritonitis due to this cause, and also to certain clinical peculiarities which belong to this form of the disease. Pelvic peritonitis is used to signify a peritonitis taking origin from the female organs of generation. The term subdiaphragmatic peritonitis should be used instead of subphrenic abscess. Fowler discusses the prognosis of bacterial invasion of the peritoneum. When infection is due to a small number of comparatively nonvirulent germs fatal peritonitis may not arise, but will be favored in its development by prolonged handling. Even a slight injury may be followed by fatal infection if the streptococcus pyogenes gains access to the area of damage. The peritoneum can dispose of a certain quantity of even virulently infectious matter, provided nothing is present to furnish

¹ Med. News, May 15, 1897.

aid and support to bacteria. Bacteria may produce peritonitis even without multiplying, as when they come in contact with the peritoneum, because of conditions which also cause effusion of serum, extravasation of blood, injury to the serous tissue, sloughing of peritoneum, or the entrance at the same time of a substance which serves as nutritive material for the germs; such a material is feces. The route of the invasion affects the prognosis. Peritonitis may arise without the presence of bacteria within the peritoneal cavity, the toxins passing through visceral walls which show no lesion. The serous fluid of the peritoneal cavity is to a certain extent germicidal, but its power is limited. Bacteria in encapsulated abscesses occasionally die (Wieland). The most dangerous method of invasion is perforation of the small bowel; the least dangerous is a wound in the wall of the abdomen. In the first condition there is an escape of great numbers of very virulent bacteria, of toxins formed in the intestine, and of fecal matter, which is an irritant to the serous surface and pabulum for bacteria. The prognosis after intestinal perforation is influenced by the size of the perforation and the rapidity with which bowel-contents escape. In perforation of the small intestine fecal matter is forced out rapidly, and mixed infection of the peritoneum quickly takes place, with the development of diffuse septic peritonitis. When the large intestine is perforated feces may flow out slowly, and limited suppurative peritonitis can occur. Comparatively few bacteria are apt to be introduced through a wound in the belly-wall, and often the peritoneum is able to dispose of them. A wound of the abdominal wall is extremely dangerous if it is associated with contusion of the peritoneal surfaces, the entrance of a foreign body, hemorrhage, or the laceration of a hollow viscus. In degree of danger, midway between rupture of intestine and wound of belly-wall, we may mention invasions due to wounds or perforations of other viscera (kidneys, pancreas, bile-ducts, ureters, etc.), and the rupture of an infectious abscess, entrance of organisms through inflammatory growth of the walls of the intestine or of a hollow viscus, infection by way of the Fallopian tubes, migration of bacteria through an area of nutritive disturbance in the wall of the gut, as in strangulated hernia.

The **treatment** of diffuse peritonitis consists in early free incision and drainage. Fowler thinks that the value of serum-therapy in this disease is as yet uncertain.

Nicholas Senn¹ suggests a **classification of acute peritonitis**. A discussion of the etiology, diagnosis, prognosis, and treatment will mislead unless we employ a comprehensive and definite classification. In order to locate the process or to trace the connection with the organ primarily diseased an anatomic diagnosis is required. Senn makes the following groups for purposes of anatomic diagnosis: Ectoperitonitis—inflammation of the attached side of peritoneum. Endoperitonitis—inflammation of the serous surface of the peritoneum. Parietal peritonitis—inflammation of the serous lining of the peritoneal cavity. Visceral peritonitis—inflammation of the peritoneal coat of any of the abdominal or pelvic organs. Pelvic peritonitis. Diaphragmatic peritonitis.

The following etiologic classification is advocated: Traumatic peritonitis—an injury establishes a communication between the peritoneal cavity and the surface of the body or some of the hollow organs, through which channel pyogenic cocci enter. Idiopathic peritonitis—many doubt if peritonitis can occur without previous injury or suppurative lesion; it is too early to deny absolutely the existence of so-called idiopathic peritonitis, but future bacteriologic study will surely find a microbe in all cases of this sort. Perforative perito-

¹ Med. News, May 8, 1897.

nitis. Metastatic peritonitis—arising from infectious processes unconnected with peritoneum; may develop during the existence of an acute infectious disease. Puerperal peritonitis.

The pathologic classification is into: diffuse septic peritonitis; suppurative peritonitis; serous peritonitis; fibrinoplastic peritonitis.

The bacteriologic classification is as follows: streptococcus infection; staphylococcus infection; pneumococcus infection; bacillus coli commune infection; gonococcus infection; tuberculous infection.

Senn's clinical classification is into: ectoperitonitis; diffuse septic peritonitis; perforative peritonitis; circumscribed peritonitis.

APPENDICITIS.

G. F. Shrady,¹ in laying down the **rules for operation in appendicitis**, maintains that increased pulse-rate usually points to the necessity of operating, as it indicates that the case is rapidly progressing. If, in addition to increased pulse-rate, there is a sudden accentuation of pain, delay in ope-

Med. Assoc., Feb. 20, 1897).

ration will be dangerous. The temperature in appendicitis is not usually high, and it affords no reliable indications for operation. Great prostration confirms the necessity for surgical interference. In some cases immediate surgical intervention is obviously demanded; for instance, when there is a collapsed condition pointing to perforation. As a rule, in appendicitis cases there is, first, a condition marked by very positive symptoms; then these symptoms lessen for a day or two, at which period of time we can make a very careful study of the case. It is wise to refuse to operate during the attack when the pulse-rate lessens, when the pain diminishes, and when the temperature falls. When an abscess forms it is best to wait until firm adhesions have been produced, unless a sudden emergency should happen to arise.

Weller Van Hook² has written a very important paper upon the **technic of operations for acute appendicitis**, a paper which is particularly notable for the practical nature of his views. He maintains that the

² Jour. Am. Med. Assoc., Feb. 20, 1897.

most important part of the operation is the protection of the normal serous coat from infection and the application of a drain of gauze. People who have never operated, or who have operated only occasionally, should be persuaded that the operation for appendicitis is not always an easy and simple affair. It is a matter for surprise, and almost horror, to find that the majority of

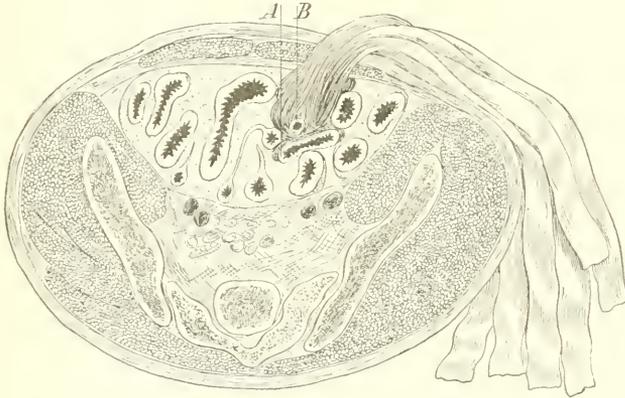

FIG. 19.—To show the application of the gauze when the appendix (*B*) lies in the midst of the small intestine, to the left of the cecum (*A*). This and the preceding drawing were made from photographs of frozen sections made by the writer after having performed the operation described in the text upon the cadaver (Van Hook, in Jour. of Am. Med. Assoc., Feb. 20, 1897).

writers give an opposite impression, or, like Sonnenburg, boldly assert that the operation is a simple one. It is the positive conviction of Van Hook that 100 cases of acute perforative appendicitis will show a higher percentage of recovery under medical treatment with incision of pointing abscesses than will 100 like cases operated upon by 100 or even 20 surgeons who are gaining

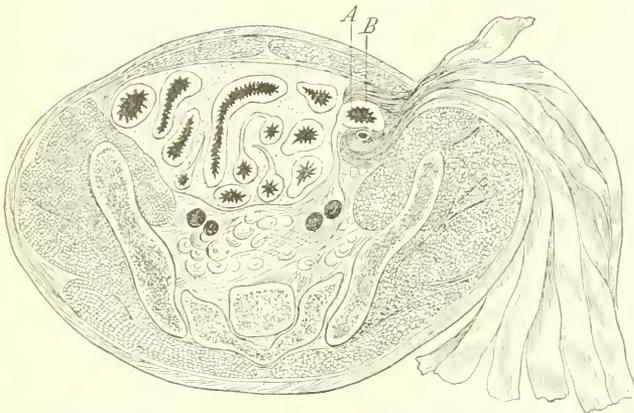

FIG. 20.—To show the relation of gauze strips to the cecum (*A*) and the stump of the appendix (*B*), when the appendix lies between the cecum and the outer abdominal wall (Van Hook, in Jour. of Am. Med. Assoc., Feb. 20, 1897).

their first experience. The loss of life from faulty operations is much greater than is the case with other pelvic and abdominal work. The reason is quite obvious. The operation is an act of violence, and of supreme violence, and is inflicted at the seat of virulent infection. There is no more appalling calamity met with by the surgeon than the passage of pus from the appen-

dicular region to previously uninfected peritoneum. What most marks the man of surgical skill is the ability to prevent this accident during the operation. Every surgeon must make a beginning some time or other; but, except in cases of urgency, an inexperienced operator must refrain from drawing blood, and experience is to be gained by assisting older surgeons. No one

should begin to operate on such cases without he has both inclination and opportunity to perfect himself in the art, and he will always find that his later cases show better results than his earlier cases. The first goal to be reached by operation is the saving of life, and we must subordinate to this petty con-

siderations merely of future comfort and convenience. The secondary objects of operation are the prevention of fistulae, the prevention of recurrent appendicitis, and the lessening of the chances of hernia. When a surgeon is about to operate outside of a hospital he should first obtain the best nurse accessible. A good assistant is necessary, and should stand opposite the operator and aid

in preventing the passage of pus into the sound regions of peritoneum, arrange the sponges and keep them warm, hold retractors, etc. It is well to have an operating-table which permits the placing of the patient in the Trendelenburg position. In an emergency an ordinary kitchen-table or dining-room table will do, and when such a table is used the patient's feet must be fastened to the end so that he cannot slip toward the head of the table, and the end of the table can be raised by placing a box or chair under it. It is not always possible, because of lack of time, to prepare the patient elaborately. Cleansing should never be rough lest it rupture an abscess-wall. Transportation of the patient is very dangerous, as a sudden contraction of the abdominal muscles may force out a great quantity of infectious material from the abscess or from a perforation into the peritoneal cavity itself. The position of the patient depends on circumstances. When pus is discovered at the brim of the pelvis we can prevent the entrance of this fluid into the pelvis by quickly placing the patient in the Trendelenburg position. If the pus flows toward the median line, the patient should be placed upon the right side. These two maneuvers can be carried out simultaneously. The site of the incision depends on the situation of the appendix and the morbid anatomic conditions which exist. The incision should afford direct access to the seat of trouble, excepting where we wish to avoid opening the free peritoneal cavity. The median incision is not used except in those unusual cases in which the cecum and the appendix lie back of the median line. The most useful method of opening the abdomen to reach the appendix in one of its usual positions is that of McArthur or McBurney. It will be remembered that McBurney makes a skin incision 4 inches long, this incision crossing at right angles or nearly at right angles a line drawn from the anterior superior spine of the ilium to the umbilicus. The incision is about 1 in. internal to the spine of the ilium, and the upper third of the incision is above the omphalospinous line. The fasciæ are cut with a knife; the muscular fibers are separated by blunt dissection. These fibers are held apart by retractors during the operation, and when the operation is completed will come together and almost perfectly close the wound. This method can be used only when good assistants are present and a small incision is required. The principle of this operation should be followed if any incision involve the lateral abdominal region; that is, the direction of the cut should follow the general course of the fibers of the external oblique muscle; muscular fibers should be cut as rarely as possible, so as to avoid nerve-trunks. It was with the idea of avoiding injury to the nerves that Kocher recommended that we should make only transverse or oblique incisions unless we happen to be operating in the median line. Van Hook is in entire agreement with Kocher's proposition. He would give up the Langenbuch incision at the side of the rectus muscle, and also longitudinal incisions over the colon. He thinks that the nerves which supply the rectus should not be interfered with, because muscular paralysis weakens the abdominal wall. The oblique incision is useful for another reason. It enables the surgeon to reach freely all ordinary areas of appendix trouble and also makes a wound parallel with the general lines of traction of the abdominal muscles, a wound which does not gape and which is not apt to permit of a subsequent hernia. The length of the incision must be sufficient to permit of necessary manipulation. It should never be so short as to interfere with safe work. There is no special advantage in a very small incision, though, of course, unnecessarily large incisions are not desirable because they increase the liability to hernia. The site of the chief pathologic activity in appendicitis can be in most instances made out, especially when there is swelling or tenderness. In endeavoring to discover

swelling or tenderness a rectal or vaginal examination should never be omitted, since it is by no means rare to find that the inflammation is located in or has extended into the pelvis. Pain at the end of micturition is a valuable sign in pointing to inflammation of the vesical peritonium. A diagnostic localization of the appendix is impossible in gangrenous appendicitis, or in perforative appendicitis in which there is diffuse peritonitis. In these cases there are absence of local swelling and the presence of widely diffused tenderness. It is very important to try to estimate the relation of the focus of inflammation to the ascending colon and to the ileum. The ileum and colon are barriers which limit the spread of infected fluids. An abscess which forms outside of the ascending colon is usually well toward the flank and extends toward the renal and hepatic regions. In such a case we can often make out by percussio the fact that the colon has approached the median line. When the inflammation is located below the mesentery of the ileum it tends to extend into the lesser pelvis, and in this case vaginal or rectal examination is of great importance. When the site of inflammatory activity is internal to the ascending colon and above the mesentery of the ileum the gravest apprehensions arise. We make out this condition by outlining the colon by means of percussio and by determining that the swelling and tenderness are toward the median line. The duration of the inflammation and the area of the swelling are points which will often enable us to have a correct idea of the morbid changes to be encountered. If the suppurative process has existed two or three weeks, there must be much adhesion and multiplication of cells. In an acute and violent condition the process is probably not limited by adhesions. An inflammation which has existed for some time, but which suddenly becomes worse, was probably limited at first, but has extended later into normal serous membrane. Uncertainty in regard to the capacity of the barriers to withstand the spread of the process is greatest between the third day and the end of the first week. Signs of violent inflammation point to local extension of the mischief. When there are mild general symptoms and an area of tumefaction which does not enlarge we are justified in assuming that the process is limited by adhesions. Edema of the skin points to adhesion of the abscess to the wall of the abdomen. Van Hook inquires as to what properties of the peritoneum can we take advantage of in operating. The normal peritoneum possesses an enormous resisting power to infection. One-tenth of the poison which is often thrown into the peritoneal cavity without producing harm would cause fatal infection if placed in the cranial cavity. In operating for appendicitis we can take advantage of this resisting power and venture to inoculate a portion of the serous membrane. Traumatism, such as mechanical and chemical irritation, drying and cooling, diminish resistance. The chief surgical resource is capillary drainage. In a closed abdomen the serous surfaces are not separated from each other by gas or air, but they lie in contact and are lubricated by serous fluid. If an infecting fluid come between these surfaces, it is disseminated widely and with great rapidity, partly by gravity and partly by capillary action. When about to open an area of infectious matter the usual custom has been to protect the intestines from contact with this matter by means of compresses. When the infected cavity has been evacuated the compresses are removed and pieces of gauze applied in their place to act as drains.

Van Hook strongly urges the application of a preventive capillary drain. Before defilement of the peritoneum has taken place the operator should apply gauze between the parietal serous layer and the region of the infection. Iodoform-gauze is generally the best material, and this gauze rather than the peritoneum beneath it is the surface to be protected by compresses. The ends

of the pieces of gauze are inserted in various spaces to prevent the dissemination of poison, not only by establishing capillary action toward the wound, but by occlusion. At the end of the operation the strips are not replaced by fresh gauze for three reasons: first, manipulation favors the entrance of bacteria into the tissues; second, the handling transfers bacteria to clean areas; third, the gauze, if properly applied, will carry away the infectious matter which has escaped arrest by the compresses. The compresses over the gauze can be changed as often as the operator desires.

Gubaroff has asserted that the beneficial action of the gauze extends for $2\frac{1}{2}$ in. on each side of its margin, and Van Hook believes that this statement is true, founding his opinion on a recent autopsy. It is very important for the surgeon to decide before operation whether he has to deal with an inflammatory area which is not mechanically limited, or with a pus-area shut off from sound peritoneum by very thick barriers, or with a genuine abscess-cavity. In a first attack of moderately severe perforative appendicitis there will be no effective adhesions up to the fourth day. Between the fourth and tenth days the new tissue becomes resistant and may be utilized in operative treatment. After the tenth day, if the abscess has not ruptured, it will probably have strong walls.

Van Hook then takes up for discussion the technic of the operation. When adhesions are absent make an incision which gives full command of the region. As soon as the incision has been made a gauze barrier is inserted about the wound so that infectious material may not come in contact with sound peritoneum. For this purpose he uses strips of sterile gauze or iodoform-gauze, each strip being $2\frac{1}{2}$ in. wide, 15 in. long, and 4 layers in thickness. A large retractor is placed under the abdominal wall at the edge of the wound, the parietes are lifted upward and away from the intestines, and the end of a piece of gauze is passed into the abdominal wall between the parietal peritoneum and the intestines at right angles to the incision and carried in for a distance of from 1 to 3 in. The retractor is now moved into another position and another piece of gauze is inserted by the side of the first one, and this process is repeated in every direction until the gauze completely surrounds the region in which the work is to be done. If the focus of trouble is in contact with the lateral parietes, the gauze barrier is applied so as to prevent any possible infection of the pelvis below or the hepatic region above, and for this purpose the incision must be low enough down to enable the surgeon to reach below the appendix. Strips of gauze are carried toward the brim of the pelvis until this avenue is well closed. The temporary use of the Trendelenburg position favors the maneuver. Especial care must be taken to protect the hepatic region from infection, a similar method being used. Strips of packing aid in preventing infection and determine an outward serous discharge. Infectious matter is carried away from the free peritoneal surface and adhesions tend to form. The visible portions of the strips of gauze are covered with compresses wrung out of warm salt solution, and loose coils of bowel are pressed aside by the compresses until the most active seat of disease is reached. The longitudinal muscular band of the colon will lead the surgeon directly to the seat of trouble. When the appendix is reached it will almost invariably be found that feces or purulent matter flow upward. This material must be caught on compresses, which are discarded from time to time and carefully replaced by fresh ones. The cecum must not be lifted up, if doing so increases the danger of infection. Before the appendix is removed a strip of gauze is carried down to the infected region so as to surround the dangerous area. If the cecum can be lifted up without risk of

infectious matter gaining entrance to parts of the peritoneal cavity which are not protected by adhesions, a piece of gauze is slipped under it; the appendix is amputated between the temporary ligature on the proximal side and a pair of forceps on the distal side. The projecting mucous membrane is touched with pure carbolic acid and a row of Lembert sutures passed over the stump of the appendix. The temporary ligature is removed, the stump is inverted, and the sutures are tied. The arteries of the meso-appendix are controlled by ligatures or suture-ligatures. If the cecum has not been lifted up, drainage is carried out by additional strips of gauze and also in some cases by a tube. If it is found that infectious material has already passed between the intestines, it is followed up with sponges, is gotten away by gentle pressure, and iodoform-gauze drains are left in contact with the infected peritoneum. It is unwise to lift lengths of intestine from the abdominal cavity to clean them. It is much better to treat them by surrounding with gauze drains. The ends of the strips of gauze should be left very long, so that they hang over the dressings at the side of the patient. The excessive length of the gauze strips favors rapidity of drainage and enables the intra-abdominal portion of the gauze to lift fluid against gravity. The next step in the operation consists in partially closing the wound. Gauze is left to emerge from the portion of the wound which is nearest to the site of inflammation. The wound is closed except at the points of emergence of gauze drains. Stitches are introduced also at the sites of the strands of gauze, and are tied in this region only when the gauze is removed. The question of the technic of the process when adhesions exist is a matter of dispute. All agree that the appendix should be removed if it is near to a focus of inflammation. Others maintain that it should be removed if it can be done without breaking down the wall of the abscess. Some say that it should be removed if it does not constitute a part of the abscess-wall. Some operators say "always remove the appendix," maintaining that operations which leave the appendix are incomplete; that undiscovered abscesses may be left; that convalescence will be prolonged; that fistulae and sinuses will remain, and that recurrence of trouble will be most probable.

Van Hook reminds us that we operate to save life. The main object to be attained when adhesions have formed is to relieve the tension of the abscess-cavity by outward drainage. To what further extent it is justified to go depends on circumstances. Secondary abscesses do not occur with any frequency, and it is not necessary to remove the appendix to discover and drain a secondary abscess. The extirpation of the appendix in some cases may disseminate the pus widely. The percentage of recurrent attacks after simple drainage is exceedingly small. The operator, especially if inexperienced, should not do too much. Let us remove the appendix if we feel sure that its removal will not disseminate pus or destroy the barrier of adhesions. On opening the abdomen first carefully surround with gauze strips as previously described; next apply gauze about the matted coils of intestines. The surgeon determines by careful palpation what portions of the bowel are nonadherent, requiring isolation from those portions near the appendix by means of packing. The deeper portions of the packing are to be carried back to the posterior layer of the peritoneum. The gauze must be spread out, must touch the neighboring bit of gauze on either side, must be free from knots and kinks, and this is best accomplished by carrying it in on the finger. Every piece of gauze which is used should come to the surface by as direct a route as possible, and the infected area is not to be attacked until the peritoneum is thoroughly protected by gauze. The gauze is to be covered over with pads. When this protection has been secured the infected area is opened and drained. The finger is pushed

gently between the coils of intestine until this area is reached. A strip of gauze is then carried into the cavity, and we may, if we wish, have a tubular drain within this gauze. If we decide not to try to remove the appendix, the intestines are retracted with gauze strips and the drains are deeply inserted. Foci of infection which are situated between the ascending colon and the right lateral abdominal wall are usually attacked with ease. The surgeon takes pains to see that the space between the anterior surface of the colon and the abdominal wall, if not obliterated by adhesions, is protected by gauze strips, and that the upper and lower boundaries of the area of infection are protected by gauze-packing. The greatest difficulty in protecting the peritoneum exists when the trouble lies between the colon and the median line and above the mesentery of the ileum. It is often found impossible in these cases to prevent pus passing into the general cavity. If adhesions are absent, the patient must be placed in the Trendelenburg position. The abdomen is opened, the gauze strips are passed as usual around the area of trouble, aseptic compresses are placed so as to catch any infectious materials from the region of the appendix, a drain of gauze is passed down to the appendix, and great care is taken not to disturb even the most delicate adhesions, because if adhesions are disturbed peristaltic action will tend to carry the liberated small intestine in the course of a few hours to a distant part of the abdomen, and this small intestine has infectious material attached to its walls. It has often seemed to surgeons that transperitoneal drainage is more dangerous than direct drainage through the vagina or rectum. When abscesses are situated in the right iliac fossa firm adhesions may exist between the walls of the abscess and the outer abdominal parietes. In such a case the incision should be made to the outside of the focus or even in the loin; the gauze drain should not be removed until between 5 and 8 days, thus allowing time for adhesions to wall off infected areas.

[Van Hook's article is worthy of a careful study and will prove of aid to any one who operates for appendicitis.]

Charles McBurney¹ writes on the **treatment of appendicitis**. He states positively that there is no purely medical measure which is capable of curing the disease. Appendicitis must be placed among surgical diseases. This does not mean that every case requires operation. We are very far from being certain as to the primary cause of appendicitis. McBurney is inclined to the view that the primary cause is probably interference with the drainage of the appendix into the colon. This interference may be brought about by a concretion in the appendix, a stricture, an accumulation of fat causing displacement, or by a kink or twist in the appendix. McBurney has never seen a case of appendicitis in which there was not interference with the drainage. If the appendix is examined before its relations have been disturbed, in many cases the obstruction will be obvious. In a patient not very susceptible to sepsis, a temporary obstruction may cause but slight constitutional symptoms, while in a patient who is very susceptible to sepsis a similar obstruction may cause marked constitutional trouble and may lead to rapid death unless relieved by operation. The preliminary treatment employed is often worse than useless, and the measures that are adopted early in the case are of very great importance as regards the prognosis. It is a grave error to give morphin in the beginning of an attack. It is true that it relieves the patient's pain, but it cloaks the symptoms and prevents an accurate study of the early stage of the condition, and it is upon an accurate study of the early stage of the condition that we found our diagnosis and base our treatment. If a patient is under the influence of morphin, we can-

¹ N. Y. Polyclinic, Jan. 15, 1897.

not detect an increase in the severity of the case or the advent of sepsis. Every patient with acute abdominal pain, whether or not he has nausea, vomiting, prostration, and constipation, should be *suspected* of having appendicitis. Such a patient should be put to bed and subjected to a careful examination. Very little opium or other anodynes should be administered. The patient should be kept at rest and be watched most carefully. If the diagnosis can be made in the first 6 hours, and the patient can be watched for 6 hours longer, the progress of the disease in this time may tell the story. Certainly in 24 hours from the beginning of the attack we are usually able to decide on the diagnosis and the probable course and result of a case. We are thus enabled to make an early choice between operative and palliative procedures. The question of when to operate in an acute attack of appendicitis cannot be answered dogmatically, as no 2 cases are exactly alike. Certain symptoms are watched for and their value considered in each case. McBurney supposes an average case: the patient, let us say, has had one or two attacks of vomiting; the pulse is strong, full, and only moderately frequent; temperature in the neighborhood of 100° ; severe abdominal pain, at first diffuse and then settling in the right iliac region. If after 6 hours the patient is no worse, there is no immediate danger. If in 12 hours the severity of the symptoms has not increased, the patient will soon begin to get better; but if the case has steadily become more urgent in 12 hours from the time when the diagnosis was made, an operation will very likely be demanded.

McBurney says that if he can safely permit a patient to get over an acute attack before operating, he prefers to do so; and if in 24 hours from the beginning of an attack the intensity of the symptoms abate, he feels that he can leave the case to Nature and can postpone operation to an interval. Such an attack ought to subside in 48 to 72 hours. If, however, during the second 24 hours of the attack he is doubtful of the outcome, he always advises an operation. Just as soon as we become sure that the disease is progressing he advises operation.

McBurney feels entirely willing to operate on all cases of appendicitis when the symptoms have practically disappeared. Treves operates when the attacks have been very numerous and when they have been increasing in severity and threatening life. McBurney thinks that when a patient has had two attacks he will as surely have a third as he will have the eleventh after the tenth, and every attack renders an operation more difficult and more risky. Ordinarily in an interval-operation we wait for 2 to 3 weeks after the attack; after this time there is no danger from sepsis and we do not expect a ventral hernia result. The mortality of interval-operations is almost nothing; but in operations done during an acute attack there is decided danger. The period of convalescence will last for at least 6 weeks and the patient may develop a hernia. The question whether it is safe to wait for the attack to pass on and defer operation, requires the best judgment of an experienced man. When we wish to operate in the interval the operation should never be done in less than 2 weeks after the termination of an acute attack, because up to this time a local septic condition may exist. After this period congestion, inflammatory thickening, and danger of sepsis will be absent. McBurney says that he always uses a gauze drain alone, except in cases of general septic peritonitis, in which, in addition to the gauze drain, he passes a glass drainage-tube down to the floor of the pelvis. He uses 10% iodoform-gauze. In the acute cases in which operation is done early it is very rare that the result is fatal. Interval-operations rarely produce a fatal result. When an operation is performed on a patient who has had numerous attacks, and when there are many adhesions and con-

siderable broken-down tissue, there is occasionally a death. The chief cause of death in appendix operations is delay. If a death is due to general septic peritonitis, this rises at a late period of the attack, after the time when the disease should have been recognized, and if there has been no delay, there would have been no septic peritonitis. In cases in which abscesses have formed, each day increases the difficulty and danger of operation. The proper time to operate when the abscess has formed has been very much debated. Treves holds that when pus has been encompassed by barriers the longer we wait the nearer the pus will be to the surface.

McBurney radically differs from Treves, and believes that the pus, instead of approaching the surface, may ascend toward the liver or descend into the pelvis. The sooner abscess-cases are operated on the better. In such cases, if the appendix has not yet softened or broken down, or if only a small amount of peritoneum is involved, the appendix can in most instances be readily removed; but when there is considerable peritonitis, with adhesions and a large amount of pus, the appendix is softened and cannot be recognized, or, if recognized, cannot be removed with safety. A discussion on the removal of the appendix in every case has been carried on in Philadelphia, and some operators maintain that the appendix should always be looked after and removed. As a matter of fact, in some cases it cannot be removed because it cannot be found. It may be buried in the wall of an abscess, and when in this situation it is usually better to abandon the search for fear of making an opening into the intestines. Furthermore, in many cases such a search will occupy a long time and lead to the necessity of greatly enlarging the wound. If the wound is cleansed thoroughly and if free drainage is established, the remnant of the appendix which is left will not be apt to be productive of harm; but if it does cause trouble at a later period, it can be operated upon then. Ill-advised search for the appendix may unquestionably lead to death. McBurney says that, as a rule, the fecal fistulæ which follow the operation for appendicitis close spontaneously; but when they do not close they should be operated upon, the only safe operation being to enter the peritoneal cavity at some other point than through the fistula itself. To enlarge the fistulous opening will lead to wounding of the intestine, but an opening above the fistula can be made easily and with safety. [It is gratifying to find the high authority of McBurney on the side of those who claim that we should not *always* remove the appendix, because in some cases it cannot be found and in others its removal will cause death. McBurney is of the opinion that appendicitis is due to obstruction to drainage of the appendix. This view is forcibly maintained by Dieulafoy, who speaks of the inflamed appendix as a closed vase. Bruns has disputed the view of Dieulafoy, and holds that appendicitis can arise from infection when the appendix is not closed, and septic inflammation does not of necessity arise when the appendix becomes a closed vase. Bruns has seen operations performed for peritonitis of appendicular origin, appendices having been removed which were not closed either partly or completely. Jalaginer maintains that whereas it is frequent to find the outlet from the appendix closed, the closure is the result and not the cause of appendicitis. Pozzi has pointed out that the appendix is a point of least resistance, and may be involved when a general infection exists. Some surgeons believe appendicitis is induced by traumatism inflicted by the psoas muscle; some that the vestigial nature of the structure makes it especially liable to disease; others that mechanical conditions induce the disease. There is no question that appendices sometimes contain concretions, but their etiologic significance is disputed. There

are probably many predisposing causes of appendicitis, and one of these causes is sometimes influenza. [What cause is most influential is uncertain.]

Arbuthnot Lane¹ writes on the **milder varieties of appendicitis**. He asserts that the only cause of the inflammation is the presence of fecal matter or some other matter in the appendix, which material the appendix is unable to get rid of. As a rule, it is fecal matter. The fecal matter may be solid or fluid, and fluid feces blocked up in the appendix will produce decided irritation. Some appendices are predisposed to the trouble because of excessive length, manner of attachment, or degree of mobility. When the appendix has been partially or completely occluded at one or more points from cicatrization of an ulcer the accumulation of secretion in the distal portion of the canal is capable of setting up a recurrent attack of inflammation. The difficulty the appendix has in emptying itself is much increased by a loaded condition of the cecum, and people who are habitually constipated are those most liable to appendicular colic. When the appendix becomes anchored it has great difficulty in expelling solid or liquid material from its interior. When the appendix contains material which it cannot expel it inflames. This inflammation may be a temporary condition involving the mucous membrane alone, or it may be so violent that the entire appendix swells and becomes gangrenous. Associated with any degree of inflammation there is a varying amount of peritonitis. In some cases there is just a little plastic lymph thrown out, in others there is a large serous exudate, and in others pus is formed. The character of the peritonitis depends largely upon the number of organisms and their virulence, and intense peritonitis involving the entire abdomen may arise when there is no perforation of the abscess-wall or of the appendix itself. It is by no means always possible to feel a tumor. A tumor, or, to be more accurate, a sense of resistance, can only be felt where matting ensues. When we have serous or purulent inflammation of the peritoneal cavity no mass can be detected, and although the appendix is much enlarged it cannot be palpated because of the rigid abdominal wall and the distension of the intestines with gas. When the appendix contains irritating material which it is unable to expel, the mucous membrane may be ulcerated by the action of organisms and stricture may follow ulceration. In some cases an abscess forms in the wall of the appendix beginning in the lymph-tissue, and these abscesses may burst into the bowel or into the peritoneal cavity. In the majority of cases adhesions form between the appendix and the bowel which is adjacent, and the abscess is thus localized. It is very unfortunate for the patient that the uterine appendages are such near neighbors of the appendix. The majority of females who have appendicitis suffer much from this adjacency, because it is very common to find that a diagnosis has previously been made of disease of the uterus or its appendages. The most common form of appendicitis, and the one most rarely recognized, is that in which the normal appendix makes an effort to force its contents into the cecum. When this process is going on the most variable symptoms may be presented. In most cases the only means of determining that this process exists is recognizing that the appendix is painful on pressure. The so-called McBurney point is of little value because the position of the appendix varies greatly. In a well-marked case of appendicitis there is usually a feeling of gastric discomfort. This is succeeded by pain, which is at first slight and intermittent, but becomes more intense or spreads over the entire abdomen, being most marked in the lower abdomen. There is apt to be vomiting. After a time the severe pain abates, and the whole abdomen is found to be tender to pressure, a spot which corresponds to

¹ Lancet, July 25, 1896.

the situation of the appendix being especially painful. In many cases during the attack it is possible to feel the appendix and to note its location. After the attack passes off there is usually persistent indigestion for a number of weeks. Many cases, however, do not give such a clear history as the above. In some cases vomiting and diarrhea are the only symptoms. In others there may be merely gastric uneasiness. In others there may be frequent micturition, pain being noted in the vesical region when the bladder is distended. Urinary symptoms indicate that the appendix is in relation with the urinary bladder. All symptoms are aggravated during the menstrual period. It is very difficult to distinguish between symptoms due to irritation of a normal appendix and symptoms due to distention of an appendix anchored by inflammation or distention of an appendix the lumen of which is constricted. The symptoms are similar, but, as a rule, are very much more severe when the appendix is damaged. Between the attacks we can usually separate these two conditions by noticing that the normal appendix is not tender and the damaged appendix is. It is important to endeavor to distinguish between these two conditions, because the former requires no operation and can be averted by regulation of the intestinal functions; whereas such treatment is without effect on the latter condition. Operative interference can be safely performed between the attacks, although the surgeon should recognize that it is sometimes wise not to operate. Lane discusses the treatment of appendicitis and lays down the following rule: in mild forms regulation of the intestinal functions will prevent recurrence. If there is great pain in an attack, give morphin, keep the patient quiet, and, if you suspect that the large bowel is loaded, administer an enema. If there are marked pain, vomiting, and general disturbance, give morphin in sufficient dose to keep the patient under its influence. When the intestines are matted about the appendix there is very little cause for anxiety, since in such cases perforation is very unusual; and if an abscess of large size forms, it will spread toward the abdominal wall. The surgeon should not be in a hurry to open these fluid accumulations unless the symptoms are urgent. We know that such conditions not unusually subside, because the colon-bacilli die or lose their virulence. When we open such collections of fluid we should adhere to the strictest antiseptic regulations, in order to prevent the entry of other organisms than those which are present. The colon-bacillus does not appear to exercise any deterrent influence on the healing of wounds, and wounds which contain the colon-bacillus will heal exactly as will sterile wounds. When there is serous or purulent peritonitis the condition is very dangerous. In such conditions, when the surgeon is in doubt, he should interfere and remove the appendix. When an abscess has formed and has not become attached to the abdominal wall, there is great danger that it may burst into the peritoneal cavity. The surgeon may hesitate to expose the patient to the risk of opening an abscess, removing the appendix, and draining through the healthy peritoneum, especially if he has not at command good assistants; but such cases demand operation in many instances immediately. The matted bowel should be wrapped in sterilized iodoform-gauze in order to protect the peritoneal cavity. When the abscess ruptures directly into the peritoneal cavity, or when a perforation of the appendix takes place into the free peritoneal cavity, only prompt interference can possibly do any good. It is far better to wipe the peritoneum thoroughly and then flush it; and if the bowels are not much distended, they should be wrapped in sterile gauze. Lane greatly prefers sterile gauze to gauze containing any irritant germicide. [Lane does not hesitate to give morphin in an attack, but we believe decidedly that it should not be given. Pain will not kill the patient, but by giving the mor-

plain to destroy the pain we may lull the patient and ourselves into a sense of security when beset by the most imminent perils.]

J. W. Elliot¹ describes a **modification of the McBurney incision for appendectomy**. He says that he has done the McBurney operation ten times. When the appendix is normally situated it is easily reached, but when it becomes necessary to enlarge the incision the operation is not altogether satisfactory. If it becomes necessary to retract forcibly the muscles, the tissues are apt to be damaged, so that healing is imperfect. When the wound has to be enlarged the advantage of the McBurney incision is gone, and we have a ragged wound with two layers of muscles which are widely striped, a wound which drains very badly if pus is met with. Elliot advises that the operation should be begun by a horizontal incision through the skin and the aponeurosis of the external oblique. This incision begins half an inch internal to the anterior superior iliac spine and reaches the semilunar line. The fibers of the external oblique are cut across; the fibers of the internal oblique and transversalis are separated as in the McBurney method. The transversalis fascia and peritoneum are opened transversely. If it is necessary to enlarge this incision, we can carry it into the rectus or enlarge it either upward or downward in the semilunar line. He recommends closing the wound by passing two stitches through the entire thickness of the abdominal wall to prevent a dead space, then uniting the edges of the external oblique with a continuous buried suture of silk. He has performed nine of these operations with great satisfaction. As in the operation of McBurney, neither nerves nor vessels are cut, and there is no anesthesia of the skin left as a legacy. When the patient is placed in the Trendelenburg position this incision gives access to the cecal region, and enables the surgeon to dissect the appendix from behind the cecum or from the pelvic ring. This transverse incision passes practically over the base of the appendix and gives more direct ingress than does the incision in the semilunar line.

Floderus² considers the **treatment of perforating appendicitis associated with diffuse peritonitis**. He reports a case which was operated upon with success two days after perforation had occurred. The operation was done by Lennander. In suppurating appendicitis the incision should be just above and parallel to Poupart's ligament. Such an incision affords perfect drainage and frequently enables us to open an appendicular abscess back of the peritoneum. The incision parallel to Poupart's ligament is rarely followed by hernia, as it does not cut motor nerves and passes chiefly through tendinous structures. When the surgeon is endeavoring to evacuate an area of appendicular suppuration he must take scrupulous care to protect the general peritoneal cavity from infection. The intestines which are against the abscess-wall should be covered with compresses of sterile gauze saturated with hot normal salt solution, and as soon as pus appears it is mopped up with small compresses. If pus wells up in such great quantities that it cannot be absorbed by the compresses, the patient is placed upon his right side and the assistant makes pressure upon the middle of the abdomen. These maneuvers keep the pus from entering the general peritoneal cavity. When the abscess-cavity is evacuated the surgeon inserts his finger and the cavity is thoroughly cleaned with small compresses. A search is made for the appendix and the diverticulum is removed as near as possible to the cecum. In suppurative cases it is not necessary to ligate the appendix and suture the stump. It is better to clamp it with a pair of hemostats which include the mesentery

¹ Boston M. and S. Jour., Oct. 29, 1896.

² Arch. f. klin. Chir., Bd. liv., H. 1, 1897.

in the bite and to remove the distal portion of the structure. The forceps are left in place for three or four days. A fecal fistula may form, but this will probably close spontaneously, and in some cases a fecal fistula is actually of value, permitting the escape of gas and favoring the renewal of peristaltic action. After the appendix has been removed the cavity which contains pus is packed with iodoform-gauze, the corners of the wound being approximated by silkworm-gut sutures. It is never wise to irrigate the peritoneal cavity unless pus has escaped into it. If irrigation is necessary, normal salt solution should be employed, and the surgeon keeps on flushing the peritoneum with salt solution until the fluid runs out clear. In some cases the pulse fails during irrigation because of irritation of the splanchnic area, and while this irrigation is being carried out an assistant should carefully watch the pulse. The after-treatment at first consists in stimulants and food to maintain the patient's strength and favor the extrusion of the poison.

Floderus advises that digitalis be given for about three days, and that this drug be succeeded by the use of injections of camphor for one week and the employment of enemata of brandy and grape-sugar. Enemata of brandy and grape-sugar are non-irritant and tend to cause peristaltic movements of the small intestine. Transfusions of salt solution are of benefit by increasing blood-pressure, by increasing the amount of blood, and by preventing a tendency to dryness of tissues. It is always wise to give diuretics. Digitalis and transfusion, of course, tend to produce diuresis. Endeavor to restore peristaltic movements as soon as possible. When the intestines are found much distended at the operation they should be punctured to allow gas to escape. After the operation small doses of calomel frequently repeated followed by a saline cathartic are of value. Repeated enemata are useful in attaining this end, and so is the passage of a rubber tube into the rectum. The patient is not permitted to take food by the mouth until peristaltic power is regained, and is fed by nutritive enemata. The pain which follows operation is due chiefly to distention, and is best treated by enemata and the employment of the tube. Morphine should never be used unless the pain is unbearable, and if it is necessary the dose of $\frac{1}{6}$ gr. should not be exceeded. The great objection to morphine is that it antagonizes peristalsis.

Golouboff¹ considers the question of whether **appendicitis** can be an **epidemic disease**. He says that in Moscow the disease is very rare, but he has seen it suddenly appear, a great number of people being affected. Appendicitis is due to intestinal microorganisms, and it seems probable that under some favorable conditions the colon-bacilli, streptococci, and staphylococci acquire unusual virulence. Epidemics of appendicitis may be compared to epidemics of tonsillitis, which are not unusual.

Arthur E. Barker² furnishes notes on the variety as to time and extent in **the production of inflammatory collections due to appendicitis**. No question is more important than the determination of the time necessary for the formation of a dangerous collection of infectious matter around a damaged appendix. In order to determine this point, Barker has made a study of a large number of cases of appendicitis. These cases may be divided roughly into 3 groups: (a) those cases in which, because of inflammation and perforation, a serofibrinous peritonitis of greater or less extent has taken place; (b) those in which an abscess has formed which is incased in plastic matter and is in reality extraperitoneal; (c) those in which the inflammation is not accompanied by the formation of any fluid outside of the lumen of the appendix. The last group may be left out of consideration for the present. Group (a)

¹ Gaz. méd., Dec. 26, 1896.

² Practitioner, Feb., 1897.

includes two classes of cases : (1) those in which there is no evidence of limitation of plastic material, the whole peritoneum being infected ; and (2) those in which the inflammatory process is widely diffused, but is bounded by plastic matter and is confined to one portion of the abdominal cavity. In group (b) are included (1) cases in which the definitely pointed abscess is within the peritoneal cavity among the intestines, and (2) those in which the abscess is behind the cecum, being more or less completely in the areolar tissue of the pelvis and loin, practically, it will be observed, outside of the general peritoneal cavity. In cases of the variety specified as belonging in class (1) of group (a) ill effects arise with remarkable rapidity. The infection spreads so quickly because it is virulent and is not limited by plastic material. This absence of plastic material is due to the effects of the products of the causative organisms. In such cases acute general septic peritonitis is manifest within a few hours. We note acute pain, fever, vomiting of green fluid, abdominal distention, and abdominal tenderness, the tenderness, it may be, being greatest in the right iliac fossa. The prognosis in these cases is almost hopeless. It is almost impossible to clean thoroughly every portion of the abdomen. Those rare instances in which a diagnosis of this condition has been made and which have recovered belong in reality, it seems probable, to class (2) of group (a), cases in which there is infection with less virulent organisms and in which a certain amount of plastic matter forms and shuts off a limited portion of the abdomen. Such cases may recover if operated on early, although their progress is apt to be very rapid. Barker publishes some very interesting illustrative cases. He states that it is quite clear that wide differences exist in the speed with which inflammation spreads from the focus of infection and in the area which may become involved. We have too strong a tendency to adopt a stereotyped view as to the course of appendicitis. In the first place, there are anatomic varieties. In the second place, the virulence of the poison varies very greatly and the power of the body-resistance also varies. In one case we may have a virulent organism acting on weakened tissues, no trace of plastic matter being found, and a large serofibrinous effusion filled with septic matter being carried over large areas of peritoneum. In other instances we have a less intense poison acting on a patient whose tissues have considerable vital resistance. Here the power of the tissues antagonizes the poison, and lymph is poured out to wall it in. Between these two extremes occur all sorts of cases. A study of many cases will lead us to be very cautious in examinations for this disease. We should study each case with care and endeavor to estimate the type to which it belongs, and should be very slow to assert dogmatically the time which has passed since the initial disturbance or the extent of the mischief which exists. When we realize the complexity of the process included under the head of appendicitis we will be lenient in our judgment of all who have found difficulty in the diagnosis and prognosis of such cases.

Robert T. Morris¹ presents **notes on appendicitis**. In 100 cases which he treated surgically there were 2 deaths. He claims that the death-rate for the same 100 cases under medical treatment would have been 28%, not of necessity in the first attack, but eventually. Appendicitis begins at an atrium of infection, which is produced in the mucosa and the serosa of the appendix. A common cause of the atrium of infection is traumatism inflicted by the right psoas muscle. In some cases injury has been inflicted by a concretion, and in rare instances by entozoa. An infective atrium can be produced also by bacterial infection injuring epithelium. An infection-atrimum in

¹ Med. Rec., Dec. 26, 1896.

the serosa arises from the extension of inflammation from the serous coat of a neighboring structure. Such an atrium once formed permits the entrance of bacteria or toxins into the appendix tissues. The results resemble those produced by bacterial invasion of the colon, but differ in degree. They differ in degree because of 2 reasons: 1. The outer tube of the appendix prevents rapid swelling of the lymphoid tissue, and as a consequence pressure-anemia occurs in the inner tube, and the compressed tissue becomes a point of least resistance for microorganisms; 2. The chief blood-supply of the appendix comes from one terminal artery, and infective inflammation occludes branches of this artery and bacteria gain the mastery in tissues which are starved of blood. The chief reason why appendicitis is rarer in women than in men has been shown by Robinson. It is because of the fact that in women the appendix is likely to be out of the way of injury by the psoas muscle.

In discussing the diagnosis of appendicitis Morris asserts that the temperature is a matter of no significance whatever in reaching a conclusion. The author positively asserts that the appendix can be palpated. He says that in an acute inflammation the abdomen is boardlike, and palpation is, of course, difficult; but in such a condition it is unnecessary, because we can make the diagnosis without it. In considering the pathology of the disease Morris sets forth his well-known views. In speaking of catarrhal appendicitis he says there is no doubt whatever that catarrh occurs in the beginning of infective appendicitis, and it occurs simultaneously with catarrh of the cecum; but it produces no symptoms which will enable us to make a diagnosis. When symptoms exist sufficiently positive in nature to call for operation the disease has passed beyond the catarrhal stage. Cases of appendicitis can, of course, subside under medical treatment; but patients often die under medical treatment, if not in the first attack, in a later attack, and those who do not die lose a great deal of valuable time by being confined in bed. No one can possibly predict what will become of a patient who is relying on medical treatment.

Morris strongly maintains the value of surgical treatment, because he thinks that each hour of delay permits of more widespread infection, and that each attack renders the ultimately necessary operation more difficult of performance. He believes that a $1\frac{1}{2}$ in. incision is sufficient for many cases—for most cases, in fact, without abscess. This incision greatly reduces the liability to a subsequent hernia. The blunt dissection plan of McBurney is a most excellent procedure. In operating in an abscess-case adhesions should be broken up and a search made for other abscesses and for the appendix. The free peritoneal cavity can be exposed without any hesitation. Gauze-packing is apt to develop obstruction, and iodoform-gauze may lead to iodoform-poisoning. [We agree with Morris that iodoform-gauze can cause obstruction, and that poisoning is more frequent than is usually supposed and commonly escapes recognition, but nevertheless we do not feel willing to abandon iodoform-gauze. It serves a useful purpose, and we know of no satisfactory substitute. It may be true that the free peritoneal cavity can be exposed without hesitation. We know, in fact, that this is often done. But absence of hesitation on the part of the surgeon may not be equivalent to safety for the patient, and we believe the patient's safety is greater when the free peritoneal cavity is walled off with gauze.]

Byron Robinson¹ writes on the **causes of the pain** in certain cases of chronic appendicitis. He draws his conclusions from many autopsies. In 230 of these autopsies he carefully recorded the conditions in the ceco-appendix region and found that over 70% of adults showed evidence of chronic

¹ Ann. of Surg., Dec., 1896.

peritonitis around the ileo-appendicular apparatus. When the appendix, the cecum, or the lower end of the ileum are in contact with the long range of action of the psoas muscle adhesion is liable to take place, and when this muscle plays upon the bowel, and the bowel contains virulent pathogenic microbes, the injury inflicted by the muscle may be responsible for the migration through the bowel-wall of microbes or toxic products. The same condition of affairs is noticed in the left psoas muscle, in which structure the meso-sigmoid can become attached. Of course, the psoas muscle does not cause the peritonitis, but is only a factor leading to the localization of microorganisms. The lower end of the ileum only may be in contact with the muscle. If the appendix ruptures when it is in contact with the psoas, it can become adherent to the muscle, and whenever the psoas muscle acts it will irritate the appendix, induce peristalsis, and cause appendicular colic. All of us have noticed cases of chronic appendicitis in which there were attacks of severe pain unaccompanied by fever, the pain being frequently developed by a long walk or a rough ride. If an appendix is outside of the range of the psoas muscle, exercise does not develop these attacks. Hence we can conclude when a patient with chronic appendicitis suffers considerable pain on muscular exercise, which pain is unaccompanied by elevation of temperature or increased rapidity of the pulse, the trouble is that the appendix is within the range of action of the psoas muscle, and that this muscle is responsible for irritating the diseased appendix into violent peristalsis. [The causative influence of traumatism inflicted by the psoas muscle, as set forth by Dr. Robinson, is a matter of considerable importance. We believe that the observations above noted are worthy of thoughtful attention. Certain it is that many people who have had appendicitis and who have not been operated upon suffer pain after prolonged or violent exercise.]

J. A. MacDougall¹ calls attention to the fact that in the **treatment of appendicitis** we should consider only acute or inflammatory conditions, for other lesions in this region do not present conditions which are so doubtful or difficult. As the appendix varies in length and in direction, it may give rise to inflammatory phenomena in various situations. Therefore, we should make a rule in any acute inflammation of the abdomen which is not explained otherwise to think of appendicitis as a possible cause. The author considers the predisposing causes of appendicitis to be the situation, the dependent position, the vestigial nature, and the plan of circulation of the appendix. The exciting causes can be divided into catarrhal, ulcerative, and infective. It is probably true that there may be some mechanical causes, as the appendix is liable to become strangulated. Traumatism is not a frequent cause, and this is confirmed by statistics of public schools. The boys in these schools are of the age at which injuries are most frequent, and yet appendicitis is rare among them. It is quite probable that there exists such a condition as catarrhal appendicitis. When this condition exists the mucous membrane becomes congested, the glands overact, the orifice of the appendix is blocked, and as a result the lining membrane of the appendix may be cast off, and when this occurs its regeneration is uncertain. It may be but partially regenerated, a permanent stricture resulting, and at other times granulation-tissue may take the place of the proper lining membrane. The ulcerating form in its relationship with stercoral concretions and foreign bodies has been proved to exist. Concretions act in various ways. Roux, of Lausanne, has proved that a concretion is not in itself dangerous, but becomes a cause of danger because of the changed vital conditions which are apt to occur about it. The presence of a

¹ Brit. Med. Jour., Oct. 10, 1896.

concretion can mechanically produce considerable suffering. The infective form can certainly occur independently of the presence of a concretion, of a foreign body, of ulceration, or catarrh; it may produce gangrene of the appendix, it may cause septic peritonitis without visible perforation, and it is a common cause of general peritonitis. There is no question that the appendix has a strong predisposition to suffer from infection. Ekehorn's experiments have proved that the bacillus coli communis obtained from mild cases of appendicitis is less virulent than that obtained from severe cases, and, therefore, there must be conditions which cause this organism to be at times more virulent or less virulent. Some of these conditions may be found in the degree of tension in the walls of the appendix, in the chemical composition of the contents of the appendix, and in the vital resistance of the individual. Some authors have ascribed the necrotic changes in the appendix to thrombosis and endarteritis, but Hawkins has never been able to find these conditions. The author then discusses the symptoms of appendicitis, the varieties, the diagnosis, the prognosis, and the treatment. When an early operation is decided upon it is usually found to be easy, but may be hard. The abdomen can be opened by either an oblique or a vertical incision. It may be difficult to reach the appendix, or this organ may be found tied down by adhesions, the latter condition being especially common in children. When the appendix is isolated it had better be removed by a circular incision of the peritoneal coat, the retraction of this cuff, the ligation of the mucous canal with fine silk, disinfection of the mucous stump with pure carbolic acid and stitching the peritoneal cuff. When it is found impossible to carry out this proceeding, because of the state of the peritoneum, we can divide the appendix about $\frac{1}{4}$ in. from the cecum after it is ligated and disinfect the stump with pure carbolic acid. In many cases we close the wound without drainage; but if there is even a trace of seropurulent or purulent matter, we must certainly drain. If we do drain, insert a provisional suture to be tied when the drainage is removed, thus obviating the tendency to hernia. When free perforation exists, when there is a rapidly gangrenous process, or when septic or purulent peritonitis has begun, the procedure must be different. If peritonitis exists from some other cause than appendicitis, and if when the patient is anesthetized we discover no evidence of harm in the right iliac fossa, the abdomen should be opened by a median incision. If in doubt as to what is the matter, especially in the adolescent male, suspect the appendix, and first make an exploration of the iliac fossa. When seropurulent or purulent matter is found in the abdomen flush it out with normal salt solution at a temperature of 110° . This fluid can be poured in the cavity out of jugs or can be introduced by means of a large irrigator with a big tube. The appendix should be removed if it can be done easily, but our decision whether to do this or not will be determined by the condition of the patient. If the intestines are found greatly distended, they should be evacuated by incision. Suppose symptoms which call for interference arise after the second day of an appendicitis, a period when it is probable that adhesions are walling in the trouble. In order to reach this diseased appendix we must first open the general peritoneal cavity, and by breaking down adhesions may bring about general peritonitis. McBurney says that although the apparent dangers of causing infection of the noninfected peritoneum are very great, in reality experience shows that the real dangers are not nearly so great. Is the removal of the appendix absolutely necessary? The writer thinks not. If the pus is evacuated, it is justifiable to let the appendix alone. In such a case we should open the abdomen by an oblique incision over the swelling. In some cases it will be found possible to employ Barling's method of stitching the abscess to

the parietal peritoneum, and, if we can do this, we will be enabled to protect the general peritoneal cavity. It will be likely, however, that the abscess is in the mass with the coils of intestines, only a thin layer of lymph being on their surface. In such a case iodoform-gauze is packed about the area, the patient is turned on the right side, and the surgeon searches on either edge of the adherent mass to see if pus be presenting there. If pus is not presenting, if pelvic exploration does not discover it, if there is no evidence of its existing behind the cecum, then the finger is directed into the angle between the ileum and the large intestine; it separates adhesions, and when it reaches the focus of trouble is retained there until careful plugging with gauze around the finger walls off the channel which has been made. The finger is withdrawn, pus is sponged up, and a drainage-tube is inserted into the channel which was occupied by the finger. The gauze will be taken out within 48 hours. If it is left in longer, it will be found to be troublesome to remove. There is another way of dealing with the pus-focus, which can occasionally be employed. It may be possible to reach pus behind the cecum by an extraperitoneal incision made 1 inch internal to the anterior superior spine of the ilium. When we operate for distinctly localized abscess about the 8th to the 12th day of the appendicitis, incise freely and make a search for any concretion. The question in such a case is, What shall we do with the appendix? As a rule, it is better to leave the appendix alone. If it is felt lying loose in the pus-cavity or is found projecting from the abscess-wall, it may be removed, and in many cases it is not necessary to ligate. But when the appendix is adherent to the abscess-wall it is a very risky procedure to attempt to remove it, for by so doing we may separate adhesions, and by permitting the escape of septic matter lead to the development of general peritonitis. Or the attempt to remove it may cause intestinal obstruction, the recently separated gut taking on new adhesions and kinking. If from the appendix, which is part of the abscess-wall, fecal matter is escaping into the pus-cavity, no attempt should be made to remove it. Irrigation, the use of gauze-packing, and the employment of frequent enemata will probably be followed by closure of the fistula. If the fistula does not close, it can be closed by operation at a later period. When we come to operate on a fistula of this sort the pus-sac should be thoroughly disinfected, the peritoneal cavity should be protected by gauze, and the gut should be freed by breaking down the adhesions. MacDougall is a believer in the interval-operation when medical means have failed; when the attacks are occurring with increased frequency; when they are so severe as to endanger life, especially if there is an induration, an area of tenderness, or a palpable tumor remaining after the attack; and when there is a constant sense of uneasiness in the iliac fossa. Many surgeons ligate the appendix near its base before its division, but MacDougall prefers the formation of a peritoneal flap after the method of Chiene. Chiene abandoned the ligation of the appendix because he lost a case from intractable vomiting appearing shortly after operation, and apparently due to the tight knot upon the appendix, and he has seen one case in which like symptoms developed, but passed away on the fourth day, at which time, because of softening, tension was relieved. In the debate upon this paper Southam said that it was the custom until quite recently to treat cases of recurrent appendicitis only by medical means. Medical means will relieve the symptoms during an attack, but are powerless to prevent recurrence. He is a believer in the radical cure by the removal of the appendix in the period of quiescence after an attack. He does not believe in removing the appendix after the first attack, because there may never be another attack when this has not been done; but after two well-marked attacks the operation is indicated,

especially if the signs persist in a quiescent period. The most important of these signs are tenderness in the appendicular region, swelling, and a sense of resistance. When the appendix is constricted or occluded and bound down with adhesions, particularly if it is distended with fluid which contains a concretion, the patient is always in danger of ulceration and perforation and the formation of pus around the appendix. Southam then reported cases of this sort to illustrate the necessity of surgical operation in recurrent appendicitis. Serious complications are avoided by removing the appendix at an early period.

In the discussion of MacDougall's paper, Rutherford Morison, of Newcastle-on-Tyne, said he also believed in operating where there had been a second attack. He, of course, operates on all cases with abscess and all cases with a very acute beginning. He prefers the oblique incision, because it does not damage the rectus muscle, as an incision in the *linea semilunaris* is certain to do. Furthermore, the oblique incision, if prolonged into the back, permits of drainage at a dependent situation and allows thorough closure of the anterior portion of the wound, so preventing hernia.

Morison described several kinds of abscess: abscess adherent to the abdominal wall, requiring a simple incision and drainage; cases in which the appendix and the abscess were on the outside of the cecum, in which case the appendix should be removed; cases in which the appendix is behind the cecum with inflammation of the retrocecal tissue, recognized by flexion of the corresponding thigh (in certain of these cases the appendix should be removed); abscess in the pelvis, in which drainage through the vagina in the female and through the rectum in the male is recommended. If an abscess is situated to the inner side of the cecum, the surgeon should practise drainage only, and should not attempt to remove the appendix. The subject was also debated by Charles A. Morton, of Bristol, Jordon Lloyd, of Birmingham, J. Crawford Renton, of Glasgow, T. Jenner Verral, of Brighton, and J. P. Bush, of Bristol.

W. Mitchell Banks said that the statistics of American surgeons filled him with amazement; they seemed to reckon their cases by the score. He has seen a considerable amount of surgical practice in the second city of the British Empire, but any single American surgeon sees more cases in a year than he has seen in all his life. The conclusion he draws is that appendicitis is astonishingly frequent in the United States, or that surgeons operate upon a class of patients which in Liverpool get well without operation. We often find that new operative procedures are employed to too great an extent when first introduced, and later suffer from unmerited condemnation. Operations on the appendix are in the first stage, the stage in which cases are hunted up and triumphs are proclaimed. In many of the cases proper diet, rest, soothing applications, and castor oil would have produced perfectly satisfactory results. Many cases are called appendicitis which have no real cause to be so designated, just as ordinary sore throats are occasionally called diphtheria. Many cases called appendicitis are in reality the old-fashioned typhlitis or colitis, and relapses are almost always due to carelessness in diet, and not to recurrent fits of inherent viciousness upon the part of the appendix. Banks speaks of a case in which the adhesions around the cecum proved that the trouble in reality began in that organ. There seems to be nothing improbable in the old idea that inflammatory products could spread from the interior of the cecum through its unprotected posterior wall and set up trouble in the loose retrocecal connective tissue. Banks says he has opened a great many abscesses which were caused in this manner, and the cases he opened were permanently cured, whereas, if there had been chronic abscess in the

appendix, the mischief ought to have returned. He thinks that the case against the appendix has been overstated. It is, however, undoubted that the so-called cases of foudroyant general suppurative peritonitis are caused by intraperitoneal appendicular abscesses which burst. These are the cases where the appendix is in serious trouble and is apt to be found gangrenous. Of course, they should be treated by prompt operation; but Banks denies that these cases are so common as to warrant us in the wholesale operating in which American surgeons would have us indulge. [The ultraconservative view as advocated by Banks is, in our opinion, quite as erroneous and even more dangerous than the ultraradical opinion of those who always operate.]

Mayo Robson¹ reports a series of cases of **appendicitis associated with general peritonitis**. He says the most important points to settle in a case of appendicitis are: Should we operate? and, if so, When? Early operation, performed as soon as the diagnosis is made, will give a much larger rate of recovery than the method of individualizing which most Englishmen still adopt. The removal of the appendix before suppuration or gangrene has taken place, or before firm adhesions form, is a very safe operation. It can be carried out through a small incision with blunt separation of the muscular fibers. If we wait for ulceration to take place, we run the risk of very serious perils and may be forced at any moment to operate under unfavorable circumstances.

Robson then records some striking and interesting cases in proof of his contention. He thinks that cases should be divided into catarrhal, sometimes acute, but generally subacute, and suppurative, which is either acute or subacute. An acute suppurative appendicitis may be followed by perforation or gangrene, and a subacute suppurative appendicitis by a localized abscess. In catarrhal appendicitis operation is not, as a rule, necessary, though it may become necessary because of recurrence of the attack. In suppurative appendicitis operation is always necessary. An acute onset, with a rapid pulse and tenderness over the appendix, without the presence of a tumor, is a condition calling for operation at once. If an attack comes on gradually, if the pulse is not over 100, and if a tumor forms early, we can safely delay. If in the course of any case of appendicitis there is a rigor, with a rise of pulse and temperature, operation should be performed. The pulse is the guide to treatment; the temperature is of but little aid. If opium is given, the general pulse-rate is decreased, and the surgeon may delay too long. When the surgeon is called into a case in which opium has been given it may be necessary for him to reserve his opinion for a few hours, during which period the opium is withheld, and if, during these few hours, the frequency of the pulse increases and the countenance of the patient is seen to be anxious, operation must be performed. If the pain ceases, or is markedly relieved, and this condition is accompanied by pronounced rise in the pulse-rate, gangrene probably exists, and operation must be performed at once. Operation must always be performed if there is abdominal distention with vomiting and rapid pulse. In subacute or catarrhal appendicitis it is well to operate in the quiescent period, as in this period operation is safe. The time to operate is from 2 to 4 weeks after the patient has recovered from the attack. After a second attack it is certain that these seizures are going to recur if the appendix is let alone, and operation should be performed.

In an operation the appendix should almost always be removed. It will occasionally happen that the patient is too ill to bear a protracted search. Sometimes the appendix is not found; Robson had such a case in which

¹ Brit. Med. Jour., Dec. 19, 1896.

pus was evacuated, and in a few weeks the second attack of appendicitis occurred. Sometimes the appendix is so buried in adhesions that it does not seem prudent to separate it, but with very few exceptions the organ should be removed. In the recurrent form it should always be removed, and when there is general peritonitis the perforated or gangrenous appendix ought to be taken away. Doubt arises only where the suppuration is localized and there is fear of opening the general peritoneal cavity in carrying out a search. In such a case the abscess-cavity is evacuated and cleansed. The longitudinal band of the cecum is followed, and this will lead to the appendix. It will be found that the appendix, as a rule, can be removed without greatly disturbing the adhesions; but even if the peritoneal cavity be opened in our efforts, harm will rarely ensue if the parts are protected with sponges. If a longitudinal band cannot be seen because it is overlapped by inflamed omentum or adherent bowel, it will usually be found possible to feel the hard, rounded appendix when the finger is carried into the abscess-cavity, and when it is felt it can generally be detached. In some cases the appendix actually projects into the abscess and can be removed easily. If none of these conditions exist, a prolonged search is inadvisable. The removal of the appendix is an advantage, because the patient is freed from the danger of subsequent attacks and of the formation of a fecal fistula, and in the search for it we occasionally discover other collections of pus which would be highly dangerous to leave undrained. In operating for general infective peritonitis many patients will die if not operated on early, and in the later stages the percentage of death will be very great. Robson has operated on 6 cases during the year, and has been fortunate enough to save 5 of them. In operating on cases of appendicitis in the quiescent period there is practically no mortality. In operating for acute suppurative cases where the suppuration is limited the mortality is slight. If general peritonitis exists, free irrigation with plain boiled water, or with weak boracic lotion, and very free drainage by several large tubes are desirable. The incision Robson usually employs is 2 to 3 in. in length, somewhat curved, and placed to the inner side of the anterior superior iliac spine, passing over the tender spot known as *McBurney's point*, which point is usually a guide to the situation of the appendix. When possible, *McBurney's* method of blunt separation is advisable. In removing the appendix Robson ligates the mesentery with exactitude, makes a circular incision through the peritoneal coat of the appendix and folds this back like a cuff, ligates the mucomuscular portion and amputates it, asepticezes the stump, applies iodoform, turns down the peritoneal cuff and ligates it over the stump. If it is found necessary to ligate the appendix close to the cecum, ligate the stump, invert it into the cecum, and apply *Lembert* sutures over it. In some cases where the appendix is so much disorganized that it is impossible or undesirable to bring it to the surface apply a catgut ligature around it and cut off the portion beyond the ligature. In closing the abdomen suture peritoneum to peritoneum and muscle to muscle by catgut, and use silkworm-gut for the superficial structures. [Robson's advice always to insist on operating after a second attack is, we believe, sound. A person who has had two attacks is as certain to have a third as a person who has had twelve attacks is certain to have a thirteenth. Many surgeons operate after a first attack, and this procedure is often, though not always, justifiable, though it is not always easy to obtain the consent of the patient. It is not always justifiable to operate after a first attack, because there may never be another. If a first attack was very severe, if it is followed by tenderness or by pain on taking exercise, operation is advisable. That Robson has saved 5 out of 6 cases of general peritonitis is an encouragement to surgeons who

are apt to look upon such cases as quite hopeless. Certainly an attempt should be made to save them.]

George R. Fowler¹ presents a study of the **differential diagnosis of lesions of the appendix vermiformis in the adult female**. He tells us that this diagnosis not unusually presents very difficult features, particularly in the following respects: 1. The proximity of the appendix to the adnexa may confuse both objective and subjective symptoms; 2. Acute conditions of one and chronic conditions of the other may coincide; 3. Acute conditions of both may coexist; 4. Chronic conditions of both may coexist; 5. Infectious inflammation of either may cause septic peritonitis, and septic peritonitis may hide the original trouble.

Fowler then reports a case of ruptured right-sided pyosalpinx which had been diagnosticated as appendicitis; a case of pelvic hemocele which was diagnosticated as appendicitis; a case of ruptured tubal pregnancy in which a diagnosis of appendicitis was made at first, a proper diagnosis, however, being made before operation; a case of right-sided hematosalpinx diagnosticated as perforative peritonitis; a case of ovarian cystoma strangulated from torsion of the pedicle, which was diagnosticated as appendicitis until a vaginal examination discovered the tumor; a case of perforative peritonitis which resembled ruptured ectopic gestation; a case of combined acute appendicitis and unruptured tubal gestation combined with suppurative appendicitis; a case of suppurative appendicitis and pyosalpinx; a case in which appendicitis had existed 4 years previously, adnexal disease of 3 years' standing, recent impacted gallstone, and dropsy of the gall-bladder; a case of chronic inflammation of the adnexa, with a neoplasm of the appendix; a case of left ovarian disease which simulated chronic relapsing appendicitis; a case of chronic relapsing appendicitis and cystic ovaritis; a case which gave a history of 3 typical attacks of acute appendicitis, in which operation disclosed an apparently normal appendix and a cystic degeneration of the right ovary; a case of right pyosalpinx, with adherent and chronically inflamed appendix; a case of ovarian cystoma and recurrent appendicitis; a case of chronic appendicitis due to adhesions between the appendix and the stump of a former salpingectomy and oöphorectomy. The main points to be borne in mind in making the diagnosis of appendicitis in the adult female are the following: appendicitis is less frequent in the female than are diseases of the adnexa. In appendicitis the history is that of a condition coming on acutely; adnexal disease is apt to show a record of a chronic condition and is usually associated with menstrual disturbances. In both appendicitis and adnexal diseases there may be acute and radiating pain, or dull and localized pain; but acute radiating pain is the rule in appendicitis and dull, localized pain in adnexal trouble. In either condition vomiting may be present, but it is far more frequent in appendicitis. In adnexal disease we may find tenderness at the site of the appendix, and it may be located elsewhere than in the right iliac fossa in appendicitis. The reverse, however, is the rule. The maximum point of tenderness of appendicitis is above the level of the anterior superior spinous process of the ilium. Vaginal examination which is not forcible rarely discovers tenderness in appendicitis, but readily develops tenderness in disease of the adnexa. In appendicitis movements of the uterus brought about by the finger rarely produce pain, but are apt to cause pain in tubo-ovarian diseases. The nearer tenderness is to the bony anterior wall of the pelvis and the median line by external examination or internal examination, the greater is the chance of pelvic inflammation existing, and *vice versa*. A chill is usually absent in appendicitis, but is fre-

¹ Brooklyn Med. Jour., Apr., 1897.

quently present in adnexal disease. Fever is apt to be present in appendicitis, but is usually absent in adnexal disease. This rule, of course, is liable to be reversed. Right-sided rigidity of the abdomen is almost invariably present in appendicitis. It is very rarely marked in tubo-ovarian disease, unless the latter condition is complicated with considerable peritonitis.

A tumor in appendicitis is rarely found before the third day; in tubo-ovarian disease it is likely to be found at the first examination. When a tumor exists in appendicitis it is usually located beneath the right rectus muscle opposite the anterior superior iliac spine, or outside of this area. In adnexal trouble it is more easily found by vaginal than by abdominal palpation—in fact, it may be missed entirely by abdominal palpation. An adnexal tumor can be well demonstrated by conjoined touch. It is very rare that an appendical mass can be felt from the vagina. The course of appendicitis is that of an acute trouble, and even in chronic cases there is usually a history of at least one acute attack. In adnexal lesions the course is usually subacute or chronic from the beginning, save when complications intervene. Perforative peritonitis is more common from appendicular trouble than from appendical disease. Perforative peritonitis arising from appendicitis is almost always fatal, because very virulent organisms are set free into the peritoneal cavity. These organisms come from the most dangerous region known—that is, the intestinal canal. The perforative peritonitis of suppurative salpingitis is not nearly so fatal, because the microorganisms are less virulent.

M. Price¹ believes that in all cases in which symptoms closely resembling those of appendicitis appear **free purgation** should be used for the purpose of making the diagnosis clear. If free purgation does not remove the symptoms, it becomes obvious that we are dealing with an inflammation of the appendix or an ulcer of the colon. [Price suggests the use of purgatives for diagnostic purposes. To give purgatives in all cases for diagnosis is not safe. The condition of the patient counts for something. In some cases the administration of powerful purgatives will lessen the chance of recovery when operation is performed.]

William Henry Battle² contributes an article upon the **surgical treatment of the diseases of the appendix vermiformis**. He proposes a method of operating for relapsing appendicitis which he thinks has elements of superiority over the methods usually followed. The directions for Battle's operation are as follows: make an incision in the right iliac region with its center corresponding to the point where it is probable that the appendix is attached. The incision is in the direction of the semilunar line and about midway between the iliac spine and the umbilicus. The incision divides the skin and subcutaneous tissue, the external oblique aponeurosis, and the outer portion of the sheath of the right rectus muscle, this part of the incision being an inch from the external margin of the sheath. The rectus muscle is separated from the inner surface of the sheath by means of the surgeon's forefinger and it is retracted toward the middle line. When the edges of the wound are retracted the deep epigastric artery will be visible on the posterior layer of the sheath and can be easily avoided. The posterior layer of the sheath, which is the transversalis fascia, the subperitoneal tissue, and the peritoneum are divided the length of the wound. The small intestines are pushed toward the center of the abdomen, the appendix region is isolated, and the appendix is amputated by the coat-sleeve method, the peritoneum over it being closed by means of Lembert sutures. The abdominal wound is closed by 3 layers of interrupted silk sutures. The deepest sutures bring together the

¹ Med. and Surg. Reporter, Jan. 2, 1897.

² Brit. Med. Jour., Apr. 17, 1897.

transversalis fascia and the structures behind the muscle. The rectus muscle is allowed to return to its original position; the second layer of sutures approximates the external oblique and the anterior portion of the sheath; the third layer approximates the skin and subcutaneous tissues. In Battle's method the undamaged rectus muscle lies between thoroughly sutured layers which do not accurately correspond, hence the risk of hernia is obviated. The surgeon must be careful not to lose sight of the aponeurosis of the external oblique in suturing. It should always be sutured in order to contribute as much strength as possible. Battle approves of the removal of the appendix after the first attack of appendicitis. Suppurative peritonitis usually takes origin in appendix disease, and early treatment is imperatively necessary. It should be possible to operate some time before vomiting comes on. We should remember, also, that purulent peritonitis is not always associated in its earlier stage with vomiting. [The use of buried silk sutures is liable to lead to trouble in the future. Kangaroo-tendon and chromic gut are better materials. We are not convinced by either McBurney or Battle that muscle is an efficient protection against hernia. The real barriers are the transversalis fascia and the aponeurosis of the external oblique, and the operator who obtains the quickest and soundest union of these structures will be responsible for fewer hernias than other surgeons.]

HERNIA.

Howard A. Lothrop¹ writes upon that obscure condition known as **hernia epigastrica**, and reports 6 cases. These cases are all of interest and worthy of study. In discussing the subject of epigastric hernia he says that we should include under this term all hernie which are found in the area bounded above by the xiphoid cartilage, below by the umbilicus, and on the sides by the cartilages of the ribs. They so commonly appear in the linea alba in comparison with other sites that they have been termed hernia in the linea alba. The term hernia in the linea alba, however, is unfortunate, as it would also include cases of hernia occurring below the umbilicus and not secondary to the laparotomy. The former term is the preferable one. Such cases were first described in 1743 by Garengot. He spoke of such a case as a gastrocele, and thought that the stomach was contained in the sac. Something over 100 years ago Richter, in speaking of these cases, stated that the stomach never is in the sac. Maunoir operated successfully in 1882, but until the article by Terrier in 1886 the operation was regarded as too dangerous to be resorted to. This form of hernia is, of course, very rare. In a series of 16,800 cases of all varieties of hernia examined personally by Berger there were 137 cases of epigastric hernia, some of the cases occurring alone, some in combination with other forms of hernia. It is very exceptional to find these cases in individuals less than 18 years of age, and most of the subjects of such a form of hernia are between 25 and 50. Astley Cooper, however, reported 2 congenital cases, and some few cases have been reported as beginning in early childhood. The vast majority of cases are in males of the working-class. As a rule, the onset is insidious. The patient complains for some time of stomach-symptoms before the hernia appears externally or when the hernia is so small as to escape detection without a careful examination. In not a few cases, however, there has been a traumatism followed by very acute local and general symptoms, and the tumor has appeared within a very few hours.

Roth suggests the following classification for such cases: first, cases due

¹ Boston M. and S. Jour., Feb. 25, 1897.

to embryologic defect, the abdominal parietes failing to close in the median line; second, cases due to congenital or acquired thinness of the abdomen; third, Cloquet's theory, which was elaborated by Witzel. This assumes that a slit is formed in the fascia. Into this opening the subperitoneal fat makes its way, subsequently followed by a pouch of peritoneum, which pouch may eventually become occupied by omentum, intestines, or by both. He reports 4 cases due to trauma. This form of hernia may follow almost immediately upon a trauma or some weeks after it. The following causes are set down as productive of a tear in the fascia: a blow in the epigastric region, a fall upon a sharp projection, an injury from a flying missile, sudden and forcible vertical tension upon the muscles of the abdomen, produced, it may be, by coughing or vomiting or by lifting a heavy weight, or by pulling, especially when the arms are lifted and the trunk is extended. Lothrop discusses fully the anatomy of this region and the pathologic anatomy of these herniæ. In discussing the symptoms, he tells us that these cases can be considered clinically under 3 groups: 1. Those in which there are no symptoms of trouble and the tumor is accidentally discovered; 2. Those which arise insidiously and progress with gradually increasing intensity of symptoms. The symptoms are first referred to the stomach. They are supposed to be due to indigestion, and are made worse by hearty meals and by exercise after eating. Drugs, except morphin, produce no relief. Examination discovers the tumor. The gastric symptoms are probably due to the fact that the omentum pulls on the stomach, the omentum being attached to the hernia. The third group of cases are those in which symptoms follow immediately after the trauma. These cases, as a rule, run a mild course for a great many years, with occasional crises. Adhesions cause the symptoms to become worse. Strangulation is very rare. If the condition is left to run its own course, spontaneous recovery will never take place. Operation, however, is safe and thoroughly curative. Palliative treatment is not to be advised unless there exist some contraindication to operation, such as old age, great prostration, or serious organic disease. The operation is conducted in the same manner as operation for any other hernia. The sac is isolated and opened. If there be a large amount of omentum present, some of it is excised. The contents of the sac are returned to the abdominal cavity and the finger is inserted inside of the ring to see that no adhesions exist at its margin. The sac is excised, the peritoneum is closed with a certain amount of tension, and the abdominal wall is sewed up in layers by buried sutures.

Charles A. Morton¹ records a case of **irreducible hernia**. The patient was a man of 21. When operation was performed it was discovered that irreducibility was due to an omental cyst. Such cysts are extremely rare in any case, but particularly rare in hernial sacs. Mesenteric cysts are occasionally formed by adhesions between the mesenteric folds, fluid which is sometimes chylous collecting in the space thus formed; but this cyst was of another variety. It resembled the peritoneal sanguineous cysts which have been spoken of by Dr. Fisher.

Stephen Paget² writes on the **treatment of cases of strangulated hernia after operation**. He thinks that occasionally the management of these cases is too severe and rigid, and that we often withhold food so long as to actually weaken the patient and interfere with his chances of recovery. Some surgeons have gone so far as to recommend feeding exclusively by the rectum. Under such treatment many cases would die which should recover. There are, of course, two classes of cases of strangulated hernia—what we

¹ Lancet, Dec. 12, 1896.

² Treatment, Mar. 25, 1897.

might call the sthenic and the asthenic, the asthenic type being met with in people who are aged, ill-nourished, broken down by work, chronic disease, or alcoholism, and especially depressed by pain, vomiting, loss of sleep, and fear of death. Nothing but the most absolute necessity can justify us in keeping these asthenic cases without brandy and food. The reasons given for keeping patients after operation on a rigid plan of treatment are that vomiting must be arrested by keeping the stomach absolutely at rest; that vomiting is very dangerous, as we may rupture a damaged intestine; and that by placing food in the stomach we cause involvement of this injured intestine or damage to it by the passage of feces. Paget questions the validity of these reasons. The vomiting stops of itself. If it lasts beyond a few hours after a successful operation, it is probably due to the anæsthetic. When the bowel has been reduced the patient is no more liable to vomit than is a patient on whom any other operation has been done. For the relief of the strangulated hernia small quantities of brandy and milk do not cause vomiting. Therefore, Paget says gives these patients a little brandy just before operation. During the first 12 hours subsequent to operation give small amounts of brandy and water or brandy and iced milk, $\frac{1}{2}$ oz. or 1 oz. every 2 or 3 hours. After the first 12 hours increase the quantity. After the first 24 hours the patient can be allowed to have some tea. Beef-tea is forbidden by some surgeons on the ground that it might cause diarrhœa, but a little beef-jelly or beef-tea so strong that it sets to jelly will not cause diarrhœa and may often be given with advantage. Opium should not be given; bromid and chloral will produce the good effects of opium without its injurious action. Do not give even a simple enema to move the bowels for at least 7 days. Paget has been speaking of the asthenic cases. All the sthenic cases he says are none the worse for the strict treatment. [That these asthenic patients require stimulation is certain, but that they require it by the stomach in the first 24 hours after operation does not seem so clear. We believe it a sound rule to give nothing by the stomach for the first 24 hours of the post-operative period, giving peptonized milk, brandy, etc., by the rectum.]

Leonard Malloy¹ reports 3 cases of strangulated hernia illustrating the importance of a minor point in the **anatomy of femoral hernia**. Each of these cases was complicated by enlargement of a lymph-gland, so that some doubt was cast on the diagnosis and some complication was encountered in operative treatment. The enlarged gland was the one which Quain tells us is constantly placed in the crural ring, and which Gray states occasionally occupies the interval between the femoral vein and the inner wall of the sheath. Erichsen says that this canal occasionally contains 1 or 2 glands, and Treves has pointed out that an enlarged gland over a hernial sac greatly complicates matters. In the first 2 cases reported by Malloy he thinks that the glandular enlargement was due to the irritation set up by the presence of a hernia in the canal.

Frank P. Williams² records a case which he calls masked suppurative peritonitis following violent taxis of strangulated femoral hernia. When the sac was opened it was found to contain the remains of omentum very firmly adherent to it, but no intestine. It was isolated, the internal ring and Poupart's ligament requiring division. A constriction was found at the internal ring. Above the constriction the omentum, being normal, was tied off and amputated, and the stump dropped back. As the sac was about to be ligated before amputation a little pus with a fecal odor was observed coming from the abdominal cavity. Exploration discovered an inverted mass of omentum just

¹ Lancet, Feb. 27, 1897.

² Am. Medico.-Surg. Bull., Oct. 31, 1896.

above the ring, from which mass greenish pus welled up in all directions. The incision was enlarged, irrigation with normal salt solution was employed, gauze drains were inserted, a median abdominal incision was made, and gauze drains were packed into Douglas's pouch and on either side of the uterus. No sutures were inserted. The patient died 78 hours after operation, the autopsy exhibiting nothing but indurated omentum and chronic parenchymatous nephritis. [A few months since, a case of strangulated hernia was brought into the Jefferson Medical College Hospital. Forceful taxis had been applied the previous day, and the serotum was bruised. On operating it was found that the veins of the pampiniform plexus were thrombosed and the perivascular tissue was suppurating. Cultures showed diplococci and colon-bacilli.]

Joseph Ransohoff¹ writes on the **radical cure of umbilical hernia by omphalectomy**, considering in this paper the umbilical hernia of adults only. He considers the various predispositions to recurrence which exist in this form of hernia. In the old operation the remains of the ring were imperfectly approximated, no muscular covering was obtained, interrupted sutures through the whole thickness of the abdominal wall made unequal pressure, and there was a tendency to fat-necrosis and integumentary sloughing. Of late there have been 3 radical improvements made: 1. The umbilical ring is excised; 2. The recti muscles are sutured to each other; 3. The fascia and muscles are sutured by separate layers of buried sutures. Ransohoff then reports three successful cases operated on within two years, a period which he deems is not sufficiently long to justify a positive faith in permanent cure; nevertheless the cure in each case is probably permanent because umbilical hernia when it is going to recur usually does so within a few months of operation. Ransohoff employs a pure metallic suture and thinks it a great aid in permanent cure.

Duplay and Cazin² believe that **buried sutures** often cause trouble; that they form points of least resistance and occasionally lead to abscess-formation. They have devised an operation by which they can avoid the use of buried sutures. The sac is drawn well down and tied upon itself, and this knot is kept from slipping by tying a series of knots in the sac or by dividing the sac and tying the two portions together. The external ring and the roof of the canal are sutured by silver wire, which is removed when union has taken place. They report 20 operations, with the most gratifying results.

W. B. Platt³ writes on the **radical cure of hernia** by implanting a section of sterilized sponge. The patient is kept in bed for 3 weeks. Platt reports 4 cases operated upon by this method.

W. B. De Garmo⁴ records **250 Bassini operations** for the cure of inguinal hernia without mortality. These operations were done upon 216 patients, 34 having been operated upon on both sides. Fifty-two of the cases were females and 164 were males. The ages of the patients varied from 5 months to over 80 years. Fifty-five of the operations were on patients under 14, 16 of them were on patients over 60, and 2 were on patients over 80. The cases operated upon in the extremes of life were instances of irreducible or strangulated hernia. Ninety-three of the cases had scrotal hernia, 55 had irreducible hernia, and 16 strangulated hernia. In 55 of the cases it was found necessary to excise some omentum, and this was done by the use of multiple silk ligatures. The largest hernia was 2 ft. in circumference, in a man 53 years of age. The tumor contained omentum, large and small bowel, and a distended bladder. This man stated that

¹ Med. Rec., Jan. 30, 1897.

² Sem. méd., Nov. 11, 1896.

³ Bull. Johns Hopkins Hosp., Mar., 1897.

⁴ Va. Med. Semi-Monthly, June 25, 1897.

in urinating he was obliged to press the tumor against the thigh with his hands, but it was only after operation that the exact condition was recognized. Twenty-four hours after operation it was found that he was passing very little urine and the catheter could not be inserted. The next day the bladder was opened through the perineum and free drainage established. There were found in the canal, besides the hernial sac and its contents, the ovary in 3 cases, the testicle in 9, and enlarged veins in a considerable number of cases. It was common to meet with masses of extraperitoneal fat larger than the thumb, in 1 case as large as a good-sized hen's egg. In a number of cases cysts were found which were usually connected with the cord. The time required for the complete healing and discharge of the patient was 14 days in 114 cases; 84 others left the hospital the 21st day. Primary union was obtained in 207 cases. In suppurating cases the infection was invariably immediately beneath the skin, not in the deeper tissue. In 1 case infection was due to a gonorrhoeal discharge which was not known to exist at the time of operation. Patients whose skin has been abraded by truss-wearing are apt to have suppuration. In only 1 case in which suppuration occurred has recurrence taken place. Double operations were all done at the same time; also some cases of inguinal and umbilical hernia. One man of 52 was operated on the same day for double inguinal and right femoral hernia. In his earlier cases De Garmo used silkworm-gut for suture of the deeper parts, allowing it to remain in. He used it in 12 cases, and in 4 of these much difficulty was experienced later by the sutures coming out. In 8 cases there was no irritation due to the sutures. In 1 case the sutures came out nearly a year after the operation. He therefore abandoned this material and adopted kangaroo-tendon. Kangaroo-tendon gives him perfect satisfaction. The author stated in 1895 that the Bassini operation cured at least 90% of patients. He is now convinced that it will cure at least 95%. Of the 6 recurrences, 3 have been reoperated upon and apparently cured, leaving only 3 lasting recurrences. [De Garmo's paper proves to demonstration that the modern operation for the radical cure of hernia is safe and successful. The fact that suppuration in the operation-wound is apt to arise if the patient has gonorrhoea has been encountered in our experience. Before operating on a male for the radical cure of a nonstrangulated hernia it is well to determine if a urethral discharge exists; and if it does exist, operation should be postponed until the urethral disorder is cured. The same trouble De Garmo met with after using silkworm-gut sutures we have seen several times. Kangaroo-tendon, if well prepared, is undoubtedly the best suture-material for hernia operations.]

J. Coplin Stinson¹ writes on the **radical cure of femoral hernia** and the preferable operation. The following operation he considers fulfils the necessary conditions to bring about a cure and obviates the faults of other methods. He makes an incision which begins $\frac{1}{2}$ in. below the spine of the pubis and which is carried upward and outward for about 3 in. parallel with Poupart's ligament. This incision lays bare the sac and the saphenous opening. The superficial fascia is dissected up in order to expose thoroughly Poupart's ligament to the spine of the pubis. The canal and femoral ring are exposed definitely by dissecting up with a blunt dissector the iliac and pubic portions of the fascia lata around the saphenous opening. The sac is free from adhesions to surrounding structures. It is then incised and any internal adhesions are loosened up. If the sac contains omentum, this omentum is removed after ligating the vessels, fixation-ligatures being employed. The neck of the sac is grasped with forceps and pulled down, and the sac with its neck and

¹ Med. Rec., Dec. 5, 1896.

with some of the peritoneum around the neck must be removed, the margins of the cut peritoneum being united by catgut sutures. Fat and glands are then removed from the saphenous opening in the femoral canal. The surgeon retracts the fascia lata, Poupart's ligament, and the deep crural arch, and thus exposes the femoral ring; if it is found that any fat or glands pass into the ring from the subperitoneal connective tissue, such fat or glands are removed. The femoral sheath is grasped with forceps and lifted up, and the inner opening is closed by suturing together the anterior and posterior layers of the sheath, the first stitch being inserted near to the external margin of Gimbernat's ligament, including some of the fibers of this ligament. Several stitches are inserted going toward the femoral vein, the last one being near the septum which separates the ring from the vein, but not close enough to constrict the vein. Poupart's ligament and the deep crural arch are next sutured to the adjacent portions of the fascia lata which covers the pectineus muscle, and to the reflections of the fascia lata which passes behind the femoral sheath, each stitch extending to but not including any muscular fibers of the pectineus. The sutures are passed so as to approach the femoral vein, but near enough to the vein to constrict it. The saphenous opening is closed, the first stitch being inserted close to Poupart's ligament, the needle passing through the pubic portion of the fascia lata on the inner aspect of the saphenous opening and then on the iliac portion of the fascia on the outer side. Suture from above downward, leaving only sufficient room at the lower angle for the full saphenous vein. The skin is closed with catgut or fine silk without drainage. This surgeon prefers a chromicized tendon for the deeper sutures.

Kocher¹ writes on the **radical cure of hernia**. He acknowledges that Bassini's method is useful in certain cases, but he thinks that in subjects who are not in condition to stand a prolonged operation some other method is preferable. Kocher maintains that his own method is safe, even when performed on old subjects, and that whereas suppuration will destroy the result of a Bassini operation, it will not destroy the result of his operation. He discusses 126 cases of inguinal hernia treated by this method. Each one of these cases recovered from the operation. There were 4 relapses. Most of the patients were over 40 years of age. Kocher has modified his operation somewhat from what he originally suggested. He found there was a certain amount of risk of the isolated sac sloughing on account of compression, and he now cuts away the sac. He believes in removing considerable of the protruding peritoneum, and to effect this makes an opening into the peritoneal cavity directly and draws the sac out of this opening, the sac being invaginated so that its serous surface is exposed throughout its whole length. After the sac is removed the peritoneal surface and the other layers of the abdominal wall are sutured.

William B. Coley² presents an elaborate article on the **radical cure of hernia**, with a report of 360 cases. He tells us that as late as 1890 Billroth's statistics show a mortality of 6%, with relapses in 32% of cases. Dr. Bull, writing in 1890, reported 3 deaths in 134 cases and 38% of relapses, and came to the conclusion that there is not any prospect of radically curing any form of hernia, most cases relapsing if allowed sufficient time. Sir William MacCormac, in 1893, estimated that the mortality in operations for the radical cure of non-strangulated hernia was 6%. Because of such figures many conservative medical men have been opposed to operations for the radical cure of hernia. That incredulity has given way to a feeling of confidence in the ope-

¹ Centralbl. f. Chir., No. 19, 1897.

² Ann. of Surg., Mar., 1897.

ration has been chiefly due to Bassini, of Padua, whose operation has been very generally accepted as the best yet put forth.

Bassini began operating by this method in 1886, and in 1890 published 251 cases, with 1 death and 7 relapses. Robert F. Weir, of New York, was one of the first surgeons in this country to take up Bassini's operation. Bassini's operation is not one of those procedures which give brilliant results only when performed by the inventor. Coley has operated for the radical cure of hernia on 360 cases, with 1 death, a mortality of 0.28%. This death was due to double pneumonia caused by ether; 326 operations were for inguinal hernia, 25 for femoral hernia, 6 for umbilical hernia, and 3 for ventral hernia. In inguinal hernia 300 cases were sutured with the kangaroo-tendon by Bassini's method, with 2 relapses, 1 with silk suture with 1 relapse; 24 cases of inguinal hernia were treated by sutures of the canal without transplantation of the cord, with 3 relapses. There were 25 cases of femoral hernia without a death and with no relapse; 15 with high ligation of the sac, with purse-string suture of the canal, and 10 with Bassini's method for femoral hernia; 55 operations for inguinal hernia in the female, with no mortality and no relapse. Umbilical and ventral hernia were operated on 9 times, with 4 relapses.

Coley then appends a table of his cases, and it is seen that the total number of Bassini operations is 300, with 1 death and 3 relapses, 280 of these cases having been carefully traced. In 97% of the cases there was primary union of the wound. The youngest case free from strangulation was 19 months of age, though he operated on 3 cases for strangulation which were all under one year of age. Only 8 cases of nonstrangulated hernia were operated on under four years of age. The oldest patient was 70, the operation being performed for an irreducible omental hernia. Some surgeons have opposed operation for hernia in children, because they think that most cases can be cured by means of trusses, and because they believe the operation in the child is less certain in its results and more dangerous than in the adult. Both of these positions are untrue. In collecting the cases of adult hernia observed in the Hospital for Ruptured and Crippled during the past four years that gave a history of hernia in early life, Coley has already found about 400 such cases. This disproves the idea that all herniae can be cured by trusses. The operation in children is no more dangerous than in adults. Adding together Broca's, Felizet's, and his own cases, we have 832 cases with 4 deaths, a mortality of less than $\frac{1}{2}$ of 1%. In fact, the period of childhood and youth is an especially successful period in which to do an operation for the radical cure of hernia. We should not lose sight of the fact that this same period is the most favorable for nature to effect a cure either unaided or aided by a truss. Out of 7000 ruptured children Coley selected 250 to operate on. He does not think that we should operate in children until a truss has been tried for a year or two without benefit. There is an exception to this rule; in femoral hernia operation should be advised at once, for there is almost no chance that a truss will cure. Irreducible hernia, or adherent omentum and hydrocele, suggests the necessity for early operation. In cases where the gut cannot be successfully retained because of lack of care it is generally wise to operate. In the adult operations may be advised in most cases of inguinal and femoral hernia up to the age of 50, unless there be contraindications. Coley advises us not to operate on very large irreducible hernia, especially in stout people. If there are numerous adhesions, it is necessary to remove great masses of omentum, and the operation is thus rendered a formidable procedure; very few of these cases are permanently cured. Inguinal hernia in

women yields admirable results when operated on by the Bassini method. The round ligaments should be dissected from the sac and the canal sutured in three layers with kangaroo-tendon. The operation is just the same in the female as in the male, excepting the transplantation of the cord. The round ligament is permitted to drop back beneath the lowermost layer of sutures. In femoral hernia the results are admirable. Six of Coley's cases of femoral hernia were under 10 years of age.

The method of Bassini for the treatment of femoral hernia consists in suture of the canal by two rows of interrupted sutures. He thinks the old method of simply ligating the sac and making no attempt to close the femoral canal should be abandoned.

In discussing rare forms of hernia, cecal and appendical, he states that in 14 cases the cecum and appendix, one or both, were found in the hernial sac. In 6 the appendix alone was found; in but 3 of these was the appendix removed. Three of these cases were of that very rare variety which he has called inguinoperineal. The hernia in these cases is reduced through the inguinal canal, but it passes alongside and beneath the scrotum until it occupies the perineal region. In every case the testis was found in the perineum, at the bottom of the sac; and the maldevelopment of the testis is undoubtedly responsible for this hernia. In one case it was necessary to remove the testicle; in another this gland was dissected loose and transplanted into the scrotum.

Coley next explains the technic of Bassini's operation, and advises the use of kangaroo-tendon sutures. Sutures should be placed above the cord, the cord passing between the two upper sutures. Many surgeons get an imperfect result in Bassini's operation because they fail to dissect back the aponeurosis of the external oblique sufficiently, especially on the inner side. Coley always uses interrupted sutures for the deeper layer, and unites the aponeurosis with a continuous suture of kangaroo-tendon. The skin is closed with fine catgut. The wound is dressed at the end of a week or ten days after operation. The dressing consists of iodoform-gauze and moist bichlorid gauze. In children the dressing is reinforced by a plaster-of-Paris spica extending from the ribs to the knee. Patients who have been operated on by Bassini's method should be kept in bed for 2 to 2½ weeks, and be permitted to leave the hospital at the end of 2½ to 3 weeks. In but two or three instances has a truss been advised after operation, most patients having been sent out without a support of any kind. Coley believes Bassini's method from a practical and a theoretical standpoint is superior to all other methods. He opposes Packard's contention that the hernial sac does not occupy the inguinal canal at all, but in the large majority of cases of oblique inguinal hernia is really ventral, only making its way out at the external ring, and therefore seeming to pass through the canal. Coley believes that the hernial sac does bear intimate relations to the cord. He has studied the relation of the sac to the cord in 271 cases of inguinal hernia, and in 269 of these cases the sac has been found in intimate contact with the cord. This was true in acquired hernia and in congenital hernia in adults and children. If we dissect with care, we will find the infundibuliform process enclosing both the sac and the cord, the cord itself resting in absolute contact with the sac. The two cases in which this condition did not obtain were both direct hernia, a form of hernia which is much rarer than is generally supposed. In these cases the cord was anterior to the sac and outside of the layer of fascia referred to. A careful study of the evidence will convince us that the cord plays a most important part in the induction of oblique inguinal hernia, and that the operations of Bassini and Halsted have

a rational foundation. Coley then gives a detailed report of his cases. [Coley's study and De Garmo's paper constitute an absolute answer to those who do not believe in the radical operation. Such a low mortality speaks for itself. A very important portion of the article is that dealing with the operation in the case of young children. The general impression has been that young children are unfavorable subjects. Coley shows that they are very favorable subjects. He is, however, judicious and conservative. He believes that most cases of inguinal hernia in children are capable of cure by a truss, and out of 7000 cases he selected but 250 for operation. We consider that Coley disproves Packard's hypothesis that in most instances the so-called inguinal hernia is really ventral.]

DISEASES OF THE LIVER, GALL-BLADDER, PANCREAS, AND SPLEEN.

Christopher Martin¹ reports a case of **rupture of the liver** successfully treated by abdominal section. The symptoms were those of intraperitoneal hemorrhage and peritonitis. The diagnosis of rupture of the liver was made and operation was performed 30 hours after the accident. The abdomen was opened in the middle line; an immense quantity of black blood escaped, and the liver was found to be ruptured. There was a tear between 1 and 2 inches deep on the under surface of the right lobe over the parietal fissure. The signs of peritonitis were obvious. The abdomen was cleared of blood by irrigation with hot water and during irrigation a fragment of liver-substance floated up. The question of how to deal with the rent was somewhat difficult. If it had been on the anterior border or upper surface of the liver, it could have been sutured with catgut or plugged with iodoform-gauze; but as it was on the posterior surface and extended backward and upward suturing and gauze-plugging were both out of the question. The operator determined to rely on the hemostatic effect of irrigation with hot water, removal of all the effused blood from the peritoneal cavity, and maintenance of drainage. The abdomen was thoroughly washed out and sponged. An incision was made above the pubes and a tube was inserted. A glass drainage-tube was inserted through the epigastric incision and carried down to the rent in the liver. The abdominal wounds were sewed up with silkworm-gut. For a number of hours after the operation there was a profuse bloody discharge from the lower drainage-tube and almost nothing from the upper tube. This patient recovered.

Martin says that the chief causes of death after a rupture of the liver are shock, hemorrhage, and peritonitis. The injury is excessively fatal, but not absolutely mortal. There have been some reported instances in which the signs and symptoms all pointed to rupture of the liver, but the patient recovered. There have been four reported cases where the patient survived the accident many days and died from other causes, in each case a postmortem examination showing that the liver had been ruptured and that spontaneous cure was taking place. It seems probable, however, that 99% of such cases die rapidly unless operation is performed. The operation done on this case saved life because of the free irrigation of the peritoneal cavity with hot water and the thorough drainage. The irrigation arrested the bleeding from the tear in the liver and removed a great quantity of blood and lymph from the peritoneal cavity. The drainage-tube is itself a valuable hemostatic. When the blood is drained away as soon as it is poured out the natural arrest of hemorrhage is promoted. The progress of peritonitis is checked by the removal of

¹ Birmingham Med. Rev., May, 1897.

the blood, lymph, and bile. The drainage obtained by making the suprapubic opening is a matter of the first importance.

Terrier and Auvray¹ write upon traumatism of the liver and bile-ducts, and consider 46 cases which are found in literature, of which number 33 recovered and 13 died. The cases which recovered were those operated upon before there had been a great amount of hemorrhage and before marked peritonitis had developed. These surgeons maintain that exploratory laparotomy should be performed as quickly as possible when there is a traumatic injury of the liver. The nature of the lesion is thus definitely recognized and the surgeon is enabled to stop hemorrhage, for the effusion of blood not only produces exhaustion but is liable to infect the peritoneum. When the hemorrhage is arrested or if it has already ceased the wound in the liver is sutured.

Vanverts² presents a paper upon the treatment of rupture of the liver. He tells us that after any serious injury of the abdomen the patient passes through a condition of collapse, through a stage when the diagnosis must be uncertain, through a stage when the signs of hemorrhage become apparent, and through a stage of slowly rising complications. The stage of collapse is usually pronounced, but in some cases it is absent. It is treated as any other collapse. During the stage when the diagnosis is uncertain hemorrhage is to be feared and the patient must be kept perfectly quiet and recumbent. An ice-bag is placed over the liver and the patient is watched attentively to determine the first sign of hemorrhage or of peritonitis. The beginning of either hemorrhage or peritonitis calls for immediate laparotomy. The incision should be in the middle line and should be long enough to permit the surgeon to see the liver. The organ must be carefully felt with the finger, especially the upper surface and posterior surface. There are several recognized methods of treating a rupture. We may employ the cautery, we may plug the wound, we may suture it. The best results are obtained by plugging with gauze, one end of the gauze emerging from the abdominal wound. The plug of gauze should be retained at least 48 hours, but should not be left later than the fourth day. If it is removed earlier than 48 hours, hemorrhage may occur. If it is left later than the fourth day, a biliary fistula may result. If it is seen that a large vessel has been lacerated, a ligature should be applied. When there is a laceration extending deeply into the liver-structure the edges of the wound in the liver should be brought together by sutures. When peritonitis begins there is very little chance of saving life, and the only chance is by laparotomy and drainage.

Orville Horwitz³ publishes a case of rupture of the liver. Five weeks before admission to the hospital this man had a fall in which he struck his right side, and testicle. He had been confined to bed for two weeks and had gone about again. Some few days before his admission into hospital a swelling appeared below the margin of the ribs on the right side which was attended with pain. It was soft and the seat of a pseudofluctuation; aspiration brought away $1\frac{1}{2}$ pints of blood. Horwitz found that the abdomen was greatly distended and tender; the swelling was the size of an infant's head at birth. There was a slight diarrhoea, the stools being chalky. The left testicle was enormously swollen and there had been an effusion of serum into the tunica vaginalis testis. The temperature was 97° , the pulse 158, and there was some jaundice. An incision was made into the swelling, a large partially organized blood-clot was turned out, and a tear $3\frac{1}{2}$ in. long and $2\frac{1}{2}$ in. width was found in the right lobe of the liver. Adhesion had taken place between the peritoneum

¹ Rev. de Chir., Oct. 10, 1896.

² Arch. gén. de Méd., Jan., 1897.

³ Therap. Gaz., July 15, 1896.

and the liver, limiting a large sac, which contained the blood-clot, and this sac was connected with the peritoneal cavity by an opening $1\frac{1}{2}$ in. in diameter, through which protruded a piece of congested omentum. The abdominal cavity was full of bloody serum. An incision for drainage was made in the left iliac fossa. The cavity was irrigated with saline fluid, a drainage-tube was inserted into the iliac incision, and the wound in the liver was packed with iodoform-gauze. The patient died the next day and no postmortem was permitted. The author states that as far as he has discovered death has invariably resulted from rupture of the liver-substance. [The view that a rupture of the liver is of necessity a fatal accident has gone down before the surgical achievements of recent years. In 1887 Edler published statistics of traumatic injuries of the liver. This table contained 543 cases, the mortality-rate being about 67%. Incised wounds show a mortality of 64.6%, gunshot-wounds of 55%, and ruptures of 85.7% (Schlatter, in *Beiträge zur klinischen Chirurgie*, Band xv., Heft ii., 1096). The *Annals of Surgery* for April, 1897, reviews Schlatter's work, and herein valuable facts will be found in concise form. Many recoveries have followed direct suture of wounds in the liver.]

F. Winson Ramsay¹ records a case of Glenard's disease in which he practised **fixation of the liver and of both kidneys**. The woman was 39 years of age. She had a tumor in the left hypogastric region, which was found to be a floating left kidney. It was operated on by Vulliet's method—that is, stitched in place by means of the split tendonous structure of the longissimus dorsi muscle. The operation did a great deal of good. In about 6 months a tumor appeared on the right side, which was found to be the right kidney, which organ was anchored by the same method. On sitting up nausea and vomiting returned, and it was discovered that the right lobe of the liver occupied the middle of the abdomen below the umbilicus. The abdomen was opened in the middle line, the left kidney was felt for and was found to be firmly anchored. The right kidney was well fixed, having only slight lateral mobility. The liver moved with great freedom, the suspensory ligament being much elongated. The upper surface of the liver was rubbed with aseptic gauze to promote adhesion. The round ligament was transfixed close to the liver; a silk ligature was passed through it and around it and tied. One end was passed from above downward around the costal cartilage of the 7th rib. The liver was firmly pressed into place and the 2 ends of the ligature were tied. The liver was thus fixed by means of the round ligament and the thoracic wall. As the extreme right lobe of the liver seemed to be mobile, a double suture of kangaroo-tendon was passed through the liver 2 in. from its right border and through the adjacent parietes; when this ligature was tied the liver was fixed in excellent position. The other organs of the abdomen were examined: the spleen was found in normal position; there was not any lengthening of the mesentery or the mesocolon. The right ovary being cystic it was removed. This patient recovered, with complete relief of all the symptoms.

Tuffier² presents a paper upon **neoplasms of the liver** in which he discusses the diagnosis and treatment. He says that it is often impossible to make a diagnosis unless exploratory celiotomy is performed, and in some cases even when exploratory incision has been made we cannot form a diagnosis without puncturing the tumor, and puncture is a dangerous procedure and has proved fatal from hemorrhage in not a few cases. It is always wise to feel the hilum of the liver to determine if enlarged glands exist. Such glands indicate secondary deposit from a malignant growth, and whenever they

¹ Brit. Med. Jour., May 8, 1897.

² Gaz. hebdom. de Méd. et de Chir., Jan. 28, 1897.

are found it is unnecessary to make a puncture. Because we do not find them, however, does not prove that a malignant growth is absent. There might be a secondary malignant growth, in which case the glands would not be enlarged, because metastasis would be by way of the venous channels and not by the lymphatic vessels, but a primary cancer of the liver invariably causes enlargement of the glands in the hilum. The question of how to arrest hemorrhage is of vast importance in operating upon the liver. We frequently find the dilated veins surrounded by tissue that crumbles away at a touch, and in such cases the temporary arrest of hemorrhage by compression of the pedicle of the liver by means of the fingers is a valuable procedure. He showed by experiments on animals that he could thus arrest a very severe hemorrhage, and he finds by studies upon the dead body that such pressure can be easily made without producing any damage in the human being. Of course, its exact value can only be determined by clinical experience. He advises that the left index finger be passed through the foramen of Winslow and the structures of the pedicle be compressed with the thumb.

David Drummond and Rutherford Morison¹ report a case of **ascites due to cirrhosis of the liver** cured by operation. The idea of the operation is to remove portal obstruction. Drummond made a series of postmortem studies on cases of cirrhosis of the liver, and in many cases where ascites were absent demonstrated that vascular adhesions existed connecting the parietes to the liver. In one case the cirrhosis had existed for almost 20 years, and yet death resulted from some other cause. In many of these cases free communication was found to exist between the portal and systemic veins. Such a communication seemed to explain the absence of ascites. It seems probable that an enlargement of the channels which normally exist between the portal and systemic circulations is sufficient in some cases to prevent the development of ascites in cirrhosis of the liver, but in most cases an accessory circulation is required. The above facts would lead us to infer that the establishment of a new accessory circulation ought to cure ascites due to liver cirrhosis. Two cases of ascites have been operated on. In the first case the clinical diagnosis was not verified at the operation or by a postmortem examination, and doubts remain as to whether the ascites was really due to liver cirrhosis. The operation in this instance failed to cure. In the second case there was not the slightest doubt of the diagnosis, for the liver was the typical hobnailed liver. In this case the operation proved a brilliant success, and the dying patient was restored to apparently perfect health. The abdomen was opened below the umbilicus; the ascitic fluid was emptied out; the liver was inspected and found to be cirrhotic. The abdomen was dried with sponges and the parietal peritoneum was scrubbed with sponges. The peritoneum covering the liver and the spleen and the portions of the parietal peritoneum opposed to them were specially scrubbed. The omentum was sutured across the anterior abdominal wall. A glass tube was left in Douglas's cul de sac and the abdominal wound was closed by silk sutures. In order to retain the parietal peritoneum in contact with the visceral peritoneum straps were passed circularly over the epigastrium down to the drainage-tube in the hypogastrium. This patient made an absolute recovery.

James F. Gemmel² reports a case of hepatic abscess in which he practised aspiration and in which recovery ensued. The diagnosis was rendered certain by introducing a small exploring-needle. About a week after this the swelling was aspirated by means of Allen's surgical pump, about 30 oz. of fluid being withdrawn. The action of the pump was reversed, the cavity was filled with

¹ Brit. Med. Jour., Sept. 19, 1896.

² Lancet, Dec. 19, 1896.

Condy's fluid and was emptied again, and this process was repeated over and over until the fluid ran out clear. The swelling gradually reappeared after this aspiration and then suddenly passed away, the disappearance being followed by a profuse evacuation of pus per anus. [We utterly disbelieve in the treatment of abscess of the liver by aspiration, because pus may get into the peritoneal cavity; because much more damage may be done by a blind puncture than by an open incision; and because aspiration usually fails to cure. Jacobson has pointed out that puncture is useless when multiple abscesses exist.]

John O'Connor¹ publishes a clinical contribution to the **surgery of the liver**. He reports a case of liver-abscess cured by hepatotomy. An incision was made over the swelling; the peritoneum was opened; and the liver was adherent to the parietes; and a director was carried into the liver, where an abscess was found at a depth of a $\frac{1}{4}$ in. The opening was enlarged by means of forceps, pus was evacuated, a drainage-tube inserted, and the cavity irrigated with Condy's fluid. The patient recovered. In case II. there were abscess of the liver and empyema. The needle of the aspirator was carried into the right pleural cavity and a little pus was removed. An anesthetic was given, a portion of the 6th rib excised near the axillary line, and a great quantity of very foul pus evacuated from the pleural sac. There was found to be a dense and fluctuating swelling pushing up the diaphragm, but there was no opening leading into the pleura. The pleura of the diaphragm and the diaphragm itself were incised. The liver was found to be adherent. A trocar was inserted and 6 pints of pus removed. A drainage-tube was carried into the abscess-cavity and no sutures were introduced into the wound on the chest-wall. This patient improved greatly and got almost well, but later symptoms of septicemia returned and the patient died about 10 weeks after operation. Postmortem examination showed that there was a sinus lined with healthy granulations passing from the upper border to the center of the liver. This was all that remained of the great abscess-cavity. Three inches internal to this sinus a small abscess was found which was superficial in the upper hepatic border, and from this a small sinus passed through the diaphragm into the anterior mediastinum, in which region pus was found, and this mediastinal focus joined the right pleural cavity by a small opening. This case is very instructive, as it shows the fact that even when we have succeeded in reaching a large hepatic abscess a more deadly satellite-abscess may be in existence. Another fact which this case shows is that the aspirating-needle is an unreliable means of looking for small abscesses. The 3d case is one in which abscess of the liver was treated by transthoracic hepatotomy. This patient recovered. It was thought for some little time that the man labored under typhoid fever, and then tuberculosis was suspected; finally, it was determined to explore the liver. There was a tender spot over the liver, and in this region a long hypodermic needle was inserted. Pus was thus discovered. The needle was left in place and a bistoury was carried into the abscess along the needle as a guide. The needle was withdrawn and a pair of forceps was pushed along the blade of the knife; the knife was withdrawn and the blades of the forceps were opened and thus the incision was dilated. A drainage-tube was introduced. This patient recovered. It may be thought that this was a rash manner of opening the abscess, but the patient's condition was so desperate that an anesthetic would probably have proved fatal. He then reports a case of liver-abscess in which hepatotomy was followed by recovery, and another case of liver-abscess in which transthoracic hepatotomy was followed by recovery.

¹ Ann. of Surg., May, 1897.

A. D. Bevan¹ recommends a **new incision in the surgery of the bile-ducts**. He has tried all of the usual incisions and thinks there are objections to each one. These usual incisions do not afford sufficient room for extensive work unless they are made very long, and if they are made very long hernia is apt to ensue. It is impossible for the surgeon to tell before he opens the abdomen for the performance of an operation upon the bile-ducts how extensive an operation may be necessary, and he should make an incision which will be equally suitable for the exploration and simple operation or an operation of great magnitude. Bevan divides his incision into a primary incision and an extended process. The primary incision is used for exploratory purposes or cholecystotomy. It is the shape of an italic letter *f*, along and even through the outer edge of the rectus muscle shown in the heavy line in Fig. 23. The extended parts of the incision are added if required. These

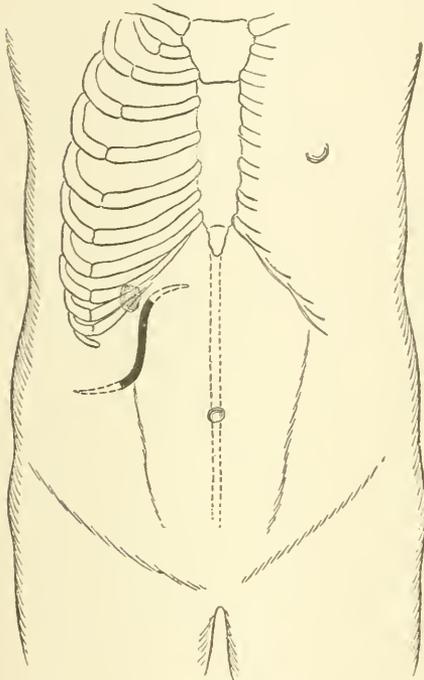

FIG. 23.—A new incision in surgery of the bile-ducts: the heavy line indicates the primary incision; and the light lines, the extended portions of the incision (A. D. Bevan, in Jour. Am. Med. Assoc., June 26, 1897).

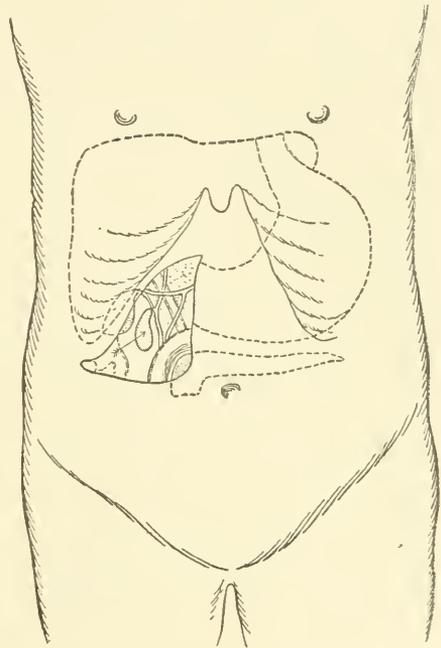

FIG. 24.—The abdomen opened and the anterior layer of the lesser omentum removed. The gall-bladder, cystic, hepatic, and common ducts, portal vein, and hepatic artery and branches are in view. Arrow is in the foramen of Winslow (A. D. Bevan, in Jour. Am. Med. Assoc., June 26, 1897).

extended parts are shown in the faint lines in Fig. 23. The extended portions may be an inch in length or 3 in. in length. This incision gives very free access to the gall-bladder and bile-ducts. The edges can be retracted broadly without tension. A very small amount of the abdominal nerve-supply is injured by the incision, even though it is made of considerable length, because the extended parts are practically parallel with the nerve-supply of the abdominal muscles. Partial division of the rectus and of the obliques and transversalis enables us to separate the incision very widely without tension. It is very improbable that a hernia will result, because the incision is close to the costal

¹ Jour. Am. Med. Assoc., June 26, 1897.

arch. Furthermore, it is well known that a cicatrix in the upper part of the abdomen is not likely to yield and produce a hernia. The structures exposed by this incision are seen in Fig. 24. Bevan closes the incision by passing silkworm-gut through the entire abdominal wall and then sutures the abdominal muscles and aponeurosis with buried catgut and ties the silkworm-gut sutures.

Carl Beck¹ debates the question, **When shall we operate for cholelithiasis?**—and reports some interesting cases to illustrate his views. His opinions may be summed up as follows: cholecystotomy should be performed as soon as the diagnosis of acute cholecystitis is made, and the same operation should be performed in chronic hydrops of the gall-bladder. It should be performed when acute attacks of biliary colic associated with fever return for a second or third time. It should be performed when jaundice is present for more than 4 weeks. It should be performed in gall-stone ileus. In all obscure cases where signs resembling peritonitis are found in the neighborhood of the gall-bladder exploratory laparotomy should be performed. Beck is a warm advocate of the operation of cholecystotomy, because it does not matter how thoroughly the gall-bladder is exposed small stones are very apt to be retained, and such stones will be discovered only if the opening is left in the gall-bladder for a reasonable time. In the so-called ideal cholecystotomy the gall-bladder is sewed up, and these small stones will not be discovered and will remain.

F. Lange² considers the **surgical significance of gall-stones.** He tells us that when retained in the gall-bladder symptoms are very rarely present, but that the symptoms are met with when the stone begins to pass through a cystic duct or the common duct. A large solitary stone may become impacted in a cystic duct, but impaction may be produced by many small stones. If the gall-stone is impacted in the common duct, the symptoms of damming up of the bile are certain to appear, and not unusually inflammation of the gall-bladder or abscess of the liver follows such a condition. It is not uncommon for a large stone to be arrested at the duodenal orifice, and when the stone is arrested in this situation it may form a fistula into the duodenum. The gall-stone may find its way through the wall of the abdomen or into some viscus from any part of the gall system. There is a very serious complication that is liable to be met with in patients with jaundice, and that is a strong tendency to hemorrhage during operations. In operating Lange is a believer in incision parallel to the rib-borders. Small size of the liver constitutes a barrier to the easy performance of the operation, because this organ when it atrophies sinks high up back of the ribs. When the liver is found in this position it is advisable to excise several of the costal cartilages. A very large liver, especially in fat individuals, is a complication. It is better to drain the gall-bladder by means of a long tube, so as to have the benefit of siphonage, and we should remember the liability of this tube to block up with fragments of blood-clot or agglutinated mucus. Irritant solutions should never be injected into the gall-bladder, for they inevitably cause colic, and if they reach the common duct or the hepatic duct will set up inflammation. Normal salt solution or boiled water is the only material proper to inject. Before opening the gall-bladder aspirate away as much of the bile as possible, having first surrounded the gall-bladder with gauze.

F. Lange, in another article,³ considers the indications for surgical operations on the common bile-duct in cases of gall-stone disease. He tells us that in quite a number of cases in which gall-stones pass the common duct there is

¹ N. Y. Med. Jour., May 8, 1897.

² Bull., Johns Hopkins Hosp., Feb., 1897.

³ Med. News, May 1, 1897.

not distinct jaundice, and it is very rare that a stone in the common duct produces prolonged and complete obstruction to the flow of bile. Usually more or less bile passes through, and in other cases the stone acts as a ball-valve, as has been shown by Feuger, and allows of a free flow of bile from time to time. The mechanical lesion alone of stone in the common duct is, as a rule, very well tolerated. The degree of obstruction determines whether the stagnating bile will produce sufficient trouble to demand operation. It is quite true that the long persistence of jaundice diminishes the safety of operation because of the great tendency to hemorrhage; therefore it is wise in cases which require surgical aid to operate before there is persistent jaundice. The group of cases to be noted are those in which complications arise; complications due to the infectious process, as when we have cholecystitis and cholangitis or ulceration from impaction. It is not unusual for cases to recover in which ulceration occurs by the stone passing into a viscus; such cases admit of expectant treatment. Suppose that there is a history of a large stone having been passed by the rectum. If attacks of colic are repeated, we may assume the probability that a stone will again pass spontaneously. If the symptoms of absolute obstruction or septic infection become marked, an operation is absolutely demanded. When infection is manifest by acute fever it means acute cholangitis, and surgical operation must be performed. We should first perform cholecystotomy, and the condition of the patient at the time of operation determines whether we shall attack the common duct at that time or not. The majority of cases are chronic or subacute, and may result in dilatation of the duct, atrophy of the glandular structure of the liver, cholangitis, pericholangitis, and abscess of the liver. In view of the danger of these complications the only rational treatment is to perform an operation which relieves the obstruction and promotes a free flow of the bile which is being secreted. [Operations for gall-stone performed early—that is, before the concretion has gotten into the common duct—show almost no mortality. Kehr, of Halberstadt, estimates the mortality of cholecystotomy at about 6%, and of cholecystectomy at 6%. The same surgeon has reported 127 operations upon the gall-bladder, with 1 death, a remarkable and encouraging showing.]

A. W. Mayo Robson's Hunterian Lectures¹ contain a masterly exposition of the **diseases of the gall-bladder and the bile-ducts**, and are certain to be considered in the future as a most authoritative discussion of the entire subject. After considering congenital malformations, catarrh of the gall-bladder and bile-ducts, and catarrhal cholecystitis Robson takes up suppurative inflammation of the bile-passages, simple empyema, acute cholecystitis, and gangrene of the gall-bladder. In speaking of the treatment of infective and suppurative cholangitis he states that it is useless to apply treatment unless we puncture and drain the infected contents of the bile-passages. Therefore, cholecystotomy must be carried out and drainage must be continued until the bile is sterile or nearly sterile. If the pus is found localized in the liver, the area must be incised and drained. General means of treatment include the following: laxatives, intestinal antiseptics, sedatives for the pain, and the treatment of symptoms as they arise. The first credit of operating for this condition belongs to Terrier.

Robson then presents the subjects of **stricture, ulceration, and rupture of the bile-duct** due to injury. In speaking of gunshot-wounds he cites the case reported by Hans Kehr as especially noticeable. In this case there was a gunshot-wound of the gall-bladder; laparotomy was performed, the wound was sutured, and the patient recovered. Extravasation of healthy

¹ Lancet, May 29, 1897.

bile is by no means as serious as is extravasation of diseased bile, and when a rupture takes place while the gall-bladder is distended or there is disease of the gall-ducts the bile is in an infected condition and causes a diffuse peritonitis which will inevitably end fatally unless an operation is performed at once. Robson speaks of a case in which he opened the abdomen, evacuated several pints of bile and pus, washed out the peritoneal cavity, passed one drainage-tube between the liver and diaphragm, one downward toward the pelvis, and one into the right kidney pouch, and this patient recovered. He alludes to a case reported by Dr. Monier Williams in which typhoid ulceration of the gall-bladder, which perforated, was successfully treated by abdominal section, and refers also to the well-known case of Marmaduke Shield, in which a patient in the 51st day of typhoid fever was subjected to laparotomy. The gall-bladder was found thick and rigid and congested, with an ulcer the size of a three-penny piece near its neck, and contained $1\frac{1}{2}$ oz. of offensive pus. The abdomen was washed out, the distended intestines were emptied by puncture, and gauze-packing with drainage applied. The patient was cured. When the gall-bladder ruptures from sudden pressure there must be a predisposition to rupture produced by ulceration or by prolonged distention. The danger of such an accident is great in these conditions, and patients with distended gall-bladders should always be operated upon, because otherwise they live in a "fool's paradise." Massage of a distended gall-bladder is futile, and its application is the height of folly. An attempt to force an impacted stone onward by pressure is very likely to rupture the wall of the gall-bladder or bile-ducts or cause perforation through an ulceration. In some cases even when primary perforation takes place an abscess-cavity is formed bounded by lymph, which cavity may again rupture and cause fatal peritonitis. The gall-bladder may perforate into an adjoining organ. It may perforate, for instance, into the liver, producing the signs of abscess of the liver; perforations of the common duct may occur into the pancreas, causing acute pancreatitis. If perforation takes place into the stomach, duodenum, or colon, the course of the perforation is usually encompassed by adhesions and the process takes place quietly. The symptoms of perforation of the bile-passages are those of perforative peritonitis; premonitory symptoms, however, point to the origin of the disease. If a case be not operated upon, death will occur in a few days from toxemia and paralysis of the bowel, although in very exceptional cases the patient may live a week or two. In these cases medical treatment is absolutely useless. If the perforation is even suspected, the abdomen should be opened in the right semilunar line. If pus and bile are discovered, they should be wiped away with gauze; and if the extravasation has extended throughout the abdomen, the entire peritoneal cavity must be flushed with a hot solution of boracic acid. If the patient is in such a condition that prolonged operation is not to be thought of, free drainage may save his life.

Robson calls attention to the fact originally pointed out by Morison that the right kidney pouch is in reality a pocket of the peritoneum; and if a stab-opening from the loin is made into this pouch, a drainage-tube carried through the stab-wound will provide for most efficient drainage. When the whole peritoneal cavity has been soiled a suprapubic incision is made and a tube is introduced for the purpose of drainage. When the patient's condition justifies it the rupture must be sought for, and, when found, in some cases it can be closed by fine sutures of silk or catgut, but, as a rule, it is best to open and drain the gall-bladder at the same time. When there is marked cholecystitis the surgeon considers the question of cholecystectomy, but the operation should not be undertaken when the patient

is in a dangerous state. It should be deferred until a later period. The author divides biliary surface fistulæ into pathologic and post-operative. A mucous fistula occasionally follows the operation of cholecystotomy when a cystic obstruction has not been removed. In two such cases Robson brought about a cure by removing the gall-bladder. In another case he followed up the tract and found that the cystic duct was blocked by a calculus, and when this calculus was removed the fistula rapidly healed. A mucous fistula causes but little trouble, as it discharges only about an ounce of fluid daily; but if the opening be permitted to close, accumulation takes place and colic ensues; hence a patient with a mucous fistula must wear a tube or an absorbent pad, or must submit to an operation. The operation of cholecystotomy will not be succeeded by a fistula if the obstruction of the bile-ducts has been removed and if the opening in the gall-bladder be sutured to the aponeurosis and not to the skin. Biliary fistula following operation is a far more serious condition than a mucous fistula. About 30 ounces of bile will flow from the fistula daily. The treatment of such cases consists in removing the cause, but in cases in which this is impossible other means must be considered. When there is no obstruction in the ducts and the fistula is small the application of a Paquelin cautery may effect a cure. In one case Robson opened the abdomen, detached the gall-bladder, and sutured the opening, and cure was brought about. Another method is to dissect the fistula with its peritoneum covering intact over the skin margin, turning in the mucous edges, suturing them, applying one or two layers of buried suture over them, and then closing the skin. When it is impossible to clear the ducts and when the gall-bladder is of sufficient size the operation of cholecystenterostomy should be performed. If the fistula is kept up by gall-stones blocked in the ducts, the ducts may be syringed daily with olive oil or a $\frac{1}{2}\%$ solution of *sapo animalis* or a solution of turpentine and ether. Biliary intestinal fistulæ are more common than surface fistulæ. This is to be expected because of the adjacency of the duodenum and colon to the gall-bladder. The author then considers intestinal obstruction from gall-stones and states that this is a very unusual condition. It may be produced in several ways. Paralysis of the bowel may follow local peritonitis in the gall-bladder region. The violence of the attack of hepatic colic may lead to volvulus of the small intestine. The obstruction may be due to adhesions left by the local peritonitis of the inflamed region. Finally, obstruction may be mechanically induced by the passage of a very large stone through and into the intestine. There are no symptoms absolutely characteristic of this form of obstruction. A surgeon should not wait beyond the time when the operation may be undertaken with reasonable hope of success. When the abdomen is opened and the stone is felt it may be possible to crush the stone through the intestinal coats; but if this procedure fails, enterotomy should be performed. If the patient's condition is so grave that it is not possible to make a search for the obstruction, temporary relief is afforded by enterotomy or by short-circuiting, and if the obstruction caused is not passed naturally it may be subsequently sought for and removed. The author then makes some remarks on tumors of the gall-bladder and bile-ducts, distention of the gall-bladder, hydrops, and dropsy of the gall-bladder. Hydrops and dropsy mean distention by mucus, and may result from obstruction of the cystic or common ducts, obstruction produced by gall-stones, stricture, tumor of the ducts, or cancer of the head of the pancreas. The mucus results from the secretion of the mucous lining, and the gall-bladder may attain enormous size. When the obstruction is associated with inflammation the fluid may become purulent and empyema of the gall-

bladder result. Robson presents the signs of this condition and elaborately discusses the diagnosis, symptoms, and signs of tumor. He says that the treatment of cancer of the gall-bladder may call for cholecystectomy; but it is very rare that the disease is sufficiently limited to permit of excision. In the 1 case in which he operated he had to associate the cholecystectomy with a partial hepatectomy.

The author presents the subject of **tumor of the bile-ducts** and tells us that the operative treatment for these growths is in its infancy. If possible, the growth should be removed; but when such a procedure cannot be carried out the gall-bladder or ducts must be opened and drained, or, what is better, drained into the duodenum or jejunum by means of a Murphy button.

Then follows an elaborate consideration of the subject of **cholelithiasis**. The author says that after medical treatment has been fairly tried and has proved unsuccessful a surgical operation should be performed. Cholecystotomy is the operation usually to be aimed at, but very frequently it happens we cannot definitely say what operation is to be done until the abdomen has been opened. The indications for operation are as follows: first, frequently recurring attacks of biliary colic without jaundice, whether the gall-bladder is enlarged or not; second, enlargement of the gall-bladder without jaundice, whether or not there is great pain; third, persistent jaundice which was preceded or accompanied by pain with or without paroxysms resembling ague; fourth, empyema of the gall-bladder; fifth, peritonitis of the gall-bladder region; sixth, abscess around the gall-bladder or bile-ducts (it matters not whether the abscess is over the liver, in the liver, or under the liver); seventh, where adhesions are producing pain and sickness; eighth, fistulæ, mucous, mucopurulent, or biliary; ninth, persistent jaundice with enlarged gall-bladder due to obstruction in the common duct; tenth, phlegmonous cholecystitis and gangrene; eleventh, gunshot-injury or stab-wounds; twelfth, suspected rupture of the gall-bladder; thirteenth, some cases of chronic catarrh of the gall-bladder or gall-ducts; fourteenth, suppurative cholangitis.

Robson says that aspiration of the distended gall-bladder through the unopened abdomen is a dangerous procedure. It is far better to make an exploratory incision than to aspirate. In these operations a narrow and firm sandbag should be placed at the level of the liver on the operating-table under the patient's back. This will bring the common duct several inches nearer the surface, cause the intestines to roll away from the liver, and open the costal angle. The most useful incision is vertical in the right semilunar line. If there be a definite tumor, the incision should be made over the most prominent part of the tumor. If there is an enlarged liver but no tumor, the upper end of the incision will begin at the upper margin of the liver. If there is neither a tumor nor an enlarged liver, the incision will start at the ninth costal cartilage and will pass downward vertically for three inches. If more room is required, it can be obtained by extending the vertical cut or by adding to it a transverse cut either outward or inward from the vertical line. The lumbar incision through which it has been suggested that we can reach the duct without opening the peritoneum is not practicable. In jaundiced patients there is great danger of hemorrhage, and the author thinks that the administration of chlorid of calcium, 30 gr. every 4 hours for a few days before operation, makes the blood more plastic and lessens the danger of excessive bleeding. This procedure was suggested by Dr. A. E. Wright, and the drug may be continued for some time after operation. The operation *par excellence* in the treatment of gall-stones is undoubtedly cholecystotomy or cholecystostomy,

The author then takes up the **technic of the operation**, discusses it most fully, considers the question of fistulae following cholecystotomy and of calculi in the common duct and the methods applicable to treatment, and in detail the operations of choledochoduodenostomy, choledochotomy, and cholecystectomy.

The entire article is worthy of the most careful study.

T. C. Railton¹ reports an interesting case of **pancreatic cyst** occurring in a girl 6 months of age. The tumor was aspirated and an operation was performed in which the sac was incised and drained from the infracostal region behind, but the patient died. An interesting fact in this case was that the tumor occupied a lateral position, possibly because of the large size of the liver in the child. This case is the youngest one which is recorded, the youngest previously reported being 17 years of age. There was no history of any injury, and it seems difficult to believe that an injury sustained during birth was responsible for the cyst. G. R. Turner² reports a case of pancreatic cyst occurring in a man. The cyst was of very rapid growth. The man was 34 years of age; he had not been injured and was apparently in excellent health, but while at dinner was seized with violent abdominal pain followed by vomiting, constipation, and distention, the symptoms greatly resembling obstruction of the bowels. For a week he improved, and then had a relapse. About a month after the first attack a swelling the size of a hen's egg was detected. This tumor varied in size from time to time and the patient kept on having occasional attacks resembling obstruction. About 9 months after the beginning of his trouble he was admitted into the hospital, and a cystic swelling was detected in the left hypochondriac and upper umbilical regions. There was an interval of resonance between the liver-dulness and the dulness due to the tumor, the superficial veins were not enlarged, and the general health of the patient was excellent. The abdomen was opened; the stomach and great omentum were visible. The cyst could not be seen, but fluctuation could be felt back of the stomach. An exploring-needle was passed through the sac, the cyst was aspirated, and 37 ounces of a thickish fluid of a dark color were withdrawn by the aspirator. The cyst was opened. The opening in the cyst was stitched to the abdominal wound and a drainage-tube was inserted. An examination of the fluid showed that the cyst was pancreatic; the patient made a complete recovery.

Rotter has stated that 75% of pancreatic cysts push forward the posterior wall of the omental cavity so that the stomach and gastrocolic omentum lie in front of them, the transverse colon below them, and the liver above them. If the tumor increases much in size, the stomach is pushed forward and the colon downward, so that the gastrocolic omentum is in front of the cyst. The transverse colon may be pushed downward until it lies back of the symphysis pubis. The case reported belonged to this class, and not to the class in which fluid collects between the layers of the transverse mesocolon. In this latter case the colon lies transversely above the centre of the cyst. In a case in which the fluid collects in the lower layer of the transverse mesocolon the gut lies at the upper border of the tumor. It is quite true that there is a case on record in which a pancreatic cyst in a child was cured by aspiration, but Turner enters a positive protest against this method. Such a procedure is highly dangerous because the stomach, the transverse colon, and the omentum are apt to lie directly in front of the cyst. Exploratory incision should always be made, and after this the cyst can be tapped with safety. An interesting

¹ Brit. Med. Jour., Oct. 31, 1896.

² Lancet, July 4, 1896.

case of pancreatic cyst is reported by Charles B. Penrose.¹ There was a lump in the abdomen and the patient suffered from backache, faintness, painful urination, and some loss of flesh. There was no pain in the abdomen; the tumor was smooth and round and obviously cystic, and was without any pelvic attachment. When the abdomen was opened a unilocular pancreatic cyst was discovered containing 2½ gallons of brownish fluid. The anterior wall of the cyst was incised, the margins of the incision were sutured to the upper angle of the abdominal incision, and the remainder of the abdominal incision was closed with sutures. The patient recovered. An examination of the fluid removed from the cyst showed that it was pancreatic. W. W. Keen² reported a case of pancreatic cyst in a girl 15 years of age. There was no history of injury or of malaria. The swelling was discovered accidentally some four years before, and was in the upper portion of the left abdomen. There was some dyspepsia because of the large size of the tumor. The tumor was the seat of occasional attacks of severe pain. Four or five months previous to visiting Keen the pain became continuous and the abdominal enlargement rapidly progressed. The patient was not anemic. The left side of the abdomen was filled with a large tumor which was apparently solid. The lower limit of the tumor was 2 in. below the line of the umbilicus and the right side of the tumor extended 4 in. to the right of the umbilicus. The upper border was lost in the hepatic and cardiac dulness. The abdominal wall was very tense. The entire area was dull on percussion, and the colon-resonance separating the kidney from the tumor was found in the left flank. The abdomen did not appear to contain any fluid. The umbilicus was deeply cupped and extremely sensitive. There was no edema of the legs, the heart and lungs were normal, and the uterus and ovaries apparently normal. The patient had never had fatty stools; there was a doubtful sense of fluctuation on percussion. The splenic dulness could not be differentiated from the dulness of the tumor. Examination of the blood showed some diminution of red corpuscles, some increase in white corpuscles, but no alteration in the structure of the white corpuscles; hemoglobin 65%; no plasmodia of malaria. The abdomen was opened, and it became evident that the tumor was a tense cyst, the stomach being spread out in front of it and intimately adherent to it. On attempting to separate the stomach from the cyst-wall the muscular coat of the stomach tore, but the mucous membrane was not injured. The tear was sutured at once. The omentum was in front of the cyst and the descending colon behind it and to the left. It was obvious that the mass was retroperitoneal, probably pancreatic. It became necessary to add a transverse incision to the vertical abdominal incision. The peritoneum below and outside of the stomach was torn through and the cyst-wall was incised. About seven pints of fluid were evacuated. The first fluid that ran out was straw-colored, but the last was chocolate-colored. The fluid was under great pressure and was forced out to a considerable distance from the table. The pancreas could not be recognized with the fingers in the cyst, nor could any stone of the pancreas be detected. The mouth of the cyst was fastened to the abdominal incision and the rest of the incision was closed. The patient recovered. The bacteriologic examination of the fluid first removed showed it to be sterile. The fluid contained 0.4% of urea and a certain amount of serumalbumin and serumglobulin. It was neutral in reaction and of specific gravity 1.017. Bile, mucus, and cholesterin were absent. The iodine-test showed that starch ferment existed, yet this ferment was without effect on food. Prof. Brubaker examined the fluid last removed and reported that starch was rapidly transformed into sugar by it. It was obvious that the

¹ Ann. of Surg., Apr., 1897.

² *Ibid.*

fluid was pancreatic. The cause of the cyst is very obscure. The tension of the cyst was so great that Dr. Keen was at first inclined to think that he was dealing with a solid tumor. He was convinced after the first examination that he was not dealing with the spleen because of the absence of anemia and the absence of a distinctly palpable lower edge. The diagnosis lay between a hydronephrosis, a pancreatic cyst, and a cyst beginning in the gall-bladder or ovary. Ovarian and hepatic disease were ruled out by the results of vaginal examination and by the fact that the tumor was fixed to the left and above. The facts that the urine was normal; that there was an absence of all renal symptoms; that there was no flush-tank symptom, and that the colon was behind the tumor, were against a renal origin. The facts that there was no pronounced loss of weight, no fatty stools, and that the tumor was very much on the left side, made a diagnosis of pancreatic cyst doubtful. The examination of the fluid is particularly interesting when we note that it did not emulsify fats and that it contained a moderate amount of urea. The loss of emulsifying power was probably due to long retention. The fluid which flowed out last did emulsify fats and acted upon starch. Another important fact is that the operation was followed by a slight pancreatic diabetes. Dr. Keen says that if he had depended for a diagnosis on tapping and examining the fluid the presence of urea would possibly have led him to infer that he was dealing with a hydronephrosis. As a matter of fact, urea is sometimes found in old simple cysts; also in ascitic fluid and in pancreatic juice. The percentage of urea was about the same as would have been found in the fluid of a hydronephrosis, but the character of the fluid was markedly different from that of a hydronephrosis. Dr. Keen did not aspirate this tumor because in such cases he looks upon aspiration as a very dangerous performance—far more dangerous than incision and far less likely than incision to give the necessary information. In this case, if an aspirating-needle had been inserted at the most prominent and tense point, it would have passed directly through both walls of the stomach; in addition to this the fluid was in such a high condition of tension that even the small opening of the aspirating-needle would have led to the forcing out of a great quantity of fluid into the peritoneal cavity. The fluid in this case was sterile, but this is not invariably the rule. In dealing with pancreatic cysts only two methods are to be considered: first, incision and drainage; and, second, enucleation. Enucleation is rarely possible, and was impossible in this case. Zweifel says that extirpation has been performed 12 times with 5 deaths. There are 31 reported cases in which incision and drainage have been done, with only 2 deaths. Of the 29 who recovered 10 labored under fistula more or less permanent.

Sendler¹ writes upon **rare tumors of the pancreas**. In one patient a diagnosis was made of malignant disease of the stomach or pancreas. On operation the stomach was found to be very low down, and above it was detected a hard tumor of the pancreas. The lesser omentum was incised longitudinally and a tumor the size of a walnut was removed; the bleeding was free, but was arrested without trouble; the lymph-glands between the pancreas and the duodenum were enlarged and were removed. The patient recovered from the operation. Examination showed that the tumor was tuberculous and that the case was one of primary tuberculosis of the pancreas. In another patient a laparotomy was performed for a supposed cancer of the stomach. The lesser omentum was divided, and it was found that the entire pancreas was enlarged and hard. It was decided that the tumor was an inoperable carcinoma, and no attempt was made to remove it. The patient recovered from

¹ Deutsch. Zeit. f. Chir., vol. xlv.

operation, but the condition gradually grew worse until it was believed that death would soon ensue. Then for no known reason the patient began to improve, and at the end of about a year she was in perfect health. Some three years later the tumor could still be felt, although greatly lessened in size. The condition obviously was not malignant disease of the pancreas, but rather chronic inflammation.

Pereira Guimarães¹ publishes the report of a case of **hernia of the pancreas** resulting from a bayonet-wound. The tail of the pancreas protruded from the incision; 48 hours after the accident it was restored into the abdomen, the wound was closed, and the patient recovered. The writer states that Quenu has collected 6 cases of pancreatic hernia with one death. In each case the protruded portion had been ligated.

Greiffenhagen² writes on the causes of **wandering spleen** and on the methods of operating. He tells us that 5 cases of splenopexy have been placed on record, 4 of which were successful. In Greiffenhagen's case the spleen was found floating during an exploration to determine the condition of a kidney which had previously been sutured. He introduced two sutures through the parietes of the abdomen, through the substance of the spleen, and through the parietes again; a third suture rendered the fixation complete. There was a considerable amount of bleeding from the stitch-holes. The results were most satisfactory. [The opinion generally held by surgeons is that splenectomy is a more certain and not a more dangerous procedure than splenopexy.] J. Bland Sutton³ tells us that the spleen may travel so wide of its normal seat that it may be brought into contact with any part of the peritoneal cavity from the diaphragm to the pelvic floor. Occasionally it will remain for days in its normal position, and then suddenly slip out and be felt by the patient in the umbilical or iliac region, and then it will pass into the pelvis. Gravity has some influence in causing the spleen to pass into the pelvis, but it is not the only cause. In one case Sutton was able to determine that when the patient lay on the right side the spleen sometimes passed into the right iliac fossa, but sometimes into the left, as if carried on by the intestines like a boat on the water. Wandering spleens are infinitely more common in women than in men, and most of the victims have borne children. A wandering spleen is always liable to engorgement. When we are operating and find a wandering spleen which is engorged, we notice that the engorged organ contracts very greatly after removal or on simple exposure to air before removal. In one case Sutton opened the abdomen and found a spleen reaching from the diaphragm to the uterus. It was withdrawn very gently and supported for a few minutes. Exposure to the air acted as a stimulant, and this enormous spleen shrunk one-third of its original size. A wandering spleen is always liable to axial rotation, and when this happens the organ looks as if it were about to burst. Axial rotation produces the same acute symptoms as ensue on rotation of ovarian cysts and as occur in strangulated hernia. A persistent rotation which completely arrests the splenic circulation permanently occludes the splenic artery and vein and causes atrophy of the spleen. A wandering spleen exercises injurious effects upon adjacent viscera. The spleen is intimately related to the tail of the pancreas, and some disturbance of the pancreas is almost certain to arise when the splenic pedicle is elongated. In some cases the pancreas became incorporated in the pedicle. There is a case on record in which a spleen passed into the pelvis and dragged the tail of the pancreas with it. A wandering spleen pulls upon the stomach, leading to

¹ Progrès méd., Oct. 10, 1896.

² Centrabl. f. Chir., Feb. 6, 1897.

³ Brit. Med. Jour., Jan. 16, 1897.

dilatation of the stomach, accompanied by vomiting and fermentation of food. It happens sometimes that the pulling upon the stomach and duodenum obstructs the common bile-duct and leads to attacks of jaundice. The long pedicle of the wandering spleen is very apt to interfere with the intestines, and such a spleen may become adherent to the small intestine, the colon, the sigmoid flexure, or the appendix. Such adhesions may cause intestinal obstruction, or they may damage the bowel-wall and favor the emigration of microorganisms with all the evil consequences that may ensue. A wandering spleen may cause acute uterine retroflexion and even uterine prolapse. In one published case a wandering spleen dropped into the pelvis and caused prolapse of the uterus, vagina, and bladder. The pressure of the spleen in the pelvis seriously interferes with menstruation. A wandering spleen may endanger life by rupture of the stomach or duodenum, intestinal obstruction, abscess of the spleen, or rupture of the spleen. Wandering spleens may be confounded with various abdominal tumors, such as ovarian cysts, tumors of the kidney, tumors of the omentum, movable kidney, and uterine myomata. It is necessary to bear in mind that ovarian and uterine tumors may simulate wandering spleens. Splenectomy for wandering spleen is a very successful operation, the rate of recovery being fully equal to the rate of recovery after ovariectomy. Sutton has collected the records of 20 cases, with one death. Some surgeons have endeavored to fasten the spleen in the left hypochondriac region, just as we would fasten a movable kidney; but the results demonstrate that such an operation is more dangerous and requires longer confinement than does splenectomy.

Sutton has never seen an evil result from a patient being without a spleen. The spleen is a highly developed lymph-gland of special functions, and there is no more reason to hesitate at removing it than to hesitate to remove enlarged concatenate glands. Many people with wandering spleen are thin and gaunt, and when the spleen is removed they retain this character.

Jonnesco¹ puts on record 2 successful cases of **splenectomy** for ague spleen. Jonnesco says this operation should be performed for malarial spleen after a trial of medical methods, when there is no leukemia, no pronounced cachexia, and no mass of adhesions. In performing this operation tear the adhesions between the spleen and diaphragm, the vessels being cut between two ligatures. The spleen is lifted out of the abdomen, and the vessels of the pedicle are separated and tied individually.

DISEASES OF THE RECTUM AND THE ANUS.

John Campbell² considers the value of **the sacral route in operations for diseases of the rectum**. He holds that in rectal cancer this route possesses certain positive advantages. We are able to tell the exact limits of the disease and thus effect a thorough removal, we can easily and completely control hemorrhage, we can reach the tissues which lie between the rectum and sacrum, and are enabled to remove infiltrated lymphatic glands and vessels, and in most instances we do not destroy the sphincter and levator ani muscles. The operation is, of course, a severe one.

Podreze³ employs the following method of **operation for hemorrhoids**: the patient is anesthetized, the sphincter is dilated, and the rectum is stuffed with cotton-wool above the hemorrhoids. Each group is grasped with forceps and the skin at the base is cut as near as possible to the mucous membrane; a

¹ Progrès méd., No. 12, 1897.

² Ibid., Oct. 10, 1896.

³ Gaz. des Hôpitaux, No. 30, 1896.

needle threaded with silk is introduced into this wound and passed around the base of the pile and out again at the wound. The thread surrounds the base of the pile; it is tied and cut and the hemorrhoid is cut; the skin and mucous membrane are then sutured together. Each pile is treated in the same manner. The rectal plug of wool is removed, a drainage-tube wrapped about with iodoform-gauze is placed in the rectum, and the wound is dressed with gauze.

D. W. S. Samways¹ treats **external piles and anal pruritus** by the application of collodion. This application causes the pile to contract and supports the contracted pile. It acts in the same way as the elastic stocking used in varicose veins of the leg. The collodion is applied on a little cotton-wool each morning after defecation. In pruritus the application of collodion causes smarting for a few minutes, which can be prevented by the previous application of cocain, but there is no itching for 12 to 24 hours after the collodion is applied.

Monin² employs the following **ointment in the treatment of hemorrhoids**: 2 oz. of camphor lanolin; 3 drams of castor oil; 1½ drams precipitated chalk; 30 gr. of hydrobromat of cicutin.

Delorme³ writes upon **Whitehead's method in the treatment of hemorrhoids**. He thinks that this plan should be employed when the hemorrhoids are internal or both internal and external, and when they are very large and form a great, circular mass. In 18 operations performed by Delorme the results were entirely satisfactory and primary union took place in each case. The cicatrix was thoroughly dilatable and there was neither retention nor incontinence of feces. Whitehead's method is a radical cure if the entire pile-bearing area is removed. The surgeon must be careful to preserve the sphincters and must always use strong sutures.

Joseph B. Bacon⁴ proposed in 1895 a new method of **treating stricture of the rectum by a plastic operation**. He used the sigmoid flexure to form a new channel around the strictured portion of the canal, and he believes that this method is a certain means of relieving malignant strictures situated above the levator ani muscles. Unfortunately, for strictures above the internal sphincter and it is not possible to perform any plastic operation which will not be followed by fecal incontinence. Gradual dilatation is unsuccessful in these strictures; the same may be said of forcible divulsion, internal and complete proctotomy, and electrolysis. Complete proctotomy gives temporary relief. For these cases he has recently devised a method which has been successful. The incision of a complete proctotomy has the shape of the letter V when the ends of the stricture retract. If we can prevent this triangle from filling up with fibrous tissue, the severed band of strictured tissue will disappear by absorption. In order to accomplish this a mucous fistula is produced between the stricture and the coccyx, so that the mucous tract will be at the bottom of the wound and prevent the union of the severed stricture-bands. In order to perform this the patient is thoroughly anesthetized, a blunt-pointed aneurysm-needle is threaded with a heavy silk ligature, and just above the internal sphincter and the median line of the posterior rectal wall the gut is punctured; the needle is carried well back into the perirectal tissue and the coccyx and up behind the stricture to above the upper limits of the stenosis. The needle is forced through the rectal wall into the rectum. One end of the ligature is now seized with a blunt hook or dressing-forceps, and one end drawn down through the stricture-opening and the needle withdrawn; the two ends of the

⁴ Quar. Med. Jour., Jan., 1897.

seton are tied and left hanging outside of the anus. It is necessary to leave the seton in place for about three months in order to get a continuous mucous tract. At the end of three months the patient is again anesthetized and the seton withdrawn. A grooved director is passed through the fistulous tract behind the stricture and the intervening stricture-band severed with a Paquelin cautery. In three cases there was partial failure, due to not taking in more tissue above and below the stricture-band, so as to catch all the scar-tissue.

W. J. Chapman¹ reports a case of **prolapse of the rectum** in which he opened the abdomen and practised ventrofixation of the mesorectum, with most satisfactory results.

A. B. Cook² writes on the **operative treatment of rectal fistula**. In every case not only should the rectum be examined, but also the lungs, although pulmonary tuberculosis is not of necessity a contraindication to operation. Every sinus must be removed. The sphincter is cut but once, and then at right angles to its fibers. The mucous opening is looked to with care, and pains are taken, especially in females, not to invade the perineum. Antisepsis greatly contributes to favorable results, and the surgeon must himself supervise the after-treatment. If during after-treatment there is an unusual amount of pain or an increase of the discharge, suspect the formation of another abscess. The two chief dangers to be apprehended are hemorrhage and fecal incontinence, but both conditions may be amended by treatment.

Llewellyn Eliot³ reports 4 cases in which he succeeded in **restoring a destroyed sphincter ani**, the muscle having been cut during operation for fistula. Eliot maintains that in cutting for fistula we should dissect out the tract and insert sutures in order to obtain primary union and so preserve the sphincter. In the cases in which he operated for destroyed sphincter he dissected out the scar-tissue and drew the muscular fibers together with silk sutures.

Charles B. Kelsey⁴ considers the indications for **celiotomy in diseases of the rectum**. Among these are cancer of the rectum and incurable non-malignant ulceration. In many cases in which an artificial anus has been formed the surgeon will be obliged later to repair this condition. After the performance of colostomy it occasionally happens that the gut prolapses extensively through the abdominal opening, and a second operation is demanded. In resection of cancer of the rectum by the method of Kraske the peritoneal cavity will be opened. All cases of intussusception marked by bloody discharge and tenesmus, in which the intussusceptions appeared at the anus, are considered by the laity as rectal disease, and many of these cases demand celiotomy. Celiotomy is required for a foreign body in the rectum, for the diagnosis of obscure rectal disease, for extensive rectal prolapse and rupture of the rectum, or, more properly, rupture of the old prolapse, permitting hernia of the small intestine through the anus, and finally for intestinal vesical fistula in the male. There are three well-recognized ways of opening the abdomen in rectal disease—the ventral, the vaginal, and the sacral.

Edward H. Taylor⁵ contributes a thorough and lengthy study on the **operative treatment of cancer of the rectum**. He studies anew and with great care the anatomy of this region. He tells us that many surgeons do not regard extensive operations for rectal cancer with much favor, as they believe these operations cannot be carried out as completely as is possible, for instance, in a breast cancer. Nevertheless, we should always remember that in

rectal cancer metastases occur late, and this fact gives a more favorable aspect to the situation. Even if we leave behind some glands which are infected, the progress of the disease in these limited areas may be extremely slow. There are numerous examples on record of prolonged life after rectal excision, and many cases have been recorded of non-recurrence for 6, 8, and 10 years. Even if only a very small percentage of radical cures were obtained, it would be much better to operate than to leave sufferers to the miserable end to which this disease dooms them. The mortality of rectum-excision varies from 20% to 25%. This means the mortality of the sacral operation. Recently the figures have shown improvement. Czerny's mortality was 5.4% by the perineal route, 19.4% by the sacral route; Iversen, 25%; Albert, 18%; Ball, 8%; and Paul, 14%. There is no question, however, that the high mortality which records have previously shown, will diminish in the future, this diminution being brought about by a more perfect technic, by minute attention to details of operation, and the preparation for operation and careful selection of cases. It is certain that a bad functional result occasionally follows this operation, and the opponents of rectal incision have often made much of this; nevertheless, it has been noted that even in the cases in which the sphincters have been excised there is a fair amount of control, except during attacks of diarrhea. Modern methods of treatment do much in aiding us to preserve the sphincter function of the bowel. When we see a patient with a rectal cancer the first questions are, Should a radical cure be attempted? and, if so, What procedure should be selected? The operation of Kraske has very widely extended the field suitable for operation, and by this method we can remove not only cancers of the upper rectum, but also of the adjacent portions of the colon. The cancers best suited for radical operation are those which are small and movable. We should always try to make out the limits of the growth, observing if it has invaded the perirectal cellular tissue, the glands, the prostate, the bladder, the uterus, the vagina, the sacrum, or the seminal vesicles; and in order to determine this several careful examinations should be made. A diagnosis is unfortunately made late rather than early as a rule, because rectal cancer in its beginning often runs an indolent course and seems to be latent. In considering the question of operation we should always take into account the patient's age, his strength, and the condition of the viscera, especially the kidneys. The two main indications in preparatory treatment are to improve the general condition of the patient and to diminish the poisonous nature of the contents of the intestines. There is no known way of making the intestinal tract aseptic. It is impossible to subject it to the action of strong antiseptics. Purgatives used with moderation are of the greatest possible value and cleanse the intestinal tract more efficiently than do all of the recommended antiseptic agents. Resorcin, salicylate of bismuth, and salol, however, can be given with some advantage. The area of ulceration abounds with virulent microorganisms, and in the neighborhood proctitis frequently exists, and for these conditions we should invariably employ frequent rectal irrigation with warm water. Rectal irrigation should be practised every morning and evening for 4 or 5 days before operation, but rectal irrigation and intestinal antiseptics only bring about a moderate amount of disinfection. The most satisfactory way to disinfect the area is by the use of the flushing-curette. The anus is dilated, so that during the flushing free exit is afforded to the stream of water and cancerous debris. This is done immediately before the removal of the growth. Preliminary colotomy was originally employed, because of the numerous unpleasant results which were found after Kraske's operation. Quénu always performs colotomy twelve days before he

excises the cancer. This operation enables us to explore satisfactorily the pelvic cavity, determine the condition of the pelvic colon, and examine the lymphatic glands. Furthermore, a preliminary colotomy facilitates disinfection of the rectum by diverting the poison, and enables us to practise thorough irrigation, and thus diminish greatly the chances of infection after operation. Many objections have been urged against it; the first, the necessary lapse of several days between the colotomy and the excision of the growth. In this time the patient's condition may grow worse and the cancer may increase its size. Again, the patient will be subjected to the subsequent closure of the artificial anus, when his condition may not be such as to justify surgical interference. Third, the performance of a preliminary colotomy may make the drawing down of the intestine in Kraske's operation a very difficult matter. This is especially the case where the distention causes the pelvic colon to rise out of the pelvis, it having been fixed in this position when the colotomy was performed. Taylor thinks the procedure has certain advantages, although he has not adopted it in any of his cases. He might be induced to employ it if he were unable to empty the bowel above the cancer by other means, and if he were unable to cleanse satisfactorily the operative field. In endeavoring to select the proper operation to perform, it is well to consider a certain number of types of cancer. First, cancers which begin below the attachment of the levator ani muscles—in reality, anal cancers. Second, those above the levator ani, which are, however, intraperitoneal. Third, those whose lower limit is at the level of the peritoneal cul de sac, the growth extending upward so as to reach to or even involve the pelvic colon. Fourth, cancers which involve the rectum extensively and reach upward for a considerable distance from the anus. If we are dealing with an anal cancer, the surface of the growth is curetted, the rectum is irrigated, and an incision is made in the skin wide of the disease, the external sphincter, of course, being removed. The dissection is carried out with scissors until sound tissue above the growth is reached. The rectum is cut across above the growth and the cut portion of the rectum is sutured to the skin. In suprasphincteric cancer the question to determine is whether the growth does or does not involve the sphincter. In both conditions the perineal operation can be employed. The best method is as follows: make a median posterior incision behind the margin of the anus and extend it deep over the coccyx; starting from the tip of this incision, follow the median raphe forward, thus splitting the posterior portion of the external sphincter and separating the levators ani. The rectum is cleared on its posterior and lateral aspects by the use of the index fingers. A pair of blunt-pointed scissors is now taken; one blade is placed in the wound just behind the anus in the interval between the rectum and the levator ani, and the other blade rests upon the skin. The intervening bridge of tissue is cut and a similar section is made on the opposite side. These lateral incisions are extended in the direction of the middle line in front, cutting the levator muscles all around away from the rectum. When the disease is quite above the sphincter zone this muscle should not be interfered with. The author then discusses elaborately the technic of the sacral and perineal methods for excising cancers above the sphincter zone, and shows why he greatly prefers the sacral method and particularly the osteoplastic resection.

Henry T. Byford¹ presents an article on the **extirpation of the rectum through the vagina**, with utilization of the vagina to replace the lost rectal tissue. He tells us that the sacral method is bloody and severe, and that removal of the rectum by the perineal incision is only applicable when the lower 4 in. mark the area of the disease. He therefore thinks that in some cases

¹ Ann. of Surg., Nov., 1896.

certainly another route is justifiable, and reports a case in which he performed this operation. The vagina was distended by means of retractors. Half an inch below and posterior to the cervix a transverse vaginal incision was made, and the vagina was separated from the underlying connective tissue about the incisions. The tumor and rectum were then separated to and above the level of the brim of the pelvis, large pads of gauze being pushed up to arrest hemorrhage. The rectum below the tumor was separated and the tumor was pulled down to the vulva, which pulling down tore the cul de sac and carried into the vagina two inches of rectum, the front surface of which was covered with peritoneum. The area which included the tumor was excised between two large forceps, and the upper end of the divided rectum was sutured into the vaginal wound, the vagina thus being turned into a rectum. The peritoneal wound was closed and the lower end of the rectum was sowed around with catgut so as to check bleeding, but not to obliterate its caliber; the rest of the vaginal wound was then sutured completely around the rectum.

Byford thinks that this technic in future cases may be improved. It would be well to enlarge the transverse incision by a median incision extending down over the center of the transverse incision—in other words, by making a T-shaped incision. It is well to employ a large amount of packing. The vaginal method has certain advantages. The vagina takes the place of the portion of the rectum which has been removed. We are enabled to remove the rectum as high up as by the sacral route and the mutilation is less, and if the peritoneal cavity is opened the danger is less. An intraperitoneal exploration can be made before the rectum is disturbed. If it is necessary to abandon the operation, we leave a less serious wound than if forced to abandon the large operation, and the patient is left far more comfortable after this operation than after sacral resection.

T. W. Elliott¹ reports a case of **imperforate rectum** in which he performed successfully Kraske's operation. The child was only two days old.

Depage² discusses **cancer of the rectum**, the indications for operation, and the technic. In operating on a patient for cancer of the rectum he is placed in what he calls the gynecological position, with the pelvis vertical; an incision is made posteriorly, the coccyx is resected, and it may be that one or two of the sacral vertebrae are removed. The rectum is dissected, the surgeon endeavoring to leave as much as possible of the cellular tissue and the peritoneum adherent to it. If possible, the superior hemorrhoidal artery is left intact. The malignant growths of the lymphatics associated with it are removed together in one piece. As soon as the growth has been resected the peritoneal cavity is closed. The upper anal segment should be invaginated into the lower segment; the preservation of the superior hemorrhoidal artery obviates the risk of gangrene. The final step in the operation is the insertion of tampons or applying layers of sutures. Depage very rarely performs a preliminary colostomy. He does so, however, where the condition of the patient is extremely bad and in a case in which the growth is so extensive that removal of the entire rectum is necessary. When we operate on a cancer in the beginning this radical operation should be performed. When we operate on a case which has far advanced we can study out the condition and perform either a radical operation or simply a colostomy, according to the indication.

DISEASES OF THE RESPIRATORY SYSTEM.

J. Lacey Firth¹ records a case of cut-throat treated by immediate suture. He tells us that Mr. Henry Morris has set forth the advantages of the immediate application of sutures, stating that we can obtain union by first intention; that natural swallowing can be performed early; that the distress of feeding by a tube is avoided; and that we avoid also the painful swallowing attended by escape of food from the wound and troublesome cough, the formation of cicatricial contractions, stricture, and aërial fistula. In a case reported by Firth the wound gaped widely and extended from the left sternomastoid almost to the right one, and passed into the food-passages below the hyoid bone. The wound in the air-passage was oval in shape and about $1\frac{1}{2}$ in. in length transversely. The thyroid cartilage was bare of muscle. The wound was cleansed. It was impossible to suture the wound in the food-passage without penetrating the mucous membrane, because the thyrohyoid membrane and the epiglottis had been cut just below the hyoid bone and there was no tissue below that bone to unite to the upper edge of the lower flap of tissue. The cut edge of the upper portion of the epiglottis was level with the lower border of the hyoid bone and was very closely fixed to it. Sutures of catgut were passed from the hyoid bone and through the epiglottis into the pharynx, and out again below through the flap of tissue consisting of epiglottis and thyrohyoid membrane. Five sutures were employed. The muscles were next sutured. The skin was then sutured, two small tubes being left in the wound for drainage. The head was fixed to the chest in the usual manner and union was obtained by first intention. [In the section on Wounds we have noted a recent article on this same subject by Henry Morris. There is no question that sutures should be inserted and an attempt be made to obtain primary union.]

George Ryerson Fowler² writes on the **surgery of intrathoracic tuberculosis**. He tells us that pleural effusions are most frequently tuberculous in origin. Many inflammatory conditions, exclusive of those of traumatic origin, have their origin in a tuberculous process, for few patients who have suffered from pleurisy escape tuberculosis. It used to be maintained that the activity of the pulmonary circulation protected the tissue from tubercular infection, and treatment used to be administered to stimulate the circulation. It is becoming very doubtful if measure directed to this end are beneficial. Laennec long ago maintained that stasis was antagonistic to tubercle, and Bier's observations on the treatment of tubercular joint-disease by the induction of venous congestion appear to confirm the views of Laennec.

It seems likely that Koch's bacilli cause effusion, and that the effused serum inhibits the growth of bacilli. Even when a pleurisy is due to Koch's bacilli the effusion is apt to be sterile, and this suggests the probability that the serum exerts a restraining influence over the development of the organisms, though it unquestionably affords a favorable culture-medium for other organisms. If these views are true, it would be an improper proceeding to evacuate the fluid contents of a pleural cavity at an early stage as long as suppuration does not occur, because the effusion by its pressure and by its antituberculous properties antagonizes the tuberculous process. Among the operative procedures applied in pleuritic effusion we may mention exploratory puncture. The hypodermic syringe is used to the exclusion of almost every other means. The operation must be performed aseptically. The needle must be long enough to penetrate the chest-wall, and the patient must be warned beforehand not to start and not to make any quick inspiration, because a sudden movement may

¹ Brit. Med. Jour., Sept. 12, 1896.

² Ann. of Surg., Nov., 1896.

break the needle. When the point of puncture is being selected remember the situation of the heart and the great vessels. In small effusions the fluid may be found at the upper limit of dullness, nothing being found at the lower limit. If puncture extends into the lung-tissue, it should not produce any serious harm. In fact, this measure can be resorted to to differentiate pleurisy with effusion from pneumonia in a doubtful case. Nevertheless, it has been shown that it is possible for such a puncture to be followed by hemorrhage into the pleural cavity. As a matter of fact, it is rarely necessary in exploring for pleural effusion to pass the needle sufficiently deeply to injure the lung. If the fluid is not obtained at one puncture, it may be necessary to puncture in other places to settle the presence of fluid or the character of the fluid. If the patient has been recumbent in one position for a considerable time, fluid obtained from the upper layer may be clear, while fluid obtained from the lower layer may show that suppuration exists. Puncture may enable us to recognize, aided by a microscopic examination, carcinoma and sarcoma. A dry tap may be due to the needle passing into the thick masses or cartilaginous callosities. If the needle fails to fill at the first puncture, the attempt should not be given up until a larger and longer needle has been employed, because the instrument may be blocked up by clots or may have entered an adhesion or thickened pleura. It occasionally happened that after an exploratory puncture in which a small amount of fluid was withdrawn the fluid that was left rapidly disappeared. Thoracentesis in tuberculous pleurisy is indicated when the effused fluid increases the dyspnea greatly or threatens life by displacing the heart and the great vessels. Puncture and evacuation of fluid do not cure the pleurisy itself; they simply remove the effusion. Hippocrates used to advise evacuation of the fluid on the 15th day; Bowditch said the proper time is 3 weeks. In a case in which there is no fever, or only slight fever, removal of the fluid may not be followed by reaccumulation. Early paracentesis is not safe. The best method of withdrawing the fluid is by means of the aspirator of Dieulafoy or Potain. It is a matter for argument how much of the fluid ought to be withdrawn at a single sitting. The larger the amount present the more may be withdrawn with safety. In a small effusion a comparatively small amount is withdrawn. In a large effusion, particularly one which has existed for some weeks, the entire amount may be evacuated, provided that syncope does not occur. If the evacuation is carried out slowly, syncope and paroxysms of coughing will probably be avoided. It is not necessary to anesthetize to perform thoracentesis. Thoracotomy should be performed if both air and fluid are present in the pleural space, if the effusion is ichorous, or if it is suppurative. In empyema or pneumothorax occurring in a tuberculous individual the advisability of this operation is a matter sometimes difficult to determine. The surgeon must consider the strength of the patient and the history of the progress of the affection. Young individuals with florid phthisis are likely to die soon after the operation. Older people who have kept up a fair degree of strength, although the disease may have existed for several years, do far better after operation. It has been laid down as a rule that suppurative effusions will not disappear without some radical interference; but there are two exceptions to this rule. Rupture may take place into the lungs, drainage of the fluid being obtained through a bronchus. Small collections may be encapsuled and absorbed. As a general thing, however, it is safe to say that when the purulent matter is accessible and the patient's strength permits of it, it is desirable to incise and drain with or without rib-resection. In most cases simple incision will not cure. The author then discusses the relative value and applicability of simple incision, resection of the ribs, trephining of a rib, curettement of the walls of

the cavity, and extensive costal resection by the methods of Estlander and Schede. He then considers the direct treatment of tuberculous cavities. The disfavor into which operations upon cavities have fallen is due chiefly to the difficulties and dangers attending methods that have previously been proposed.

Attempts have been made to inject cavities, and enough has been found out to show that systematic treatment of pulmonary cavities is possible. If a circumscribed pulmonary affection exists, and the patient's strength is fairly well maintained, a surgical operation to reach the cavity may be attempted. The only cases suitable for such a proceeding are those in which there exists a slowly progressing and isolated tuberculous focus; but it is not always possible to be sure the disease is stationary or but slowly progressive. To operate, if a case has come to a standstill, will do nothing but harm. The presence or absence of adhesions between the costal and pulmonary pleura is of great importance. These occur in many cases of extensive cavities which are situated superficially; but if they fail to occur, the post-operative progress of the case will be greatly complicated. The exact location of the cavity is of great importance. Only a small area of pulmonary tissue can be reached by the surgeon. The field for operation is bounded above by the clavicle, within by the manubrium, externally by the lesser pectoral muscle, and below by the second rib. It has been maintained that when only one cavity has been operated on adjacent cavities inaccessible to operation have been favorably influenced. It is more difficult still to attack successfully bronchiectatic cavities. It is very difficult to locate them, and they are usually multiple. Maclaure would limit operation in tuberculous cases to circumscribed cavities that are without peripheral tuberculous infiltration, and to certain cavities of doubtful nature formed at the expense of both lung and pleura, pulmonary abscess consecutive on tuberculous spondylitis, and tuberculous caries of the ribs. Certain cases have been reported as cured by direct incision, and have been called tuberculous abscesses; but these abscesses of the lung are not of necessity tuberculous in origin. When they are tuberculous in origin they arise from a small focus of circumscribed tubercle in which there has been mixed infection with the bacteria of suppuration; but many cases are not tuberculous at all. In reaching a cavity the lung-tissue should be divided with a Paquelin cautery-knife heated to a dull red. If the instrument is inserted slowly, there will be but slight hemorrhage. The pulmonary tissue is not sensitive, and, if the pleura is incised, the anesthetic can be withdrawn. Tuffier proposes to separate the parietal pleura, and thus avoid opening the pleural space; but the proposal has never been generally accepted. Richard expressed the view that the operation in most cases is impracticable. After opening the tuberculous cavity Roux advises that the two layers of the pleura be sutured together. Willard proved by experiment on animals that the pleura can always be made to unite by direct suture, or by drawing the lung into the opening made by the rib-excision and suturing this to the edges of the opening. This should be done before operation; the pleural space is thus excluded and its infection avoided. Resection of the lung would seem to be a rational method of procedure in pulmonary tuberculosis; but when we come to reflect, we remember that the pulmonary structure is more susceptible than any other tissue in the body to infection by the tubercle-bacillus, and its anatomical peculiarities favor extension of the infection and reinfection of parts whose vital resistance has been lowered.

Gluck and Schmidt performed experimental resection on dogs, and these operations led to the hope that the operation could be successfully applied in phthisis, but the experiments on animals have not increased the confidence of

surgeons in the possibility of extirpating an entire lung. The latter procedure is not justifiable. Tuffier reports the first successful case of pneumotomy for pulmonary tuberculosis. The disease was limited to the right apex and the diseased area was resected. Two years after the operation there was no return of the disease. Reclus is a disbeliever in resection of diseased portions of the lungs. He says in extensive disease it is useless, and in small foci it is unjustifiable, as the latter frequently disappear under other treatment. Fowler, in conclusion, discusses tuberculous lesions in the mediastinal spaces and tuberculous pericarditis.

J. McFadden Gaston¹ sets forth an improved **method of exploring the thoracic cavity**. He makes a trap-door opening through the wall of the thorax. In performing this operation the arm should be raised above the head. An incision is carried downward through the soft parts and ribs from the 3d to the 8th rib inclusive, in the mid-axillary line, without cutting the pleural lining. A transverse incision is begun over the upper extremity of this cut along the upper border of the 3d or 4th rib, and a single transverse incision over the lower extremity of the first cut along the border of the 7th or 8th rib. These transverse incisions are carried front to the costal cartilage. The pleura in each line is divided by means of scissors, and the detached margin of the flap is elevated; the trap-door opens upon the hinges formed by the costal cartilage and admits of examination of the chest and mediastinum.

J. E. Platt² considers treatment of **wounds of the air-passages**. Until a few years ago almost all authorities discountenanced the use of sutures in wounds opening the air-passages. In 1892 Henry Morris recorded a number of cases in which he applied sutures. Pellard advocated the same treatment, reporting 10 cases, of whom 2 died and 7 recovered, with 1 incomplete recovery. Treatment: when the condition permits, chloroform, clean wound, suture the opening. In some cases close the wound entirely; in others put in tracheotomy-tube. If the larynx or trachea is divided near the vocal chords, a tube is best, as edema of the chords may follow. If the epiglottis is injured, do laryngotomy or high tracheotomy before closing the laryngeal wound. Do not use the wound for insertion of the tube, but make a fresh vertical cut. One case in which the tube was used in the wound was followed by stenosis from cicatrization. Silk is the best material for suturing. Feed with liquid food by the mouth, except when the epiglottis is injured or when the larynx or trachea is divided, or when the pharynx or esophagus is opened—then feed by the rectum. The conclusion reached is that wounds of the throat should be treated by primary sutures when the condition of the patient permits; use antiseptic precautions; use chloroform for the anesthetic; suture the cut muscles; correct the inversion caused by the platysma muscle. Wounds of the air-passage should be closed; make a fresh vertical wound for the tube when one is used; use silk for suturing the larynx or trachea; except in special cases, feed by the mouth. [There can be no doubt that the surgeon's duty is to suture, in the hope of obtaining primary union; and, further, there can be no doubt that primary union can generally be obtained.]

H. Milton³ gives the description of an operation on the cadaver by which the **mediastinum is exposed** from the thyroid cartilage to the xiphoid. An incision begins at the notch, and by sawing through the sternum the structures beneath are exposed. Another method is to begin at the junction of the xiphoid with the gladiolus and cut up. The author has done this on the living with success. The operation is described on a case of infiltrating

¹ Med. News, Nov. 7, 1896.

² Brit. Med. Jour., May 8, 1897.

³ Lancet, Mar. 27, 1897.

tuberculous disease of sternum with tuberculous mediastinal glands. Remarkably little hemorrhage occurred. The costal respiration ceased, but the diaphragm worked freely. Nearly all the sternum was removed. Little shock followed. The wound was packed with gauze for 48 hours, then closed. Recovery ensued and the respiration was easily carried on.

DISEASES OF THE VASCULAR SYSTEM.

Bosc and Vedel¹ publish some experiments on the **effects of intravenous injection** of various solutions. They find that distilled water is very injurious when injected into the veins, but that ordinary water is not harmful or certainly far less harmful than distilled water, and in an emergency it would be quite justifiable to inject common water. Solution of common salt is entirely harmless if the amount of sodium chlorid is not greater than 3 times the amount of sodium chlorid normally present in the blood. The best strength to use is 7 : 1000. Artificial serum is in no sense superior to ordinary saline solution.

Reverdin² asserts that **sodium sulfate** administered in small doses is a **valuable styptic agent**, which is particularly useful in hemorrhagic diathesis and epistaxis, capillary hemorrhage, and like conditions. Its great use is in arresting oozing. It will not arrest bleeding from arteries or veins. It increases the rapidity of clotting of the blood, and it can be given intravenously or by the mouth, but hypodermatic injections do not produce styptic results. The dose is $1\frac{1}{2}$ gr. every hour until the bleeding is controlled.

Bienwald³ reports a case in which he stopped a hemorrhage in a hemophilic by taking blood from a healthy person and applying it to the oozing wound.

Lewis A. Stimson⁴ discusses the use of **intravenous saline injections in shock**. He says that it is well known that these injections are of benefit when administered after a severe operation accompanied by considerable hemorrhage and shock, but it is not so generally known that the same method is of advantage even if shock is not accompanied by hemorrhage. Stimson reports several cases to confirm this statement. He also tells us that in severe septic conditions the use of these injections is of great advantage. He saw them used for this purpose by Prof. Pozzi, of Paris, in a case of puerperal septiemia. Stimson reports a case of his own, and tells us that the good effects of intravenous injections are due to the increase of intraarterial pressure and the freedom with which osmosis is in consequence carried out. It seems also possible to believe that the large additional amount of water favors excretion and metabolism, diminishes the production of harmful compounds, and favors the elimination of those which have been produced. It is not directly curative, but it stimulates the organism and may enable it to recover from shock or to throw off septic attacks, and during this period we can employ other remedial measures. The technic is one of extreme simplicity. A graduated nozzle, which is carefully sterilized, is fitted with a rubber tube 3 ft. long, terminating in a glass nozzle. The solution is prepared by mixing 92 gr. of common salt with a quart of water and sterilizing it by boiling. That amount is secured practically by using a large teaspoonful of salt. The temperature at which it should be injected is 105° . A vein is exposed with a ligature slipped beneath it and the vein opened half across by cutting with scissors. The tube is filled with water, the glass nozzle is passed into the vein, and the ligature is tied so

¹ Gaz. des Hôpitaux, p. 398, 1896.

³ Sem. méd., May 5, 1897.

⁴ Med. News, Dec. 19, 1896.

as to keep the tube from slipping. The vessel which holds the solution is raised 2 or 3 ft. above the bed and the solution is allowed to run in. Some have maintained that hypodermoclysis is equally beneficial; it is certainly much simpler. [There can be no question that Stimson is right. Again and again have we seen pure shock without hemorrhage successfully combated by saline transfusion, rectal injection of saline fluid, or hypodermoclysis. In grave conditions transfusion is the preferable method. We always use Collin's apparatus. It enables us to measure the amount used and certainly excludes air. We have never used saline transfusion for sepsis, but consider its employment in this condition justifiable. In post-operative anemia the procedure is sometimes of great utility.]

William Horrocks¹ reports an interesting case of **acute aneurysm of the abdominal aorta**. Both iliac arteries were occluded by emboli and the patient was paraplegic. One interesting symptom was the presence of hemoglobin in the urine. The postmortem examination showed that the paraplegia could not have been of spinal origin, because there was no spinal lesion discovered and there was no interference with the circulation in the lumbar arteries.

Charles Watson MacGillivray² reports a case of that rare condition, **inguinal aneurysm**. The patient was 64 years of age, and had suffered from an aneurysm for about a year. The artery was tied by Abernethy's method, the incision being somewhat modified to suit the case. The incision was placed further upward and outward than in the typical Abernethy operation. On the second day there was found to be again slight pulsation in the sac, and this was well marked on the fourth day. This pulsation diminished somewhat, but did not entirely disappear, and 2 months later a bruit again became perceptible. It was evident from a careful study that blood passed into the aneurysm, but chiefly from the distal side. Compression by flexion, tourniquets, weights, and elastic bands below and over the tumor was tried, but it produced only temporary lessening of the signs. Two methods of treatment suggested themselves as worthy of thought: 1. Excision of the aneurysm and tying the branches which entered it; 2. Cutting down on the distal side and tying all the arteries that entered from below. The first did not seem advisable, as the original size and position of the swelling suggested adhesions to the peritoneum above and to the vein on the inner side. The second method was decided upon. This was carried out and the patient made a complete recovery.

Edmond Souchon³ reports an interesting case of **high femoral aneurysm** which was cured by the synchronous ligation of the external iliac and superficial femoral arteries below the sac, by excision of the sac, and ligation of the common femoral for hemorrhage. The external iliac was ligated by Sir Astley Cooper's method. The superficial femoral was then ligated below the sac. The intention was to dissect out the sac, but as soon as the integuments were incised it ruptured spontaneously. There was a considerable amount of hemorrhage from the proximal end of the sac. The bleeding orifice was plugged by the finger while a ligature was passed around the artery.

John B. Murphy⁴ reports two cases in which after resection of blood-vessels in the human being he practised **end-to-end suture**. In one case the femoral and internal saphenous veins had been injured by a pistol-bullet. An incision was made, the wounds in the saphenous were closed by the use of a continuous silk suture, the profunda branch of the femoral vein was sutured,

¹ Brit. Med. Jour., Jan. 16, 1897.

² Lancet, Aug. 29, 1896.

³ New Orl. M. and S. Jour., Aug., 1896.

⁴ N. Y. Med. Rec., Jan. 16, 1897.

and the wounds of the femoral vein were closed by a continuous silk suture. Infection took place from the injury and suppuration occurred. Five weeks later severe hemorrhage began. An incision was made, and it was seen that the hemorrhage was due to a slough an inch in length of the inner side of the femoral artery. The artery was tied above and below the slough and the damaged portion of the vessel removed. The patient recovered without any edema or any signs of circulatory trouble. In the second case the common femoral artery was perforated by a pistol-ball $1\frac{1}{2}$ in. below Poupart's ligament. A considerable portion of the walls of the artery was damaged; the bullet passed downward and backward, and perforated the femoral vein just above the junction of the profunda. The artery was gently clamped and the wounds in the femoral vein secured by continuous silk suture. Half an inch of the continuity of the artery was removed after about 2 in. of the artery had been exposed and the vessel had been isolated. At the proximal end for one-third of an inch the adventitia was turned up, and the proximal end was invaginated into the distal end and held there by 4 double threads. The threads were carried completely through the walls of the artery. A row of sutures was carried around the overlying distal end, passing through the media of the proximal end. The adventitia was then pulled down over the line of junction and sutured, and the clamps were taken away. Pulsation at once returned in the vessel; no edema of the leg ensued, and the circulation of the limb was restored from the moment of operation. As a result of numerous studies by the author, he has reached the conclusion that resection and suturing should only be applied to large-sized vessels, and that the vessels upon which this operation is performed must be handled most delicately, otherwise inflammation will ensue and thrombosis will take place. [The last case was brilliant in the extreme and opens up a new field in the surgery of the arterial system.]

Daniel H. Williams¹ reports a very remarkable case in which there was a **stab-wound of the heart and pericardium**. The pericardium was sutured; the patient recovered, and is alive 3 years afterward. The man was 24 years of age and was stabbed through the 5th costal cartilage. The internal mammary vessels, the pericardium, and the heart were damaged. The wound was 1 in. long, $\frac{3}{4}$ of an in. to the left side of the sternum, and in the long axis of the 5th cartilage. The probe could not be made to enter deeply, but during the night there was a great deal of hemorrhage, cough, pain over the heart, and shock. The following morning a careful examination demonstrated the fact that the knife had passed through the 5th costal cartilage in its long axis deep enough to enter the internal mammary vessels. When the weapon had been withdrawn the cartilage closed behind it and thus prevented the introduction of a probe. It was decided that an operation must be undertaken. The wound was lengthened toward the right side as far as the middle of the sternum, and over the centre of this incision a second incision was made. The second incision was about 6 in. in length and passed over the middle of the cartilage and the 5th rib. The sternum, the cartilage, and about 1 in. of the 5th rib were exposed. The cartilage was separated from its sternal junction and also from its attachment to the rib. Its inner attachments were separated, but its upper ones were left in place. The incised piece was lifted upward, and ready access was given to the internal mammary vessels, which were ligated above and below with catgut. In order to secure more room an incision was made in the 5th intercostal space. A small punctured wound was discovered in the heart. This wound was $\frac{1}{10}$ of an in. in length. The wound in the pericardium was $1\frac{1}{4}$ in. in length. There was no hemorrhage from either the

¹ N. Y. Med. Rec., Mar. 27, 1897.

heart or pericardium. The pericardial wound, having been irrigated with normal salt solution at a temperature of 100°, was closed with a continuous catgut suture. The intercostal wound and the subcartilaginous wound were closed with catgut, and the cartilages and the skin with silkworm-gut. The result proved that there was no cardiac, pericardiac, pleural, or wound infection. This patient went on fairly well for about 3 weeks, when evidences appeared of pericarditis with effusion and pleuritis. An incision was made in the 7th intercostal space in order to drain the pleural cavity, and 80 oz. of bloody serum were removed. After the operation adhesive straps were applied to the chest. The patient left the hospital well.

The author tells us that experiments upon the lower animals have been made to determine whether it is feasible to suture the heart and pericardium. Philippov made some of these experiments and Del Vecchio made some, and the conclusion was that suture of the heart and pericardium was practicable in the human being. Ferrarresi reports a case in which, as the result of a stab, the left internal mammary artery was cut at the level of the 4th cartilage. He resected from the 3d to the 5th cartilages to reach the internal injury. He decided that the woman's condition did not warrant suturing the heart, so he sterilized the wound, lightly compressing the heart, and arrested bleeding by sterilized tampons. The patient recovered. Turner reports a case of a man who received an incised wound over the left 5th cartilage. The cartilage was split, blood spurted into the air and hissed out at each heart-beat and each respiration, and the pleura filled with blood. The man lived $4\frac{1}{2}$ months. The left pleura became filled with pus, so the 5th rib was resected posteriorly to permit of drainage. The man died finally of what is called cerebral apoplexy. The postmortem showed that the left lung was collapsed, and the pleura adherent to the pericardium; the pericardial and cardiac wounds had healed; the wound in the heart was $\frac{3}{4}$ in. long, and had penetrated $\frac{5}{8}$ in. into the septum between the ventricles, and the left coronary artery had been divided. Dr. Elkton has insisted that it is very difficult to determine the existence of a wound of the pericardium and heart. There is no pathognomonic symptom, and the diagnosis is only reached after a study of all the symptoms. Moullin on one occasion made an attempt to suture a wound of the heart and failed. In most wounds of the heart an antiseptic tampon is used to control hemorrhage and prevent infection. The *Index Catalogue* does not give a single case describing suture of the pericardium or heart in the human subject. [In the Congress of German Surgeons, 1897, Rahn¹ reported a case of stab-wound of the heart. He resected the 5th rib and found a wound of the right ventricle $1\frac{1}{2}$ cm. in length. This wound was closed with 3 silk sutures and the pericardial cavity was packed with gauze. The patient recovered. G. Sandison Bock² communicates a case of perforating wound of the pericardium and left ventricle. The wound in the ventricle was sutured by Parrozzani, of Rome. The patient recovered. Durante³ has reported a case of wound of the left ventricle which was sutured by Farení. The patient lived several days and died from causes unconnected with the heart-wound. Cappelan⁴ reports a case of stab-wound of the left ventricle. He resected the 3d and 4th ribs and sutured the wound in the heart. The patient lived $2\frac{1}{2}$ days.]

E. P. Hershey⁵ reports a most interesting case of **sacculated aneurysm of the innominate artery**, which was **treated by the introduction of gold wire and the use of galvanism**; 14-karat gold wire was taken and drawn out to No. 28 gauge, and the jeweler who drew it out conceived

¹ Lancet, vol. i., p. 1306, 1897.

³ Rev. de Chir., p. 335, 1897.

⁴ Norsk Magazin for Loegevidenskaten, Mar., 1896.

⁵ Therap. Gaz., Sept. 15, 1896.

the idea of snarling the wire, so that when it passed through the needle it would bunch itself rather than coil. The needle used was a hypodermatic needle with a caliber of about 22, and it was completely insulated by the application of layers of gum-shellac varnish. The current was supplied by a 30-cell galvanic battery, and was passed through a McIntosh milliamperemeter. The patient was prepared antiseptically for the operation. When the insulated needle was passed through the sac blood spurting to a considerable height, but this was arrested the minute the introduction of the wire was begun. The intention was to fill the cavity entirely with wire, it having been supposed that 10 ft. would accomplish this; but after $2\frac{1}{2}$ ft. had been inserted the wire kinked and no more could be introduced. The wire was cut off about 3 in. from the needle; the positive pole of the battery was attached to the wire, and the negative pole was attached to a flat wet sponge covering an iron plate, which plate was placed on the skin of the back directly opposite the aneurysm. As the current passed the patient was at first uneasy and suffered from a certain amount of pain from the negative electrode. The number of cells was gradually increased, the current being kept at 70 ma. The needle as it swung rhythmically was a guide as to what was taking place. During fully three-quarters of an hour the motions of the needle never varied; but when a change took place in the motions of the needle the current was cut down to 60 ma.; as the motion of the needle became less the resistance became greater, until, finally, at the end of one hour and five minutes 40 ma. were used, the motion of the needle being then barely perceptible. At this time, instead of the existence of a soft, pulsating mass characteristic of aneurysm, there was a hard tumor which was very much smaller than the original sac. The needle was hard to remove, coagulated blood cementing it in place. It was gotten out and the wire cut off close to the skin, pressure being made around the point of exit. As soon as the tension was released the wire slipped out of sight, there having been sufficient spring in the mass of wire to pull the single strand into the sac. This man was very greatly improved by the operation. Nine and a half months after operation he is in excellent condition; he still has some pain in the chest, but the symptoms of aneurysm have entirely subsided. This aneurysm was closed by actual clot-formation.

Moore, of London, was the first to practise introduction of wire into the sac. His treatment was not successful. It is not to be wondered at when we reflect that he inserted 25 ft. of wire, and that this was practised before antiseptic details were carried out. Levis tried the introduction of horseshair; Schrotter used Florence silk. Macewen, of Glasgow, has suggested a method of treatment which consists in scratching the inner wall of the aneurysm, thus setting up inflammatory action and thereby strengthening the wall. Considering the fragile character of the sac, this is indeed a hazardous operation.

There have been ten cases reported in which aneurysm has been treated by the combined method of the introduction of wire and the application of electricity. Burresi reported a case in which 17 in. of No. 30 wire were introduced. The current was applied for 25 minutes. A firm clot formed, but the patient died in 100 days.

Barwell passed 10 ft. of steel wire into one division of the sac in a large aneurysm of the ascending and transverse parts of aorta; 10 ma. for one hour and ten minutes. At the end of six hours there were evidences of consolidation. On the fourth day a secondary sac rapidly increased in size. Death occurred on the 7th day. The postmortem showed the first sac contained a considerable amount of fibrin which closely united the sac and the wire. Roosevelt reported a very bad case of aortic aneurysm into which he intro-

duced 225 ft. of fine steel piano-wire, and passed a current of 25 ma. for half an hour. The patient was obviously improved by the operation, but death occurred on the 23d day.

Abbe reported a case in which he introduced 100 ft. of No. 1 aseptic catgut; a portion of the tumor became firmer, but another portion was found to be advancing rapidly. Nine days after this he inserted an aspirating-needle and passed 150 ft. of fine sterilized wire into the sac, and for half an hour employed a current of 50 ma. The anode being applied, followed by 100 ma. for an hour and reversed; cathode the active pole. The tumor-wall was thought to be firmer, but pulsation continued and rupture took place on the second day.

Kerr introduced 6 ft. of silver wire into an aneurysm reaching from the base of the heart to the beginning of the left subclavian artery. He applied a current for 50 minutes. Both pain and pulsation were improved, but death occurred on the 18th day, and postmortem showed that a firm clot had formed about the wire as well as on the sac-wall.

Kerr reported a case of aortic intrapericardial aneurysm in which electrolysis had been tried without success. He then introduced 10 ft. of silver wire and applied a current for half an hour. Six months afterward the patient was in excellent condition, and the case is considered a cure.

Rosenstein reported a case of aneurysm in the ascending portion of the arch. Galvanopuncture was employed twice: first, a single needle was used and 70 ma. were passed for 20 minutes. Thirteen days later this was repeated with two needles. No benefit was observed. Five and a half weeks later something over 2 ft. of wire were passed into the sac. Pulsation disappeared the 7th week and complete recovery followed.

Stewart reported a case of thoracico-abdominal aneurysm into which $2\frac{1}{2}$ ft. of wire were inserted, a current of 70 ma. having been passed for an hour. It ruptured on the ninth day. The postmortem showed that there were firm clots in all parts of the aneurysm, with softened ones of recent origin. Stewart also reported a second case which was greatly benefited by the introduction of fine gold wire, and the application for an hour and a quarter of a current of 80 ma. Taking into consideration these cases that have been reported, we have 30% of cures, 20% benefited, and 50% fatal, and in none of the fatal cases was death due to the operation.

DISEASES OF THE LYMPHATIC SYSTEM.

De Forest Willard¹ writes on **tuberculosis of the superficial lymphatic glands**. He tells us that the seat of invasion is to a great extent influenced by injuries or abrasions. The fact that the legs are but slightly exposed to sources of injury renders tuberculous disease of the lymph-glands of the groin unusual. The hand, though considerably exposed to injury, is protected by hard epithelium; but the face and neck are very liable to scratches, eczema, trivial wounds of the skin and mucous membranes, catarrhal inflammation, etc. A slight area of injury is more apt to give entrance to tubercle-bacilli than are large wounds, probably because in large wounds the tissue-changes are more active. When germs once enter, the vigor of the opposition by the organism depends upon its inherent vital resistance. The first point of arrest of the bacilli is usually in the lymph-nodes, and at this point the organism may be successfully arrested if the tissue-resistance of the individual is at a high level. At times the glands originally infected fail to arrest the

¹ Ann. of Surg., Dec., 1896.

trouble, or a number of bacilli pass the point of infiltration and reach other glands, the route depending upon the direction of the lymph-current. In the neck it may be along through the superficial or the deep glands. Willard commends attention to the diagram prepared by Gerrish, which shows how infection from the brow, eyelids, or outer cheek will be first arrested in the glands of the parotid region, while infection from the frontal, nasal, and deep buccal region will be arrested first in the submaxillary glands, and will then be carried to the superficial cervical. When the infection begins in the deeper tissues of the cheek, or the upper jaw or the cavity of the nose, or the roof or floor of the mouth or the tongue, it will be carried to the internal maxillary glands and thence to the deep cervical. The deep cervical glands may also be infected from the pharynx, the larynx, and the trachea, and the infection may be distributed from them to the superficial mediastinal and the axillary glands. The resisting power of the glands in the groin seems to be lessened by the existence of a syphilitic element, and clinical facts indicate that the bacteria of syphilis and of tuberculosis are not antagonistic.

One method of the arrest of the tuberculous process is the blockage of the lymph-spaces by inflammatory exudate. It is rare for infection to travel into the periglandular connective tissue, and it is still rarer for it to travel in a direction opposite to that of the lymph-stream. In some cases both the superficial and deep glands are affected at the same time. If the lymphatics fail in their power of resistance, the infecting material will be carried into the general circulation and produce distant disease and even miliary tuberculosis. The virulence of a caseous focus is dependent upon the spores rather than the bacilli, and these spores may retain a power of infection for an indefinite period. Willard calls attention to the fact that though he has very frequently seen tuberculosis of different parts of the body ensue on tuberculous disease of the lymph-glands of the neck, he has never seen cervical lymphadenitis result from tuberculosis of the lungs. The author then contrasts certain points of diagnosis. He says that in syphilitic infection we should be able to find the initial lesion or the evidences of the initial lesion, and if the disease be in the second or tertiary stage, we should find obvious evidences of its existence. A simple inflammation or an acute suppurative inflammation is very rapid in progress, and there is either a traumatic cause of the condition, or else the existence of a septic cause, such as scarlatina. In cancerous involvement of glands we can usually find a primary trouble, the enlargement of the glands being secondary to this, as a rule. Primary cancer of lymph-glands is a rare condition. Sarcoma is usually single. It reaches a great size, rarely suppurates, grows rapidly, involves the surrounding tissues, and does not caseate. Secondary lymphosarcoma is a rare condition. Adenomata are single, not multiple. Lipomata are single. Pseudoleukemia shows enlargement of glands in other parts of the body and the affected glands do not caseate. In lymphadenoma there are enlargement of the spleen and increase of the number of white corpuscles in the blood. In tubercular disease it may or may not be possible to find the organism.

Willard is an advocate of early operation, but he does not believe that it is advisable when only 1 or 2 glands are involved to lay open the neck to its entire extent. He would remove the obviously infected glands, but not the non-indurated ones. The operation, when the mass is extensive, is a serious one. The surgeon is often unable to tell before the incision is made whether the deeper glands are implicated or not. He is working among vital parts, and yet the operation must be thorough. A large incision is necessary for safety, and it is sometimes necessary to lay aside the sternomastoid muscle. When the glands

have become adherent to the skin this infiltrated tissue should be excised. We should be careful, if possible, not to open the capsule, as the diffusion of tuberculous matter in the wound is a very unfortunate event. Care should be taken not to tear off short branches of the jugular veins. Such an accident is liable to be followed by the entrance of air into veins. If such an opening be made, the fingers should at once close the aperture and then compress the carotid artery against the carotid tubule. The next procedure is to ligate the vein or apply lateral ligature. It has been suggested that in such an accident the wound should be kept full of water to prevent the entrance of air. Willard has not found this nearly so effective as finger-pressure. With pressure on the proximal end of the vein the blood from the distal end will keep the wound clearly filled. Pressure should be continued until the vessel has been secured. Artificial respiration may be practised to prevent immediate collapse, and electricity may be employed if available. Lateral suturing in these cases has proved most satisfactory.

It is rare that the pneumogastric nerve, the descendens noni, or phrenic is injured; but when we lift them from their beds the diaphragm is apt to be interfered with for a time. It has long been observed that dyspnea and congestion of the lungs were more apt to follow neck-operations than operations upon any other part of the body. Injury of the pneumogastric is not necessarily fatal, but is, of course, serious, and will probably be followed by broncho-pneumonia, edema, or some other lung-trouble. If we should happen to divide any of these nerves, they should be immediately sutured with fine silk or chromicized gut.

Willard is very fond of using iodine in these conditions, and believes that it markedly inhibits the growth of the microorganisms and stimulates the production of healthy granulation. Iodine injected into sinuses greatly aids in their closure. He has never seen any benefit result from the intraglandular injection of iodoform or chlorid of zinc—in fact, such measures hasten suppuration. If the patient refuses operation, he can gain considerable by the internal use of arsenic, iron, cod-liver oil, potassium iodid, guaiacol, or creasote, by living in good air, and employing proper food. The above means should be employed in both operative and nonoperative cases. Sero-therapy is still in its experimental stage. Antiphthisin gives negative results. He has had no experience with the use of asepticin and antituberculous serum. Nuclein and protonuclein he has used chiefly locally. These agents favor the production of healthy granulations. A mixture of thymol iodid, or aristol, and protonuclein is of great value in sluggish granulation. [There can be no doubt that in some cases tuberculous glands arise secondarily to enlarged tonsils and adenoids. In such cases R. Sims Woodhead has found bacilli in the tonsils or the adenoids. H. Starck has shown the causative influence of carious teeth. In 113 cases of tuberculous glands 41 were obviously secondary to caries of the teeth, and in 2 cases tubercle-bacilli were found in the teeth-sockets.¹ Nicoll says that in 80% of cases the cause of the glandular enlargement will be found in the nasopharynx, and that many nasopharyngeal catarrhs are tubercular. Dieulafoy has found bacilli in the tonsil and glands of the tongue. It is always to be remembered, however, that numbers of tubercle-bacilli may be found in the mouth of a healthy individual. Another fact of importance to remember is that it is not always possible to make a clinical diagnosis between malignant lymphoma and tuberculous adenitis. It sometimes happens that tuberculous glands attain a large size without softening, and that enlarge-

¹ Münch. med. Woch., xliii., 145, 1896.

ments due to malignant lymphoma do soften. In fact, Dietrich has asserted that malignant lymphoma may be combined with glandular tuberculosis.]

J. Crawford Renton,¹ in a discussion of the **treatment of tuberculous glands of the neck**, stated that he recently advocated free excision of the glands, but the result of this procedure is far from satisfactory. In the cervical region it often happens that, after we have removed all of the glands that are enlarged, other glands enlarge and require removal. On account of this repeated enlargement of remaining glands he has recently gone back to the old method of treatment, and now only dissects out glands where softening has commenced and where the smallest possible incision can be made, and where the gland can be removed entire by a small incision after it has been lessened by partial enucleation. [Such a method cannot protect the system from invasion. Thorough extirpation is preferable.]

Harold J. Stiles² presented a paper on **tuberculous disease of the cervical glands**. He tells us that the treatment of tuberculous glandular abscess consists in incision, scraping with Volkmann's spoon, the application of pure carbolic acid, and stuffing with iodoformized worsted. The incision should be made parallel to the skin-creases, and, unless the abscess be very small, ought to be large enough to admit the finger. The scraping is kept up until all caseous or purulent matter has been removed from the wall of the cavity. When this has been accomplished the wall of the cavity will feel smooth. The application of pure carbolic acid is an important element in the treatment. Iodoformized worsted is a better agent than iodoform-gauze. It is softer, more elastic, absorbs better, and is a better capillary drain. Another advantage of this iodoform worsted is that it is very convenient for packing sinuses, and it can be prepared freshly with great ease. The carbolic acid does not cause sloughing. It often happens that a deep gland becomes adherent to the cervical fascia, bursts through it, and causes an abscess subcutaneously. In all such subcutaneous collections the surgeon should open the abscess by a moderately large incision and make search for an opening in the deep fascia, and through this opening find the remains of the caseating glands. Caseous and purulent tuberculous adenitis is very difficult to deal with when situated behind the pharynx or in the region in front of the auricle. The most common cause of retropharyngeal abscess in children is tuberculous adenitis. The abscess may be reached by three routes: by the mouth, by Chiene's plan of making an incision at the posterior edge of the sternomastoid, or by Burekhardt's plan of incision in the anterior triangle. The best method is that of Chiene. The great advantage of this over the old method of opening through the mouth is that the abscess can be treated aseptically. Tuberculous adenitis of the preauricular region is under the cervical fascia and close to the parotid gland and the facial nerve, and the tuberculous gland adheres to these structures and also to the skin, and it is seldom proper to attempt to excise it when it is immovable. In fact, a salivary fistula may arise from simply scraping the gland. Scrape it through a very small incision made at its lower part. If the gland is but slightly caseous or is altogether solid, if it has existed for months, and is uninfluenced by general treatment, it should certainly be excised if it is still movable. Excision of a movable gland in this situation is but a trifling operation, and but a slight scar is left. If glands in the neck are adherent to the veins, nerves, and other deep structures, the difficulties are vastly enhanced. In this case we should have large incisions in order to get a clear view of every structure before we cut it, and we should not mistake stretched veins for bands of fascia. A blunt dissector will be a

¹ Brit. Med. Jour., Sept. 12, 1896.

² Ibid.

great aid in the operation. If one gland is softened so that it fluctuates, treat this gland by scraping and the use of pure carbolic acid before excising the mass. Do this in order to prevent infection of the wound, and we will then be enabled to suture the wound after completion of the operation. In this operation take care that the patient's hair and the chloroform-mask do not infect the wound. The best apposition is obtained by the use of a continuous suture of horseshair or fine silk, the assistant lifting the edges of the wound and putting them on the stretch while it is being sewed. Stiles says that we must not suppose that he advocates excision in all cases. It should be the rule in adults when the disease is localized to the neck, but there are many instances in young children where it is not advisable. In young children there is generally some local source of infection, the gland-disease is very active, and softening and abscess-formation are almost certain to occur. This makes complete excision a very difficult matter because of the matting together of the structures which ensues. The older the child the more must the question of complete excision be entertained. The operation is not advisable in very young children. It may not be possible to accomplish excision at one operation. It is often wise to do but one side of the neck at a time, and two or even three operations may be necessary in order to eradicate the disease completely. If the patient is approaching adolescence, if he is otherwise in good health, if the disease is of long duration and has resisted all other treatment, and if there be no persistent source of primary infection, excision is to be practised. In case of extensive tuberculous infiltration of both triangles of the neck operate by the plan of Chiene—that is, remove the jugular vein along with the mass of glands. This makes the operation easier and more thorough. In speaking of the points of diagnosis it is commonly stated that when tuberculous glands reach any considerable size they always caseate; but Stiles has seen tuberculous glands as large as pullet's eggs, which exhibited no trace of caseation. Surgeons are apt to speak of such glands as examples of simple lymphomata. The microscope often shows that non-caseous glands are tuberculous.

George Ryerson Fowler¹ reports a case of **elephantiasis of the lower extremity** which was cured by ligation of the external iliac artery. The boy was 16 years of age, and 7 years before he had suffered from double suppurating inguinal adenitis. The mass on the left side was opened, but the right side evacuated itself spontaneously. Shortly after this the lower extremity of the right side began to enlarge, and this increased to a considerable degree. Fowler then submits the measurements of the 2 limbs to show the difference between them. The patient was placed in the Trendelenburg position; a 3-in. vertical incision was made in the right semilunar line and the external iliac artery was ligated by the transperitoneal method. The patient recovered without trouble from the operation and was greatly improved by it; 6 weeks after the operation the legs were practically of the same size. Fowler says that the transperitoneal ligation of the iliac artery is easy, but is no easier than the extraperitoneal method of ligation, and it increases the dangers to the patient because of the possible onset of peritonitis.

Carnochan originally suggested ligation of the femoral below Poupart's ligament in this disease. Hueter suggested ligation of the external iliac artery. Fowler believes this is the first case in which Hueter's suggestion has been carried out.

¹ Brooklyn Med. Jour., Feb., 1897.

DISEASES OF THE THYROID GLAND.

Gayet¹ makes a report on the **treatment of Basedow's disease** by the plan of Jaboulay—that is, by removal of the cervical sympathetic ganglion and division of the nerve below the ganglion. The patient had had an exophthalmic goiter for 5 years; ether was given, and an incision 3 in. in length was made on the left side, beginning about 2 fingers' breadth below the mastoid process and running down close to the posterior edge of the sterno-cleido-mastoid muscle. This muscle was retracted and the structures below exposed. The pneumogastric nerve, the internal jugular vein, and the carotid artery were drawn forward. This maneuver exposed the sympathetic, and the fact that it was the sympathetic which was exposed was made manifest by the dilatation of the pupil when the nerve was irritated. The cervical ganglion was removed with several of its branches, and the trunk of the nerve was cut below the ganglion. On the right side the same operation was performed, differing only in the fact that the trunk of the nerve was sectioned above the ganglion. On the evening of the operation the exophthalmos had absolutely disappeared. Improvement continued during the next day, and on the 8th day the patient left the hospital apparently well. The operation of complete removal of the thyroid gland is not practised in these days because we know it occasions myxedema.

Incomplete removal is the favorite operation. Four-fifths of the patients operated upon recover, but recurrence is common, and often after operation very rapid growth takes place. Sometimes thyroid-intoxication follows operation. The operation of simply exposing an exophthalmic goiter is not often curative, and occasionally the symptoms of systemic intoxication follow its performance. Ligation of the thyroid arteries is an operation of considerable difficulty. The division of the sympathetic nerve is a safe procedure and is easily performed, and the favorable effects seem to be permanent. [Thyroid extract is not useful in true exophthalmic goiter—in fact, it is believed to aggravate the condition. Some hours after the performance of a partial thyroidectomy sudden death may occur, and the cause of such death cannot be determined by autopsy. Delore recently reported such a case. Operation in exophthalmic goiter is often difficult, as the capsule and blood-vessels are very friable and the administration of an anesthetic is fraught with peculiar danger. We disagree entirely with the view of Lemke that exophthalmic goiter is always a surgical disease. It is sometimes a surgical disease. It should pass into the hands of the surgeon if medical treatment fails, or if evidences of grave toxemia are present, and if marked dyspnea exists.]

The *Annals of Surgery* for March, 1897, contains an abstract translation of an article by H. Bergeat, of Tübingen, the abstract having been made by Charles L. Gibson, of New York. Bergeat considers **300 operations for goiter** performed in the Tübingen clinic. He tells us that the proportion of females to males is 2.5 to 1, and that in the male sex goiter is apt to begin between the 14 and 17th years and in the female between the 12th and 16th years. The majority of goiters occur in people who are obliged to perform hard manual labor. The list contains only 2 cases of complete extirpation. The operation of choice has been intraglandular enucleation, but there are a number of examples given of extracapsular extirpation. It is the opinion of the author that we can often combine these 2 methods with advantage. He holds that every nonmalignant goiter which is increasing rapidly in size ought to be operated upon, but we should never operate simply to relieve disfigure-

¹ Lyon méd., No. 30, 1896.

ment. In young people it is well not to be in too much of a hurry to operate, because goiters which begin at the time of puberty may undergo spontaneous cure. Respiratory disturbances are the usual conditions rendering an operation necessary. The majority of these patients had respiratory disturbances; 21 complained of difficulty in swallowing; in 33 the vocal chords of the goiterous side were in a condition of paralysis. There were 89 cases of parenchymatous goiter, 73 of cystic goiter, and 116 of the combined forms. In 53% the right lobe was the one almost wholly affected, in 22% the left lobe, in 7% the middle lobe, and in 18% the point could not be determined.

The author tells us that the parenchymatous form rarely comes to be operated on until it has lasted for some 14 or 15 years; but the cystic form, as a rule, requires operation within about 4 years. Of the 300 operations, 79 consisted in unilateral extirpation, 176 of enucleation, and 45 of the combined method. In 10 cases the operation was performed without the use of an anesthetic. The author greatly prefers operating without an anesthetic in a state of incomplete anesthesia, because incomplete anesthesia is very unsatisfactory. Besides this, when the patient is not anesthetized the recurrent laryngeal nerve can be recognized if it is grasped. It is very important to arrest hemorrhage. The average length of stay in the hospital after the extirpation of a goiter is 11 days, and after enucleation 9 days. In nearly every case there was some elevation of temperature during the course of the healing of the wound. This was due probably to septic absorption. The ultimate results of 84 of these cases were determined, and two-thirds of them show recurrence in some form.

The conclusion of the author is that one-sided extirpation is favored by the results. Operation for malignant growths of the thyroid is practically useless, and not a case survived operation after a year.

Charles A. Morton¹ discusses the **cause and treatment of sudden dyspnea in goiter**, and also reports a case in which the middle lobe of the thyroid was excised for this condition. He tells us that a person who has a goiter, but who has not suffered from dyspnea at all or who has only suffered moderately, may have a sudden attack which may be fatal. None of the theories that have been advanced to account for this are entirely satisfactory. A very few cases have been caused by hemorrhage into the goiter; but, of course, this condition is excessively rare. The theory of Rose is that the pressure of the enlarged thyroid makes the tracheal rings non-resistant, so that the trachea is apt to be bent and its lumen become obstructed. He thinks that in these cases of sudden dyspnea the trachea becomes kinked from relaxation of the muscles, which maintain the head in such a position as to keep the tube open, and that this is probably brought about either during sleep or anesthesia. But Morton shows that these cases do not occur always during sleep or anesthesia, and that very urgent dyspnea is rarely brought on by the relaxation of the muscles during sleep, for if the position of the neck were the cause of the dyspnea alteration of the position should relieve it, yet this is not the case.

Dr. Hurry thinks that the dyspnea is originated by some unusual exertion; that this unusual exertion, by originating a little dyspnea, leads to the bringing into action of extra muscles of respiration, and when they act the lobes of the thyroid are pressed against the trachea more; but, as a matter of fact, this dyspnea does not always come on because of unusual exertion.

Bristowe believes that the condition is due to inflammatory enlargement of the tissues and edema of the mucous membrane, but we know that this dyspnea is not particularly associated with laryngeal catarrh. Morton inquires if

¹ Bristol Med.-Chir. Jour., Sept., 1896.

pressure on the recurrent laryngeals can be the cause of the dyspnea. Its onset appears to be too sudden to be due to goiter-pressure on the nerves. Moreover, we cannot obtain relief by opening the air-passages above the goiter, and in the case here reported two severe paroxysms of dyspnea came on after the performance of laryngotomy. There is no doubt that a patient who is going about with a very small air-channel may suffer from urgent dyspnea when there is, any sudden demand for an unusual quantity of air. This was the cause in Jacobson's case, where fright was responsible for the attack; but all the cases do not show a history of some cause which would make them out of breath. In fact, in some of the reported cases dyspnea came on when the patient was quiet in bed. Morton reports such a case. In this case Morton opened the air-passages above the goiter and passed a tube down the trachea. The dyspnea was relieved and the patient soon was able to breathe as well without the tube as with it. The cause of the paroxysm, therefore, had departed; but after a few whiffs of chloroform were given the extreme dyspnea came on again, and later, while the operation of excision of the isthmus was being performed, dyspnea arose without any apparent exciting cause. We may, of course, assume that the chloroform acted in the same way as the sudden fright; but why, with a cannula in place, did dyspnea come on during operation? In this case Morton performed excision of the isthmus of the thyroid gland, and the result proves that excision of the isthmus alone is not always sufficient to relieve these patients, as in this case it was necessary to retain the tube for weeks after the operation. When we consider the great difficulty of reaching the trachea below the isthmus, the best thing we can do in these urgent cases is to open the air-passages above and pass a long cannula or catheter past the obstruction. If there is room between the isthmus and the cricoid cartilage, that is the best point; but if there is not, laryngotomy must be performed. We cannot expect to get a cannula or catheter down the narrow and devious trachea, through the mouth and glottis. The dyspnea is so rapidly fatal that we cannot undertake to excise a lateral lobe, and excision of the isthmus alone is useless. If the goiter is chiefly back of the sternum, we should perform a tracheotomy above the isthmus and attempt to pass a catheter into the right bronchus. After doing this the question will arise as to what form of excision to undertake. The existence of a septic laryngotomy-wound will prevent an aseptic course in the thyroidectomy-wound, and hence the removal of the isthmus alone may be practised with advantage, as excision of the isthmus is nearly always followed by atrophy of the remaining portions of the gland. It has been suggested that division of the fascia in the median line of the neck may give relief, the lateral lobes being thus to a certain extent freed from compression against the trachea; but opening the air-passages above the goiter and passing a catheter beyond the obstruction will be more likely to succeed. We should remember that compression of the trachea by unilateral goiter means compression by a cyst or an adenoma, and not by an ordinary goiter. If a cyst is present, the dyspnea can be relieved by drainage. Dyspnea from an adenoma would require the same treatment as dyspnea from an ordinary goiter.

Riedel¹ reports 2 cases in which there was some **chronic inflammation of the thyroid gland, with the formation of a mass of extreme hardness.** In this condition the tumor is closely adherent to the adjacent tissues, and it is impossible to separate the trachea and large vessels of the neck from the tumor. In the 2 cases reported by the author it was necessary to abandon attempts at removal. In one of these cases thyroid extract was administered without any benefit.

¹ Verhandl. der deutsch. Gesellsch. f. Chir., XXVth Congress, 1896.

DISEASES OF THE MUSCLES AND TENDONS.

Lejars¹ reports a very unusual case of **osteoma of the ligament of the patella**, the tumor having no connection with the patella itself or with the tibia. It was composed of compact bone-tissue and was as large as a walnut. It was necessary to remove it because it interfered with joint-motion. The tumor was removed without seriously injuring the ligament of the patella, and a portion of this ligament which was cut was sutured together. No loss of function followed the operation.

Hartmann² makes a study of 22 cases of **wry-neck** operated on in the Rostock clinic. In about one-third of the cases the result was perfect; in two-thirds it was imperfect. The cases were treated by division of the sternocleido-mastoid, the division having been sometimes open and sometimes subcutaneous. The author maintains that after division of the sternomastoid the muscle is apt to unite without any shortening, and that the failures in the operation are due to degenerative processes uninfluenced by the operation. Mikulicz recommends the entire removal of the muscle, but Hartmann asserts that this operation has had but a limited range of usefulness. The degenerative processes in the muscle will be arrested spontaneously eventually, and all that will be necessary will be to cut the shortened muscle.

Quervain³ considers **operations on the spinal accessory nerve for spasmodic torticollis**. He concludes that their chief value is as an abortive. In 61 cases that have been reported there were only 12 cures, although 22 cases were improved. Kocher was so disappointed with operations on the spinal accessory that he devised an operation which consists in completely cutting across all of the muscles which are involved. He treated 12 cases; 7 of them were completely cured. The other 5 are still being treated by manipulations and gymnastics, which Kocher holds must always be employed after this operation. The cross-cutting of the muscles does not cause atrophy, paralysis, nor rigidity of the head.

Andrew J. McCosh⁴ records a case of **rupture of the tendon of the quadriceps extensor** treated successfully by suture. This accident is by no means rare, and yet it is very often overlooked. It is very important that these cases should be treated properly soon after the injury. In many of them it is certain that surgical operation is not required, but in the majority of cases when there has been complete rupture either above or below the patella the nonoperative treatment is unsatisfactory. This is especially true of rupture above the patella. Maydl collected 40 such cases, and found that there was complete recovery in only about 60%, and in the 23 cases collected by J. B. Walker there was a complete recovery in 70%. Walker collected 21 cases, with complete recovery in 90% after suture. These operations are not absolutely devoid of risk, and this should be borne in mind. The most favorable time to perform the operation is when the acute stage of joint-hyperemia has passed away—that is, about 5 or 6 days after the accident; but the operation can be performed even when several weeks have passed away. In the first case reported by McCosh there was a delay of 8 weeks, and yet the recovery was perfect, and in the second case there was a similar delay which did not appear to influence the final result. The author reports 3 successful cases. In the first case there was complete separation of the quadriceps extensor tendon from the upper border of the left patella. A 6-in. vertical incision was made, which

¹ Gaz. hebdom. de Méd. et de Chir., Feb. 21, 1897.

² Ann. of Surg., Mar., 1897, from Beiträge zur klin. Chir., B. xv., H. iii.

³ Sem. méd., Oct. 14, 1896.

⁴ Ann. of Surg., Mar., 1897.

at once entered the joint and exposed the lower portion of the tendon and the patella. The hardened and irregular end of the tendon and the border of the patella were trimmed off. The operation disclosed the fact that the tendon had been torn directly from its attachment to the bone and had pulled with it some of the periosteum, but the lateral expansions of the tendon were only partially torn off. The joint was irrigated with hot saline solution and 3 drill-holes were made in the upper end of the patella, in which and through the thickness of the tendon silkworm-gut sutures were passed. The synovial membrane and the lacerated portions of the lateral expansions were sutured with catgut. The silkworm-gut sutures were tied and the incision closed by silk sutures without drainage; the limb was hyperextended and put up in a plaster-of-Paris splint, which was worn for 6 weeks. The patient made a complete recovery. [Operation is preferable because it saves months of time and is far more certain in result. It must be done if separation of an inch or more has taken place. If the separation is less than this, it is justifiable, though scarcely desirable, to apply the mechanical treatment if this treatment is found capable of bringing the ends in contact and holding them.]

Janni¹ reports a case of a soldier who during a march was seized with a very violent pain in the middle third of the left leg anteriorly and toward its outer side. This pain passed away after a few days' rest, but returned whenever an attempt was made to walk. This condition kept up for several months. Examination of the painful area showed that there was a small spot where the muscular resistance was less than throughout the rest of the leg. An incision was made and there was found a **rupture in the aponeurosis**. Janni then made some experiments on dogs, and discovered that after there was a small laceration of the fascia without muscle-injury no muscle-hernia occurred during either contraction or relaxation. [The author's experiments seem to show that, except under some very extraordinary condition, a muscle is not able to rupture its own sheath, but clinically we know that simple muscular contraction may cause a rupture of the sheath.]

Howard Marsh² delivered a clinical lecture on **displacements and injuries of muscles and tendons**. The most familiar examples of displacements of tendons are displacement of the tendon of the peroneus longus to the front of the external malleolus, of the tendon of the tibialis posticus to the front of the internal malleolus, and of the long tendon of the biceps inward or outward from the bicipital groove of the humerus. Displacement of a muscle is a rare condition and but few muscles are liable to it. Muscles which act in a straight line and do not pass over any bony prominence are not liable. The muscles which are liable may be grouped under certain headings: those which have their tendons deflected and which, as they pass around a bony prominence which acts as a pulley, rest in a groove which is bridged over by a ligamentous expansion. We see this in the case of the peroneus longus and the tibialis posticus as they pass behind the malleoli. From a consideration of the deflected course of the extensor digitorum pedis it would seem as if this muscle should be liable to displacement, yet there is no example of this injury on record. The reason of the immunity becomes clear when we consider the structure of the annular ligament. The next group of muscles which are liable are those which pass over bony prominences, and that undergo considerable subjacent movement to one side or the other of the tendon line. This is illustrated by the long head of the biceps cubiti. Those that slip over some bony ridge or projection, as a bundle of the splenius capitis or one of the tendons of the obturator internus. The symptoms of the muscular dislocation

¹ Riforma med., Nov., 1896.

² Brit. Med. Jour., July 25, 1897.

are obvious when the tendons can be seen and felt beneath the skin. In other cases diagnosis must rest on indirect evidence. In the third group diagnosis may be impossible; the surgeon can only have a suspicion that the injury exists. In this group the history may be of very great assistance in reaching a conclusion. In treating these cases we should place the part in a position so that the muscle is relaxed, and we can then effect reduction by means of manipulation. When reduction has been accomplished, if the muscular sheath is unlacerated, no treatment will be needed; but if the sheath has been lacerated, after-treatment is of the greatest possible importance. The peroneus longus is an example. As soon as the displacement has been reduced the foot should be placed at right angles with the leg, should be a little bit inverted, and be put up for a month in a splint of leather or plaster-of-Paris. This will give time for the torn edges of the sheath to grow together. Gosselin in a case of dislocation of the peroneus endeavored to cause inflammation by permitting the tendon to slip in and out for a few days with a view of securing adhesions, but Marsh doubts very much the advisability of endeavoring to promote inflammation. The question shall we operate always comes up. He has had no experience with operation, and does not know of an instance in which it has been performed. Published cases show that repair may take place without operation. Whether or not such an operation is advisable cannot be decided until experience has accumulated as to the results of treatment by fixation in an appropriate position. If we find that the results of this plan are not satisfactory, operation will certainly be indicated. Some would infer that immediate suture might be followed by the formation of adhesions between the tendon and its sheath; but if these should form, they would serve to keep the tendon in place, and at the worst they could only embarrass the action of a single muscle which was already out of gear. As a matter of fact, though, after an antiseptic operation adhesions are not likely to form. In speaking of rupture of muscle, Marsh says that he means rupture of single muscles by their own contractions during ordinary movement. Some examples of such injuries are then submitted. Marsh discusses **rupture of the ligamentum patellæ**, and reports a case which he sutured.

The treatment consists in the use of a posterior splint, with some means to keep the patella in place, or else suturing. In many cases the former method has given satisfactory results. When it is employed the patient should be kept in a horizontal position for two months, and should wear some form of retentive apparatus for from three to six months longer. Rupture of the quadriceps muscle in the thigh is an injury in regard to which considerable doubt exists. Some maintain that it will be followed by great impairment of function, and that the patient should not be permitted to walk for months without an apparatus. The correct view, however, seems to be that in the generality of cases the limb may be safely used for careful walking, without support, within about four months after the accident. A diagnosis of rupture of a muscle depends on a history of muscular effort, a sudden pain, and a sensation as if a part had been struck—possibly a distinct snap and the existence of a gap. When a tendon is ruptured there may be very little swelling at first, but when a muscle is torn there is usually a great deal of swelling, due to extravasated blood. In some cases, as when the quadriceps extensor is ruptured, the limb is powerless; but in others, for example, when the tendo-Achillis is torn, the patient may be able to walk with comparatively little difficulty. Experience shows that when a tendon, for instance the tendo-Achillis, is ruptured, if the limb is placed in a position in which the origin and insertion of the muscles concerned are approximated, and the ends of the

tendons are not widely separated, the result is usually good. Whether operative interference is likely to secure a better result is uncertain. Two circumstances justify and may demand interference. First, wide separation of the ruptured ends, which cannot be corrected by other means. Second, a considerable extravasation of blood. If the fleshy parts of the muscle are torn, it is useless to attempt to suture the ends, as the stitches will not hold; but if a large blood-clot is present and near the surface, it will be advisable to expose the swelling by a free aseptic incision and remove the clot. At the same time any available portions of the sheath of the muscle should be sutured.

Perimoff¹ has devised an **operation for the cure of dislocation of the peroneal tendons**. An incision is made, the external malleolus is exposed, and the periosteal bone-flap is lifted up to right angles with the malleolus. This flap has the shape of a trapezoid. The flap-hinge is the posterior border of the external malleolus, and as long as it remains in position the tendon cannot slip forward. The flap is kept upright by driving two nickel nails into the malleolus until bony union has taken place. A plaster-of-Paris bandage is applied and worn for 6 weeks. The nails are removed in the 3d week. [If we are called to a patient who has suffered from this accident for the first time, it is proper to treat him by rest, pads, and bandages. In some 6 weeks the tendon will probably become firmly held. But a patient who has once had this accident is liable to suffer again from a slight cause, and the tendency to dislocation may become habitual. Operation must then be performed.]

R. Carmichael Worsley² reports a case in which he obtained union of the cut tendons of the extensor primi internodii and extensor ossis metacarpi pollicis 5 years after division. The ends were separated by $1\frac{1}{2}$ in. of fibrous tissue, but the result was most satisfactory.

S. E. Milliken³ publishes an additional paper on his method of **tendon-grafting and muscle-transplantation** as applied to the deformities ensuing upon infantile paralysis. He has operated 14 times on 9 patients. The operations were classified as follows: transplantation of the sartorius muscle into the sheath of the quadriceps extensor of the thigh, transplantation being partial or complete; grafting the extensor proprius pollicis to the paralyzed tibialis anticus; attaching the tibialis anticus to the paralyzed extensor longus digitorum; attaching the extensor proprius pollicis to the paralyzed common extensor; attaching the gastrocnemius to the paralyzed peroneus longus and brevis; the extensor longus digitorum was attached to the paralyzed tibialis anticus once; the extensor proprius pollicis was attached to the paralyzed extensor longus digitorum; the flexor longus pollicis was transplanted onto the anterior surface of the leg and attached to the tendon of the paralyzed tibialis anticus; the deltoid was attached to the tendon of the paralyzed triceps of the upper extremity. Milliken tells us we should preserve the sheaths of the tendons and should operate with absolute asepsis. If we follow these rules, we shall be able to obtain primary union and the grafted or transplanted muscle will be most capable of usefulness. In only 1 of his 14 operations did union fail to take place. The functional result of such operations is excellent.

BONE-DISEASES AND FRACTURES.

Cramer,⁴ of Cologne, discusses Bardenheuer's method of correcting bone defects by means of **splitting a metatarsal bone in the long axis** to make

¹ Rev. de Chir., Sept., 1896.

² Brit. Med. Jour., Mar. 20, 1897.

³ Med. Rec., Nov. 28, 1896.

⁴ Verhandl. der deutsch. Gesellsch. f. Chir., XXVth Congress, 1896.

up for the loss of bone in the adjoining metatarsal. In 5 cases he had a most excellent result. In 4 cases he split a metatarsal bone in its long axis and bent the half over to overcome the loss inflicted by removal of the adjacent metatarsal bone. The bone can be very easily divided with a chisel and one of the joint-surfaces is left intact. In not one case did the transferred fragment undergo necrosis.

Delbet¹ writes on the **operative treatment of hallux valgus**. He excises the bursa and resects the projecting portion of the metatarsal bone. The extensor tendon commonly prevents the placing of the toe at once in the correct position; therefore it is well to draw this tendon forward and to anchor it to the metatarsal bone by a sheath made of periosteum. This operation is very satisfactory and corrects the deformity. [Kirmisson maintains that while tendon-contraction does take place, it is secondary and not causative. Regnier, on the contrary, asserts that in young persons the contraction is often primary, and simple tendon-section will cure; whereas in adults the contraction is secondary to arthritis, and cuneiform osteotomy is the proper operation. Our experience is that good results can be obtained in adults by removing with a chisel the projecting portion of the metatarsal bone and leaving the tendon undisturbed. An ordinary osteotomy will often be curative. It is rarely necessary to operate upon children. Dawbarn believes that the operation above advised is insufficient. He makes a half-moon incision on the upper aspect of the joint, the convexity of the cut being outward. The joint is opened and the head of the metatarsal bone removed. The toe is straightened on a sole-splint and the flap sutured. The shortening of the toe causes the contracted and displaced tendon of the extensor proprius to return into place. (See remarks by Weir, Willy Meyer, Dawbarn, L. Pileher, Wm. T. Bull, A. J. McCosh, in *Annals of Surgery*, April, 1897.)]

Ischwall and Reyer² advise the **treatment of bone-cavities by pouring in melted salol**, and say it is an advantage to combine the salol with iodoform, which dissolves in it readily. The cavity to be plugged should be first carefully disinfected.

Ziematzky³ makes a report on Lannelongue's method of **treating bone-tuberculosis by zinc chlorid injections**. The zinc chlorid is employed in the strength of 10% dissolved in distilled water, and injections are made under the periosteum or ligaments about once a week. A number of punctures are made, 1 minim being injected at each puncture, and about 15 minims being injected at one sitting. The effort is made to surround the tuberculous area with the zinc chlorid. The injection causes considerable pain, and it may be necessary to administer an anesthetic. This drug destroys the bacilli, irritates the tissues, and produces cicatrization. It was used in some 40 cases with most excellent results.

Bayer⁴ writes on **Bardenheuer's method for restoring the anterior supports of the foot**. In one case the distal end of the first metatarsal bone had been destroyed, and also the proximal end of the first bone of the toe. The area of necrosis was removed. The lateral ligament of the second metatarso-phalangeal joint was cut; the metatarsal bone was forced inward and against what remained of the proximal phalanx of the great toe. The metatarsal bone was held in place by gauze-packing, which was gradually removed until granulation-tissue prevented the return of the bone to its normal position. A silver-wire suture united the fragment of the phalanx to the distal end of the metatarsal bone. He reports another case in which the fifth metatarsal

¹ Rev. de Chir., p. 329, 1896.

² Therap. Gaz., Jan., 1897.

³ Rev. de Chir., Aug., 1896.

⁴ Centralbl. f. Chir., Dec. 27, 1896.

bone was destroyed. The necrosed bone was removed; the head of the fourth metatarsal was loosened from its ligaments and forced outward to take the place of the fifth metatarsal. In both cases the result was excellent, the 2 anterior points of support of the foot being restored.

Joel E. Goldthwait¹ reports a case of **achillodynia** due to an exostosis of the os calcis associated with an interesting form of bursitis. In this case a skiagraph was taken in which the exostosis was plainly visible. An operation was performed and this projection of bone removed. On drawing aside the tendo-Achillis a bursa of considerable size was opened. The lining membrane of this bursa was in folds because of hypertrophy, and these folds undoubtedly were pinched between the tendon of the bone during exercise, a condition which was responsible for the attacks of severe pain. In such cases we should remove the exostosis and also the bursa.

Kredel² reports two cases of **congenital coxa vara**. Both hips were affected and there were other malformations—viz., marked knock-knee and club-feet. The author believes that the deformity arose in utero because of want of room. The deformity is not the same as that met with in rickets, and in these cases of congenital coxa vara there was marked adduction, which is not present in rickets. [Coxa vara was first described by Müller in 1889, and was named by Hofmeister. It is a condition of incurvation of the neck of the femur. The commonly accepted view is that the deformity is rachitic, but Kredel's cases of congenital coxa vara show that the condition may be non-rachitic. Ogston, Czerny, Roth, Hoffer, and others have written upon coxa vara. Ogston's extremely able article was published in the *Practitioner*, April, 1896.]

J. Lynn Thomas³ reports a case of **double Colles's fracture** in which skiagraphs were taken. He draws attention particularly to the fact that the skiagraphs show fracture of the styloid process of the ulna in each case, and he wonders whether we have not been in error in assuming that fracture of the ulnar styloid is so rarely associated with Colles's fracture.

M. L. Harris describes a **dressing for fracture of the clavicle** which he has used during the past 10 years with gratifying results. Take a piece of roller-bandage 5 or 6 ft. long and lay it over one shoulder like a suspender. Bandage the chest by a bandage 3 or 4 in. in width and about 10 yds. in length. This bandage is applied very firmly. Next take a piece of muslin 3 yds. long and as wide as the length of the arm from the axillary fold to the bend of the elbow; fold this muslin in the middle, and, beginning at the ends, tear down the centre to within 2 in. of the fold. We thus obtain a four-tail bandage. The arm is passed through the fold so that the untorn portions lie opposite the external surface of the humerus. The tails are passed behind the body and in the same direction, and when these tails are drawn on the arm is pulled backward and inward and the scapula upward and forward, while the tip of the shoulder and with it the outer fragment of the fractured clavicle is carried upward, outward, and backward (Fig. 25).

Tillmanns⁴ makes a report on 5 cases of **fracture of the femur** in which the fracture resulted from twisting; 2 of these patients had locomotor ataxia. The other patients seemed to be well, and the explanation of the occurrence of the fracture was in doubt. Several years afterward Tillmanns followed up the patients who were apparently healthy and found every one of them suffering from locomotor ataxia. Experiments which this surgeon conducted in the dissecting-room tended to prove that a normal healthy femur cannot be broken

¹ Boston M. and S. Jour., May 27, 1897.

by a moderate twist or strain. In other words, in cases of fractured femur due to slight twists the bone is displaced.

Rudolph Matas¹ makes a report on a **simple method for reduction and fixation of a fracture of the zygomatic arch.** After the aseptic

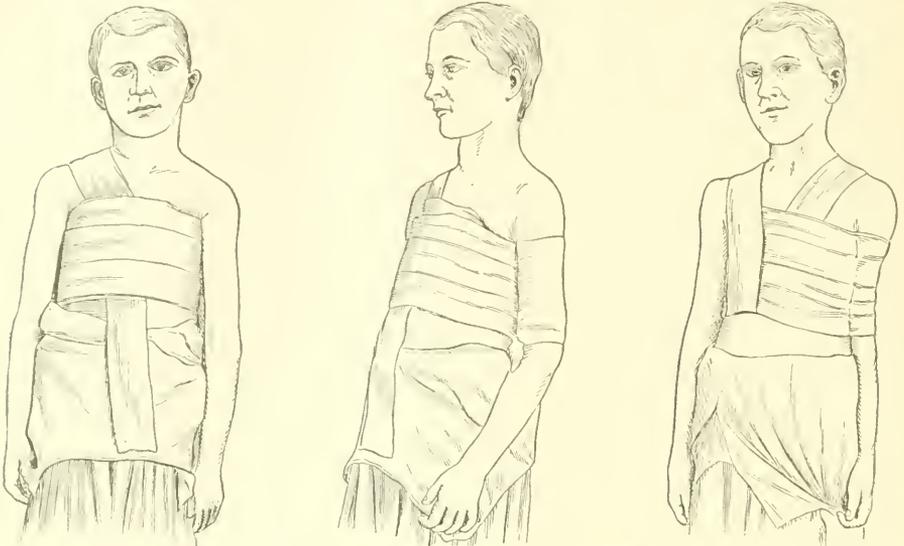

FIG. 25.—Dressing for fracture of the clavicle (Harris, in Chicago Med. Rec., Sept., 1896).

preparation of the skin a large semicircular Hagedorn needle threaded with silk is entered an inch above the middle of the displaced fragments and is carried under the fracture and into the temporal fossa, and emerges again a $\frac{1}{2}$ in. below the inferior border of the fractured arch. A strong piece of silver wire about

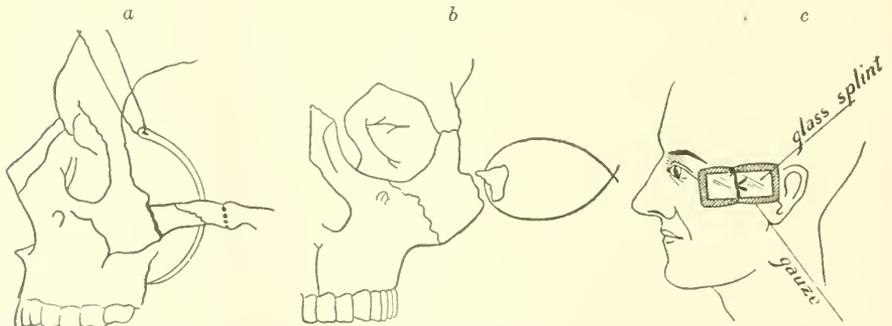

FIG. 26.—*a*, curved needle carrying traction wire under fractured arch; *b*, wire *in situ*, ready for traction to replace displaced fragment; *c*, fracture reduced; apposition maintained by a glass splint (microscopic slide) resting on a layer of iodoform-gauze. The wire is twisted firmly over the glass slide (Matas, in N. Orl. M. and S. Jour., Sept., 1896).

1 ft. in length is attached to the silk and pulled through the needle-track. By twisting the ends of this wire together a loop is formed which permits of traction on the fragments. The fragments are pulled into place by means of traction. An ordinary glass microscope-slide is wrapped in iodoform-gauze and placed over the seat of fracture, and the wire twisted firmly over this. The

¹ New Orl. M. and S. Jour., Sept., 1896.

wire splint and dressings can be removed on the 9th day. This dressing gives an excellent result (Fig. 26).

Robert F. Weir¹ discusses the **replacement of depression in fracture of the malar bone**. The injury is not very common, but when it occurs the resulting deformity is very great. There is trouble in mastication because of pressure on the temporal muscle by the zygomatic end of the fracture; correction of the deformity is very difficult by old methods. Dr. Weir had 2 cases. In these he administered ether, incised the mucous membrane above and external to the canine tooth of the upper jaw, and opened the antrum by the use of a small bone-gouge. He inserted a steel sound through this opening and easily lifted the depressed bone into place, retaining it by packing the antrum with iodoform-gauze. This packing was changed on the 4th day and was dispensed with on the 10th day.

C. J. Edgar² reports a case in which the **scapula was fractured by muscular action alone**. Most of the text-books make no allusion to such an occurrence, and some say that fracture of the scapula can only result from direct violence. This man had endeavored to check the progress of a vehicle by catching hold of the spokes of one wheel with both hands.

John B. Roberts³ makes a thorough study, clinical, pathologic, and experimental, of **fracture of the lower end of the radius** with displacement of the carpal fragment toward the flexor surface of the wrist. He believes that this displacement would be as common as the dorsal displacement if patients fell as frequently on the back of the hand.

A. Herbert Butcher⁴ discusses the **treatment of recent transverse**

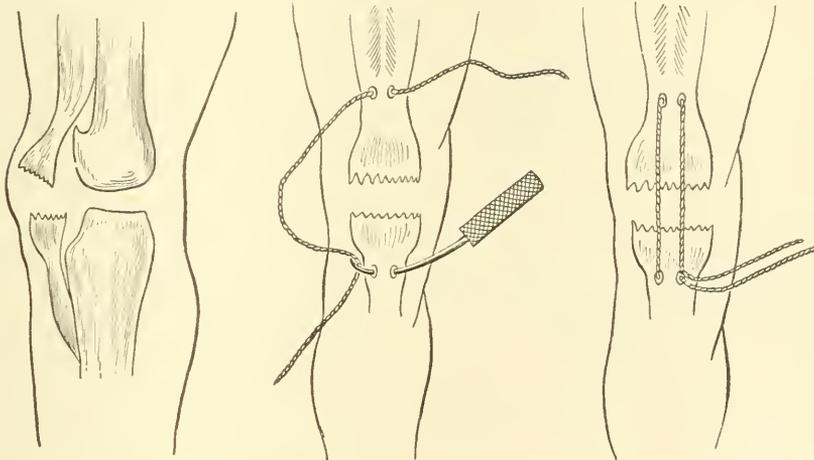

FIG. 27.—A. Herbert Butcher's method of treating recent fractures of patella (Brit. Med. Jour., Sept. 26, 1896).

fracture of the patella. He finds that if we pass a ligature over the anterior portion of the patella, instead of around it, the two ends of the bone can be held together with less traction. In transverse fracture the upper portion of the bone sinks down, the lower edge of the upper fragment is thrown forward, giving a direction forward and downward to the whole upper fragment, instead of directly forward. This is due to the fact that the posterior process

¹ Med. Rec., Mar. 6, 1897.

³ Am. Jour. Med. Sci., Jan., 1897.

² Montreal Med. Jour., Feb., 1897.

⁴ Brit. Med. Jour., Sept. 26, 1896.

of the quadriceps tendon ties it down to the femur. Therefore, the fractured edges are more widely separated anteriorly than posteriorly. In order to overcome this condition Mr. Barker, Kocher, and others incise the joint and pass silver wire round the patella. As equally good results can be obtained by keeping out of the joint; Butcher prefers to do so. He takes a handled needle, arms it with a strong carbolized silk ligature which is waxed, and passes this ligature through the quadriceps tendon close to the upper margin of the patella. The needle is withdrawn, leaving the ligature in place. The needle is again threaded with one end of the same ligature, is reentered through the same skin-puncture, and is passed from above downward over the anterior portion of both fragments and brought out below the inferior border of the lower portion of the broken bone. The unthreaded needle is passed over the opposite side, deeply through the ligamentum patellæ, and brought out a little distance from the opposite border through the same skin-puncture which is occupied by one end of the silk ligature, with which it is threaded and withdrawn. The needle, being now unarmed, is threaded with the free end of the silk ligature which was first passed through the quadriceps tendon, and, being inserted through the same skin-puncture, is passed subcutaneously as on the opposite side from above downward and brought out from the ligamentum patellæ at the same puncture already occupied with the opposite end of the ligature. The broken fragments are then rubbed together until crepitus is obtained, the ends of the ligature are tied in a reef-knot, and a posterior splint is worn for a few weeks.

Francis S. Watson¹ sutures a fractured patella by the following method: open the knee-joint by a semicircular incision, the convexity of which is down-

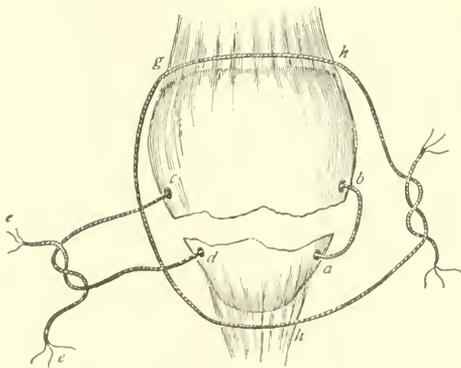

FIG. 28.—Watson's method of suturing fractured patella (Boston M. and S. Jour., Oct. 1, 1896).

ward, remove clots, bone-fragments, and tissue-shreds, and irrigate the joint with sterilized water. Saw the ends of the fragments off so that they will fit evenly. Each fragment is bored transversely, and the sutures are passed through these openings, the openings being made as far from the fractured edges as possible. This method of drilling the bone is preferable to drilling it vertically, because sutures introduced through transverse holes are far less liable to tear out from the bone than when passed through vertical holes. The suture em-

ployed is that suggested by Dr. Lund—three strands of single silkworm-gut braided together. It may be well, in order to insure a good result, that a second suture be passed through the tendons close around the upper and lower ends of the fragments.

George W. Spencer² considers the treatment of **fracture of the clavicle** by incision and suture, and reports 2 cases which were operated upon by W. Joseph Hearn. In the 1st case it was found impossible to retain the fracture in position by any of the ordinary dressings. An incision was made; the bone-ends were found to be dentate, and between them lay the lacerated subclavius muscle. The bones were wired together by silver wire and the result

¹ Boston M. and S. Jour., Oct. 1, 1896.

² Am. Jour. Med. Sci., Apr., 1878.

was most satisfactory. In the 2d case a small piece of loose bone could be distinctly felt under the skin and over the depression caused by the fall of the outer fragment downward, inward, and forward. The inner end of the outer fragment could not be detected. Hearn, fearing that it might do damage to some important structure, decided to operate. When an incision was made a portion of bone, triangular in outline, was found to have been broken off completely from the inner fragment. This small piece was removed. Another piece of bone was found attached only to the periosteum. This was replaced and held in position by throwing a ligature of kangaroo-tendon around the outer fragment and including the attached piece. In this case, also, the subclavius muscle was between the fragments. The inner end of the outer fragment was long and rigid, and was caught in the remaining fibers of the subclavius muscle, which, fortunately, prevented the sharp ends of the bone from injuring the blood-vessels. The fragments were wired together and the result was most satisfactory.

James Porter Fiske¹ writes on the **ambulatory treatment of fractures.** The splint that he uses is a plaster cast extending from the tips of the toes up to and around the tuberosity of the tibia, so that in walking the body-weight is supported by the upper part of the cast. After reducing the deformity the limb is held in a suitable position and the splint is applied as follows: the limb is bandaged with the ordinary muslin roller from the tips of the toes to the knee-joint; the plaster-of-Paris bandage is applied over this. Cotton-padding is not used because it is desirable that the splint exert equal pressure at each point and so fix firmly. In a great many cases the patient can walk without support as soon as the plaster has become firm; but, as a rule, he is advised to keep his leg in a horizontal position for 24 hours, and if at this time the dressing feels comfortable and there is no swelling of the toes, he is permitted to walk. Fiske has never seen a fracture of the leg but which, at some time during the progress of healing, was suitable for treatment by the ambulatory method. If there is a great deal of swelling due to edema or effusion of blood, equal pressure should be applied, the fragments fixed, the leg raised, and the patient kept recumbent until the swelling disappears, and then the ambulatory dressing can be applied. It is advantageous to apply the ambulatory splint very soon after the accident, the pressure serving to prevent edema. If we are dealing with a compound fracture, the limb should be aseptized, an aseptic dressing applied, and the fragments fixed; if infection does not occur, the ambulatory splint is applied at a later period. If there has been very extensive injury of the soft parts, it is not well to apply the ambulatory splint until the condition of the tissues improves. In most cases solid bony union is not obtained any sooner by this method than by the old method, but the after-treatment is much shortened, as we do not have to contend with the usual stiffness.

The splint is worn from 28 to 35 days. In some cases it has been worn for 6 weeks. After the splint has been removed the hot and cold douche is used upon the leg, and also massage until stiffness has entirely gone. The advantages of the ambulatory method are that the patient is able to be up out of bed and about; that there is but little muscular atrophy or stiffness of the joints; that the duration of after-treatment is much lessened and the general health of the patient is well maintained. The author reports 56 cases of Pott's fracture, in 38 of which the ambulatory splint was applied during the first 24 hours, and in 18 of which the splint was applied from 3 days to 21 days after the receipt of the injury. Besides this he reports 101 cases of fracture of the

¹ Med. News, Feb. 13, 1897.

lower third of the fibula, 7 cases of fracture of the middle third, 2 of the upper third, 9 of the lower third of the tibia, 13 of the middle third of the tibia, 14 of the tibia and fibula, 24 of osteoclasis, and 11 of non-union, treated by this method.

E. H. Bradford,¹ of Boston, writes on the ambulatory treatment of fractures in children. The late Mr. Thomas, of Liverpool, many years ago treated fractures by an ambulatory method, applying the splint which he devised originally for the treatment of tuberculosis of the knee. He treated fractures of the femur, of the patella, and of other bones by this method. Bradford thinks that the ambulatory treatment possesses certain special advantages in dealing with children. He treats cases with a modified Thomas splint, in some cases combined with the use of a plaster-of-Paris bandage. The means that are at our disposal for ambulatory treatment are as follows: plaster-of-Paris with crutches and Thomas's splint, or ring perineal splint and hip traction-splint. In fractures of the leg a splint is used which takes its bearing upon the lower end of the femur. It is not pretended that the ambulatory treatment is to be used in every case; but when it can be used time will be saved, the patient will be more comfortable, and there will be no increase in danger. If dealing with a fracture of the thigh, we can use an ordinary traction-splint with a pelvic band, accompanied by coaptation splints. This can be readily made by fastening a steel rod $\frac{1}{2}$ in. in thickness to a steel bar 1 in. wide and $\frac{1}{4}$ in. thick, bent so as almost to encircle the pelvis and provided with perineal straps. A windlass traction attachment can be added at the bottom, or buckles can be fastened to which the traction-straps are secured. An easily made emergency apparatus was suggested by Dr. Hall, of the Massachusetts Hospital. An ordinary wooden crutch is suspended from the shoulders so that the crutch portion presses in the perineum, the length being such that the crutch projects an inch or two below the sole of the foot; at the bottom of this a bracket of iron is secured, buckles are fastened to it, and the crutch is attached to the leg by straps; when the foot on the sound side is raised by a block the patient can walk about with comparative ease. This form of apparatus is more available in adults than in children. In fractures of the leg in children it is a difficult matter to obtain a bearing on the condyles of the femur or the head of the tibia, because these bones are not completely developed. In such cases the Thomas knee-splint should be used, because it takes its bearings from the perineum. This form of treatment can be applied in all fractures of the lower extremity except where there is great deformity, or where the fracture is in the upper third of the femur. In such cases it will be necessary for the child to remain longer in bed than where the fracture is lower down, because the upper fragment is so extremely short. When the patient becomes convalescent and union is found to be sound the bottom of the splint is removed and the rods are bent to fit in the socket in the sole of the shoe. A bandage is wound around the apparatus and the leg to steady the limb. Thomas's knee-splint, it will be recalled, is made by fastening to an oval ring, made of steel $\frac{1}{4}$ in. in thickness, 2 rods of similar size which are secured at the bottom to an iron bar, which serves as a foot-plate.

W. Bruce,² in speaking of **fractures of the lower end of the humerus**, calls attention to the difficulty of keeping the fragments in place and of the ill-results which frequently follow the treatment of such fractures. He thinks such a great mass of callus is thrown out because of bad coaptation and want of proper rest. In this case chloroform should be given before the fracture is set, both for the purpose of diagnosis and to facilitate reduction. In cases where swelling is very great it is well to do nothing for a

¹ Ann. of Surg., Oct., 1896.

² Brit. Med. Jour., Oct. 24, 1896.

day or two, but at the earliest opportunity the fracture must be set. The best splint is the trunk of the patient; no arm-splints are required. It is a very great advantage to have no constriction on the limb of the patient. Place the elbow at an acute angle and lay the arm across the chest over a sheet of cotton-wool, apply a bandage including the trunk and the injured limb, and every day open this dressing and examine the fracture. In a little while make gentle passive motions, and later on apply massage. This method of treatment gives the best results of any of which he has knowledge. [The question when to begin passive motion is much disputed. Motion made early moves the joint, but also moves the fragments; movement of the fragments leads to the formation of a large amount of callus, and the large amount of callus forms bone in quantity, which bone blocks the joint. We believe passive motion should not be made for 4 weeks. Dawbarn¹ has recently discussed this question, and our views are in accordance with his.]

George Woolsey,² after discussing the use of **massage in the treatment of fractures**, comes to the following conclusions: the treatment of fractures, especially of fractures near joints, by ordinary methods of immobilization or by ambulatory treatment is not entirely satisfactory. By employing massage and passive motion we can shorten the time necessary to obtain bony union by a third or a half and obtain a better functional result. In fractures about or in joints this treatment is especially valuable. If applied very early, it abolishes swelling and relieves pain, hastens the formation of callus, and prevents muscular atrophy and stiffness of the joints and tendons. The patient wears splints, which every day are removed and massage applied for 15 or 20 minutes. This treatment, combined with the ambulatory method, offers the best prospect for a speedy cure. If we are dealing with an oblique fracture of both bones in the leg or arm, or an oblique fracture of the femur or humerus, or a fracture in the middle of the limb with a strong tendency to displacement, we must then immobilize until consolidation takes place.

John B. Roberts³ warmly advocates the use of **exploratory incision in the treatment of some fractures and dislocations**. He tells us that the employment of the Röntgen rays has often proved that fractures which were thought to be thoroughly reduced really deviate considerably from normal relations. A belief in the value of exploratory incision, which he long ago announced, has been strengthened during recent years. Allis, of Philadelphia, advocates this treatment in fractures of the upper third of the shaft of the femur. Arbuthnot Lane has employed it in fractures of the tibia and fibula near the ankle. McBurney uses it in fractures of the upper end of the humerus complicated with dislocation. Dennis advises it in fracture in which it is difficult to secure thorough coaptation; but, excepting in fractures of the cranium and patella, most surgeons prefer to obtain imperfect results rather than to advise immediate exposure of the fragments by exploratory incision. Roberts advocates incision in cases in which we are ignorant of the exact lesion or in which we cannot reduce the fragments, or cannot perfectly immobilize, or cannot deal satisfactorily with complications. In these cases the incision is the least of two evils. Fracture of the patella he never treats by incision and suture of the bone, because he has always so far been able to bring the fragments into apposition by a splint, by hooks, or by subcutaneous suture. With aseptic precautions the incision is almost devoid of risk, and many advantages will follow on its performance. We can make out the exact line of separation. We can be certain that we have effected coaptation. Not

¹ N. Y. Polyclinic, July 15, 1897.

³ *Ibid.*, Jan. 16, 1897.

² *Med. News*, Mar. 20, 1897.

only will the bone-fragments be replaced, but the torn periosteum will be restored, and bands of muscle, fascia, and nerve will be lifted out from between the fragments. We thus lessen the chance of deformity, non-union, neuralgia, atrophy, and ankylosis. When the fragments have been adjusted they can be kept in this position by sutures or pegs, or needles or screws, or ferrules; furthermore, the vessels are ligated and muscles and nerves sutured. Pain is relieved if due to extravasated blood or inflammatory exudate. In some cases where there has been a large amount of interstitial pressure incision averts the danger of gangrene. The pain during the course of treatment is less because the fragments are perfectly immobilized. Fat-embolism is very unlikely to occur, because broken-down fat is permitted to escape. Ankylosis will rarely happen. Repair of the break and restoration of function take place more rapidly than under ordinary methods of treatment. We know that by ordinary methods of treatment it sometimes happens that even a slight change in the axis of the bone will prevent a perfect functional result. We can obviate such a condition by the open incision. In vicious union of fractures open incision with osteotomy is preferable to fracture by the use of the osteoclast. Dislocations which are not easily reduced by manipulation when the anesthetic is administered should also be subjected to open incision. In recent dislocations where manipulation fails and in old dislocations arthrotomy should be performed, a final effort at reduction by manipulation being made just before operation. Open incision and restoration of the dislocation are safer than attempting to drag an old dislocation forcibly into place. After the incision has been made, if restoration is impossible, the head of the bone can be excised.

A. P. Gould¹ has made some remarks on the **treatment of fractures** that are of great practical value. He tells us to take the utmost pains to make an exact diagnosis of the existence, of the position, and of the condition of the fracture, and the number and position of the fragments. Anesthesia is a very great aid in making a diagnosis. It is as much a surgeon's duty to give an anesthetic to aid him in arriving at an exact diagnosis as it is to give an anesthetic for some grave surgical condition. Anesthesia permits diagnosis and greatly facilitates proper treatment. This teaching will be considered by many as rank heresy. The second great aid is the use of the *x*-rays and the fluorescent screen. After arriving at a diagnosis the surgeon's next duty is to reduce the fractures at once, as the longer we wait the more difficult this reduction will become. Reduction must be complete and not partial. We must not wait in a half-way house, obtaining some improvement to-day in the hope of getting more improvement to-morrow. The surfaces of the fracture are nearly always uneven or jagged, and when these surfaces are accurately put altogether they hold together. Hence a fracture which is once well set rarely slips apart. Recurrence of displacement probably means imperfect reduction. The methods which are suited to secure this perfect adjustment of the fragments vary with different cases. Displacement may be caused by the violence of the traumatism, the action of gravity, or the pull of muscles. The pull of muscles is overcome by relaxation, not by opposing them with extension or counter-extension. The fragments should be thoroughly replaced before a splint or a bandage is applied. We should never trust an apparatus to correct a displacement. All apparatus which are supposed to force a broken collar-bone into position are miserable failures. If we wish to obtain repair of this fracture without deformity, we are obliged to place the patient on his back in bed. We cannot correct the deformity of Colles's fracture by a splint, but we first correct the displacement and then maintain the fragments in their proper

¹ Lancet, June 12, 1897.

position by placing the limb on a splint. Should we or should we not extend to fractures the same development of surgery that we have extended to other injuries and diseases? What can operation do for simple fracture? It can exactly replace fragments, and it can mechanically fix them in place, and in an old ununited fracture it opens up again the medulla and so leads to the formation of a plastic callus. Such an operation, of course, must only be undertaken when we are certain we can maintain an a-septic wound. We must realize that the fitting together of the fragments may be a matter of great difficulty, and that the surgical means of holding the fragments together are not altogether perfect, except in fractures of the patella or uncomplicated oblique fractures of the tibia. These operations are difficult and are not to be undertaken lightly; the cases in which it is necessary to operate are few, but in these few cases the surgeon should put to himself the question whether the difficulties can with reasonable certainty be overcome by operation. If they can be, and he has the necessary means at his command, he ought to operate. Gould would not for a moment advocate a general employment of operations for simple fractures; such a practice would be needless, dangerous, and ill-advised. [The use of an anesthetic for diagnostic purposes is, in our opinion, not only valuable, but often indispensable. In the United States it is taught positively that in examining a case of supposed fracture in which the diagnosis is obscure ether should be administered. In injuries in and about the elbow-joint an examination should be made under ether, unless the x-rays are accessible and clear up the diagnosis.]

DISEASES OF THE JOINTS.

R. W. Lovett¹ writes on the **treatment of sprains**. These injuries may be classified under four headings: contusions, ligamentous injuries, joint-synovitis, and tenosynovitis of the muscles about the injured joint. The use of the word "sprain" is unfortunate, and it is far better to name accurately the special injury which exists. Mild cases of sprains may be most satisfactorily treated by massage daily and the use of a bandage. In severe sprains Lovett has never used immediate massage, because he believes that in a recent severe sprain massage may make the condition more acute. In severe cases he applies the massage only when the heat and sensitiveness disappear. In other words, he applies it at the time it is advisable to stimulate the local circulation. In sprains of the ankle-joint the best results are obtained by immediately applying wet millboard strips over layers of sheet wadding and then applying a tight and even bandage. This dressing is left in place for two or three days, at which time the swelling has largely abated. At this period a severe sprain requires the application of a plaster-of-Paris bandage from the toes to below the knee. This bandage is split, and every two or three days is removed to permit extension of the joint. When the acute symptoms subside massage is begun, and after the application of massage the plaster is reapplied for 24 hours. Gradually the plaster is discontinued, and is replaced by a flannel bandage. The hot and cold douche is valuable in association with massage. It is inadvisable to apply plaster-of-Paris immediately, because in 24 hours there will be a subsidence of the swelling which will leave the plaster loose. If the swelling should happen to increase, constriction will be brought about. Half-way measures are almost useless; cotton bandages and hot water are but makeshifts. Sticking-plaster is better, but lacks precision. We may lay it down

¹ Boston M. and S. Jour., June 17, 1897.

as a rule that a sprain is either slight enough to be treated from the first by massage, or is severe enough to demand efficient fixation for a day or two.

J. O. Mumford,¹ on the **treatment of sprains**, tells us that the old practice of immobilizing sprains is now generally conceded to be impractical. Even in cases in which there is considerable laceration we should use at first the hot and cold douche for about 10 minutes in order to allay pain, then rub and knead the joint for some 15 minutes, and apply a flannel bandage. The part is then rested perfectly for 24 hours. On the 2d day the kneading and stroking are more thoroughly done and a little passive motion is used, and this plan is continued daily. Massage and passive motion are valuable because they keep up the lymphatic circulation and thus aid in carrying off inflammatory exudate, and proper nutrition is maintained by passive motion, which is substituted for the active motions indulged in in health. In a sprained ankle the old treatment of immobilization is objectionable. It leads to the formation of adhesions, functional impairment, and pain, and, if there be tuberculous tendencies, favors the production of a tuberculous joint. The same statement may be made of the wrist, the knee, the shoulder, and other joints. Properly applied, massage will prevent these complications. A very important adjunct to this treatment is the use of a skilfully applied flannel bandage. The surgeon ought to apply this himself. A masseur is seldom acquainted with the general principles of bandaging. The bandage should be broad, cut bias, and cover all the parts as far as the adjacent joint on either side, an extra pad being placed over the injured joint. After the first 24 hours the patient is permitted to go about on crutches, and after the 3d day a little weight is brought upon the foot. Two or 3 weeks are often sufficient time to render a sprained joint actively useful.

Douglas Graham² says that in a mild sprain of the foot and ankle, if at the time of the injury the patient is wearing a boot which fits him, let him keep that boot on and walk about with moderation. If the boot is not rendered snug by reason of the swelling, it should be laced more tightly. This is what may be called walking off a sprain. It is the application of automatic massage. Massage properly applied is a plan that is well suited to sprains of all degrees of severity, and it can be used alone or with fixed dressings and bandages. It should not be immediately begun after the reception of the injury. Motion either active or passive should not be encouraged in spite of pain caused by it. Rest and support can usually be obtained in the intervals between the application of massage by the use of a neatly applied bandage; but if the bandage does not give enough support, then a splint or plaster bandage which can be easily removed should be applied. If the joint is so tender that massage cannot be directly applied, the manipulations should be commenced on healthy tissue some distance above the joint and nearer to the trunk, by gently stroking in the direction of the returning currents of lymph and blood and gradually proceeding downward. The returning currents are by this method pushed along more rapidly and make room for exudations to be carried away. Each hand should make alternate strokes, using the whole palmar surface. After stroking for a few minutes in this manner, deep manipulation, or massage properly so-called, may be brought into play, beginning above the painful joint and gradually approaching the objective point. This maneuver decidedly lessens pain, but does not decrease ordinary sensations. The parts beyond the sprain are treated in the same manner. By this alternate stroking and kneading we will soon be able to apply firm pressure over the joint that was but recently very painful, so that the pressure not only will not hurt, but will be very agreeable, and very soon motion can be added to the

¹ Boston M. and S. Jour., June 17, 1897.

² *Ibid.*

pressure. By these manipulations the effusion and exudation are spread over greater surfaces and brought into more points of contact with veins and lymphatics. Continued bandaging in the treatment of sprains will cause atrophy of the muscles. Rubber bandages should never be used except temporarily—they strangle the tissues; a cotton-flannel bandage is infinitely more comfortable and renders greater service. Bandages which are cut bias he never uses, because they stretch more at the edges than in the middle, and it is impossible to obtain equable pressure with them.

Graham arrives at the following conclusions: 1. A sprain is a wrench of the joint in which there was partial displacement of the articulating surfaces followed by immediate replacement. 2. The symptoms are pain, swelling, discoloration, and, as a general thing, heat with impaired motion. The swelling may render the diagnosis difficult by hiding a fracture which is underneath. The diagnosis is favored by whatever quickly reduces heat, pain, and swelling, such as massage, bandaging, and elevation. These means are valuable for diagnosis and also for treatment, and recovery under their aid can be brought about in one-third of the time required for recovery under absolute rest and fixed dressings without massage.

Hayward W. Cushing¹ discusses **excision and erasion of the knee-joint**. In the operation as ordinarily performed the knee-joint is laid open by a curved incision in front. The crucial ligaments are divided and the ends of the femur and tibia are resected, great care being taken not to damage the epiphyseal line. The patella may be removed or may be left in place. The ends of the bones are fastened together by nails or by wires, the wound is closed with drainage, and the surgeon hopes for ankylosis. As a rule, sinuses form. This operation, though called excision of the knee, is really excision of the knee-joint. It simply removes the knee-joint, and does not remove the synovial membrane and foci of bone-disease at or beyond the epiphyseal line. It hence becomes perfectly evident that such an operation cannot be considered radical. The operation advised by Cushing is radical. The joint is opened and carefully inspected, and all diseased synovial membrane is removed with scissors and forceps; then the bone is attacked with a chisel, gouge, and curet, rather than a saw. Diseased bone is scooped out; the bones are united by sutures passed through the periosteum; the wound is closed without drainage and dressed with sterile gauze fixed by plaster-of-Paris. This operation gives primary union in 3 weeks and firm bony union in 8 or 9 months. When the disease is limited this operation is called an erasion; when the disease is extensive it is called an arthrectomy. If the after-treatment is properly conducted, the leg will be found to be nearly always straight; but we should remember that fixation should be continued as long as there is any tendency to contraction. Do not omit fixation as soon as the operation-wound is healed or as soon as there is apparently bony union, because contraction can occur months afterward. The typical operation of excision should be reserved for the correction of deformity from bony ankylosis.

C. B. Lockwood² writes of a new procedure which he calls **osteoplastic excision of the knee**. He has performed this operation on several occasions. It is not done on every case of tuberculous arthritis of the knee, but each case is treated on its merits. Some cases are treated by rest and local applications, some by drainage, some by arthrectomy, some by the ordinary operation of excision, and some by the operation herein described. This operation is used when there is progressive tuberculous arthritis with pulpy synovial membrane and ulcerated cartilage, with but little caries and but little displace-

¹ Boston M. and S. Jour., Sept. 17, 1896.

² Lancet, Mar. 13, 1897.

ment of the ends of the bone. The operation must not be delayed until sinuses form, because it will then be apt to be followed by septic inflammation. The ordinary method of excision has certain great faults; one is that the limb is apt to become flexed and rotated. The skin-incision is of very little importance, just so as it permits the entire disease to be removed. The antero-internal vertical incision of Langenbeek gives better access to the pouches above the patella and saves us from cutting the ligament of the patella, but it does not satisfactorily expose the posterior angles of the joint. The removal of the patella destroys the attachment of the quadriceps extensor femoris muscle, which is one of the chief reasons that flexion of the joint is so apt to follow this operation. In some cases, of course, the patella is in a state of advanced disease and cannot be retained; but even in such cases it is possible to preserve the aponeurosis over it and at its sides. When the patella is sound there is another reason why it should be allowed to remain in place; it may be possible to fasten its sawn surface to the tibia and femur, both of which are sawn to receive it. The ligaments are very important. The crucial ligaments are especially important, as they tend to prevent displacement of the tibia backward and forward. The usual operation of resection of the knee retains the patella, destroys the ligament of the patella, the lateral ligament, the crucial ligaments, and the interlocking articular ends of the bone, and leaves bony surfaces which are unsupported by ligaments and are smooth and flat, and, as a consequence, very easily displaced. In order to meet these objections Lockwood has devised the following operation: a transverse incision is carried across the center of the ligamentum patellæ from one femoral tuberosity to the other; the ligament of the patella is divided and the joint opened. It is not well to open the joint by the vertical incision, nor is it advisable to open it by sawing through the patella transversely. The latter proceeding is objectionable because the patella may be diseased, and, further, because a divided patella is not suitable for fastening to the tibia or femur. When the joint has been opened the knee is bent to a right angle and the joint is carefully inspected. The diseased synovial membrane is thoroughly removed with knife and scissors. It will occasionally be found necessary, in order to reach all of the diseased synovial membrane, to carry the ends of the transverse incision upward. It is convenient to leave untouched the part of the synovial membrane which is behind the femoral condyles until the femur has been sawn. Healthy ligaments ought to be preserved. It remains to be seen whether it is proper to keep both of the crucial ligaments, but it is certainly very difficult to remove all of the synovial membrane without cutting the anterior crucial ligament. The posterior crucial ligament can very often be preserved, but it would be better to destroy both crucial ligaments than to leave any diseased membrane behind. As the internal and external lateral ligaments are outside of the joint, it is very much easier to save them. The articular surface of the patella is now sawn off; and the trochlear surface of the femur is also sawn off so as to leave a flat surface on which the upper portion of the sawn patella will fit. The femur is now raised vertically by an assistant and the greater part of its articular surface taken away by two other cuts which begin at the convexity of the condyles at the edge of the articular cartilage. These saw-cuts are carried obliquely into the intercondylar notch of the femur until they converge, entering the notch at the edges of the articular cartilages and below the notch of the crucial ligaments. These saw-cuts make a groove or hollow in the femur and leave some articular cartilage front and back of the condyles (Fig. 29). The cartilage is to be removed with the sawn bone. The tibia is treated on the same principle as was the femur, two oblique cuts being carried upward from

the epiphyseal line to converge at the base of the spine (Fig. 29). The articular cartilages are removed. The advantages of this method of sawing the femur and tibia are as follows: we still preserve the fitting of the tibia into the condyloid notch, and lateral displacement cannot take place. The wedging in of the tibia prevents rotation of that bone, and, further, very large areas of sawn bone are brought into contact and a very small amount of the epiphysis is removed. As the leg is extended the bones become tightly fixed and jam the wedge of the tibia into the notch in the femur, and as long as extension is maintained they remain in this position. The operation is completed by sewing the ligaments of the patella with silk sutures and closing the wound.

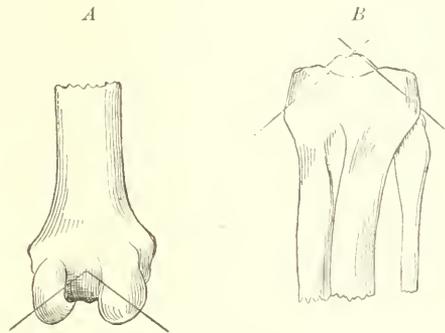

FIG. 29.—A, showing section of femur; B, showing section of tibia (Lockwood, in *Lancet*, Mar. 13, 1897).

John Ward Cousins¹ tells us that **excision of the knee-joint** is only to be performed under conditions which are reasonably favorable. There are many contraindications, such as disease in other organs, especially disease of the excretory or nervous system. The very young and the aged are not suitable subjects. Excision should not be practised in acute diseases of the knee-joint; in such conditions amputation is the proper resource. The operation is performed in chronic articular disease in which there are destructive changes within the joint. In some cases it is impossible to arrive at a conclusion as to what should really be done until the joint is opened. The Röntgen rays will undoubtedly prove of great aid to us in coming to conclusions in doubtful cases. Extensive disease does not of necessity condemn the joint to amputation if other features of the case are not unfavorable for excision. The operation is thought to be unsuited to very young children or elderly people. Under the age of 5 the chances of a good result are small; after the age of 10 the results are better; but when we recall that the lower extremity of the femur is not completely ossified until the age of 20, and that the upper epiphysis of the tibia joins the shaft between the 18th and the 25th year, it will become evident that the best period for this operation is between the 15th and the 30th year, because in this period bony union will be more readily obtained. Excision in children does not interfere with the future growth of the limb. The method that Cousins employs to operate he calls jamming the bones. The joint is opened by an anterior incision with the convexity downward. The ligamentum patellæ is divided and the crucial ligaments are cut sufficiently to allow flexion of the joint. The bones are divided beyond their epiphyseal lines and as little bone as possible is removed; necrotic areas are cut out, and the cut bony surfaces are forcibly jammed together. This secures immobility and favors rapid union. The diseased synovial membrane is all dissected away; it is not necessary to employ any peg to hold the bones in position. After jamming has been practised strong catgut sutures can be introduced between the periosteal surfaces and between the cut ends of the ligamentum patellæ. No more of the patella than absolutely necessary should be removed. If there be only slight caries of this bone, the foci of disease can be cleaned out with a sharp spoon. In some cases it will be necessary to remove completely the

¹ *Brit. Med. Jour.*, July 25, 1896.

articular surface and also the concave surface of the femur upon which the patella moves.

Nichans¹ describes a **new method of incising the knee-joint**. He begins the incision 4 in. above the patella, carries it downward along the inner border of the rectus tendon, and then takes it by the side of the patella to the tubercle of the tibia. At its lower extremity he makes a short transverse cut. The tubercle of the tibia is chiselled off and the wound is carried into the joint. When the limb is flexed the patella and the flexor tendons can be pushed aside, when the anterior half of the joint is readily accessible. If exposure of the entire joint is necessary, the lateral and crucial ligaments must be divided. The author believes this operation is of value because it does not injure the extensor tendons of the leg and thoroughly exposes the synovial pouch, which runs up above the patella.

V. P. Gibney² writes on the **treatment of stiff and painful joints by superheated dry air**. Gibney uses Tallerman's apparatus. He has reported 8 cases in which the improvement brought about by the superheated dry air was very great.

R. F. Tobin³ makes a report on **osteotomy of the femur as a treatment for the early stages of tuberculous disease of the hip**, saying that we may take it as granted that in the early stages of morbus coxæ the operative removal of the affected parts gives very unfavorable results, and that we must seek cure by giving rest to the joint, combined with constitutional treatment. There is one unfortunate fact, and that is, that the position of greatest ease for the joint is one which is a position of great awkwardness for the limb, which is flexed, abducted, and everted, and any attempt to straighten the limb will increase the tension of the joint. Extension by weight and pulley, if the weight is heavy enough to keep the leg straight, drags the spine into lordosis; if it is less heavy, the leg becomes less straight and there is less lordosis. Dr. Thomas's splint is an excellent contrivance, of course, to support the limb, but does not overcome during both night and day all the drawbacks of the position. Being satisfied that the awkward position the thigh assumes in cases of morbus coxæ is a great obstacle to obtaining satisfactory results from treatment by rest, Tobin has endeavored to meet the difficulty in the following manner: in the early stages of the disease he performs osteotomy of the femur on a level with the lesser trochanter and places the limb in a straight position as regards the body, allowing the upper fragment to maintain its position of ease.

Alexandroff⁴ asserts that atrophy and degeneration of the bones and muscles and **hypertrophy of the subcutaneous layer** beneath the skin go hand in hand in **early coxalgia**. Hypertrophy of the subcutaneous cellular layer of fat increases as the case gets worse, and eventually involves the entire limb. The effacement of the fold between the buttock and the thigh is due to this hypertrophy. The author has devised an instrument to measure the difference of thickness in the layer as contrasted with the thickness of the same tissue on the opposite extremity. Atrophy of the limb associated with hypertrophy of this layer is the most important sign to diagnosticate tuberculous osteoarthritis, and it will be found before other symptoms are manifest. If the above-named conditions are absent, there is no tuberculous lesion of the hip-joint, even if other symptoms would indicate its existence.

A. G. Miller⁵ maintains that the **muscular atrophy** which accompanies

¹ Centrabl. f. Chir., No. 16, 1897.

² Internat. Med. Mag., Apr., 1897.

³ Brit. Med. Jour., Apr. 24, 1897.

⁴ Presse méd., Dec. 9, 1896.

⁵ Edinb. Med. Jour., Sept., 1896.

tuberculosis of the joint results **from a diminished blood-supply** caused by contraction of the main blood-vessels of the limb.

DISLOCATIONS.

Edward Sutcliff¹ records a case of **complete lateral dislocation of the forearm**, resulting from a fall on the right elbow. The forearm was flexed, semipronated, and widened over the elbow-joint. The inner condyle was extremely prominent and the trochlear surface of the humerus could be distinctly made out. The forearm could be readily rotated and the head of the radius could be felt revolving. The patient was anesthetized, and reduction was readily effected by extension around the knee and manipulation of the joint. A perfectly useful joint followed the injury.

W. J. Welsh² writes on the treatment of **old dislocations of the elbow**. He says that much force is very dangerous in old dislocations and may do irreparable damage. The olecranon prevents reduction. The proper plan is to cut into the joint, divide the triceps tendon, remove the olecranon, and bring the radius and ulna into place, retaining them there with the hope of establishing ankylosis. He reports a case in which he carried out this procedure with gratifying results.

The treatment of **old dislocations of the shoulder** is considered by F. B. Lund.³ The obstacles to reduction may be the adhesion of the capsule to the glenoid cavity, the healing of the rent in the capsule behind the head of the bone, thickening or calcification of the capsule, pulling off of the great tuberosity, or filling up of the glenoid cavity. An old dislocation presents a different picture from a recent dislocation. The bony points stand out distinctly because of the atrophy of the deltoid and the scapular muscles. The elbow is not away from the side, because the stretching of the deltoid allows it to fall in. Rotation of the head of the humerus is nearly or quite absent. The arm can be very rarely abducted to a right angle, but abduction is only possible by elevation of the scapula. Backward elevation is not possible. Forward elevation can be carried to a right angle. The author reports from the records of the Boston City Hospital 24 cases, of which 22 were treated by manipulation. The cases reduced by manipulation were of 6 weeks' duration, with the exception of Dr. Burrell's case, which was 8 months. Fourteen of the cases were successful, 13 of them under 6 weeks. There was 1 failure at 6 weeks. In only 1 case of over 6 weeks was the reduction effected by manipulation; there were thus 10 cases in which manipulation failed, and only 1 of these was of less than 7 weeks' duration. In one of these failures resection of the head of the humerus gave an excellent result, and in 1 recurrent case excision of the capsule succeeded. In 2 of the unsuccessful cases the surgical neck was fractured during attempts at reduction. These cases show that when 6 weeks have elapsed after an injury it is improbable that manipulation will succeed in effecting restoration, and its employment may lead to fracture of the humerus or rupture of the axillary artery. If at this late period reduction is to be effected, it must be brought about by arthrotomy with or without resection of the head of the humerus. The results of arthrotomy during the last 6 years are distinctly more encouraging than were the earlier results.

A. H. Tubby,⁴ as to the present aspect of the **treatment of congenital displacement of the hip**, says there are 3 methods of treatment: exten-

¹ Lancet, Feb. 27, 1897.

³ Boston M. and S. Jour., Apr. 29, 1897.

² Med. Rec., Sept. 19, 1896.

⁴ Lancet, May 1, 1897.

sion in recumbency or by apparatus, operation, and forcible reduction. He has tried extension in recumbency in 2 cases, with considerable promise of success. If it is not possible to subject the patients to prolonged recumbency, weight-extension can be put on at night and the extension instrument can be worn during the day, the patient being allowed to walk about. This plan can be used in children under 4, but not in older subjects. Hoffa's operation is an extremely severe procedure and is very frequently followed by unsatisfactory results. The operation of Lorenz has been advocated by a number of surgeons, but Lorenz himself has recently modified his opinion of the value of the operation, and in his recent cases has carried out bloodless reduction with success. Prof. Schede, who has tried operative plans extensively, has come back to treatment by rest combined with extension and abduction. Forcible reduction can be carried out by the maneuvers of Paci as follows: the patient is recumbent; the surgeon flexes the patient's leg on the thigh and the thigh on the pelvis. The movement of the head of the femur downward is assisted by direct pressure. The thigh is now slightly abducted, and is then strongly rotated outward and extended. The movement throws the head of the femur into or on the acetabulum. Paci has reported 15 cases in which the results were admirable. Lannelongue endeavors to fix the head of the femur in its new position by injecting at intervals of 3 or 4 weeks a few drops of a 10% solution of zinc chlorid. Lorenz has modified Paci's method. He lowers the head of the femur by traction, depresses it by forcible flexion, followed by forcible abduction, and fixes the femur by a plaster-of-Paris bandage, to be worn for several months. After the reduction Mikulicz employs an apparatus to make extension with considerable abduction. Tubby himself does not think that it is possible to deepen a shallow acetabulum in such a way that the femur can be retained. In the cases of Lorenz's operation which he has seen the results have not been satisfactory. Hoffa's or Lorenz's method is very rarely necessary, and is only justifiable as a last resource. The best method of treatment will be found to be forcible reduction as practised by Lorenz.

Noble Smith,¹ in an article on **congenital dislocation of the hip**, says that dissections have proved conclusively that malformation of the part is very frequent. The head of the femur may be unnaturally small, the acetabulum may be very shallow. Some observers, however, have maintained that the bony parts of the joint are practically of natural form. Mikulicz believes that the joint is normal at the time of birth. Smith says that these diverse views lead us to infer that in different cases different conditions exist, and it is very important to differentiate between cases in which the bony parts are normal and those in which they are abnormal. The Röntgen rays are very useful in arriving at this conclusion. Smith reports a case in which the rays were used to great advantage. This child when 2 years of age was examined, and was found to have dislocation of both hip-joints. The new joints admitted of free motion, but when the attempt was made to draw the heads of the bone down into position they were arrested by coming in contact with a hard substance which was thought to be the ridges of the acetabula. Smith arrived at the view that this was probably not a congenital dislocation, but a dislocation received during birth. He recommended an attempted reduction under chloroform, but the parents refused to subject the child to this treatment. Two years later the patient was seen again, and was found to have a very awkward gait and increasing lordosis. The case was benefited by applying an apparatus to support the abdomen in a more natural position. Lately a skiagraph of both hips was taken by Mr. Sidney Rowland. The picture shows

¹ Brit. Med. Jour., Dec. 12, 1896.

that the acetabula are well formed, demonstrating that if the heads of the bone had been reduced in the first instance they would have remained *in situ*. The heads of the bones seem to be normal in shape. This picture would go to confirm the clinical judgment that the case was really one of dislocation at birth rather than of congenital dislocation.

VENEREAL DISEASE.

A. Gutheil¹ makes a report upon the use of **argonin in the treatment of gonorrhœa**. He claims that, as a rule, injections cause gonococci to disappear from the discharge in about 9 days, the drug producing no irritation. After the disappearance of the gonococci the use of argonin is abandoned and ichthyol is employed for about 3 weeks. The author tells us that a remedy for gonorrhœa should kill gonococci, should not add to inflammation, and should not damage the mucous membrane. Solutions of lead and zinc and tannin are not germicidal; corrosive sublimate and potassium permanganate are germicidal, but are very irritating. Argentamin is germicidal, but irritant. Argonin is a white powder, and is a combination of albumin, silver, and an alkali. The strength of solution used is $\frac{1}{2}\%$. [This agent was introduced by Röhmann and Liebrecht as an improvement on Schäffer's argentamin. J. W. Daniel, in a paper in the *Am. Therapist*, states that argonin is not irritant, is not precipitated by chlorids, and is not decomposed by albuminous matter; its use quickly allays ardor urinae and inflammation. In uncomplicated cases he uses a solution of a strength of 5%, introducing it for the first few days of the attack 6 or 8 times daily by means of a urethral syringe. Later in the case, besides injections by an ordinary syringe, he gives 2 injections a day with a long-nozzle syringe. Jadasohn published a report in *Arch. f. Dermat. u. Syph.* He uses argonin in solution of a strength of 1.5–2%, and maintains that this agent does not coagulate albumin and rapidly kills gonococci; it is not irritant and is very valuable in the treatment of gonorrhœa. The fact that argonin is not astringent renders it useless in nonspecific urethritis.]

Geo. Knowles Swinburne has made a favorable report on argonin.² He holds that the drug causes rapid disappearance of gonococci and allays inflammation, though *relapses* may occur. D. T. Kreissl³ thinks highly of argonin. If the duration of the case is less than 5 days, he finds 12 daily injections of 8% solution are usually enough. In cases over 5 to 10 days old injection for 18 days is usually enough. When the gonococci are not found in 3 consecutive examinations, stop the use of argonin and employ for a few days a mild solution of potassium permanganate. Argonin is of little value in chronic cases.

O. Werler⁴ claims that **citrate of silver** (itrol) does not irritate the urethra, and kills gonococci passing deeply under the mucous membrane. He uses it in solution of a strength of 1:8000, gradually increased up to 1:4000.

A. S. Hotaling⁵ reports 50 cases of gonorrhœa treated with **permanganate of zinc** injections of a strength of gr. ss–ʒj of aqua, gradually increasing to $1\frac{1}{2}$ gr. Alkaline diuretics are given internally. The average period of cessation of discharge was 9 days after beginning treatment.

H. M. Christian,⁶ writing on the **duration of acute gonorrhœa**

¹ Deutsch. med. Woch., No. 35, 1896.

² Jour. Cutan. and Genito-Urin. Dis., Aug., 1896.

³ Chicago Med. Rec., Jan., 1897.

⁵ Med. News, Nov. 7, 1896.

⁴ Berlin. klin. Woch., No. 37, 1896.

⁶ Therap. Gaz., Jan. 15, 1897.

under treatment, states that the general idea among both the laity and a large number of practitioners is that gonorrhœa is a disease that may be cured in 3 weeks. He presents a series of cases from the University of Pennsylvania, Genito-Urinary Department, showing: 1. Gonorrhœa is much more serious than usually supposed; 2. Two-thirds of uncomplicated cases require from 6 to 10 weeks for cure; 3. Four weeks is necessary in anterior urethra cases; 4. The importance of urinary examination before declaring a cure is very great. [Christian states several most important facts. We concur entirely with his views on this subject.]

J. Janet,¹ discussing the **abortive treatment of gonorrhœa**, claims that in every case in which he used the potassium permanganate before the acute symptoms showed themselves he has been able to suppress the gonorrhœal process without complication. The treatment lasts from 8 to 12 days. Janet believes the treatment has its limitations, because few patients can spare the time or expense, and only the specialist can conform to the severe regularity. Vigueron, of Marseilles, has used Janet's method for 5 years, and found it strikingly successful in the first 36 hours of the disease. Guiard, of Paris, believes in weak solutions from 1 : 6000 to 1 : 10,000. Janet agrees with Guiard as to weak solutions, and regards the irrigation of the entire urethra as important, though it may be omitted for the first day or so. An abstract of this debate in the French Assoc. of Genito-Urinary Surgeons will be found in the *Jour. of Cutaneous and Genito-Urin. Dis.*, Feb., 1897.

James Moore² considers the internal use of **methylen-blue in gonorrhœa**. He gives 3 gr. of methylen-blue three times a day and 15 gr. of potassium citrate three times a day. After the subsidence of acute symptoms he also employs injections of alum solution (gr. 3 to oz. 1 of hot water). It is useful in first attacks, cuts short the acute stage, and lessens the suffering of the patient. The drug is borne to the seat of disease by both the blood and urine, and acts by staining the organisms and the soil in which they grow. [Personally we have not been greatly impressed with the value of this drug in gonorrhœa. In first attacks it does seem to shorten somewhat the acute stage, but occasionally it produces strangury.]

König³ discusses **gonorrhœal arthritis**, and advises us invariably to examine the urethra if acute joint-inflammation exists. He says that gonorrhœal arthritis is the most usual form of joint-inflammation, many supposed cases of puerperal arthritis and chronic articular rheumatism in females being gonorrhœal. The joint most likely to suffer in woman is the wrist, in man the knee. Careful observers have found gonococci in joints, but other organisms may be found. Ankylosis is likely to follow gonorrhœal arthritis. If the case is one of simple effusion, the joint should be punctured and injected with carbolic acid. If para-articular infection also exists, the joint must be opened and washed out. Movements are employed if ankylosis threatens. Pain can be relieved by the application of a plaster splint; but as this favors ankylosis, do not employ it unless driven to it, and try first the administration of potassium iodid (45 gr. a day) and the injection of iodoform emulsion. [The common impression that a joint-inflammation occurring in a person who has a urethral discharge is of necessity gonorrhœal rheumatism, is erroneous. Gonorrhœa gives a man no immunity from ordinary arthritic inflammation. The diagnosis of gonorrhœal rheumatism is not unusually an inference or a guess. Gonorrhœal rheumatism begins more gradually than acute rheumatism, and

¹ Ann. d. Mal. d. Org. gen.-urin., p. 1013, 1896.

² Brit. Med. Jour., Jan. 16, 1897.

³ Centralbl. f. Chir., No. 48, 1896, abstracted in Ann. of Surg., May, 1897, by Daniel N. Eisendrath.

not only attacks the synovial membrane, but in many instances also the capsule and the tendons about the joint. The case is apt to be prolonged, and ankylosis is common. Suppuration is unusual. The disease attacks one or several joints, but is a-symmetrical as a rule.]

An editorial¹ on the **diagnosis and prognosis of chronic gonorrhœa**, quoting Kopp,² shows how little reliance can be placed on microscopic examination of urethral threads. Von Schlen,³ of Hanover, added the third glass test. Pezzoli⁴ examined the urine and washings from different parts of the urethra, and concluded that the urethral glands and pockets in the acute stages of a gonorrhœa are almost always affected; and in cases of chronic anterior urethritis the gonococci will be found oftener in the glands of Littre and pockets of Morgagni than in the anterior urethra itself. In chronic posterior urethritis the prostatic follicles are also involved almost without exception.

Finally, irritant injections must not be overlooked as a means of cure, but can only be of value in the anterior urethra.

Ferd. C. Valentine⁵ gives a detailed description of apparatus and technic for irrigation of the urethra and bladder, in both male and female. The solutions used are potassium permanganate, corrosive sublimate, silver nitrate, and cupric sulfate. The apparatus is simple in construction and easy to keep aseptic.

Reginald Harrison⁶ considers the **cause of suppurations in male and female generative organs**, occurring in gonorrhœal affections. Many forms of gleet, he says, are re-infections from the bladder, though in most instances the prostate is the only part showing indication of contact with septic products, the mucous membrane of the bladder being insensitive to gonococcal influences. He advises examination of the vesical urine obtained by catheter for the gonococci. He employs vesical irrigation with antiseptics, using Condy's fluid, boric acid, and silver nitrate. Borocitrate of magnesium given internally he has found valuable in sterilizing purulent urine; give 5j t. d. in water; this does not disagree with the stomach. Salicylate and benzoate of sodium together he has also found of use, giving 15 gr. of each t. d. in chloroform-water. He also finds good results in irrigating sinuses, by filling the bladder with the solution and allowing the patient to void it, part escaping by the urethra and part by the sinus.

Chas. C. Godding,⁷ writing on **non-venereal bubo**, states that the affection is quite common in the British navy, both in the home and foreign departments. The inguinal glands alone are attacked, the existing cause being a sprain, or an abrasion on the penis or toe, but there may be no appreciable cause. The glands may or may not suppurate. The constitutional condition is usually low before the onset, and progressive debility and anemia follow. In 7 years the yearly average was 733 cases among 56,000 persons, or about 13 per 1000. Three cases are reported with detailed symptoms. He believes the condition to be one of lymphadenitis, and the best treatment increasing doses of arsenic.

J. Clifford Perry,⁸ writing on **venereal buboes**, states that the percentage of gonorrhœal buboes in the U. S. Marine-Hospital Service is 2½%.

Ducrey states that he has found the **germ of soft chancre**, but the germ fails to fulfil Koch's law. Taylor claims the soft chancre is not due to a specific germ. The evidence is that a chancroidal bubo is caused by the absorp-

¹ Jour. Cutan. and Genito-Urin. Affections, Mar., 1897.

² Internat. Jour. Surg., p. 307, 1893. ³ Centralbl. f. Krankh. d. Harn. u. Sex. Org., 1893.

⁴ Arch. f. Dermat. u. Syph., 1896.

⁵ Med. Rec., June 5, 1897.

⁶ Lancet, June 26, 1897.

⁷ Brit. Med. Jour., Sept. 26, 1896.

⁸ Am. Jour. Med. Sci., Nov., 1896.

tion of toxins or ptomaines resulting from the action of the germs in the chancre lesion. The author's treatment consists in the injection of 20-30ml of the **benzoate of mercury** in non-suppurating buboes at several points. In a report of 22 cases treated by this method the greatest number of injections was 4, and the time of healing was from 5-26 days, or an average of 13.9 days, as compared with 33.76 days average by the excision method. For suppurating buboes he uses Hayden's method of a skin puncture at the most fluctuating point, evacuation, irrigation with peroxid of hydrogen, then with corrosive sublimate 1:1000, then filling with warm 10% emulsion of iodoform in vaselin and applying cold bichlorid dressing.

B. Percy Crandell,¹ on **venereal disease in the navy and its prevention**, states that the loss to the service from this cause is equal to 122 men for 6 months, or 721 cases out of 10,625 men. His conclusions are: 1. Circumcision is advisable before or immediately after enlistment; 2. Applicants should be placed on probation before final enlistment; 3. Periodical examination of crew should be insisted upon; 4. Examining parties going ashore, before going and after returning; 5. Using individual washing materials should be a rule; 6. Registration and inspection of prostitutes would prove an aid.

R. A. Stirling² calls attention to **gleet of syphilitic origin** appearing about 2 months after the primary lesion. He believes this to be a very early secondary manifestation and antecedent to the symmetrical redness on the faucial pillars. This gleet is contagious, and is rebellious to antisymphilitic treatment, responding to injection of zinc chlorid gr. ss, ʒj of aqua, gradually increased in strength. This discharge is not due to ulceration or mucous patches. It is an infectious syphilitic discharge. Its continuance is the probable cause of the stenosis which is not unusual in syphilides.

Chas. G. Cumston,³ writing on **epididymitis of tertiary syphilitic origin**, states that this symptom may appear from 2 to 20 years after the chancre, attacking preferably those from 35 to 45 years of age, venereal excess being the usual exciting cause. He reports a case which was supposed to be tuberculosis of testicle, but after a course of mixed treatment recovery took place. The affection begins in a subacute form, with or without pain. In syphiloma of the epididymis the caput or the whole organ may be involved, is firm and resistant, irregular, with indurated spots, and lacks the adhesions found in gonorrhoeal epididymo-orchitis, and is unilateral. There is also a tendency to sclerosis or gumma. Tertiary syphilitic epididymitis may be mistaken for gonorrhoeal, tuberculous, or malignant tumor, or cyst.

An editorial⁴ on **syphilis of the kidneys and its treatment** states that it is established that syphilis may attack the kidneys both in the secondary and tertiary stages; its frequency is not settled, writers varying widely. The symptoms in early secondary attacks develop about 2 or 3 months after a chancre. There is edema or frequency of urination, headache, and digestive trouble. The urine shows blood and casts. Late nephritic lesions are like ordinary chronic nephritis.

Welander⁵ concludes that mercury must be given cautiously, and that nephritis due to secondary syphilis is rarer than that caused by full doses of mercury. It is important therefore, in treating syphilis, to examine the urine frequently, and when albuminuria and cylindruria are seen to be cautious in the administration of mercury.

Arthur H. Ward,⁶ writing on **the primary lesion of syphilis**, advo-

cates the microbial theory of syphilis, holding that the lesions are caused by the toxins, and the induration is due to chemotaxic action causing migration of leukocytes. He enters quite fully into the pathology of the disease.

Lane¹ discusses the **treatment of syphilis** by the intravenous use of mercury. He uses a solution of cyanid of mercury of a strength of 1%, and in the average case injects $1\frac{1}{4}$ gr. (20m). In a severe case for the first few injections he uses double this quantity. Injections are used at first every other day, but are soon given every day. The skin over the elbow is rendered sterile, a fillet is tied around the arm, the needle is introduced into a prominent vein in front of the elbow, the fillet is loosened, the mercury is injected, and the needle is withdrawn. The author maintains that the method is entirely safe, causes rapid improvement, is painless, does not disturb the intestinal tract, and can be easily regulated according to the susceptibility of patients. He strongly commends this mode of using mercury in cerebral syphilis. It occasionally happens that the method cannot be used because of the impossibility in some individuals of making the veins prominent.

DISEASES OF THE BRAIN AND OF THE NERVES.

J. Leonard Corning² recommends the use of **congealed oils to prevent the reunion of nerves** after subcutaneous division. He introduces an oil in the wound after the nerve-trunk has been divided, and applies cold to congeal the oil. The melting-point of the oil should be at least 3° above the normal blood-temperature. A good non-irritant oil may be obtained by melting oil of theobroma over a water-bath and adding paraffin until the melting-point of the mixture is over 105°.

Robert Abbe³ writes on the **intradural section of the spinal nerves for neuralgia**, and reports 3 cases in which he divided portions of the posterior roots of the brachial plexus or resected them at their origin from the cord. The field of this operation, though necessarily small, will probably prove to be important, especially in cases of acute neuritis starting in the peripheral nerve and ascending.

Mayo Robson⁴ reports a case in which the **spinal cord of a rabbit was successfully used as a graft** in the median nerve of a man of 29; 7 months before, he had fallen on a scythe, which had produced a deep cut on the inferior and inner aspect of the arm, dividing the brachial artery. At the time of injury a surgeon had tied the artery and sutured a divided nerve. It was evident that there had been a complete division of the median, ulnar, and internal cutaneous nerves, and it was decided to operate. An incision was made along the line of cicatrix and a transverse incision was added to this 1 in. above the elbow. The ulnar nerve was firmly anchored in fibrous tissue and the lower end of the proximal portion was bulbous and connected by fibrous tissue to the upper end of the distal portion. The severed internal cutaneous nerve was discovered and sutured. About the middle of the upper arm the bulbous end of the upper segment of the median nerve was discovered. The upper end of the lower segment was found just above the elbow. The fibrous tissue between the ends of the ulnar nerve was excised and the two portions of nerve united by grafting strands of the sciatic nerve of the rabbit, so as to fill up the gap and produce continuity. The ends of the median nerve could not be brought nearer together than $2\frac{1}{2}$ in. The spinal cord was dissected from a recently killed rabbit, and this was used as a graft to join the ends of the

¹ Brit. Med. Jour., Dec. 12, 1896.

² Boston M. and S. Jour., Oct. 18, 1896.

³ Med. Rec., Dec. 5, 1896.

⁴ Brit. Med. Jour., Oct. 31, 1896.

median nerve. Fine catgut was the suture-material employed. The edges of the wound were approximated and the arm placed on a right-angled splint. Healing took place by first intention, and 10 days after the operation sensation was obviously returning, and in another week it returned more markedly. After about 4 months the nutrition of the hand was very greatly improved. It felt warmer and the man was able to pick up small objects. The power of flexion of the wrist and abduction of the thumb was increased, but there was no sensation over the ulnar distribution. Six years after the operation the right forearm is only $\frac{1}{8}$ in. less in circumference than the left forearm. All the muscles except the abductor of the thumb are as well developed on the right side as on the left, this being true even of the interossei. The movements of the arm are completely restored, and are almost as perfect as those of the left arm. Flexion of the fingers and the grasp have completely returned, sensation is entirely restored, and the electrical reactions, except those exhibited by the abductor of the thumb, are normal. In this case, although recovery has been slow it is complete, except in regard to the abductor pollicis. This case demonstrates absolutely that we can restore nerve-continuity by grafting. We do not know whether the rabbit's cord assumed the function of the nerve, or whether it simply acted as a basis on which nerve-tissue was constructed. Why it is that the restoration of function in the ulnar area required a longer time than in the median distribution it is impossible to say. [A great variety of plans have been employed in endeavoring to restore nerve-function after a loss of nerve-substance. A plan which suits one case may not suit another. Von Bergmann has proposed in some cases to shorten the limb by bone-resection, so as to permit the approximation of the separated ends of the nerve. Létiévant has suggested the attachment of the proximal end of the peripheral portion of a cut nerve-trunk to a near-by uncut nerve-trunk. A flap may be formed on the central stump, or flaps can be made upon both the central stump and the peripheral stump. The suture *à distance* may be employed, cutgut passing from cut end to cut end (Assaky). Vaulair employs a tubular suture. Schüller stretches the nerve. Other surgeons have implanted a piece of nerve from one of the lower animals or from a recently amputated human limb. When two nerves which run in the same direction and near each other are cut obliquely Tillmanns sutures the long central stump to the short peripheral stump, and *vice versa*. Huber, of Ann Arbor, recently reviewed this subject most ably and reported some striking experiments of his own. He tells us that nerve-implantation has been performed 14 times, success being obtained in but 3 cases, and he asserts that the implanted portion always degenerates and serves only as a support for growing axis-cylinders. Robson's case is a brilliant success and is unique.]

A. E. Morison¹ describes a **method for locating the fissure of Rolando**: "The measurements may be made with a piece of sterilized silk marked off by knots to form the triangle, or by defining the sides of the triangle by means of the surgeon's finger, whose length is already known. A point is taken half-way between the glabella and the external occipital protuberance, and the breadth of the little finger behind it (about $\frac{1}{2}$ in.) indicates the apex of the triangle. An isosceles triangle is then mapped out on the scalp; its sides are $3\frac{3}{4}$ in. long. One lies in the middle line forward from the point mentioned above. The base measures $4\frac{1}{8}$ in., and is anterior. The posterior side of the triangle is over the fissure of Rolando. Trigonometrically the apical angle of this triangle is $67^{\circ} 27' 52''$, and this is practically identical with the angle formed by the fissure and the middle line of the skull worked

¹ Brit. Med. Jour., No. 1868, 1896.

out by other methods, and, from an examination of a large number of skulls of various sizes, is constant and correct."

R. Abbe¹ reports a case in which he **implanted some rubber tissue under the dura mater.** A year has passed since the operation and no ill effects whatever have become manifest. The patient suffered from Jacksonian epilepsy. Adhesions between the dura and the brain were found over the arm-center. These adhesions were broken up and a bit of rubber tissue was placed between the brain and the dura and the dura sutured over it.

Payr² describes some instruments he has devised with the object of **exploring the cranial cavity by means of small perforations** made in the bones. He uses a fine drill and syringe, straight and curved needles, capillary glass tubes, a glass rod (one end of which is right-angled and drawn into a thread), and also harpoons. The author has made many experiments on animals in order to discover whether it were possible by the use of small perforations in the cranium to determine the existence of a fluid collection in the brain or under the meninges, and the nature of the fluid removed, to secure minute portions of brain-substance for histologic examination, and to prove the existence or absence of pulsatile movements of the dura. Pulsation of this membrane can be shown by the mounting of the fluid in the capillary glass tube which is passed into the cranial cavity through the drill-hole, and it can also be shown by movements of the glass rod when that is inserted. He tells us that we may determine if the collection of fluid is pus, hydatid material, or blood by the use of an exploring-syringe. The situation of the growth and its nature can be ascertained if we remove a small portion by the harpoon. Through one of these drill-holes we can penetrate the lateral ventricle, and it is even possible that by a ligature passed through 2 drill-holes we could arrest hemorrhage from the middle meningeal or a venous sinus. [The above procedures appear to us fanciful, dangerous, unsurgical, and unsatisfactory. It is certainly safer to trephine and explore than to plunge instruments into the brain on the trust to Providence principle.]

Gilbert Barling³ reports 3 cases of **otitis media with brain-abscesses.** In the 1st case otitis media was followed by extradural suppuration and abscess of the cerebellum. Operation was followed by recovery. In the 2d case otitis media was followed by abscess of the cerebellum, and trephining was followed by death. Necropsy showed the existence of a second abscess. In the 3d case cerebral abscess followed otitis media, and recovery ensued upon operation.

Marchant and Herbet⁴ write on **resection of the Gasserian ganglion.** They come to the conclusion that some forms of facial neuralgia are due to lesion of the ganglion. This lesion is inflammatory in nature, and the proper treatment is destruction of the ganglion. In some cases in which there has been no ganglionic lesion and yet the neuralgia has ceased after the ganglion has been extirpated, we must assume that the cure has been brought about by destruction of this nerve-center. The best route to reach the ganglion is the entrance through the temporosphenoidal region, because by this route we are readily led to the ganglion by finding the inferior maxillary division in the foramen ovale. Complete extirpation is certainly possible, but in the majority of the cases which have been recorded incomplete destruction was practised by means of cureting or crushing. Some surgeons only resect the branches of the ganglion. The accidents which most commonly result from the operation are hemorrhage from the middle meningeal or the dural vessels and cerebral

¹ Ann. of Surg., Jan., 1897.

³ Brit. Med. Jour., June 12, 1897.

² Centralbl. f. Chir., No. 31, 1896.

⁴ Rev. de Chir., Apr., 1897.

compression. Septic infection may take place, and secondary hemorrhage may occur, as may iodoform-poisoning and eye-trouble. Immediately after the operation anesthesia is noted in the area supplied by the three chief branches of the ganglion, but this anesthesia is not persistent. Relapse is less common after destruction of the ganglion than after removal of its main branches. An examination of the statistics would not indicate that complete removal of the ganglion gives a better result than simple destruction of it. Out of 95 recorded cases there were 17 deaths. By the temporal route the death-rate is $12\frac{1}{2}\%$. In Rose's method the death-rate is $20\frac{1}{2}\%$. The mortality is the same for complete extirpation of the ganglion as for incomplete removal of it.

Louis McLane Tiffany¹ makes an elaborate study of **intracranial operations for the cure of facial neuralgia**. He says that a consideration of operative measures resolves itself at the present time into a consideration of intracranial operations for the removal of the Gasserian ganglion and nerves, or either of these structures. The history of operative measures for the relief of neuralgia shows that the first operations were done on peripheral nerves, and that surgeons gradually advanced in the central direction. With each advance toward the center fresh hopes of cure were raised. The removal of Meckel's ganglion and the superior maxillary nerve excited confident hopes. Peripheral operations will cure many cases, but not all of them. In some cases the trouble returns, and the question to be considered is whether or not the ganglion of Gasser when removed absolutely cuts off the pain-route in nearly all cases. Tiffany is careful to state "in nearly all cases," because it is beyond question that some cases of neuralgia are expressive of a central lesion. The credit of first removing this ganglion is accorded to Rose. Andrews, of Chicago, had thought out a similar method, but Rose operated before him. The Hartley-Krause operation has been more frequently done than any other procedure. Doyen has devised a method of reaching the ganglion by the temporal route. Tiffany then describes Doyen's operation. The total number of Gasserian-ganglion operations collected is 108; nearly $\frac{2}{3}$ of these were operated upon by the Hartley-Krause method, $\frac{1}{4}$ by Rose's method, 7 by Horsley's method, 4 by Doyen's method, 4 by a method of Quenu, 1 by Navarro's plan. There were 47 operators. The patients varied in age from 20 years to 79, and there were more men than women. The right side was twice as often affected as the left side. In 22 cases all of the divisions were affected; in 10 cases only the 3d division; in 6 cases only the 2d division. In the remaining cases the 2d and 3d divisions were affected. There was no instance in which the 1st alone was the seat of pain; the 2d and 3d were always affected with it. In fact, it is a question whether, when the 1st division is affected, it is not affected reflexly. There seems to be nothing that we can with justice claim as the cause of facial neuralgia. In some cases spasm of the facial muscles accompanied the pain, but there was no case in which the muscle-spasm sometimes accompanied the pain and sometimes did not. In some cases, when the patient made an effort to keep the face-muscles quiet during the pain, trembling of the corresponding side of the face occurred. The areas of distribution of the pain correspond to the divisions of the fifth nerve above. Paroxysms can be induced by moving or handling the involved area. There are very generally extremely hyperesthetic points which when touched cause a pain-paroxysm. There may be a scarlet flush over the pain-area during a paroxysm. Heat and cold may also serve to develop pain-paroxysms. A central operation is rarely seriously considered by the patient until the materia medica has been exhausted and peripheral operations have been performed

¹ Ann. of Surg., Nov., 1896.

without avail. Many of these patients become addicted to morphin. The one persistent condition which is found present in the victims of facial neuralgia is arterial sclerosis, and it exists in the ganglion as well as in the branches. It is not certain, however, that a sclerosis is more positive in the Gasserian ganglion and branches the subject of pain than in the Gasserian ganglion and branches not the subject of pain on the opposite side of the same individual. The best operation is the Hartley-Krause method. This gives excellent access to the ganglion, which can be seen well together with its branches. If we decide that removal of the sensory route near to the ganglion is expedient, it can readily be performed; and again, motion of the lower jaw cannot be impaired, as it may be by the Rose operation. The osseous flap can be cut with a chisel, circular saw, etc., but it must be large enough to admit of safe work. The opening must be as low down as the zygoma. Preliminary ligation of a carotid artery may predispose to necrosis of the flap, soft and osseous. If ligation is decided upon as advisable, it is a question whether it should not be done very shortly before the Hartley-Krause operation. There seems to be no special advantage in replacing the bone-flap, as the temporal fascia makes a very firm scar. The advantage of not replacing the flap is that we leave a permanent route by which the interior of the head can be reached at any time without trouble. The dura can be separated from the base very easily by a piece of cotton held in forceps, the cotton pressure serving to diminish the bleeding. If there is excessive bleeding, gauze-packing applied for a short time will arrest the flow of blood and permit the continuation of the operation. The bleeding is venous and comes from vessels which pass between the bone and the dura. The middle meningeal artery may, of course, be wounded. The 2d branch is the first one which comes into view, then the 3d is found and the ganglion is exposed. The lifting of the brain from the floor of the skull is rendered much easier by making an incision in the dura and evacuating some of the cerebrospinal fluid. There is no doubt that the ganglion and branches can be removed after they have been thoroughly exposed, but the advisability of so removing them is questionable. The first branch is never affected alone, although it may be involved reflexly, and when the first division is removed there is apt to be trouble of one sort or another. The eye-involvement manifests itself by corneal anesthesia and panophthalmitis. The above are the two chief reasons why it is not advisable to take away the upper portion of the ganglion and the 1st branch, but rather to remove the 2d and 3d branches with the corresponding portions of the ganglion. The ganglion should always be uncovered, and the portion indicated excised. We should consider the expediency of trying to save the motor fibers which accompany the 3d branch. Tiffany says that, as a rule, he has not taken the pains to do this, yet he has thought that he recognized them, being able in one case to make the muscles of mastication contract by passing a tenaculum into the 3d branch close to the bone. Another reason why it is desirable to leave the motor route is that it might become necessary at a future time to operate on the other Gasserian ganglion, and, if we did the ordinary operation, there would be bilateral paralysis of the muscles of mastication. The motor root should be spared, as it often can be. The operation should be finished at one sitting, if this is possible, and the wound should be drained. Entire closure of the wound without drainage will be likely to make trouble. Of the 108 reported cases, 24 died. Tiffany then analyzes the causes of death. The study of the cases proves conclusively that intracranial excision of the 5th nerve relieves pain, certainly for a time, and possibly permanently; but pain may recur again, possibly in the territory which was presided over by the excised branch, possibly in other

branches. If the Gasserian ganglion is removed, there is never recurrence of pain; that is, after known removal pain does not recur, but in cases in which the ganglion has been picked or everted away we do not know that it has been entirely removed, and in some of these cases pain has recurred. In cases in which pain has recurred after operations on the ganglion the operation has been attempted removal rather than known removal.

Conjunctivitis, anesthesia of the cornea, and ulcer of the cornea have been frequently observed on the side of operation, but when the eye is protected from injury it recovers as a rule. Ross, Krönlein, Keen, and Tiffany have been obliged to enucleate an eye after operation. Sewing the lids together avoids irritation from the presence of foreign bodies. Such results show the importance of leaving the first branch, and thus avoiding eye-injury. If eye-irritation occur, the organ should be covered with a watch-glass. Ordinary sensation in the nerve-trajectory is abolished over a small area and is irregularly present over a larger area. We often find ordinary sensation where pain-sensation is abolished. The secretion of saliva is unaffected. It is not always possible to say what cases require the central operation, but the following suggestions may be of assistance to the surgeon: intracranial operation is to be considered if more than one branch of the nerve is affected; if the painful area receives filaments from the branches near the exit from the head, the tongue, the temporal region, etc. If the pain is not due to constitutional disease; if there is any cause central to the ganglion; if other measures have failed; the operation which Tiffany advises is the removal of the lower $\frac{2}{3}$ of the ganglion with the 2d and 3d branches as far as their points of exit from the skull all in one piece, the upper 3d of the ganglion and 1st branch not being excised. Tiffany then presents an epitome of all the published cases.

H. M. Thomas and W. W. Keen¹ report a successful case of **removal of a large tumor** from the left frontal region in which the lateral ventricle was opened and packed with iodoform-gauze. The tumor weighed $2\frac{1}{2}$ oz., and its dimensions were $3\frac{1}{2}$ by $2\frac{1}{8}$ by $1\frac{9}{16}$ in. After the tumor had been removed a clot was seen at the bottom of the cavity. Keen removed this by lifting it out. He then discovered that he had opened directly into the ventricle at a point where the anterior cornua joins the main cavity. A piece of iodoform-gauze was carried into the cavity occupied by the tumor, the end of the gauze filling the anterior portion of the lateral ventricle. This patient was greatly improved. Five months after operation he had no head-symptoms, was perfectly free from headache, and was in excellent health and spirits. Exophthalmos of the left eye, which was marked, had disappeared, and the muscles of the face on the two sides acted equally. The vision of the left eye had improved somewhat, but he still was unable to see well enough to walk alone.

B. Sachs and A. G. Gerster² write on the **surgical treatment of focal epilepsy**, and consider 19 cases upon which they operated. They report 3 of these cases cured, 5 improved, and 11 unimproved; 3 of the 11 died as a result of the operation. The authors have come to the conclusion that, if a long time has elapsed since the injury, operation will fail, and that in most cases operation is not of benefit. They advise operation in cases of essential epilepsy in which the onset of the disease or the traumatism was but 1 or 2 years previously. If there is obvious skull-injury, surgical operation is advisable, even if years have passed. In many cases ordinary simple trephining is enough, and this is particularly true in cases in which the epilepsy is due to a cystic condition of the brain or in which there was an injury of the skull. If the epilepsy has lasted a very short time, and if the evidence indicates the

¹ Am. Jour. Med. Sci., Nov., 1896.

² Ann. of Surg., Feb., 1897.

existence of a very limited area of disease, a portion of the cortex should be excised. Remember that cortical lesions are frequently microscopic, and the mere fact that the tissue appears normal does not contraindicate excision of the area. It is justifiable to attempt surgical treatment in epilepsy associated with infantile palsies of cerebral origin, if the palsy is not too old. In long-standing cases of epilepsy no surgical procedure is of any use.

Charles B. Nanerode¹ writes on the **operative treatment of Jacksonian epilepsy**, and comes to the following conclusions: Removal of a discharging lesion in cortical and Jacksonian epilepsy is palliative only, the operative scar infallibly becoming a new source of irritation. The sooner the operation is done after the establishment of the disease the more prolonged will be the immunity. It is possible that trephining performed very early may cure, especially if we find any really reliable method to lessen the area of the scar and to prevent adhesions between the brain and the membranes. In competent hands the operation is not so dangerous as to forbid our urging trephining in this class of epilepsies, especially when done early, because the chance of a prolonged immunity is greater and the fits are likely to be lighter and to recur at greater intervals after the relapse than before the trephining. When the intervals between the fits are so short that the paroxysms are practically continuous the removal of the discharging-center is a life-saving measure. It is a great mistake to permit the patient to resume work early, particularly manual work, after one of these operations, because muscular effort may lead to congestion of the encephalon and the reestablishment of the convulsions. Operation removes but one of the factors causative of epilepsy, but the too ready response to stimuli still remains and can only disappear, if it ever disappears, after a prolonged period. The individual must avoid everything which may excite acute cerebral congestion or constant congestion. He, therefore, must avoid excitement of mind and body and mental strain for a prolonged period or possibly for the remainder of his life. [There can be no doubt that the high anticipations which were once entertained as to the curability of epilepsy by operation have not been realized. Von Bergmann does not think that permanent cure can be obtained. Occasionally a case is really cured; sometimes operation renders a patient more amenable to medical treatment and leads to prolonged improvement. As a rule, the most we can expect is improvement, which may be very temporary, but which not infrequently lasts for a year or more. We believe, with Dana, that freedom from fits for a year or more is worth the suffering and slight risk incurred by operation. Early operations upon cases of traumatic origin offer the best prospects of gain.]

William N. Bullard² makes a statistical study to determine the **permanent or later results of fractures of the skull**. His conclusions are as follows: Out of 70 persons who had had fracture of the skull, 37 presented no symptoms when examined some time later; only 7 presented serious symptoms, and in 4 of these it is very doubtful if the symptoms were due to the injury. The most frequent consequences were headache, deafness, dizziness, and inability to resist the action of alcohol. Out of 15 cases in which operation (trephining, etc.) had been performed, 12 had no symptoms. In one it was doubtful whether the symptoms were due to the injury; in another the symptoms were very slight. The other was deaf, but had no other trouble. We are, therefore, justified in concluding that those cases in which trephining was performed have shown much better results than those in which no operation was performed.

¹ Ann. of Surg., Aug., 1896.

² Boston M. and S. Jour., Apr. 29, 1897.

DISEASES OF THE SPINAL COLUMN AND SPINAL CORD.

Enderlen¹ maintains that in **fracture of the lumbar region of the spinal column** operation is not justifiable unless the fracture involves the arch of the vertebra and is comminuted or complicated, or unless bone-fragments have damaged the cord. If such complications do not exist, it is a difficult or impossible matter to diagnosticate fracture from concussion and bruising of the cord, and an early operation is never to be thought of in either one of these conditions. The author is also opposed to operating for the removal of a blood-clot, because the clot may undergo absorption by process of nature after the lapse of, it may be, months, or even, as in one instance on record, after the period of 2½ years. Cases have been reported in which it is claimed that the operation proved of great benefit; but it is uncertain whether the benefit was due to nature or the operation. Even when the cord is subjected to pressure it is not well to operate early, and we should allow some three weeks to pass before we operate. In 95% of all cases the vertebral body is the seat of the injury. The reports of cases operated on would indicate that fracture of the arches has been almost as common as fracture of the body. In view of the fact that postmortem observations show that 95% of the fractures met with are fractures of the body, we would of necessity conclude that fractures of the body are far graver in their consequences than fractures of the arch, and fractures of the arch are more readily reached for surgical treatment. The author reports a case in which there was fracture of the 6th dorsal and 1st lumbar vertebrae, followed by anesthesia and sphincter-paralysis. Some 6 months later the patient died of phthisis. The postmortem examination showed that there had been a slight injury of the 5th and 6th dorsal vertebrae and a fracture of the body of the first lumbar vertebra, fragments of which had been driven into the spinal cord. There was an almost complete transverse cord-injury.

De Forest Willard² writes on **laminectomy in spinal caries paraplegia**. He concludes that the prognosis in the paraplegia of Pott's disease is hopeful, except in those cases in which the cord has been actually destroyed. Laminectomy should not be undertaken until the patient has been treated for at least a year by rest, fixation, extension, and the administration of alternatives. The operation is extremely dangerous: 24% die from immediate shock, 36% die within 1 month, 46% die within 1 year, and 65% are not improved by the operation. The dangers are from hemorrhage, shock, and reflex disturbances from manipulation of the cord. Nevertheless, the operation is called for in selected cases when careful and persistent treatment has failed. [Willard's conclusions are eminently wise. Laminectomy is only to be thought of in a few selected cases.]

Chipault³ discusses **acute osteomyelitis of the vertebræ** and reports 3 cases, with a notice of 28 cases seen by others. His conclusions are that the vertebræ may be alone the seat of trouble, or other bones may also be affected, and there may be various visceral lesions. In only a few cases have the causative germs been sought for. In 4 cases staphylococcus pyogenes aureus was discovered, and in another case staphylococcus pyogenes was found; 19 cases out of 23 were males, and all the cases but 4 were less than 20 years of age. In some cases the exciting cause has been traumatism, in others fatigue and chilling of the surface of the body. The changes induced are identical with those of osteomyelitis anywhere. The lumbar region is the most commonly affected. The arches are affected more frequently than the bodies, and the bodies more

¹ Deutsch, Zeit. f. Chir., Bd. xliiii., p. 329.

² Jour. Nerv. and Ment. Dis., Apr., 1897.

³ Gaz. des Hôpitaux, Dec. 12, 1896.

commonly than the lateral portions of the vertebrae, but in some cases several portions of the vertebrae are attacked. In only 2 cases in which the vertebral bodies were involved was there spinal curvature. The absence of this spinal curvature, Chipault tells us, is due to the dorsal decubitus and the hyperostosis which quickly ensues. The vertebral joints may become involved, or pus may collect. The situation of the collection of pus varies with the situation of disease. If the bodies are diseased, the pus will pass forward, forming a retropharyngeal abscess, a mediastinal abscess, a psoas abscess, or a pelvic abscess. If the posterior parts of the vertebrae are diseased, a dorsal abscess is formed. Inflammation of the cellular tissue about the membranes of the cord, of the membranes themselves, or of the cord, may occur. The general symptoms of vertebral osteomyelitis are high fever, weak and rapid pulse, delirium, diarrhea, and the passage of small amounts of albuminous urine. The local symptoms are influenced by the seat of trouble. When the posterior portion of the vertebrae is the seat of disease brawny swelling can be made out, the swelling being in the middle line, in the neck, on one side, or in the middle line in the dorsal and lumbar regions, but always on one side in the sacral region. Fluctuation is very rarely detected. When the bodies of the vertebrae are attacked spinal rigidity and acute sensibility are noted, with other symptoms which depend on the region attacked. In some cases meningomyelitis may be present. The treatment consists in incision, removal of the pus and any sequestra, disinfection, and drainage. [The pressure-symptoms of acute osteomyelitis come on very suddenly. This is in contrast with tuberculous disease, in which there is a gradual onset of pressure-symptoms after a prolonged period dominated by evidences of irritation. The sudden onset of pressure-symptoms has led Müller to attribute them to edema of the cord. Makins and Abbott discussed this subject most carefully last year. See *Year-Book* for 1897.]

Thelwall Thomas¹ reports two interesting cases in which he succeeded in curing sacral meningoceles by excision.

F. Calot² writes on the **treatment of the deformity of Pott's disease**. His method is as follows: the patient is anesthetized and laid upon his face. One assistant takes hold of the hands and another assistant grasps the feet, and strong traction is made. An assistant supports the pelvis and lower abdomen, another the upper abdomen and chest. It is often necessary to resect the spines of the projecting vertebrae and remove the thickened skin above these spines. After this operation has been performed the surgeon is able to apply pressure where it is needed. In some cases when the deformity is maintained by bone-deposit the author resects the spines and laminae and performs cuneiform osteotomy of the ankylosed bodies of the vertebrae. Whatever means are taken to correct this deformity should be followed by the application of a plaster-jacket for the head, neck, trunk, and pelvis. This jacket is worn for 3 months, when a fresh one is applied, which is also worn for 3 months. The patient then has placed upon him a poroplastic jacket and is allowed to walk about. Calot has operated on 37 patients without a death; 5 of the patients were straightened forcibly. In 30 resection of the vertebral spines, and in 2 cuneiform osteotomy was performed. Several of the patients had been deformed as long as eight years. Some of the operations were performed when the disease was active, some when it was passive. The results in some of the cases were very remarkable. Calot tells us that in the early stages of Pott's disease we should apply pressure over the diseased

area and use extension in order to prevent deformity. [Calot was preceded by Chipault in treating the deformity of Pott's disease by forcible correction.]

DISEASES OF THE PENIS, THE URETHRA, AND THE TESTICLE.

Arthur H. Ward¹ reports a case of **persistent priapism**. The patient was unmarried and 32 years of age, and came to the hospital with the statement that his penis had been continuously erect for 5 days. There had been no illness or accident, the patient was temperate, and there was no evidence of malaria; 8 days before admission he had had sexual intercourse; 5 days before admission he arose at night to make water, and on returning to bed erection occurred and continued. There was no emission and no sexual desire, and turning in bed caused much pain in the body of the penis. The erection was limited to the corpora cavernosa, the glans and corpus spongiosum being flaccid. Pulse and temperature were normal. There were no signs of local hemorrhage. Micturition was accompanied by pain and straining, and a soft catheter was used. The spleen was enlarged. The penis was treated with lead water and laudanum and the patient given cathartics, diuretics, and anodynes. Later potassium iodid was administered internally. Gradually the penis became less rigid, and on the 7th day fluctuation was detected over the corpora cavernosa and the spleen was found to have increased in size. Arsenic was added to the treatment. Examination of the blood showed that leukocythemia existed. By the end of the 8th week the penis was normal and the patient was able to have normal erections without pain. The author believes that the priapism was due to spontaneous thrombosis of the corpora cavernosa, caused by erection when the blood was leukocythemic. It would have been possible to squeeze out blood-clots through incisions, but incisions in such a case might be followed by disastrous infection, and might leave as a legacy distortion from trabecular adhesions. Incisions are only justifiable if suppuration occurs. The fact that the corpus spongiosum was not involved proves that the condition was not due to reflex irritation or cerebral excitement, and the same fact is proved by the persistence of the priapism for weeks. The author publishes a table containing the records of 12 cases of priapism.

J. N. Bartholomew² writes upon the **radical cure of hydrocele** by a new ambulatory method. An incision $\frac{1}{4}$ in. in length is made at the most dependent portion, the incision reaching to but not passing into the tunica vaginalis. The sac is dissected loose from the infundibuliform fascia and is loosened up to the epididymis. The sac is now opened, and the wall of the empty sac is pulled through the small incision and cut off close to the epididymis. The testicle is examined, and any granulations or cartilaginous bodies are removed. The incision contracts to $\frac{1}{2}$ of its original length, requires no stitches, and serves to drain the parts. After the completion of the operation the testicle is strapped as in a case of epididymitis, and the patient is permitted to walk about.

E. A. Southam³ discusses the radical cure of hydrocele by excision of the sac and furnishes notes of 22 cases. Southam does not employ drainage, but after the operation elevates the scrotum and applies pressure by means of wood-wool pads. This radical operation should be performed in the following conditions: if the patient wishes a radical cure, but does not care to take the risk of a failure of the method of injection; if the hydrocele is old, with thick and rigid walls; when injection has failed; when a sac suppurates after tapping;

¹ Lancet, Apr. 24, 1897.

² Jour. Am. Med. Assoc., Apr. 24, 1897.

³ Lancet, Mar. 20, 1897.

when a hematocele forms after tapping; when an inguinal hernia exists with hydrocele and we desire to cure the hernia radically; when, as a consequence of previous tapping, the testicle adheres to the scrotum; if the hydrocele is multilocular; if the hydrocele is encysted.

Weissblatt¹ reports a case of **fracture of the penis**. The patient when drunk had bent the penis violently. The next morning the organ was enormously swollen and discolored. On one side there was distinct thickening, due to laceration of a corpus cavernosum. The patient was placed in bed and treated by the local use of lead-water and laudanum and cold, and recovered in 2 weeks, although the spot of thickening remained. In 6 weeks the patient was able to indulge in sexual intercourse, although there was an area of thickening still existing the size of a pea.

Gwilym G. Davis² advises the following **method of amputating the penis**: bleeding is controlled by a rubber tube caught around the base of the penis; a circular incision is made through the skin to the tunica albuginea; an incision is made through the spongy body, the urethra is dissected up for half an inch, and the cavernous bodies are cut transversely at this point. Vessels are ligated with fine gut; the catgut sutures are passed through the outer edge and substance of the cavernous bodies on each side. When these are tied the cut surface is folded in the middle and forms a straight union upward from the projecting urethra. The urethra is slit in 3 places so as to form 3 flaps reaching back to the cavernous bodies. The corners of the flaps are cut off, leaving 3 triangular flaps which, when opened out, make one large triangle, the apex of which is above and the base below. The skin is sutured to these flaps by catgut.

W. G. Handley³ advocates the performance of **inguinal instead of scrotal orchidectomy**. An incision is made in the line of the cord and over the external abdominal ring. This incision is slightly curved, its convexity being downward and outward, and is about 1½ in. long. The cord is isolated and pulled upward. Traction is kept up upon the cord, and the tissues are freed from the advancing cord and testicle by means of a blunt dissector. The testicle is taken out of the incision and removed, and the cord treated as usual. The scrotum should be invaginated through the wound in order to find and tie bleeding points. The incision is closed by a continuous horsehair suture. This wound, unlike a wound in the scrotum, can be approximated with accuracy, and infection is far rarer after inguinal than after scrotal orchidectomy. In the new operation there is no risk of hemorrhage in the tissues after castration, and the wound can be dressed and thoroughly protected with ease.

Ramon Guitéras,⁴ in an article upon the treatment of stricture of the male urethra, describes the **treatment of stricture** by means of Fort's linear electrolyzer. The author states that the instrument resembles in outline the Maisonneuve urethrotome, although the blade is dull and is made of platinum. The blade of the instrument is connected with the negative pole of a galvanic battery. The chamois-covered positive pole is placed over the pubis or thigh, and the guide is carried into the urethra until the blade comes in contact with the stricture, when the current is turned on and the blade passes through the stricture. The current is turned off, and, if there be another stricture, the instrument is passed on until the next constriction is encountered, when the instrument is passed through it in the same way. The blade does not become heated and the operation causes very little pain. The current-strength is from 10-20 ma. It requires from 30 sec. to 4 min. to pass through a stricture.

¹ Deutsch. med. Zeit., Dec. 24, 1896.

³ Lancet, Dec. 12, 1896.

² Univ. Med. Mag., Jan., 1897.

⁴ Med. Rec., Nov. 14, 1896.

The operation brings the urethra up to the size of a No. 18 F. sound. After the use of Fort's instrument the urethra can be enlarged still more by the passage of larger bougies, or, if the stricture is anterior, by the performance of internal urethrotomy. This operation does not lacerate as much as does the operation of Maisonneuve, is not so painful, is not attended with hemorrhage nor followed by infection, and micturition afterward is but slightly painful.

Guitéras's conclusions on the treatment of stricture are as follows: Whatever treatment is employed urinary antiseptics must be given. If the meatus is small, the beginning of treatment is meatotomy. If possible, dilatation should be employed rather than cutting. In very small strictures continuous dilatation gives excellent results. It should always be used to enlarge the urethra for gradual dilatation or for the introduction of a guide if cutting is necessary. Oberlander's dilator is the best instrument for gradual dilatation. If dilatation fails to cure, urethrotomy must be performed. If a filiform bougie is passed only with great trouble, do not carry a tunnelled catheter over it unless it is proposed to operate at once, because to do so lacerates the urethra. If an operation becomes necessary to cure a small anterior stricture, most surgeons advocate internal urethrotomy by the plan of Maisonneuve; but Fort's operation is safer. If it is necessary to cut an anterior stricture the caliber of which is over 18 F., use Otis's urethrotome. If a perineal operation is necessary, avoid Coek's operation if possible. In a perineal operation it is well to use the tunnelled catheter threaded over a filiform as a guide. No special method of section is applicable to all cases. Never do perineal section without a guide unless obliged to; and if we can use a guide, use the largest one which can be inserted. There is no operation which will permanently cure a small and densely fibrous stricture of long standing. After operation such cases must be watched as long as the man lives.

Fort, in a letter to the *Medical Record*, Jan. 9, 1897, corrects some statements made by Guitéras about the operation of linear electrolysis. He says his instrument in no wise resembles the urethrotome of Maisonneuve, as it is composed of but one piece, and is like a whip which has a platinum blade projecting near the center. The operation lasts generally from 20 to 30 sec., and should never last longer than 1 min. After operation pass, not an 18 F. sound, but a No. 22-24 F. After operation it is never necessary to perform internal urethrotomy. [There can be no question that Fort's method is a great improvement upon the older plan of electrolysis. The older operation has been completely abandoned, because results were often bad and never permanent, healthy tissue as well as diseased tissue being acted on by the current. Fort's instrument enables us to act purely upon diseased tissue. This operation causes so slight an amount of pain that it is not necessary to cocaineize the urethra, and the patient is not confined to bed. It is claimed by some that the cure is permanent, but this point is doubtful. The method of Fort has been practised and praised by Chas. Chassaignac, Bruce Clarke, Stevenson, Charles, Beni Madhab Baso, and others.]

A. J. Jonas¹ discusses **retrograde catheterization in impermeable deep urethral strictures**, and reports 4 cases. He says we may completely loose the proximal end of the urethra when performing a perineal operation for impermeable stricture. If this happens, attempt to discover the lost tube by making pressure above the pubes and in the rectum, in the hope that a stream of water will flow from the proximal end of the divided urethra and so disclose the situation of the canal. If we cannot discover the lost urethra by this means, perform suprapubic cystotomy and follow this by retrograde cath-

¹ Med. Rec., Feb. 6, 1897.

eterization. The passage of a catheter from behind forward furnishes a guide to enter and enables us to complete the formation of a channel. Jonas uses a large elastic tube for retrograde sounding, thinking it safer than a metal instrument. This tube is kept in place for a time to secure perineal drainage. In impermeable stricture the cicatricial structure should be extirpated. No instrument is passed through the anterior urethra until the perineal drainage-tube has been permanently removed (when urine has become clear and nearly free from epithelium, triple phosphate, etc.). When the perineal tube is removed a sound is introduced from the meatus every day, the size of the instrument being progressively increased until a full-sized one can be used. [The practicability of safely excising large areas of diseased urethra has been proved by Eugene Fuller,¹ who in 1 case excised the entire bulb, 1 in. of penile urethra in front of the bulb, and the anterior $\frac{1}{2}$ in. of the membranous urethra. In another case he took away $1\frac{3}{4}$ in. of urethra. The results were excellent. Fuller doubts the value of grafts in these cases. His custom is, after completing the resection, to make a low cut dividing "the deepest portion of the membranous urethra, the lowest portion of the perineal structures, and some of the circular fibers of the sphincter ani." By this route a rubber drainage-tube is carried into the bladder. A rubber catheter is passed from the meatus to the perineal tube. The perineal structures about the catheter are sutured. The urethral tube is retained for a week or 10 days.]

L. Bolton Bangs² considers **stricture of the urethra in male children**. Most cases reported have been congenital malformations; some have been due to traumatism. Acquired stricture from non-traumatic post-natal causes has received but scant attention. Cases are upon record of children of 2 years of age or more who have received blows upon the perineum or who suffered from injury of the urethra by calculus, and who later in life presented symptoms of extreme gravity. Such cases should be treated at an early period after the accident, and the tissues of the urethra should be saved by the performance of perineal section and the securing of drainage. In a child who has been subjected to a perineal bruise and has been improperly treated stricture will develop very rapidly. The etiology of acquired stricture is often uncertain. In some there is positive history of gonorrhoea, in some there is an uncertain history of an inflammation; in many there is no evidence of a preceding inflammatory condition. Many of these obscure cases of stricture in young adults arise from an extension into the urethra of balanoposthitis. Bangs reviews the literature of the subject and reports 2 cases: 1 a boy 3 years and 5 months old, and 1 a boy of 15, in which it seemed probable that the strictures arose from the urethral extension of a balanoposthitis.

DISEASES OF THE BLADDER AND PROSTATE.

L. Comitzer³ writes on the **diagnosis and treatment of tuberculosis of the prostate**. He tells us that this disease is more common than is usually supposed. It is frequently impossible to tell at the postmortem which portion of the tract was the original seat of disease; but in the studies by Kzrywicki it is seen that out of 15 cases of tuberculosis of the genito-urinary tract 14 had tuberculosis of the prostate, and that the process had its beginning in the prostate, as the most ancient deposits were found in this organ and spread from it as a central focus. There are multiple foci which undergo caseation and increase in area, and occasionally, though rarely, run together. These

¹ Med. News, July 25, 1896.

² Med. Rec., Apr. 10, 1897.

³ Centralbl. f. d. Krankh. d. Harn, u. Sex.-Org., p. 14, 1897.

deposits, as a rule, break into the bladder, the rectum, the urethra, or the perineum, and where they break they leave a fistula. The bladder is very likely to be attacked, and the process may advance up the ureter to the kidney, and may lead even to general tuberculosis. In some cases the disease reaches the seminal vesicles and the epididymis. It seems in some cases as if infection by gonococci had prepared the soil for the tuberculous process. The author then reports a case in which the diagnosis was made by observing abscesses. There was difficulty in urination associated with rectal tenesmus, and pain which passed into the perineum and was greatly increased by walking. The patient was weak and lost a great deal of flesh; but there was no mucopurulent urethral discharge and no hematuria. In these cases catheterization is painful, due in early conditions to prostatic swelling, in later conditions to ulceration. Rectal examination shows that one lobe is probably larger than the other, and that the gland is sensitive on pressure. An area of softening may in some cases be detected by the finger. The condition of the urine depends upon the condition of the bladder; if it is tuberculous, the urine will be cloudy and purulent and almost invariably acid. We may find bacilli in the urinary sediment or may not, and the fact that we do not find them does not forbid the diagnosis of tuberculosis. The cystoscopic examination is of very great importance, as we can determine by it whether or not the bladder is affected. In early stages of the disease miliary tuberculosis may be present; in later stages, ulceration. If the bladder is not affected, the diagnosis of the disease may be made by pressing out the prostatic secretion and making a bacteriologic examination. The prognosis is, of course, unfavorable, although cure occurs in some few instances. It is always necessary to examine into the condition of the seminal vesicles, as they are very frequently involved. The proper treatment depends on making an early diagnosis. Mansedel wrote in 1892 that the opportunity for operation comes with the formation of abscesses. The author refers to three of Czerny's cases, in one of which the entire gland was converted into a caseous mass. He approves strongly of the saying of Guyon that it is as necessary in the patient with urinary trouble to examine the prostate frequently, as in the patient with rheumatism to examine the heart frequently. [N. Senn, in his address before the American Surgical Association in May, 1896, discusses thoroughly the subject of tuberculosis of the prostate. He says it is a proved fact that the prostate can be the seat of primary tuberculosis, and that it usually occurs in young adults. This distinguished observer states that the symptoms resemble those of chronic prostatitis; hectic fever and wasting are only observed if other organs are also involved. During the early stage of the disease parenchymatous injections of iodoform-glycerin emulsion are indicated.]

The British Medical Association, at the Carlisle meeting in July, 1896, discussed **the surgical treatment of prostatic hypertrophy.** David MacEwan¹ opened the discussion. His views are as follows: Mercier devised the operation of urethral prostatectomy in 1856, but the proceeding was generally looked upon as a surgical freak. The first positive step in the road of progress was when Sir Henry Thompson and Mr. Harrison proposed bladder-drainage as a treatment for prostatic cystitis. It was discovered that the operation of lithotomy when accompanied by removal of a portion of the gland, was occasionally followed by very great improvement in the symptoms of prostatic trouble, and this led to the operation of perineal prostatectomy. McGill, in 1889, called attention to the value of the suprapubic route and introduced the operation of suprapubic prostatectomy. Further advance has been made by the introduction of combined operations, as in the methods of Bellfield, Nicoll,

¹ Brit. Med. Jour., Oct. 10, 1896.

and Alexander. In 1893 J. William White brought to the attention of the profession the operation of **double orchotomy**. [The term orchotomy is used by some and orcheotomy by others. We believe neither is correct. To signify the removal of the testicle the proper word is orchicectomy or orchidec-tomy.] To obtain a knowledge of the results of double orchotomy we turn to White's table of 111 cases. White's conclusions are that in 82% of the cases rapid prostatic atrophy follows operation. In 52% cystitis disappears or greatly lessens. In 66% more or less vesical contractility returns. In 83% the troublesome symptoms are ameliorated, and in 46.4% the local conditions become practically normal. The mortality is 18%; but if we exclude unsuitable cases, it is 7.1%. MacEwan says that one cannot examine this table closely without noting that the details of many of the cases are too insufficient and vague to admit of a just judgment as to the amount of success which followed the operation. The previous histories are very meager in many cases, especially as to the employment of the catheter, and many are reported too soon after operation to permit of the formation of an estimate as to the permanency of the result. In many cases other methods of treatment were also employed at the same time, and this makes it difficult to say how much of the relief was due to the orchotomy and how much to the auxiliary measures. Nevertheless, this table shows that in a large number of cases the operation has caused a diminution of the obstruction and an amelioration of the concomitant evils. The author has collected a number of reports of cases published since White's paper. The number of operations has been 52; 42 of these were successful, 4 were not improved, and 6 died; 38 of these cases were reported with fulness, and the prostate diminished in size in 17 of the 38; in 6 no diminution occurred; in the remaining cases the symptoms were relieved, but the size of the prostate is not given. The best method of performing the operation is to make a 2-in. incision through the lower portion of the raphe, both glands being delivered through the one opening. When the cord is divided the vessels should be tied separately. Ligation *en masse* increases the risk of suppuration. The author then reports 3 cases of his own, all of which were improved.

He next discusses the rationale of the shrinkage of the prostate. In considering the amelioration of the functional symptoms he says that the lessening of the congestion accounts for the relief of pain and tenesmus. The cystitis is relieved, because the mucous membrane is brought to a healthier state by better circulation and partly because the bladder obtains some physiologic rest when the obstruction is lessened. If the walls of the bladder are thick and sacculated, and no benefit at all can be obtained if the pyogenic infection has extended up the urinary tract and pyelonephritis has developed. The return of the functional power of the bladder is chiefly due to the removal of the obstruction. It has been noticed that the operation is occasionally followed by mental disturbance, but the majority of these cases have not resulted directly from the operation, but are due to septic absorption or uremia. Orchotomy performed for disease of the testicles is never followed by mental disturbance, and it is therefore a just inference that maniacal states which arise after the operation has been performed for enlarged prostate result because of associated morbid conditions. In regard to unilateral orchotomy the evidence does not show that atrophy of half of the prostate is an ordinary consequence of removal of the corresponding testicle in cases of disease. A few cases of unilateral orchidec-tomy have been reported, but a correct decision can only be reached after further experience.

Mr. Harrison proposed as a substitute-operation resection of the vas deferens. If it can be shown that this operation is capable of producing as good results, it should receive the preference. It is safe, it is easy of performance, and would be more acceptable to the patient. White found on experiments in dogs that the operation produced loss of weight in the gland in every dog that died after 8 days. Guyon thinks that the operation produced some effect, although not nearly as great as that produced by bilateral orchotomy. Pavone thinks that bilateral resection brings about the same atrophy as White's operation. We may conclude that division of the vas occasionally induces atrophy of the prostate, but that the bulk of evidence seems to show that but little change occurs in the testicles; 37 cases of this operation have been reported, and 26 of these are said to have been successful. In 3 there was some improvement; 4 were failures, and 4 died from causes not connected with the operation. In a few of the cases it is mentioned that distinct shrinkage occurred in the prostate; but this diminution is not so positive as we find recorded as following orchotomy. Guyon records a case in which the operation brought relief, but the diminution in the size of the prostate was scarcely appreciable. In Helferich's 10 cases, 8 of which were successful, there was a diminution of the size of the prostate in only a minority. Atrophic changes are said to take place more slowly than after orchotomy, and it is possible that these cases may have been published too early. More positive statements are made in regard to the effect upon the functional symptoms. Definite amelioration has occurred in 26 of the cases. There is no mention of specific mental disturbance except in one case by Dumstrey, of Leipsic, in which there was a diminution of bodily and mental vigor lasting 14 days, the patient's former briskness never being quite restored. The operation can be performed without an anesthetic. The vas is separated from the other structures of the cord, is caught between the finger and thumb a little below the external ring, an incision is made through the skin, an aneurysm-needle passed beneath the vas, and this structure isolated a short distance above and below. The needle is armed with a double catgut ligature and withdrawn. The vas is tied in two places and the intervening portion is cut away; the wound requires no sutures. Mr. Harrison says that we should attack only one vas at a time, and if the object is not sufficiently attained we may then attack the other. It is probably wiser, however, to deal with both sides simultaneously.

The author of this paper concludes that in a considerable proportion of cases castration brings about more or less atrophy of the enlarged prostate. The atrophy occurs most easily in the soft and elastic forms of hypertrophy, but it may also take place in the hard even when associated with general arteriosclerosis. The best effect is obtained when the enlargement of the gland is general. Sessile enlargement of the median portion may yield to castration, but intravesicular outgrowths are better treated by prostatectomy. Cystitis when not far advanced may be relieved or even cured. If the cystitis is associated with septic infection of the kidneys and with distressing bladder-symptoms, drainage of the bladder will be of more value. Vesical contractility may be restored even after years of catheter-life. Even if voluntary power does not return, the operation may bring relief to the patient if catheterism has been difficult, painful, and frequently necessary. With the exception mentioned double orchotomy will give as good results as prostatectomy, with a smaller death-rate. Resection of the vas acts more slowly in reducing hypertrophy of the prostate. It is a simpler operation, will be looked upon by the patient as more acceptable, and can therefore be recommended earlier.

Reginald Harrison, in discussing the paper of MacEwan, said that there can

be no doubt that the removal of the testes or their atrophy, however obtained, is liable to be followed by shrinkage in the size of the normal prostate. The facts which have been gathered are sufficient to warrant a trial of vasectomy either on one or both sides. The cases in which Harrison has practised vasectomy may be divided into 2 groups: first, those in which only 1 vas has been divided; second, those in which both vasa have been resected either simultaneously or at intervals of some days. This surgeon has performed single vasectomy 12 times and double vasectomy 10 times. Of the 12 cases of single vasectomy, 7 derived permanent benefit from the operation. In the remaining cases there was either no benefit or the patient could not be traced. If both vasa are divided, it is well to have an interval of a month or so between the operations. The risk is less, and it might happen that the operation on the single vas relieved the too frequent micturition. Out of the 10 cases of double vasectomy there was very great benefit in 5, benefit which Harrison believes to be lasting. Of the remaining 5, 2 have not derived much advantage from it, 2 cannot be traced, while the 5th case is a recent one. That many of the troubles connected with enlargement of the prostate may be combated by castration or vasectomy is undoubted, but there are some pathologic conditions of the prostate which are not influenced by either procedure. Harrison does not oppose the operation of castration, but he calls attention to the fact that besides the mortality which attends it certain distressing mental disturbances are liable to follow it.

C. W. Mansell Moullin said that there is no single method of treatment for cases of enlargement of the prostate, and that statistics on such a subject drawn from all sorts of cases by different surgeons of different nationalities are worthless. There are undoubtedly many cases in which treatment by the catheter can be practised, and also many in which the prostate should be removed by the suprapubic or the perineal route. It is true that the mortality of suprapubic cystotomy is estimated at as high a figure as 20%, but the estimate is scarcely fair, because in 75% of the cases cystitis and pyelonephritis were present. Suprapubic prostatectomy performed when the urine is aseptic and the kidneys are sound has a very different result.

Mayo Robson published a series of 11 cases, with only 1 fatality. Moullin performed the operation 5 times without a death. He performed orchotomy 11 times, with an excellent result in 6 cases and relief in 2; 3 died, from heart-failure, apoplexy, and uremia respectively. He has always performed the bilateral operation, and does not think the unilateral operation is likely to be useful when there is marked inequality of the lobes. He has performed vasectomy 3 times, twice with conspicuous benefit, although the prostate did not diminish much in size.

[J. William White¹ believes that a patient with moderate prostatic enlargement, little or no pain, and 3 or 4 oz. of clear residual urine, and especially if he is not very old, retains sexual capacity, has healthy kidneys, and is in good general condition, should not be subjected to castration, and should be instructed in the use of a catheter. If such a patient develops severe pain which is not controllable by remedies, or if the amount of residual urine rises to 12 oz. or more, vasectomy is indicated. If a patient has decided enlargement, with 8-10 oz. of fetid or mucopurulent residual urine, with pain and difficulty in passing a catheter, an operation must be performed. If a patient is becoming old and the sexual power is weak, vasectomy is performed. If a patient is younger and sexual power is good, prostatectomy is indicated. Vasectomy is employed if there is renal disease and failure of the general health in a man well

¹ Univ. Med. Mag., Apr., 1897.

advanced in years. Castration is employed in a very old man with good general condition and healthy kidneys. In very serious cases of enlargement in which there is cystitis, with retention of urine, and in which the use of the catheter is difficult and painful, castration is indicated, though vasectomy may be first tried.]

A. T. Cabot¹ considers the question of **castration for enlarged prostate**. He says it was a great surprise to find that the mortality of this operation was high. Experience has shown that this mortality was not an accident, happening in the first 100 cases. Many patients who submit to castration are already suffering from disease of the bladder and kidneys that is tending to a fatal issue, and many of them die from this disease rather than from operation. White recognized this fact, and in his first series eliminated 13 of the 20 fatal cases, bringing the collected death-rate down from 18% to 7%. Such a revision of statistics is proper if we are comparing this with other operations performed upon persons in good health, but it is improper when we are making a comparison with other operations carried out upon the same variety of patients. It is this latter comparison which Cabot proposes to make. It is evidently improper to rule out cases in which death from pyelonephritis followed operation unless similar cases are excluded from the statistics of the other operations. It would seem better to take all cases as they come, trusting that they will distribute themselves with reasonable fairness through the different sets of statistics. He has excluded from this table cases in which other serious conditions existed to complicate the prostatic hypertrophy, conditions such as vesical stone and tuberculosis. When White's table is revised on the same lines we reduce his cases to 104, with 19 deaths, a mortality of 18%. Cabot has obtained reports of 99 other cases, of which 20 died. When these are added to White's cases we have a total of 203 cases with 39 deaths, the mortality for the entire series being 19.4%. So high a death-rate from so slight an operation is surprising. We should remember that an operation performed for the relief of a serious pathologic state has its danger much increased if it does not completely and at once relieve the condition. When an operation is performed for enlarged prostate the obstruction is slowly removed by shrinkage, but the shrinkage is slow and is of slight immediate use in stopping the back-pressure on the kidneys. This is a source of great danger and goes a long distance toward explaining why there is such a trivial difference in the mortality of castration and prostatectomy. The latter operation is far more severe, but it provides for ample drainage. Prostatectomy is an operation in which skill and a correct technic make the greatest difference in the fatality. As a consequence, the statistics show a constant improvement in the rate of mortality. White found, when his paper was written in 1893, that the more modern statistics of prostatectomy show a mortality of 14.9%. Cabot advances the belief that the correct death-rate of prostatectomy is under 20%, hence the operation stands upon the same footing as castration in its fatality when applied to all cases of advanced hypertrophy. Among all the reported cases of castration performed in middle life or advanced age there is not one in which there has been any **loss of masculine characteristics**. It is too early to state whether these patients will show diminished vigor as age advances, although there are some facts which should lead us to be watchful for evidence upon this point. We know that some neurologists believe that these glands exert an influence upon the nervous system even in old age, and Brown-Séquard's experiments in the use of animal extracts led him to believe that they have a distinct power of improving nutrition and increasing the force of the

¹ Ann. of Surg., Sept., 1896.

nerve-centres. In 99 cases of orchotomy mental disturbance followed 11 times immediately upon the operation. In 6 cases the condition was maniacal, in 5 there was loss of mental balance, and in several a melancholic tendency arose. Of the 6 maniacal patients 1 had previously shown symptoms of mania. Cabot reports a case of his own in which mental disturbance followed the operation and in which testiculin was administered with the greatest benefit. In some cases the operation has a decidedly depressing effect upon the strength, leading to severe shock. In other cases the patients have reacted well from the operation and the wounds have healed, but at the end of a short time they failed without any marked change in the symptoms and died. When a postmortem is performed on such a case it is usually found that pyelonephritis existed, but nevertheless it is important to note that those patients who carry successfully partially disabled kidneys for a considerable time succumb after a slight operation without any symptoms pointing to an increase of the renal condition, seeming to show that by the removal of the glands the vital force of the individual was diminished. It has been noticed after this operation that patients frequently suffer from flushes of heat similar to those experienced by women at the menopause, and even distinctly hysterical phenomena have been noted. Nevertheless, it is proper to state that in some cases nervous excitability which existed before has been relieved by the operation. In order to determine the real result it is necessary that the patient be under observation for a considerable length of time, for it often happens that while the patient is in the hospital he seems to have obtained very decided relief, but after he resumes his less regular habits of life this relief is found to be transitory. Indeed, the time which has passed since the operation first began to be practised is too short to determine the permanency of results, but we know definitely that in a few cases relapses have occurred and irritability and obstruction have returned.

Cabot's tables show that 79 cases survived operation; in 18 of these cases the reports were meager, and we are left with 61 cases to study; 5 of these were not improved; 1 improved for a time but later suffered a relapse. In 4 cases the catheter was still used, but entered with greater ease. In 27 cases retention, which had existed at the time of operation, disappeared. In 2 cases catheter-life, of 11 years, in 1 of 18 years, was cured by the operation. In the remaining 24 the power of urination was not entirely lost, but had been greatly impaired. In all these there was decided improvement. These facts show that in 9.8% of cases there was failure, in 6.6% moderate improvement, and in 83.6% very great improvement. If further experience justifies these statements, we shall be able to say to the patient he has 8 chances in 10 of getting through the operation all right, and if he gets through it all right he has a little more than 8 chances in 10 of obtaining positive relief.

In comparing these results with those of suprapubic prostatectomy we may take the cases in Moullin's table which occurred after 1889—42 cases; 6 of these cases are too vague for consideration, which leaves us 36 cases; 8.3% were not improved, 8.3% were somewhat improved, in 83.8% the power of urination was restored. We thus see that the two operations were remarkably parallel in their results both as to mortality and restoration of function. The author then considers the changes in the prostate which follow castration and lead to a diminution in its volume. It seems to be certain that myomatous tissue of the prostate is not affected by castration, and it is very difficult to determine whether the conditions in the prostate found after death are due to changes following castration or are degenerative changes already present in a pathologic organ before the operation was performed.

The second theory accounts for the reduction in size by supposing it to arise from changes in vascularity. This theory best explains the quick relief which immediately follows operation. The fact that retention may be relieved and yet subsequently recur opposes any belief in early anatomic changes. The phenomena are better explained by the vascular theory. It is probable that the alteration in the blood-supply plays a considerable part in the changes observed in the prostate, while the atrophy and disappearance of portions of the gland may bring about a final, permanent reduction in the size of the organ. Observations made during the past year have not borne out the suggestion that the third lobe is especially likely to shrink after castration. Whereas there is uncertainty as to the means by which shrinkage of the prostate is brought about, there is no doubt whatever that in the greater number of the patients operated on there is a considerable diminution in size.

The author then considers the **choice of operation**. A large and succulent prostate gives the best chance of improvement by castration, and if the obstruction is due to close apposition of the lateral lobes, relief after castration may be confidently expected. This is especially true if the bladder is free from bacterial infection. Such cases are not especially favorable for prostatectomy, because they require the removal of large portions of the gland, and such an operation is decidedly serious. If the obstruction is due to a valvular third lobe or to masses which pass into the bladder and encroach on the urethral orifice, castration is not particularly efficient, and this condition is well treated by prostatectomy. Between these two conditions we have every degree of combination of obstruction by pressure and by valve, and these cases constitute debatable ground; but there is one thing which is undoubted, and that is, when the urine is still aseptic we may venture to do an orchotomy, but if the urine contain pus, we should prefer the suprapubic operation. In cases in which there is great dilatation of the bladder after long, chronic retention we know that hemorrhagic cystitis or pyelonephritis may follow an attempt to establish catheter-life. In such a case it seems possible that orchotomy may permit the distended viscus to relieve itself gradually without any danger of infection. Myomatous and fibrous prostates are not especially affected by orchotomy. In considering ligature and division of the vas deferens, Cabot says he has obtained reports of 22 cases, which gave a most unfavorable showing, for 7 of these cases died. Two of these deaths were due to hemiplegia; 1 was a suicide, the man having become maniacal after operation. The other deaths were due to internal conditions, generally of the kidneys. Of the remaining 15, 3 showed no relief; in 5 improvement was marked, but 1 of these afterward relapsed; in 7 there was great improvement. The operation seems to have no advantage over castration in point of mortality, while it is less satisfactory in obtaining relief. The records of unilateral castration are not of positive value. In some cases there was a decided diminution of the corresponding lobe of the prostate, while in others no change could be detected in the gland.

The author's conclusions are as follows: prostatectomy has a slight advantage in the matter of mortality over castration, and later improvements in technic will probably render this advantage more marked. Prostatectomy permits of a thorough examination of the bladder and the discovery and correction of other conditions which we know of or suspect, stones being frequently removed in this way without increasing the gravity of the operation. Prostatectomy confines the patient for a longer period and is occasionally followed by a fistula. It is not yet certain whether any permanent loss of vigor follows castration when performed on old men. The nervous defects which

sometimes immediately follow the operation suggest the suspicion that with the loss of the testes the system may lose some tonic effect exerted by these organs. The functional results of the two operations seem nearly equal, and the tendency to relapse is about the same after either. The reduction in size of the prostate is largely due to diminution of congestion, but later a degeneration and absorption of considerable portions of the gland may occur. The glandular elements are especially affected by this atrophy. Castration is particularly efficient in large, tense prostates when the obstruction is due to pressure of the lateral lobes upon the urethra. The special field of prostatectomy is in the relief of obstructive projections which act as urethral valves, but a skilful operator may correct any form of enlargement by prostatectomy. Prostatectomy is applicable to more cases than castration, and is the operation to be selected when an inflamed condition of the bladder makes drainage desirable. [White combats many of the statements of Cabot in the same number of the *Annals of Surg.* in which the paper of the Boston surgeon appears (Sept., 1896), and Cabot analyzes White's statements in the *Annals of Surg.* for Jan., 1897. The real status of the question may be obtained by reading these articles.]

Samuel Alexander¹ writes on the **radical treatment of prostatic enlargement by prostatectomy.** He says that we can choose between three plans of proceeding: 1. Having the patient use a catheter for the rest of his life; 2. Removing the obstruction; 3. Establishing and maintaining an artificial channel. We cannot estimate too highly the usefulness of careful catheterism. A great many people who have even decided prostatic enlargement may live comfortably for many years if a catheter is regularly and properly used; but there are certain patients who are unable to use a catheter or who refuse to use it, and there are other patients to whom the proceeding does not give relief. In such conditions we must choose another method. As soon as it is recognized that palliative treatment is failing in its design we should employ some radical method of procedure. The conditions which call for operation are as follows: Retention of urine due to prostatic growth around the internal orifice of the urethra, or in the prostatic urethra, which makes the patient absolutely dependent upon the catheter. When vesical irritability continues and cannot be entirely relieved by the use of a catheter and bladder-washing; such patients are liable to develop seizures of hematuria and inflammation of the bladder. Again, when in spite of the careful employment of a catheter the amount of residual urine steadily increases and the expulsive force of the bladder steadily diminishes. When the use of a catheter becomes more difficult progressively and when the use of an instrument gives rise to hemorrhage. When the use of a catheter is followed frequently by cystitis. When cystitis continues and cannot be arrested by treatment. When the patient cannot use a catheter or will not use it, or will not take the requisite antiseptic precautions to make the procedure safe. An operation should fulfil three conditions: at once completely remove the obstruction; do but little injury to the mucous membrane; enable us to establish through drainage. The operation which Alexander prefers is an addition to or modification of Nicoll's operation.

Oppler² **sterilizes catheters by the use of formalin.** A 2% solution of formalin is placed in an apparatus and the catheters are exposed to the vapor for 6 hours. The catheters lie in a tray above the formalin-solution.

Reginald Harrison³ reports an interesting case of **extroversion of the**

³ Med. Rec., May 1, 1897.

bladder which he treated successfully by the performance of left nephrectomy and transplantation of the right ureter in the loin.

F. Tilden Brown¹ discusses the value of **air-distention of the bladder in suprapubic cystotomy**. Some time since he wrote to a number of surgeons to find their views on the best means of rendering the bladder accessible in the suprapubic operation. He found the views were very diverse: 23 use water rather than air for vesical distention, with or without other aids; only 3 use air-distention alone of the bladder; 10 of these surgeons use Petersen's bag; 12 use the Trendelenburg position, or some modification of it, in addition to other artificial aids; 4 never use the Trendelenburg position; 1 uses the Trendelenburg position only. The author thinks that air-distention is of very great value. The bag of Petersen is effective, but it is troublesome and not altogether safe. If air is used, the bag is not required, and we should abandon the use of the bag in favor of air. The use of air was first suggested by Bristow in 1893, and was first put in practice by Keen a month later. Bristow showed that a diseased bladder may be readily ruptured. Water is incompressible; air is extremely compressible; hence a diseased bladder is less likely to rupture from air than from water. He further said that, if the bladder could be dilated by anything, it could be best accomplished by the use of air. With the conclusions of Bristow Brown agrees. He quotes Richardson, of Boston, to the effect that by air-distention the prevesical space may be made to reach very high above the pubes. The injection was made by Keen with a Davidson syringe; but Brown maintains that this syringe will frequently fail when used to pump air. The most useful apparatus to employ is the pocket-bicycle air-pump. This instrument may also be used for making the air-test of a ruptured bladder, as has been alluded to by Keen. Keen's plan in this condition is to insert a catheter and empty the bladder of any urine which is present, and after the urine flows out connect the catheter with a disinfected Davidson syringe over the distal end of which a mass of absorbent cotton is tied. Air is pumped into the bladder, and if there is no rupture we can make out the tympanitic and rounded bladder above the pubes. If there is a rupture, the air will pass into the general peritoneal cavity. In order to distend the bladder with air previous to cystotomy Brown says we should pass a soft-rubber catheter into the bladder and retain it by a bandage. The bladder is washed out, and the Trendelenburg position is not used unless the patient has a pendulous abdomen or it is noticed that light will reach the bladder best when the hips are elevated. The air-apparatus is attached to the catheter and left lying on the towel stretched across the thighs. An incision is made above the pubes until the transversalis fascia is exposed, and the pump is then used to bring the bladder closely against this fascia; the lumen of the catheter is closed by an artery clamp, the peritoneum, if seen, is lifted upward, and the bladder is opened. Each in-and-out piston-action of this air-pump is about equal to moving 1 oz. of water.

Engene Fuller² writes on **operative interference in aggravated instances of seminal vesiculitis**. He claims that chronic nontuberculous conditions may be treated successfully by extirpating the sac, but that this proceeding should be applied only to extreme cases associated with severe subjective symptoms. Before extirpation is employed stripping should be tried, extirpation being resorted to only when stripping and incision have failed. Kraske's incision is the best method. The sexual functions can be maintained perfectly when but one seminal vesicle is strong and healthy. A sub-

² Jour. Cutan. and Genito-Urin. Dis., Sept., 1896.

acute epididymitis is to be expected after the performance of the operation, but the corresponding testicle does not atrophy.

Henry Morris¹ advocates the employment of **bimanual examination of the urinary bladder** in diagnosticating vesical hematuria from renal hematuria. He thinks that this procedure is a matter of the very greatest importance. It is useful in the male, and is even more useful in the female. He cites several cases in which he was enabled to make a diagnosis by this method.

D. F. Keegan² furnishes some notes upon **stone in the bladder**. He tells us that the majority of vesical calculi we encounter in girls and women should be removed by litholapaxy. There remain two other modes of removing stone from the female bladder—vaginal lithotomy and suprapubic lithotomy, but it is very rarely that either of these operations should be employed. He furnishes a report of 20 cases of stone in females, 18 of which were treated by litholapaxy. He agrees with Mr. Gilbert Barling, that in boys lateral lithotomy and litholapaxy are safer than suprapubic lithotomy. Indian surgeons long ago reached the same conclusions as Mr. Barling. Keegan presents the records of 780 operations performed on boys for vesical stone, and there were only 2 suprapubic lithotomies and 2 median lithotomies in the entire list. The litholapaxies were nearly twice as many as lateral lithotomies. The stay in the hospital was four times as long after lateral lithotomy as after litholapaxy. The death-rate from litholapaxy was less than half that which followed lateral lithotomy. In 509 litholapaxies in boys the percentage of deaths was 2.35. Unquestionably the best operation for a boy 7 or 8 years of age, who has a urethra of normal caliber and suffers from a small and uncomplicated stone, is litholapaxy. A surgeon is not justified in cutting such a boy because he does not have the necessary instruments for litholapaxy, or because he does not know how to use them successfully. The case should be referred to some individual who is able to perform it. In considering the comparative safety of litholapaxy, lateral lithotomy, and suprapubic lithotomy in patients of all ages, the author shows a death-rate of 3.9% for litholapaxy, 11.2% for lateral lithotomy, and 42.17% for suprapubic lithotomy. Suprapubic lithotomy should be very rarely employed. An expert litholapaxist may attack a stone that weighs between 2 and 4 oz. with absolute confidence. If he meet with a stone which cannot be attacked successfully with a No. 16 or 18 lithotrite, lateral lithotomy or perineal lithotripsy is preferable to the suprapubic method. It seems certain that in India, in the next decade, peritoneal lithotripsy will occupy the place now held by lateral lithotomy in dealing with very large and hard calculi in adult males. Experience proves that suprapubic lithotomy is not more successful than lateral lithotomy in dealing with very large calculi, and perineal lithotripsy should be given a fair trial in these extremely difficult cases.

Godfrey Goodman³ employed the **phonendoscope** attached to a stone-sound in detecting stone in the bladder, after the ordinary method failed to detect stone. The sound of the contact of the instrument with the stone was very positive.

Reginald Harrison⁴ delivered the Bradshaw Lecture for 1896 upon **vesical stone in prostatic disorders**. He considers the various means for relieving prostatic hypertrophy and vesical calculi, agreeing with Dr. Cabot's opinion that castration is especially successful in dealing with large, dense prostates, in which the lateral lobes make pressure upon the urethra, but that the operation is of little value if the prostate is myomatous and fibrous.

P. J. Freyer,¹ on the best **methods of removing large calculi from the bladder**, inquires, What are we to regard as a large stone? It is impossible to draw a definite line, but we shall be assisted by considering the advantage of the patient and the operator's experience. A stone of $1\frac{1}{2}$ oz. would be small in an adult but large in a child of 3 or 4 years, as large comparatively as a stone of 3 oz. in an adult. Again, a novice in the operation would regard a stone of $\frac{1}{2}$ oz. as a large one, whereas an expert would look upon it as a very ordinary affair. We may define a large stone as one weighing 2 oz. and upward. Bigelow's method is undoubtedly the best for calculi of all sizes, provided only that this operation is feasible. Calculi of about 3 oz. in the adult, and of a corresponding weight in the child, should be removed by a perineal lithotomy, and beyond that by suprapubic incision. The author has removed stones of 6 and 8 oz., however, by the Bigelow method, and larger stones have been removed by other operators. The author would lay it down as an absolute rule that in no case in the male or female, adult or child, should a stone, whether small or large, be subjected to a cutting operation until after a trial litholapaxy is found not feasible.

Richard Baker² records **200 cases of litholapaxy**, with a mortality-rate of 1%. The largest stone weighed 2 oz. 3 drams 10 gr. There were 195 males and 5 females.

W. S. Forbes³ reports an interesting **case of litholapaxy**, in which he successfully removed from the bladder of a man 30 years of age a willow twig 7 in. long, heavily encrusted with urinary salts.

DISEASES OF THE KIDNEYS AND THE URETERS.

Maurice Richardson⁴ reports 2 cases of **wound of the kidney**. In each of these cases only the liver and kidney were damaged. There was some bleeding into the abdominal cavity from hemorrhage back of the peritoneum. In each case there had been complete perforation of the kidney and some of its secreting structure had been destroyed. In each case it was necessary to make extensive exploration before determining what was to be done. In 1 case the renal vein and the pelvis of the kidney were very badly lacerated. In the other case they were uninjured. In the 1st case nephrectomy was performed and death ensued. In the 2d case drainage was introduced and the patient recovered. It seems that in the case in which nephrectomy was performed death was due to failure of the other kidney to carry on the work of excretion. The surgeon in such a case as this wonders if he might have saved the injured kidney; whether the best proceeding would not have been simply to drain, believing that, even though injured, it might perform a certain amount of excretory function. Of course, the doubt arises whether gangrene would follow with certainty the laceration of the renal vein, although it is possible that the well-recognized anomalies of the kidney-vessels might keep up the organ's vitality. The question whether or not it is better to treat all wounds of the kidney by a conservative plan can only be certainly determined by additional experience.

Albarran⁵ reports **66 operations upon kidneys** with 6 deaths, a mortality of 9%. He performed 7 complete nephrectomies with 1 death, 1 partial nephrectomy which was successful, 21 nephrotomies with 2 deaths, 5 nephrolithotomies with 2 deaths, 1 case of anuria operated on on the 10th day and

⁴ Ann. of Surg., Dec., 1896.

⁵ Rev. de Chir., Nov. 10, 1896.

followed by death, 23 operations for floating kidney without a death, and 4 exploratory nephrotomies without a death. After a number of these operations very grave reflex phenomena occurred, and they were invariably accompanied by oliguria. The most pronounced symptoms were intractable vomiting and epigastric pain, or pain in the lumbar region. The pupils were contracted, the patient was pallid, the pulse small and very rapid, and the temperature normal. These symptoms rarely last beyond 24 or 36 hours, but in some cases they continue despite the intravenous use of artificial serum. In 1 of the nephrorrhaphy cases the symptoms lasted for 2 days, and in another for 3 days, disappearing in both on the administration of hot alcoholic drinks. [We have witnessed such phenomena upon several occasions.]

E. Hurry Fenwick,¹ writing on the use of the **cystoscope**, maintains that this instrument enables us to lower the mortality of the operation of **nephrectomy**. He cautions us not to examine with the cystoscope any patient who is known to have tuberculosis of the epididymis or prostate or malignant disease of the bladder, but in all other cases the examination should be made, the surgeon being ready to operate at once on completion of the examination. The cystoscope must be used with great care, otherwise it may produce death, causing kidney-trouble secondary to ascending sepsis. Every case of pronounced hematuria should be examined with the cystoscope, a kidney-operation or bladder-operation being carried out if necessary on the termination of the examination. In every case of severe pyelitis unassociated with trouble in the genital or lower urinary tracts the cystoscope will show if both kidneys are present or if one is absent, and will point out the diseased kidney. A better mode of exploration in women is catheterization of the ureters. [The value of the cystoscope is very great if it is used by a trained and skilful man. When used by an untrained man no information of value can be obtained, and great damage may be done. A cystoscope in the hands of an expert is an instrument of surgery; in the hands of a bungler it is a deadly weapon.]

Albarran² discusses the **enlargement of the kidney and polyuria** which take place in attacks of **intermittent hydronephrosis**. He thinks that in the early stages of the disease the enlargement is chiefly due to congestion, and not to retention of urine in the pelvis of the kidney. He says that when there is complete retention of urine in the bladder the kidneys increase one-third in volume, and, if this retention is not soon relieved, ecchymoses arise in the parenchyma of the kidneys, and blood-clots may be formed. If the ureter is ligated, the kidney increases greatly in size for the first few hours, and yet very little urine collects in the pelvis. Albarran operated on a patient who suffered from intermittent hydronephrosis, and there was not a sign of dilatation of the pelvis or of the kidney at the operation. In 3 other cases he made the same observation. He has seen 2 cases of intermittent hydronephrosis with movable kidney in which hemorrhage occurred with the attacks of pain, and in which operation showed there was no dilatation whatever resulting from pressure. The polyuria which commonly follows an attack is due to excessive urinary secretion, and not to the flow of urine which has previously been retained in the pelvis of the kidney. Albarran reports a case in which there was extreme polyuria with but very slight increase in the size of the kidney, and in which operation proved that the pelvis of the kidney was not dilated. [This view is radically opposed to accepted teaching, but Albarran's report renders it highly probable that he is right.]

² Ann. d. Mal. d. Org. gen.-urin., No. 11, Nov., 1896.

Tuffier¹ considers the surgical treatment of **tuberculosis of the kidney**. We now know that primary tuberculosis may occur in the kidney, and that this condition may remain local for a considerable length of time. Operation is only to be performed when medical treatment has failed, and it is employed in the treatment of complications rather than in an attempt to cure the primary tuberculosis. Tuffier has operated on 15 cases. He tells us that the most common indication for operation is infection from renal products which are septic. This infection is manifested by various symptoms. We may have the symptoms of pyelonephritis or of large collections of tuberculous matter without pyuria. The last-named condition is difficult to diagnose from tumors of the kidney, liver, or spleen. We are likely to have present hectic fever and emaciation. In cases of this sort Tuffier has operated 9 times. He has performed 5 nephrotomies, with 1 death from operation; 2 secondary nephrectomies after nephrotomy; and 1 complete primary nephrectomy. The operations are too recent to judge of the final result.

J. William White and Alfred C. Wood² discuss **surgical affections of the kidneys**. They think the tendency of the profession is to be too conservative in dealing with these conditions, and that a surgeon should by rights have charge of a chronic painful affection of the kidney. One serious obstacle to advancement in this branch of surgery is the trouble in reaching a certain diagnosis. Renal symptoms may follow abscess-formation and spinal caries. A perirenal abscess may be caused by the extension of an appendicular abscess or a subphrenic abscess, and diffuse suppuration about the kidney may be mixed up with hydronephrosis, pyonephrosis, or tumor of the kidney. A smooth stone may be impacted in the parenchyma of the kidney and give rise to no symptoms; but, as a rule, the patient has distinct symptoms—namely, pain in the loin, which is fixed or radiates toward the genital organs or the upper portion of the thigh; irritable bladder; gravel, blood, and pus in the urine; acid urine; and attacks of renal colic. Palpation is only occasionally of use. Morris has pointed out the extreme difficulty of determining the presence of a calculus by direct palpation of the kidney. The use of the Röntgen rays may be of great aid to diagnosis. When there is an abscess of the kidney fever is apt to exist. The most common symptoms of hydronephrosis and pyonephrosis are the dull, heavy, persistent pain in the loin; and after a time the appearance of a distinct tumor, or at least fullness. In pyonephrosis the urine contains pus. Of course, pus may be found in cysts; but when the pus comes from the kidney the urine is usually acid, while in pus from the bladder the urine is usually alkaline and the microscope will probably detect characteristic elements. The writers approve of Tuffier's classification of movable kidneys, namely, into the painful, the dyspeptic, and the neurasthenic. They do not believe that the cause of movable kidney has been certainly made out, but it is probable that several causative influences are at work in the production of this condition; for instance, the absorption of the fatty capsule, pregnancy, pendulous abdomen, the presence of a mesonephron, heredity, etc. The paper then discusses anuria and various operations which are performed upon the kidney. [The surgeon must be very cautious before deciding to perform nephrectomy. A great many patients die some time after this operation because of the failure of the other kidney to undergo compensating hypertrophy. Wagner's dictum that a kidney must not be removed unless the existing disease threatens life, is a good star to steer by. Before doing a nephrectomy the surgeon should ascertain that another kidney exists and that it is competent. The first point can usually be determined by watching the ureteral orifices with a cyst-

¹ Brit. Med. Jour., Apr. 3, 1897

² Ann. of Surg., Jan, 1897.

toscope; the second, by catheterizing the ureters. In some cases partial nephrectomy can be performed instead of complete extirpation. The value of this procedure in some wounds, innocent tumors, imbedded calculi, and localized abscess has been amply demonstrated. The catheterization-test is not absolute, as in horseshoe-kidney there may be two ureters and but one kidney. [Exploratory incision is the real, positive test.]

J. Wesley Bovée¹ discusses **uretero-ureteral anastomosis**. The pioneers in this work have been Pawlik, Kelly, Fenger, and Van Hook. The first operation on man was performed by Schopf, in 1886; 11 cases have been recorded, and Bovée adds another case in his own experience. There has been much discussion as to the actual length of the ureter, the estimates being from 10 to 16 in. Cabot shows that bands from the fibrous coat of the ureter are connected intimately with the peritoneum, and that in three points the caliber of the ureter is distinctly diminished. Bovée discusses the anatomy of the ureter fully and considers the recorded cases of uretero-ureteral anastomosis. He advocates cutting the ureter obliquely and applying rectangular sutures, alternating with interrupted sutures. He does not use drainage except in pus-cases. He tells us that, next to ureteral anastomosis, bladder-graft is decidedly the best alternative. It has been performed by Penrose, Kelly, and others. Van Hook has suggested sewing a part of the bladder-wall into the form of a canal when it is necessary to meet a short portion of the ureter. Most of the operations have been done within the peritoneal cavity. The only extraperitoneal operation was done by Baumann. Van Hook believes that rectal implantation is very dangerous, and should only be performed when the bladder has become badly diseased. When it is done the vesical opening of the ureter must be removed in order to preserve the natural valve. Nichaus in one case successfully implanted the ureter in the urethra. The author concludes that the operation of uretero-ureteral anastomosis when possible is preferable to any other form of ureteral grafting, to nephrectomy, and to ligation of the ureter. It should be performed either by lateral implantation or oblique end-to-end anastomosis, although we can with safety use the transverse end-to-end or the end-in-end method. He maintains that constriction of the caliber does not usually follow suturing of complete transverse section. Nephrectomy for transverse injury of the ureter alone is an unjustifiable procedure. Simple ligation of the ureter to produce cessation of kidney function is too uncertain to justify its performance. Drainage is not required if the wound is perfectly closed and the tissues are aseptic.

Arpad G. Gerster² furnishes a contribution to the **surgery of the kidney and the ureter**. He reports a case of hydronephrosis of traumatic origin in which nephrotomy was performed, the nephrotomy being followed by a plastic operation on the proximal orifice of the ureter. The patient was cured. He reports a successful case of nephrectomy for a hydronephrotic floating kidney; a case in which closure of the ureter followed nephrectomy, and cure succeeded on extirpation of the ureter; and a case of double pyelitis with intense cystitis, in which nephrectomy of the left side caused temporary improvement. He also records a case of hydatid of the right kidney which was cured by exposure of the tumor, incision, and evacuation. He makes a plea for earlier operations in acute inflammations of the kidney, and gives the history of a case to prove his point. He records cases to illustrate the rapidity with which the kidney may become involved in septic processes. He also discusses tumor of the kidney and some other interesting conditions. He arrives at the following conclusions: that early nephrotomy should be per-

¹ Ann. of Surg., Jan., 1897.

² Am. Jour. Med. Sci., June, 1897.

formed in suppurative processes and infection of the kidney and in acute, non-suppurative forms of nephritis. He reports two cases of tumor in which extirpation was followed by cure.

Jordan Lloyd¹ considers the **impaction of stone in the ureter**. He says that when the ureter is partially obstructed with stone the urine secreted is of low specific gravity, poor in urea, and does not contain albumin. The symptoms vary according to the point at which impaction has occurred. Impaction close to the bladder produces symptoms simulating the classical symptoms of stone in the bladder. Impaction higher up simulates renal stone. There is usually hematuria, and pus as a rule is found. A sharp, stabbing-pain can usually be elicited by forcibly prodding the loin. If the symptoms point to kidney stone, but prodding the loin causes no pain, the probability is that the stone is in the ureter. Exercise increases the pain of renal stone, but does not increase the pain of ureteral stone. He reports three cases of ureteral stone.

Christian Fenger² writes upon **operation for valvular stricture of the ureter**. Pelviotomy was performed and four stones removed from the ureter above a valvular stricture, and this stricture was treated by longitudinal ureterotomy over the stricture, excision of the stricture, and a plastic operation on the ureter. The wound in the pelvis was left open after a bougie had been passed into the ureter. The wound healed in six weeks and the patient made a complete recovery. In this case Fenger made the incision between the 12th rib and the rim of the pelvis forward for about 9 in. from the border of the erector spine muscle, and after isolation of the pelvis, which he found somewhat dilated, he laid bare the ureter and felt a nodular mass 2 in. below the pelvis. When he incised the pelvis longitudinally about one ounce of urine escaped. On passing the little finger down the ureter for about an inch he could not feel a stone, but on manipulating the ureter with the other hand he succeeded in squeezing four stones up into the pelvis and removed them from the wound. When the sound was passed down from the pelvis into the ureter it was arrested $2\frac{1}{2}$ in. below the pelvis at a point where palpation detected thickening. A longitudinal incision $\frac{3}{8}$ in. long was made into the ureter upon the end of the sound, above, through, and below a transverse valvular stricture. An instrument passed through an opening below the stricture easily entered the bladder. The longitudinal wound was held open, and this part of the urethra was stretched over the index finger while the valvular stricture was cut off from within by scissors, the muscular coat of the ureter being left intact. A plastic operation was now performed on the ureter after the method which Fenger proposed in 1894.

Willy Meyer³ writes on **catheterism of the ureters** in the male with the help of the ureter cystoscope, and makes a report of 7 cases. He shows that Kelly's method is not suitable to men, because of the limits of dilatability of the urethra and the presence of the prostate gland. He uses Casper's instrument, but the urethra must be sufficiently large to permit the passage of the instruments, the bladder must have a capacity of at least 4 or 5 ounces, and the fluid within the bladder must be kept transparent. He reports 7 cases in which he successfully catheterized the ureter. The bladder should first be washed and cocaineized, and should be filled with clear fluid before the instrument is introduced.

Hugo Maas⁴ writes on **suppuration of the fatty capsule of the kidney**, a tissue very prone to suppuration because of its vascularity. Pus formed in such a deep-seated situation reaches the surface very slowly, and a large

¹ Brit. Med. Jour., Oct. 24, 1896.

³ Med. Rec., May 1, 1897.

² Am. Jour. Med. Sci., Dec., 1896.

⁴ Ann. of Surg., May, 1897.

retroperitoneal abscess forms which endangers important organs because of their proximity. No one causative factor of this suppuration has been elicited. In some cases it follows pyelonephritis, calculous pyelitis, or gonorrhœal suppuration in the pelvic fascia, metastasis from carbuncles, from empyema and other foci of suppuration. Israel, it will be remembered, reported a case in which carbuncle was associated with a perinephric abscess. Twenty-two cases of perinephric abscess are reported, with 5 deaths. [These abscesses are often due to traumatism, a very slight bruise, or wrench or twist leading to a trivial hemorrhage and so establishing a point of least resistance. Violent coughing may also be causative. Niebergall¹ has insisted on the causative influence of slight traumatisms in producing these suppurations, and mentions the following: taking a false step, riding in a jolting wagon, riding horseback, digging, stamping violently with the feet, carrying a heavy load, or lifting a great weight.]

Oscar Bloch² records a case in which half the **kidney invaded by a morbid growth** was removed. He says that when we have come to the conclusion that an operation is necessary in a kidney-case the question always arises as to the existence or condition of the other kidney. Surgeons have endeavored to clear up this doubt in many ways. Under these circumstances we naturally ask if it be not our duty to save as much as may be of the kidney-structure; in other words, to perform partial excision instead of total extirpation of the entire organ. If this operation is possible, it is very much better, as when we leave a man with a single kidney he will fare very badly if this becomes the seat of disease. There are but very few cases in literature in which a partial removal has been performed. This is chiefly due to the apprehension of hemorrhage during the operation and partly to the fear that the kidney-wound would not heal, but would leave a fistula as a legacy. Experiments on animals have shown that these fears are unfounded. Bleeding can be controlled and the kidney-wound may heal—in fact, may heal with great rapidity. A case is reported by Bloch of a patient who suffered from pain and hematuria. An incision was made and the growth was found in the kidney. The tumor was in the lower third of the kidney. The portion of the kidney containing the tumor was excised, only one artery bleeding, which was easily seized. The incision, which was transverse, began at the lower part of the pelvis and ended at the convex part of the kidney. A piece the size of half a normal kidney remained. Two bleeding arteries in the hilus were ligated. The surfaces of the wounds in the lower part of the kidney were brought together with 3 sutures of catgut, each suture grasping the wound on the convex part of the kidney and including distinct bridges of tissue; the bleeding was slight. Only 3 sutures were applied to the convex part of the kidney, for fear of stasis of blood between the surfaces of the wound; yet gaps were nowhere to be seen between the sutures. The portion of the kidney left was 7 cm. long and 5 to 6 cm. broad. The cavity in which the kidney rested was dried with gauze; the pedicle was carefully palpated and found to be sound. The interior of the capsule was cleaned and sutured with catgut sutures, so that it covered the stump; but room was left to permit of free drainage. The stump of the kidney was replaced quite under the diaphragm. The vertical portion of the wound was closed with 3 deep sutures. Five ligatures were applied to the arteries in the muscle-wound and a drainage-tube and a bit of iodoform-gauze were inserted. The muscle-wound was closed with 11 catgut sutures. This patient completely recovered, and 9 months after operation he was perfectly well, and there was no blood in the urine. Examination of the tumor showed that it was an adenoma

¹ Deutsch. med. Zeit., Aug., 1896.

² Brit. Med. Jour., Oct. 17, 1896.

undergoing degenerative changes from bleeding in the tissues. At the site of amputation the kidney-tissue was proved by the microscope to be normal. The author then discusses reported cases in which partial nephrectomy has been performed.

W. F. Brook¹ reports 2 cases of **nephrolithotomy** to illustrate the value of heavy percussion in the loin in the diagnosis of renal calculus. In one of these cases deep pressure over the kidney caused pain, and heavy percussion below the tip of the last rib caused acute pain in the loin. In the second case the kidney on palpation was not tender, but heavy percussion over the kidney in the back caused stabbing-pain in the loin. The author calls attention to the similarity of the symptoms in both cases. In one case the most acute pain was at McBurney's point; in the other case at a corresponding spot on the left side. In both the classical symptoms of renal calculus were absent. Neither blood nor pus was found. In the absence of the acute, stabbing-pain on percussion in the loin it would have been impossible to diagnosticate the stone in either case. Jordan Lloyd first drew attention to this symptom.

Reginald Harrison,² in an address before the Medical Society of London, considered the **treatment of some forms of albuminuria by renipuncture**. Early in the present year Mr. Harrison narrated 3 cases in which albuminuria completely disappeared after digital exploration and puncture or splitting of the kidney-capsule. The operations were undertaken for another purpose, but the result in each case was good. The first case was scarlatinal nephritis, the second was nephritis from exposure, and the third was nephritis from grippe. Newman, of Glasgow, has reported 2 cases of albuminuria which ceased after the performance of nephrorrhaphy, and Hoerber, of Homburg, reports a case in which albuminuria disappeared after an incision. Harrison believes that in these cases the albumin disappeared as the result of the operation. In one class of cases the tension was due to inflammatory hyperemia and in the other to mechanical obstruction of the vessels. Analogues may be found in other portions of the body. Iridectomy is performed in glaucoma; puncture or limited incision may be of great benefit in acute orchitis, relieving tension and preventing damage to secreting structure. The kidney is capable of gradual distention, but cannot distend from sudden force. We might infer that, as the kidney is normally a double organ, both glands must be submitted to the operation, inasmuch as in ordinary nephritis both kidneys are similarly involved. This does not, however, of necessity follow. Strong sympathies exist between two glands, and impressions upon one gland may be reflected to the other, and relief afforded to one kidney usually assists the other. When the excretory power of one side is lessened or arrested the other organ takes up the whole of the work. This operation may be employed in scarlatinal nephritis, in which the albumin does not disappear from the urine rapidly and completely. There are 2 groups of these cases: in the first the kidney-trouble is grave from the very start; in the second group the symptoms do not tend toward recovery even after a considerable time. In these cases the kidney should be exposed by a moderate incision in the loin. The operator should feel the organ both in front and behind, aided by pressure exercised by the hand of an assistant over the front of the abdomen. If, with albumin in the urine, the kidney is found in a state of tension, 3 or 4 punctures may be made through the capsule in various directions, and if the organ is in a high state of tension a limited incision should be made in the cortex. The wound should be packed with gauze or a drainage-tube should be inserted. The fact that tension exists in the kidney can readily be made out when an ex-

¹ Brit. Med. Jour., Dec. 19, 1896.

² Ibid., Oct. 17, 1896.

amination is made. In some instances it will be so marked that the organ will resemble a bursting plum. [In the case reported by Keen and Stewart the capsule of the kidney was incised and a portion of the organ was removed for microscopic examination.¹]

Willy Meyer² writes on **early diagnosis and early nephrectomy for tuberculosis of the kidney**. He is a profound believer in the value of a cystoscopic examination of the bladder and catheterization of the ureters. He reports a case in which there was a tuberculous kidney, the process passing down the ureter to the bladder, an injected area on the bladder-surface near the mouth of the ureter being seen. An operation showed the kidney to be tuberculous. Tubercle-bacilli were found in the urine in these cases. He tells us that a recent appearance of frequent micturition in a hitherto healthy individual who has not been infected with gonorrhoea is very suggestive of tuberculous kidney, especially if this is associated with permanent, or more particularly intermittent, voiding of turbid urine with or without blood. If, in a case with such symptoms, the cystoscopic examination shows a healthy bladder with one ureteral opening clearly inflamed or swollen, we are certainly dealing with primary tuberculosis of the kidney to which the inflamed ureter belongs.

F. Tilden Brown³ has made an elaborate study of **renal tuberculosis**. He takes up for consideration the methods of infection, the pathology, the symptomatology, and diagnosis. He tells us that the early symptoms will depend somewhat upon the mode of infection—whether it was arterial or ureteral. Invasion by the vessels may be nearly or quite without symptoms until the disease has advanced to a considerable degree. A careful urinary analysis always permits of a comparatively early diagnosis. The following is a summary of the different symptoms and signs of the disease: the existence of a tumor which corresponds to the position of a kidney; this tumor may or may not be painful on palpation. It may be the seat of spontaneous pain which is often intermittent, or it may be a center from which pains radiate to different portions of the abdomen, spine, groin, outer side of the thigh, or the opposite and healthy kidney. It is well to remember, however, that there may be no obvious enlargement of the kidney. The other symptoms to be mentioned are pallor and emaciation, edema of the lower extremities, reaction after the injection of tuberculin, albuminuria, moderate fever, night-sweats, dysuria, pyuria, hematuria with acid urine, turbid urine seen by the cystoscope emerging from the ureter, and the finding of tubercle-bacilli in that urine which we know to come from one or the other kidney as obtained by ureteral catheterism. Emaciation is of little importance, because it is such a common symptom of disease, and many patients do not show emaciation for a considerable time; the same remarks apply to pallor and cachexia. Edema of the extremities results simply from impairment in the quality and alteration of the quantity of the blood. The existence of albuminuria in tuberculous kidney has been a matter of great dispute. The reason of this divergence of view can be readily explained. When the tuberculous lesion is in free communication with the urinary tract serum, leukocytes, and blood-corpuscles mix with the urine in greater or less quantity, and in such a condition boiling and the acid-test show the presence of so-called albumin. In this sense slight albuminuria is a not infrequent symptom of renal tuberculosis. But when the tuberculous focus is still enclosed in the parenchyma these products are not mixed with the urine, and the uriniferous tubules and glomeruli which are undisturbed are functioning normally, and albuminuria is very rare. If albuminuria does appear, it

¹ Lancet, Sept. 24, 1897.

² Med. News, May 1, 1897.

³ N. Y. Med. Jour., Mar. 20, 1897.

will be associated with the presence of casts and tuberculous epithelium. Such a condition arises from nephritis due to overaction of the excreting channels brought about by the irritating waste-products of the system at large. Undoubtedly in many cases of renal tuberculosis there is no albumin in the urine, but we can only definitely settle this question when able certainly to distinguish between globulins and true albumins.

The reaction to tuberculin is a very uncertain diagnostic test; at least it is uncertain in human beings. Escherich's report shows that its importance in diagnosis is limited. If, however, we have a patient with a slightly enlarged or tender kidney, with a moderate evening pyrexia and slight polyuria, and if tuberculin in such a case produces a distinct reaction, we should suspect the existence of renal tuberculosis, order the patient a change of climate, and institute restorative treatment. Dysuria cannot be called a symptom of kidney disease unless associated with tuberculous lesions of the lower portion of the urinary tract. In most of the victims of tuberculous kidney there is discomfort arising from frequency of urination rather than from real pain. Enlargement of the kidney is a noticeable symptom in the well-advanced cases of both varieties of the disease. In the ascending variety intermittent hydronephrosis may occur. An enlarged kidney is usually uncomfortable or painful on palpation, and is commonly the seat of attacks of local and radiating pain. In nearly all cases of tuberculosis of the kidney there is a slight afternoon or evening pyrexia, possibly not more than 0.5° . This symptom would tend to exclude calculus, and a septic kidney would be associated with a far greater rise of temperature. In the later stages of tuberculosis of the kidney the afternoon temperature will be frequently as high as 103° , and night-sweats will probably occur. In the early stages of the disease the pulse is not particularly involved, but later in the case it becomes rapid and weak. Polyuria is one of the earliest symptoms which attend the formation of a tuberculous area in the kidney. Pyuria and hematuria occur only when the tuberculous focus is in communication with the urinary tract. Pyuria of tuberculous kidney is an acid urine, and when pyuria exists there is nearly always hematuria. The blood may be present in small amounts or in very large amounts, and the bleeding may take place at long intervals—months, it may be even years. Frequency of micturition is the symptom most apparent to the patient, and it is the symptom for which he usually comes to seek relief. If this polyuria is marked at night as well as in the day, the suspicion of the existence of tubercle is increased. At periods during the progress of the disease the frequency of micturition is for a time abated. When the cystoscope shows turbid urine emerging from the ureter which belongs to an enlarged and tender kidney, and when this urine is withdrawn from the bladder by a sterile catheter, or, better still, when it is brought into a centrifugating tube by means of Casper's or Nitze's instrument, and it is found to contain bacilli, or if it is found that injection of this urine into a guinea-pig produces tubercles, the diagnosis is certain. If there are lesions of the bladder, of course the diagnosis is somewhat obscure. The microorganisms which most resemble the bacillus of tubercle are the lepra-bacillus and the smegma-bacillus. All grades of this disease may be classified for the purpose of preliminary treatment under two heads. The rich must be sent to another climate, pay scrupulous attention to hygiene and alimentation, and take invigorating drugs. An attempt may be made in the poor to approximate the treatment outlined for the rich, and if it is possible for the poor man to go away and live in another climate, he should do so. Theoretically it would seem that the treatment of these early cases should be a radical surgical operation, but practically it has been

shown that the impairment of the strength which temporarily follows upon nephrectomy does the individual great harm when there is an early tuberculous lesion. It is very probable that there is another lesion in the body somewhere besides the one in the kidney; even if this lesion is not active, any impairment of the individual's health and strength may cause its rapid progress and dissemination. If this small tubercular focus in the kidney is found at an early period, and the individual is in an excellent state of health, a nephrectomy would probably be the best thing for the patient; but because a number of these early cases can be cured by other than surgical measures it is thought right to employ them before advising operation. In some cases it occasionally happens that this form of treatment must be delayed until some urgent condition has been relieved surgically. For instance, the sudden appearance of marked pyuria, with fever, in a patient with enlarged and tender kidney, or the sudden onset of severe hematuria with moderate fever, calls for operation. When these symptoms are present in the early stage of the disease nephrectomy is indicated unless there is a tuberculous focus in the other kidney. Nephrectomy should also be performed when the individual has had every advantage of climate and medical treatment and yet the tuberculous focus is advancing. The evidences of this advance are loss of appetite and strength, diminution in weight, increase in the pyuria, the pain, the fever, and the size of the kidney. We would not entertain the idea of radical surgical cure when in addition to an undoubted area of tuberculosis in the kidney the lower urinary tract is positively involved, when it is probable that the other kidney is affected, when in the male the prostate, seminal vesicles, or testes are attacked, and in the female the bladder, peritoneum, Fallopian tubes, or ovaries; but even in these cases, when the chief trouble is certainly in one kidney and the ureter is unable to afford adequate drainage, operation may be performed as a tentative rather than as a curative measure. It is in this sort of case that surgeons were formerly in the habit of recommending nephrotomy, but Brown believes that nephrectomy is preferable. If in the advanced cases serious renal hemorrhage occurs, nephrectomy is the only proper treatment. The figures of Continental surgeons show a mortality from nephrotomy of 13%, and from nephrectomy of 30%. In some statistics Brown has collected in New York, out of 28 nephrectomies there were 2 deaths, a mortality of 7.1%. These nephrectomies were not all done for tuberculosis, but the operative mortality of nephrectomy performed for tuberculosis is certainly as low as the mortality for nephrectomy performed for any condition requiring operation. The author then discusses the methods of performing nephrectomy.

Bayard Holmes¹ writes on **tuberculosis of the kidney** and records some interesting cases; his conclusions are as follows: tuberculosis of the kidneys is rather a common disease; it usually begins in the kidney, passes down the ureter to the bladder, and ascends to the other kidney, and is for a long time a unilateral trouble. It is progressive, and destruction cannot be arrested by medication, and offers a very unfavorable prognosis. Diagnosis is made by the symptoms of cystitis, with the low temperature and rapid pulse and dilated heart, tubercle-bacilli in the urine, tuberculosis of the bladder about the ureteral orifice of the diseased kidney, pyuria or hematuria, with diminution of the normal constituents of the urine from the diseased kidney, normal urine in increased amount from the sound kidney, sometimes pain, tenderness, and enlargement in the situation of the diseased kidney. When one kidney is healthy and the other diseased the indications are absolute for removal of the tuberculous organ together with its ureter; but if both kidneys

¹ Jour. Am. Med. Assoc., Sept. 5, 1896.

are diseased, no operation should be undertaken. The fact that the other kidney is competent can be proved by repeated catheterization of the ureters before nephrectomy. For some days before the removal of the kidney toxic elements should be eliminated from the blood by the use of a liquid diet, irrigation of the colon, and hydration of the system. The safer operation is extraperitoneal lumbar nephrectomy. In women the ureter should be completely removed through the vagina. Any remaining tuberculosis of the bladder should be treated locally by curetting or excision. Catheterization of the ureter is not dangerous, and can easily be carried out in women by Simon's cystoscope or the cystoscope of Pawlik or Kelly; in men we may use the instrument of Casper.

WOUNDS, BURNS, ULCERS, SHOCK, ETC.

William Turner¹ presents some remarks on **wounds of the heart** and furnishes the notes of a case in which death took place 4½ months subsequent to a heart-wound, cicatrization being shown by the postmortem examination. He tells us that there is a firm belief in the popular mind that the heart is the most vital structure of an animal, and that in order to destroy an animal with the utmost certainty the effort should be made to injure the heart. Hunters act on this idea. The rules of the army direct that when a person is to be executed the firing-party must point their weapons at the heart of the culprit, with the idea that suffering will thus be minimized. It has been supposed that if the substance of the heart be even touched by a foreign body the action of that organ must necessarily cease immediately. The experience of most surgeons, however, positively disproves these notions. Turner saw a child of 2 years with a sewing-needle driven into the heart. The needle had disappeared in the chest, but its head could be felt beneath the skin knocking against the finger with each heart-beat. The needle was cut down upon and extracted, and no harm apparently resulted to the heart or the child. Some years ago the dead body of a man was discovered by the police. There was a series of some 10 or 12 wounds over the region of the heart. A large butcher-knife was buried in one of these wounds, and the right hand, covered with blood, grasped the handle of the knife. There could not be the possibility of a doubt that these wounds were self-inflicted. At the postmortem it was found that three of the wounds had penetrated the cavity of the heart and caused laceration of the heart-walls. It followed, therefore, that after the heart had been at least twice penetrated by a large butcher-knife and very greatly damaged, the individual had retained sufficient physical strength and mental determination to inflict a third wound on the same organ. Most of the records point to the fact that wounds of the heart are seldom, if ever, immediately fatal. Out of 29 collected cases only 2 were fatal within 48 hours. A stag ran 60 yards after being shot through the heart. An examination showed that the left auricle had been practically destroyed and that the left ventricle had been completely torn through. There is a thoroughly authenticated case in which a bullet was found imbedded in the substance of a soldier's heart six years after he had been wounded, he having died from another cause.

Turner then cites some interesting examples of penetrating wounds of the heart which were not immediately fatal. In his own case, which he then proceeds to describe, there was a cicatrized wound over the intraventricular septum. The patient was a Maltese, who was admitted to the hospital collapsed and bleeding from a wound in the left side of the chest over the heart. He had been stabbed in a quarrel. There was a considerable amount of arterial blood

¹ Brit. Med. Jour., Nov. 14, 1896.

issuing from the wound synchronous with cardiac systole, and air was also passing out with hissing noises on each movement of respiration. The heart's sounds were muffled and the pulse at the wrist was scarcely to be detected. The patient seemed to be on the verge of death, but he gradually improved. A month after the injury the discharge was purulent and abundant, and the pleural sac was converted into a large suppurating cavity; the 5th rib was resected posteriorly to permit of drainage. $4\frac{1}{2}$ months after the injury the patient was allowed to sit up, but one morning he had a convulsion and died. The postmortem showed that he died of an apoplectic clot. Examination showed that there was a cicatrix in the pericardium corresponding to the external wound, and immediately subjacent to this was discovered a cicatrix on the anterior surface of the heart itself. This second cicatrix was $\frac{3}{4}$ in. in extent, and was placed over the intraventricular septum about $1\frac{1}{2}$ in. from the apex. It was found on section to have penetrated $\frac{5}{8}$ in. into the muscular substance of the heart, the left coronary artery and vein having been divided. It seemed certain that after infliction of the wound the pericardium must have filled up with blood, and yet cardiac action was not thereby arrested. [The subject of wounds of the heart is discussed in the section upon the Vascular System, p. 369.]

Charles H. Lemon¹ writes on **gunshot-wounds of the kidney**, and reports 2 cases. These lesions are not common, because the kidneys are deeply placed. Years ago Larrey and Dupuytren recognized the necessity of providing free drainage in kidney-wounds, but during the War of the Rebellion surgeons neglected this advice. The *Surgical History of the War of the Rebellion* contains the reports of 78 cases of gunshot-wounds of the kidneys, and but 26 of these recovered. Every one was treated upon the expectant plan, and no incisions were made for exploration. Accumulated experience has shown that in penetrating wounds of the kidney adjacent viscera are often wounded, but that, unlike incised wounds, there is rarely infiltration of the retroperitoneal tissues. The author commends to the attention of those who are interested in this subject the paper read by Prof. Keen before the American Surgical Association this year. Among those tabulated are all cases of traumatism of the kidney reported since 1878. In this last are 19 cases of gunshot-wound of the kidney. Of these 19 cases 10 recovered. Lemon relates 2 cases which happened in his practice, both of which recovered. In the first case he made an exploratory lumbar incision exposing the left kidney along the track of the bullet. The perinephric tissue was found to contain clotted blood and urine, and the wound was discovered on the inner convex border of the kidney. When a probe was introduced it was demonstrable that the ball had not lodged in the kidney. The direction of the bullet was such that it was evident that the pelvis of the kidney had not been penetrated anteriorly. No further exploration was made. In order to arrest hemorrhage the tear was plugged with iodoform-gauze. The deep structures of the back were sutured with catgut and a gauze drain inserted along the track of the bullet. In the second case an exploratory incision was also made. The incision was made in the right loin parallel to the last rib, to expose the kidney. The kidney was thoroughly exposed, and a wound found in it which easily admitted the index-finger on the posterior surface about its center an inch external to the pelvis. There was little or no extravasation of urine and no clotted blood in the perinephric tissue. The wound was closed after a strip of gauze had been packed into the opening on the posterior surface of the kidney. The author quotes approvingly the words of Prof. Keen: "If the surgeon has reasonable evidence that the

¹ Jour. Am. Med. Assoc., Jan. 9, 1897.

kidney has been probably traversed by a ball (and all the more so if it is certain that it has been so wounded) and the patient is evidently in grave danger, as shown by the general symptoms of internal hemorrhage and by the physical signs of a large lumbar hematoma, or of intraperitoneal bleeding, I take it for granted that all of us would recommend an exploratory operation with a view of determining the extent of the injury to the kidney and the proper treatment."

Assistant Surgeon A. Wells¹ reports 2 cases of **snakebite** treated successfully by the use of **potassium permanganate and strychnin**. In the first case the remedies were administered by means of the stomach; in the second he enlarged the punctures made by the fangs of the snake's teeth and introduced the permanganate crystals, injected strychnin in the arm, and gave the permanganate internally in solution in doses of 5 gr.; both patients were cured.

H. P. Keatinge² reports a case of **snakebite treated by antivenene serum**. A child was bitten on the forearm by an Egyptian cobra; she almost instantly became unconscious. The village barber made several small incisions on the arm and forearm. When brought to the hospital she was cold and collapsed, pulseless, with rambling delirium. It was found that the forearm had been coated with Nile mud, which is a favorite native remedy; 3 in. below the bend of the elbow 2 distinct holes were seen passing through the skin and corresponding to the fangs of the serpent. It was noted that the pupillary reflexes were absent; the pupils were moderately dilated. The child became comatose. Twenty c.c. of antivenene serum were injected under the abdominal skin. In 4 hours her condition was distinctly improved. Ten c.c. of the antivenene serum were again injected. She then slept during the night and the next morning was notably better. The serum used was **Calmette's antivenene serum**. Another case of recovery is reported by Surgeon-major S. J. Rennie.³ L. S. Alexander⁴ reports a case of rattlesnake-bite treated by **rattlesnake-bile**. An incision was made in the bitten area and the bile was poured into the wound. No other treatment was employed except the administration internally of ammonium carbonate. There was not a particle of swelling and the man suffered no inconvenience of any description. Surgeon-captain C. W. R. Healey⁵ reports a case of snakebite which was treated as follows: the wounds were enlarged, a strong solution of potassium permanganate was applied, a ligature was tied at the base of the injured finger, the hand was placed in hot water, and bleeding was encouraged by pressure from above downward. The man was given aromatic spirits of ammonia, which he vomited, and after that he was given some brandy, which he retained. The patient was subsequently placed in bed and given strychnin hypodermically. In spite of this treatment he died. Ram Dhari Sinha⁶ reports a case of snakebite treated successfully with **liquor ammonia**.

Ottinger⁷ maintains that **venomous insect-stings** should be treated by the application of **pure ichthyol**, or a mixture of equal parts of ichthyol and lanolin. This remedy mitigates the pain and greatly lessens the inflammatory reaction. If, when the surgeon first calls, swelling already exists, ichthyol is applied, sheet India-rubber is laid over this, and an ice-bag placed on the India-rubber tissue. Ottinger advises the administration internally in such a case of 10-drop doses of a mixture of equal parts of ichthyol and spirit of ether. V. Dinshaw⁸ reports the case of a boy who was stung by a **scor-**

pion. His relatives administered musk, which produced no improvement. The surgeon ordered arrack, which is a strong spirit, giving half an ounce with an equal quantity of water. Two doses were given within 5 minutes. Next, 10m of aromatic spirits of ammonia in an ounce of water were given. Three doses of this were administered, when the patient began to improve. In this case the symptoms were extremely grave, but the patient made a complete recovery. Patients who are stung by scorpions develop all the signs of collapse.

E. M. Foote¹ writes on the effect of **formalin-gelatin in suppurating wounds.** He has made a number of clinical experiments in the use of this agent, and concludes that the formalin possesses a distinct antiseptic action.

SKIAGRAPHY.

[During the year there have been many interesting cases reported of the use of the Röntgen rays, and surgeons have come to a more accurate conclusion as to the value of this new process, the relative value of the fluorescent screen and the skiagraph, of the methods of locating the exact situation of a foreign body by the process, and of the destructive effects and erroneous conclusions which may occasionally follow upon its use.]

J. E. Stubbard² has compared 73 cases of pulmonary tuberculosis, examined by **the Röntgen rays**, with 15 normal individuals. His conclusions are as follows: 1. Slight haziness indicates the beginning of tuberculous infiltration, which may or may not be accompanied by dulness on percussion. 2. Decided shadows indicate consolidation, the extent of which is in direct relation to the comparative density of the shadow thrown on the fluoroscope. 3. Circumscribed bright spots surrounded by narrow rings of dark shadow or located in the midst of dark areas indicate cavities. 4. Intense darkness, especially at the lower portion of the lung, indicates old pleuritic thickenings over consolidated lung-tissue.

Surgeon-major Whitehead³ has published a skiagraph of a **case of fractured femur.** This picture appeared to be a recent fracture of the lower end of the femur, in which there were considerable deformity and overriding of the lower end of the upper fragment, whereas in reality the picture was of a fracture close above the knee-joint which occurred six months ago. The lower end of the upper fragment was jagged and irregular, as if Nature had made an attempt to round it off, and no projection of bone could be felt at the seat of fracture. There was half an inch of shortening and the man walked without pain or trouble. From a surgical point of view the result is as good as could have been expected. It is not probable that the bone is really as sharp as it appears to be in the skiagraph. It is probable that the x -rays traversed the more recent callous material, which really does round off the end, without throwing a shadow on the plate.

Edmund Owen, in speaking of a similar case of his own, suggests a misuse to which skiagraphy may be put in the future. He inquires what a British jury may think when a skiagraph of a case is being explained by a sharp advocate of a claimant for damages for malpraxis. In Mr. Owen's case the x -rays showed a deformity which really did not matter, as the result is as good as the surgeon could achieve, and the author remarks that imaginative patients may consider themselves badly treated if they have their broken bones skiagraphed.]

Herbert B. Perry⁴ has reported an interesting case in which he was able to

¹ Med. News, Nov. 14, 1896.

³ Lancet, Mar. 20, 1897.

² Med. Rec., May 22, 1897.

⁴ Med. News, Mar. 20, 1897.

demonstrate by the *x*-rays the presence of the point of a pair of **scissors in the knee-joint**. He performed an operation and removed the foreign body. He located the foreign body in the joint first by the use of a fluorescent screen. In order to have some landmarks to work by in performing the operation he took a long, flat key, smeared the point with ink, and passed it between the light and the knee and the knee and the screen until it was seen to touch the skin at the location of the foreign body. In this manner the distal and proximal ends of the scissors-point were noticed on the external and internal surfaces of the knee. The mark was afterward made indelible with nitrat of silver.

Leonard Freeman¹ publishes several **interesting skiagraphs**. He records one case in which a diagnosis was made of epiphyseal separation of the wrist. After 14 weeks two skiagraphs were taken, when it was seen that the anterior half of the right epiphyseal line was obscured by a shadow representing a growth of new bone, the border of the epiphysis being tilted downward from the shaft. The bone, therefore, was in an apparently incorrect position, yet the final result was good. He also publishes a picture of a fracture of both bones of the forearm, another through the lower extremities, and a fracture of the styloid processes of the radius and ulna.

F. J. Clendinnen² publishes **skiagraphs of the blood-vessels** of the ankle and knee-joint. In order to obtain these he injects the arteries with a solution of red lead. The bone offers less resistance to the rays than the injected vessels, and the arteries can be seen back of the bone as well as in front of it. This method promises to be useful in the study of anatomy and pathology.

Eugene R. Corson³ records 4 cases, with skiagraphs, of injuries which had been diagnosed as **Colles's fracture**. He shows that there had been no fracture of the radius, the great deformity being due to arrachement of the ligaments from excessive flexion of the wrist. It is very important to treat this sprain. If there is simply a fracture of the radius without a tear of the ligaments, almost any treatment is successful; but, as shown by Hamilton, a severe sprain will be followed by marked deformity, and it is in the latter cases that suits for malpractice are apt to be brought.

Schier⁴ makes a report upon the value of the Röntgen rays in detecting **bullets in the head**. In a patient who was shot five years previously in the right brow the symptoms indicated that the bullet might be lodged in the ethmoid bone. The skiagraph taken from different directions showed that the bullet was located near the petrous portion of the right temporal bone, in the neighborhood of the Gasserian ganglion.

Willy Meyer⁵ makes a report of a man who had attempted suicide by shooting himself in the right temporal region; he had been trephined, but no search for the bullet had been made. The patient recovered from the operation, but motor symptoms developed in the left arm and leg. *X*-ray photographs faintly revealed **three foreign bodies** in line with each other, two of them evidently the split bullet, the third either a part of the bullet or a splinter of bone. Two of the foreign bodies are on one side of the median line and one is on the other. The case is looked upon as beyond surgical relief. It is interesting to note that exposure to the *x*-rays brought about an extensive loss of hair over the posterior half of the head. Philip D. Bunce⁶ reports a case in which a bullet was located in the motor area of the brain with *x*-rays. Operation was not advised because it was believed that the destructive changes

¹ Ann. of Surg., Apr., 1897.

³ Med. Rec., May 8, 1897.

⁵ Ann. of Surg., Apr., 1897.

² Intercol. Med. Jour. Austral., Jan. 20, 1897.

⁴ Wien. med. Presse, No. 33, 1896.

⁶ Med. Rec., Apr. 17, 1897.

in the brain were permanent. Brissaus and Londe¹ report a case in which a pistol-bullet imbedded in the brain was successfully skiagraphed. As the ball was situated in the temporal region, it was obvious that the existing hemiplegia was not due to the presence of the bullet, but resulted from injury the bullet had wrought in its passage, hence that no surgical operation was justifiable. L. E. Henschen and K. G. Sennauer¹ have reported an important case in which the *x*-rays showed a bullet in the brain. Two skiagraphs were taken. The first showed the ball in the occipital region; the second showed it to the right of the median line. An operation was performed, the ball was removed, and the patient recovered.

J. William White, Arthur W. Goodspeed, and Charles L. Leonard³ report an interesting series of cases in which the *x*-rays were used, and discuss the subject of **the value of the *x*-rays**. They tell us that the most obvious and simplest use of the skiagraph is in detecting foreign bodies imbedded in any of the tissues. They then discuss the cases in which foreign bodies have been found in certain organs and viscera, and the detection of foreign bodies within the organism itself, such as renal, vesical, and prostatic calculi.

George R. Fowler⁴ reports a case of **lateral dislocation of the elbow-joint** in which the skiagraph failed to make the injury evident. This was due to the fact that the individual who used the apparatus was not aware that there was likely to be a lateral dislocation. Under an anæsthetic lateral dislocation was perfectly evident to the examiner's fingers. He also reports a case of **gunshot-wound of the head** in which the bullet was located by means of the Röntgen rays and the telephonic probe and was removed by operation.

A. P. Laurie and John T. Leon⁵ report a case in which a **vesical calculus** was successfully skiagraphed after an exposure of 7 min.

Sidney Rowland⁶ presents a study of **the *x*-rays and their application**. In the region of the skull their use is practically confined to the discovery of foreign bodies. The conditions are not very favorable, for the skull forms a more or less opaque screen; but bone is not absolutely opaque, and by prolonged exposure it is possible to locate a bullet in the brain. A tuberculous focus in the cervical spine can be made out. In discussing the use of the *x*-rays in the thorax he tells us that by the use of the plate a skiagraph of the heart can be obtained; but a skiagraph is only a shadow of the outline of the heart, nothing is shown of the condition of the valves or cavities. For the diagnosis of foreign bodies in the trachea and bronchi, or imbedded in the substance of the lung, the skiagraph will reveal all that can be desired, providing these bodies are opaque to the *x*-rays. The rays are especially useful in the case of children who have swallowed marbles and small coins. In making a diagnosis of spinal caries the sternum and ribs act as a screen to the rays; but if the rays are directed, by adjusting the tube laterally to the sternum, so as to traverse an intercostal space, the difficulty will be overcome and we shall be enabled to obtain a slight oblique spinal projection. In the abdomen the rays are valuable in detecting foreign bodies, locating a Murphy button; and diagnosing lumbar caries, fracture, or dislocation. If the surgeon is going to operate for a foreign body, it should be seen just before operation; otherwise the position may be altered by the peristaltic action of the intestines. The question as to the value of the *x*-rays in the diagnosis of vesical or renal calculus is still open. If the bladder shows no shadow upon it, that is no evi-

⁶ Brit. Med. Jour., Oct. 3, 1896.

dence that a stone does not exist in the kidney; but if a decided shadow exists, proof is positive that a foreign body is present. In some cases a positive diagnosis can be given, but in any case the information should be sought for. The limbs prove themselves most adapted to the purposes of the skiagraph. It is in the elbow-joint that the greatest use will probably be found for the skiagraph in surgery. This joint is very easily skiagraphed, and we are able to distinguish between separated epiphysis, epicondylar fractures, and many other intricate combinations of lesions. We can also use the fluorescent screen without elaborate precautions. In the forearm and wrist the application is practically limited to the diagnosis of fractures and the recognition of the position of foreign bodies. It is not a simple matter to diagnose a dislocation of the metacarpal bones with the aid of a skiagraph, as here a side view is difficult to obtain, and an anteroposterior view does not give us all the information we desire, and it is in this direction that displacement must occur.

In considering the lower extremity, what we have said about the upper extremity also applies. The hip-joint presents several conditions in which early diagnosis is invaluable, but it is often very difficult to obtain a satisfactory skiagraph. In most cases, however, there is no difficulty in obtaining one. In early tuberculous disease we may be able to make a diagnosis by the skiagraph. In cases of congenital dislocation the process gives us valuable information as to the extent of the acetabular rim. [In a later article Sidney Rowland considers the method of using the Röntgen apparatus, and tells us that the rays occasionally produce some very curious effects upon the skin. In one case there was exfoliation of the skin and nails of the hands.]

Robert G. LeConte¹ reports an interesting case in which a **bullet** deeply imbedded **in the tissues of the neck** was located by a skiagraph.

E. E. King² records an interesting case in which **lesions of the skin**, hair, and nails were produced by the action of the *x*-rays.

Maurice H. Richardson³ presents a series of **22 cases**, illustrating the importance of the use of the *x*-rays in the routine office practice of a general practitioner, taken, as he says, by one who knew nothing about photography, nothing about electricity, and very little about physics. He advises the use of the Röntgen rays as an aid to diagnosis, and insists upon their value because of the medico-legal aspect of many of these cases. When it has been employed the surgeon is able to locate the exact situation of the fragments in fractures, which is of the utmost value in routine practice.

W. S. Forbes⁴ reports a case in which he obtained a skiagraph showing a **crochet-needle 3 in. long in a girl's bladder**, the needle being imbedded in a mass of uric-acid incrustation.

Henry Morris⁵ says that, owing to the position of the kidney close to the vertebral column and deep beneath the muscles and ribs, the *x*-rays have not as yet been of use in diagnosing **biliary or renal calculi**. Calculi formed of lime salts show a deeper shade than those composed of uric acid and urates. Over-exposure often causes failure in skiagraphing calculi, and Morris suggests as short an exposure as possible, supposing the rays are strong enough to reach the renal region. James Swain⁶ objects to Mr. Morris's assertion that the Röntgen rays are not of assistance in diagnosing renal calculi. He succeeded in skiagraphing an oxalate stone and successfully removed it, and in another case he has skiagraphed a stone which the patient will not have removed. He also knows of another case in which the stone was skiagraphed

¹ Ann. of Surg., Aug., 1896.

³ Med. News, Dec., 1896.

⁵ Lancet, Nov. 14, 1896.

² Canad. Pract., Nov., 1896.

⁴ Jour. Am. Med. Assoc., June 26, 1897.

⁶ Ibid., Dec. 5, 1896.

and removed. Chappins and Channel have shown that calculi in the urinary passages may be demonstrated by the *x*-rays, and, further, that it is often possible to determine by skiagraphy the character of the stone, the composition, and causation, by differences in the appearance of the skiagraphs.

Francis Johnston and C. Thurston Holland¹ report 2 cases of **halfpenny in the esophagus** recognized by means of the *x*-rays. In one case the child had swallowed the halfpenny 2 days before, and the skiagraph showed the coin distinctly in the gullet. The second case had a doubtful history of having swallowed a halfpenny 5 months before, and the coin was distinctly visible by means of the *x*-ray. In Case I. the coin could be seen most distinctly with the fluorescent screen. In Case II. the screen showed the coin faintly apparent behind the upper part of the sternum, but the attempt to obtain a radiograph was unsuccessful.

H. Becekman Delatour² has reported a case in which he removed a foreign body from the esophagus by esophageal forceps guided by the fluoroscope. The patient had swallowed an iron washer $\frac{9}{16}$ in. in diameter. The object was so distinctly visible when looked at by the fluoroscope that Delatour at once thought of the possibility of passing a pair of forceps guided by the fluoroscope and grasping the washer from above. The fluoroscope was applied to the back and showed the disk. A pair of flexible bullet-forceps were then passed into the esophagus and were visible in the fluoroscope; the forceps were made to grasp the washer, and had withdrawn it about an inch when the child made some efforts at swallowing which dislodged it from the grasp of the forceps and it slipped back to its former position. More chloroform was given and an attempt was made with a pair of alligator-forceps, with the same result. In the third attempt a pair of esophageal forceps were passed until they were seen to be $\frac{1}{2}$ in. below the washer; they were then opened and closed, and seen to grasp the foreign body, which was then successfully withdrawn. [White expressed the view that such a procedure might be successful 9 months before the appearance of Delatour's article.]

W. B. Bannister³ reports a case of **x-ray traumatism** due to exposure for four hours in two sittings, a slight redness resulting. About a month later the patient was exposed to the *x*-rays for twelve hours during four days. This was followed by necrosis of the abdominal skin over an area 12 by 15 in., and the patient was confined to bed for a month. The beard on the chin and the thumb-nail were destroyed, and there was agonizing pain of a burning character. The author attributes this effect to action upon the terminal nerve-filaments, probably on the vasomotor nerves.

J. William White⁴ records a case in which a jackstone was detected in the esophagus by means of skiagraphy. [This case was reported in the *Year-Book* for 1897. W. W. Keen and A. C. Wood have reported similar cases.]

Péan⁵ has written upon the value of skiagraphy in detecting foreign bodies in the esophagus and has reported a recent case. A child had swallowed a coin ten days before. Because the child was still able to swallow liquids the physician had decided that the coin had gone into the stomach, but a skiagraph showed that the coin was lodged, and led Péan to decide upon the performance of an operation. The fact that in many cases after foreign bodies have been lodged the individual can still swallow liquids may lead to the lapse of considerable time before there is a recognition of the real condition. Skiagraphy enables the surgeon to know that a foreign body is present, enables him to

¹ Brit. Med. Jour., Dec. 5, 1896.

³ Ibid., Jan. 23, 1897.

² Med. Rec., May 1, 1897.

⁴ Ann. of Surg., Aug., 1896.

⁵ Bull. de l'Acad. de Méd., No. 48, 1896.

determine accurately its situation, and also to decide upon the operation which is most suitable.

O. L. Schmidt¹ has published an interesting skiagraph of an **aortic aneurysm**. An exposure of seven minutes was required to take the picture, the plate being placed on the chest and the discharge-tube back of the patient. The picture shows the inner ends of the clavicles, the sternum, the diaphragm, and the upper border of the liver. The heart throws a triangular shadow; the aneurysm is seen as a large round shadow in the centre of the picture. The second picture was taken with the plate posterior and the discharge-tube in front, and this showed that the aneurysm had extended downward on the side of the vertebral column. The patient died some weeks later, and postmortem examination showed that the aneurysm was almost the same size as was indicated in the picture.

Henry C. Drury² reports a case in which a man was exposed to the *x*-rays for an hour in an attempt to obtain a skiagraph of the region of the kidney. Three hours later he had an attack of nausea which soon passed away. Six days after this he was again exposed to the rays for 1½ hours. After leaving the laboratory he was again nauseated; next day the abdomen was reddened, and on the third day this redness had become very marked. On the fourth day a crop of vesicles appeared, which increased in size and number and became confluent and then ruptured. 18 days after the second exposure there was a patch on the abdomen like eczema, from which the **epidermis had exfoliated**. This patch gave origin to a profuse seropurulent discharge and was 7½ by 8¼ inches in area. In 16 weeks there had been some healing, but there was still a considerable area which was covered by a false membrane.

William S. Hedley³ tells us that in using the *x*-rays we must be careful not to produce on the plate **artificial deformities**; that is, the shadows must be thrown upon a flat surface, never upon a curved one. It therefore becomes obvious that sensitized paper must not be adapted to the curves of the body, as this would make the skiagraph absolutely misleading.

Samuel Lloyd⁴ has recently shown the value of the *x*-rays before and after **osteotomy**. The case was that of a girl whose femora were crossed. Each thigh bone was subjected to osteotomy and was produced in the position for reunion. The fact that the union was perfect was determined by the use of the *x*-ray apparatus. The bones could be seen very readily by placing the Crookes tube under the operating-table and holding the fluoroscope above the thigh bones. The observer has also had most satisfactory results in studying fractures about the knee and elbow and diseases of the bones of the hand.

W. S. Hedley⁵ considers the **usefulness of the x-rays in medicine and surgery**. He tells us that in fractures of the extremities the use of this process has become almost routine, not only to recognize the existence of fractures before reduction, but to study them for the application of splints. Foreign bodies in the esophagus have been clearly shown. Luxations of the hip have sometimes been recognized, and renal and vesical calculi have been darkly defined, but no results as practically useful as those obtained by the skiagraph in the surgery of the extremities have yet accrued to medicine. The skeleton of the thorax is readily seen, and organ after organ is beginning dimly to take form. The light space occupied by the lungs can be contrasted with the dark lines of the ribs, the diaphragm is visible to the extent of its movements, and the shadow of the living heart in action can be thrown upon the screen.

¹ *Medicine*, Apr., 1897.

³ *Lancet*, Apr. 3, 1897.

² *Brit. Med. Journ.*, Nov. 7, 1896.

⁴ *Jour. Am. Med. Assoc.*, Apr. 24, 1897.

⁵ *Treatment*, Mar. 25, 1897.

Boucharde has shown by this means the presence of fluid in the pleura, and he has also demonstrated cardiac hypertrophy and aortic aneurysm. The convex surface of the liver is clearly seen, and a hydatid cyst has been demonstrated there, but the lower surface of the liver has not been defined. The kidney cannot be differentiated. When the stomach is distended with gas it can be made out as a light spot on a dark background, but it is not possible to verify the existence of a large cancer of that organ. The x -rays have not yet established any claim to therapeutic usefulness. They are not fatal to the diphtheria-bacillus. It is stated that when they were applied to a cancer of the mouth pain was diminished by prolonged and frequent exposure. Despergues has reported a case of cancer of the stomach treated in this way, and he claims that the general condition of the patient was improved, the pain disappeared, and there was a diminution in the size of the stomach. In view, however, of what is known of the effects of suggestion in relieving the pain of cancer, even for a long time, these observations must very largely increase in number before they are seriously considered. There can be no doubt that the x -rays occasionally produce traumatic effects—severe dermatitis and ulceration. Crocker reported a very striking example of this in the *British Medical Journal* of January 2, 1897. Daniel, of the University of Virginia, it is stated by the *New York Medical Record*, secured a simple depilatory action without any inflammation.

Edmund E. King¹ describes cases in which marked **changes** were produced **in the skin**, hair, and nails of an individual he was operating on by the x -ray apparatus.

W. H. Peck² considers recent contributions in skiagraphy and discusses reported cases of x -ray dermatitis.

OBSTETRICS.

BY BARTON COOKE HIRST, M. D., AND W. A. NEWMAN
DORLAND, M. D.,
OF PHILADELPHIA.

The Chief Features of the Year's Work.—The much-mooted question, Shall we or shall we not favor the higher education of midwives? has agitated obstetric circles in this country and in England. There are two ways in which it may be answered: either we must admit these women to a recognized standing in obstetrics, and then, of course, they must be educated for the safety of the women who entrust their lives and health to their care; or else they should be prohibited from practising their calling, and their places filled by well-educated medical men. In this country we have no place for midwives save in the foreign colonies in the hearts of our great cities, where they are mainly found, and even here they should be supplanted by skilled men, and thereby the continued mortality from puerperal sepsis be greatly diminished. The serum-therapy of puerperal sepsis following the usual course pursued thus far by the various antitoxins, as of tuberculosis and diphtheria. The cases hitherto reported in which it has been employed clearly demonstrate that at the best it can have but a very limited field of usefulness in puerperal infection. The same may be said for vaginal section for extrauterine gestation, which has been advocated in some parts of the globe. If ever an operation to be desired, it must of necessity be only under the most unusual circumstances. The study of the fetal appendages has been most assiduously pursued, and our knowledge of their methods of growth and development, the pathologic changes to which they are subject, and their effects upon maternal and fetal tissues is daily becoming more rounded and accurate. Notably is this true of the placenta and of that curious and grave condition—malignant deciduoma. The dangers of labor after ante-fixation of the uterus are now well recognized, and operations are being done mainly after the period of sexual activity is over. Owing to its greater mortality and the increased difficulty in its performance, the operation of symphysiotomy, as was predicted last year, has been largely abandoned in favor of Cesarean section.

PRELIMINARY AND GENERAL CONSIDERATIONS.

The Question of Midwives.—R. R. Rentoul¹ enters an earnest protest against the licensing of midwives in England, rightly claiming that it is a movement not in the best interests of public health and of public safety. He argues that the proposal to supply the poor with midwifery practitioners only partly trained in obstetrics, and wholly untrained in medicine and surgery, is a distinctly retrograde step and conducive to the production of crime, in that it

¹ Lancet, Jan. 16, 1897.

will aid in concealing criminal stillbirths and the nefarious business of the abortion-monger. He believes that with the existing arrangements of the poor-law medical service in the United Kingdom, and without establishing any partially educated midwifery practitioners, they have now the means by which all poor pregnant women can be supplied with fully educated medical attendants. In addition, through the workings of the various nursing-associations, suitable nursing can be provided free of cost for such worthy poor. For those women who are willing to pay a part of the medical fee, maternity clubs and provident dispensaries have been provided. [Our views upon this very vital question have already been given here, and our stand remains firm for the higher education of the obstetric student and the unequivocal denunciation of the licensing of midwives.]

Telegony.—[It has long been believed and tacitly acknowledged by many honest observers that the progeny of one sire may be influenced in color, formation, or other out-standing characteristic by a previous sire, by which the mother has produced offspring. Especially is such a belief rife among veterinarians and horse-breeders, and several well-known cases have often been quoted in support of this theory. This is also true of some instances in the history of medicine and obstetrics.] In an able paper A. L. Bell¹ endeavors to disprove such a belief. He states that to account for the influence of a previous sire there are two theories advanced: 1. That the spermatozoa of the first sire pass up the Fallopian tubes to the ovaries and are absorbed by the unripe ova contained therein; and that these spermatozoa, though of insufficient power to fertilize the unripe ovum, have yet sufficient power to alter the development of that ovum subsequently, when it is fertilized by the spermatozoa of the second sire. 2. That there is an interchange of constituent parts of the fetal and maternal blood-currents, the exact amount of interchange not being defined. It is asserted that some part of the fetal blood enters the maternal circulation—not perhaps as blood, but in one form or other—and the fetal element thus given up to the mother is kept by her and enables her to impress the characteristics of the offspring of a previous sire on subsequent offspring of a different sire; that is to say, the first sire impresses his own offspring with certain of his own characteristics; this offspring impresses the mother through the blood-current; the mother, in turn, transmits the peculiarities of the first sire to her subsequent progeny by means of the blood-element she is said to have received from her first offspring.

In refutation of the first assertion, Bell claims that when a spermatozoon is absorbed into an unripe ovum it must surely die, so far as its individual existence is concerned, by becoming part of the ovum; and it seems incredible that a dead sperm-cell can exert any influence on the development of an ovum by which it was absorbed months before, unless the ovum possesses some special power of preserving not only *its own latent* power, but the potency of the sperm-cell on which it depends for the special growth intended by Nature. As regards the second theory, Bell supposes for argument that this influence of a previous sire exists in fact; he is then driven of necessity to the conclusion that the fetus actually gives up to the mother, besides the waste-products, some essential part of its blood, carrying with it the key to hereditary transmission. If so, then the blood of the mother must become more and more mixed with each succeeding pregnancy, and be liable, therefore, to impress on her offspring the peculiarities, not of *one* sire only, but of *every previous sire* to whom she has borne offspring. It is impossible adequately to comprehend where such a theory would lead us, utterly at variance as it is with what we know of the

¹ Indian Med. Rec., Aug. 16, 1896.

definiteness of the physiology of Nature. He further argues that if it be possible for a sire to influence subsequent progeny not his own, it is fair to expect that he will be able to influence subsequent progeny which are his own; so that we should find, at least in a certain number of cases, the children of the same parents consecutively resembling more and more strongly their father; but, so far as he has observed, the first child is just as likely to resemble the father as any of the later children.

THE PHYSIOLOGY OF PREGNANCY.

Obesity as a Cause of Sterility.—J. V. Gaff,¹ in discussing the etiological importance of obesity in sterility, states that in obese subjects the uterus, tubes, and ovaries will be found firmly packed into the pelvis and surrounded by layers of fat; the fat-cells interspersed between the unstripped muscle-fibers and connective tissue surrounding the follicles are so thick and cause so much pressure that it is impossible for the ovum to escape from the ovary; large masses of fat crowding down upon the cervix bend the canal of the uterus forward, producing an aggravated condition of antelexion, and thereby effectually preventing the entrance of semen to the uterus. During copulation the uterine round and broad ligaments by their concerted action cause a suction from the vagina toward the ovaries, greatly facilitating the movement of the semen. When they become encumbered with large quantities of fat they are no longer able to perform that function, and the semen is retarded or is lost on its way toward the junction with the ovum in the tube or ovary. Compression of the tubes by masses of fat obstructing the passageway through is another fruitful cause of sterility. [That this relationship between obesity and sterility exists is substantiated by statistics. Kish has enumerated over 200 cases of obesity associated with amenorrhœa and sterility, without other appreciable cause. Philbert has described 5 cases wherein pregnancy occurred through adopting a thorough and vigorous system of hydropathic and dietetic treatment. Abortions in obese women are frequent. Stoltz has cited the case of an obese woman who had 5 consecutive abortions which he could attribute to no other cause, and Goubert cites the case of a very fleshy woman who had 8 consecutive abortions from the same cause.] Vedeler² has observed 310 cases of primary sterility. All the women had been married more than one year; 72 were married 10 or more years; and of the others, the average duration of marriage was 3 years. In only 50 cases was the husband examined, either directly or indirectly; of this number of men, 38 had certainly had gonorrhœa, and probably more. In 34 cases of the wives of these men, 11 suffered from perimetritis, 10 from ovariosalpingitis, 3 from metritis, 2 from cystitis and vulvitis, and 8 from vulvovaginitis. If this proportion existed in the entire number of husbands of the remaining 260 women, 235 would have had gonorrhœa, and 210 would have infected their wives. As a matter of fact, in 198 sterile women the same inflammatory processes were found as in those whose husbands had undoubtedly had gonorrhœa; 64%, therefore, suffered from this disease. The abnormal conditions which were found to exist in the 310 women were as follows: 1. Inflammatory processes: 66 suffered from perimetritis, 45 from salpingitis, 42 from metritis, 18 from vulvovaginitis, 15 from ureterocystitis, 12 from endometritis; in all, 108 cases. 2. Non-inflammatory conditions: (a) Anatomic abnormalities: atrophy of the uterus, 22 cases; persistent hymen, 7 cases; stenosis of the external os, 6 cases; conical cervix, 3 cases; defective uterus or vagina, 2 cases; unclassified, 27 cases; in

¹ Jour. Am. Med. Assoc., Jan. 23, 1897. ² Am. Medico-Surg. Bull., Mar. 25, 1897.

all, 67 cases. (b) Pathologic-anatomic abnormalities: uterine fibroid, 23 cases; ovarian cyst, 5 cases; uterine polypus, 2 cases; vaginismus, 7 cases; hematocele, 4 cases; syphilis, 3 cases; chancre, 1 case; in all, 45 cases. The author believes that the cause of the sterility lay in the men in 70% of cases, and in the women in 30%.

Precocious Puberty.—An interesting case is reported by A. J. Price.¹ The patient, aged 6 years and 7 months, presented a luxurious growth of downy fur on the face, well marked on the upper lip; the body was shapely, the curves graceful, the hips broad, the breasts well developed, and the mons veneris, which was thickly covered with hair, suggested the appearance of a woman past puberty. The sexual organs were normal in formation, with the exception of a slightly hypertrophied clitoris. Her voice was as coarse as that of an adult woman. The hair on the pubis and under the arms was first noticed at the age of 18 months. Early in her 4th year blood-stains were frequently found on her undergarments, which the parents did not attribute to menstruation until a few months later—during the latter half of her 4th year—when that function set in more perceptibly and regularly. The child never showed any disposition to play with other children, but rather sought the company of older persons, and was bright and reasonable beyond her years.

Ovulation, Menstruation, and Conception.—Strassmann² reports the results of a series of experiments to determine the causation of menstruation. Eight experiments were performed upon bitches, the abdomen being opened under antiseptic precautions and sterile fluid injected into the ovary. It was found that the increase in the vascular tension of the ovary which followed such injections produced the phenomena of menstruation, including the characteristic changes in the mucous membrane of the uterus. Strassmann finds in the results of his experiments an explanation of the discharge of blood which has been so often observed to follow the removal of one or both ovaries or any operation that interferes with the nervous supply of the genital organs. His experiments and the observations of operators show that menstruation results from an altered condition in the vascular tension of the ovaries produced by a nervous stimulus. The results of his most interesting studies may be summarized in the following description: the ripening of the ovum produces an increase in the vascular tension of the ovary, causing nervous stimulus to be transmitted to the uterus and bringing about the characteristic enlargement and turgescence of that organ and its lining membrane which are observed at menstruation. This increased vascularity of the womb prepares it to nourish the ovum if impregnated. When conception does not occur the ovum escapes, and with it are discharged the surplus blood-supply and epithelial soil which were prepared for it. As has been stated by others, each menstruation is the birth of an unimpregnated ovum. This teaches us that conception most readily occurs, outside the uterus, within the tube, pregnancy usually beginning as an extrauterine or ectopic gestation. Conception most frequently occurs not immediately after menstruation, as has been supposed, but during the 2 weeks immediately preceding a menstrual period. Menstruation itself is a sign that conception has not occurred. In reckoning the date of confinement the last day of the last menstrual period, which has usually been taken, should not be considered as the probable time of conception, but a period preceding by a week or ten days the first menstrual epoch at which menstruation did not occur. Thus, if the last day of the last menstrual period is stated to be the first of a given month, the period of gestation should be counted, not from this date, but from the 20th or possibly the 25th of this

¹ New OrL. M. and S. Jour., Aug., 1896.

² Arch. f. Gynäk., Bd. lii., H. 1, 1896.

month. It is believed that a more accurate estimation of the date of confinement can be obtained by reckoning in accordance with these results. [This will be a most desirable result if experience will verify the deductions of the writer.]

Stansbury Sutton and Gordon¹ relate two extraordinary cases for which they do not profess to account. On October 20, 1892, Sutton removed 2 large multilocular ovarian cysts from a woman aged 28. The ligatures lay close to the uterine cornua. On June 10, 1894, the patient gave birth to a male child weighing 10½ pounds. On February 25, 1896, she was again delivered. Gordon in March, 1894, removed both ovaries and tubes from a woman aged 33, the subject of chronic pelvic disease. From a few months after the operation she menstruated regularly till June, 1895, when she became pregnant, and was delivered of a healthy child in March, 1896. The only explanation is that the stump of one tube must have opened, allowing an ovum from a piece of ovarian tissue to pass through into the uterus. In a second case, in which pregnancy followed 3 years after operation, it was not absolutely certain that both ovaries were removed.

Superfetation.—P. Gustin² reports a case of a woman convalescing from typhoid fever who expelled a fetus of 3 months and one of 6 weeks. A. L. Bailey³ records a twin pregnancy in which a 4-months fetus was expelled, followed by the birth of a full-term fetus. The small child was wrinkled and flattened out, and the cord shrivelled up like a string; the placenta was anastomosed with the larger one and showed calcareous degeneration of the whole side whence was given off the small cord. [This was undoubtedly a case of fetus papyraceus, and not an instance of superfetation.] In addition Bailey records a true instance of superfetation, a full-term child being delivered together with one of 4 or 5 months. H. W. Mills⁴ relates the case of a woman, aged 42 years, who, in her first pregnancy, aborted at 3 months. Six months later she miscarried in her second pregnancy, discharging a fetus of about 16 weeks and a fresh, healthy ovum of about 7 weeks.

Placental Tissue, Fresh and Old.—In a paper read before the Obstetric Society of London, Nov. 4, 1896, T. W. Eden stated that the placenta, like other caducous structures, commences to degenerate for an appreciable time before it is cast off, and, in fact, this is the immediate cause of its being shed. The first and most important change is slowly progressing obliteration of a certain number of branches of the allantoic (umbilical) arteries, principally in the marginal cotyledons, the affection being in the nature of endarteritis. The corresponding capillaries and veins remain unaltered until the circulation through them is suspended by the ultimate complete obliteration of the arterial branches supplying them. Then they become thrombosed. This process may be detected as early as the seventh month, and at term the total number of arteries affected is considerable, though few of them become altogether obliterated, except in the marginal cotyledons. The first effect of the diminished blood-supply is atrophy and degeneration of the epithelial covering of the villi, which undergoes hyaline or fibrous degeneration (coagulation-necrosis). Layers of true fibrin are deposited over the degenerated areas from the maternal blood. In this way the villi become enclosed in thick layers of fibrinous material, and neighboring villi become welded together. Scattered areas of consolidation are thus formed in the spongy placental tissue, to which the name of "white infarct" has been applied. Some of these may attain the size of a pea or a filbert, and even an entire cotyledon may be consolidated.

¹ Am. Gyn. and Obst. Jour., July, 1896.
² Med. Age, Aug. 10, 1896.

³ Arch. de Gynéc. et de Tocol., July, 1896.
⁴ Lancet, Mar. 13, 1897.

The structures involved in the areas of degeneration become atrophied, and in the larger infarcts are seen evidences of fatty and calcareous degeneration. Another form of consolidation, known as the "non-fibrinous infarct," sometimes occurs in the ripe placenta. This form is probably due to blocking of the maternal arteries, and not to fetal endarteritis. It is clear that a process similar to that of fibrinous infarction occurs in the extraplacental chorion, causing atrophy and disappearance of its villi. Infarction represents the extension to the placental chorion, during the later months of gestation, of changes that occur with regularity in the extraplacental chorion during the earlier months. It is not a pathologic change, but is the natural outcome of the processes of evolution and decline. Thrombosis of the subplacental sinuses has been stated by Friedländer and Minot to occur as early as the seventh month; but as the number of sinuses affected is not great, and as there is free anastomosis, the intervillous circulation is probably not materially hindered. The superficial layer of the serotina is the seat of a degenerative process akin to that affecting the chorionic epithelium. The change begins in the intercellular substance, which is converted into a deeply staining fibrillated material allied to fibrin. The protoplasm of the decidual cells is involved and ultimately their nuclei break up and disappear. The change begins at the surface, but often extends irregularly into the deeper layers. Fibrin from the maternal blood is deposited on the degenerated surface. At term coiling serotinal arteries may sometimes be found thrombosed for a considerable distance, and veins are often more or less completely blocked by deposits of fibrin.

Occasionally this process of separation fails to take place, and then there results the condition known as retained placenta. By *retained placenta* is meant one which has been retained in utero after the death of the fetus, irrespective of the period of gestation to which it belongs or of the length of time that has elapsed between the death of the fetus and the evacuation of the uterus. There are two factors to be borne in mind: 1. The morbid condition leading to the death of the fetus, which may have directly affected the placenta; and, 2. The arrest of the fetal circulation—*i. e.*, the death of the villi. Changes due to the first factor may be called primary, and those due to the second factor secondary. When the changes are far advanced the difficulty of distinguishing primary from secondary changes is very great.

For practical purposes it is necessary to distinguish two groups: (*a*) cases in which the placenta has been retained for only a short time after the death of the fetus, which is born in a nonmacerated or but slightly macerated condition; and (*b*) cases in which the placenta has been retained a considerable time and the fetus is more or less markedly macerated. In the second group the primary changes are obscured by the superimposed secondary changes, so that the best chance of studying the primary changes occurs in the first group. The secondary changes, on the other hand, are more pronounced in the second group, though their beginnings may be found in the first. In the past no serious attempt has been made to distinguish between primary and secondary changes, and much careful work has therefore been invalidated.

When the fetus perishes the placenta may remain attached to the uterine wall and the maternal circulation through the intervenous spaces continue, although the fetal circulation through the villi has ceased. Although technically dead, therefore, the villi remain in contact with the maternal blood, and are thus preserved from decay; so much so that, after retention for several weeks, areas of villi may be found that can scarcely be distinguished from those of a living placenta. At the same time the villi never appear to show the least trace of growth or multiplication, and in retained placenta signs of recent

activity are altogether wanting. The condition of the extraplacental tissue is in marked contrast to that of the placenta proper. The membranes, the cord, and the tissues of the fetus itself necrose with rapidity, because there is nothing to preserve them from the fate of dead organic matter. When the maternal circulation through the intervillous spaces is maintained no marked change occurs in the placental villi, but gradually that circulation is arrested and, as the villi become cut off from the maternal blood, they perish. We have thus to trace: 1, the arrest of the maternal circulation; 2, the changes that result to the villi; and, 3, the changes in the extraplacental tissues. The arrest of the maternal circulation occurs by a process similar to that already described, in connection with the formation of white infarcts in the living placenta. The obliteration of the intervillous spaces in the retained placenta appears to be due rather to progressive failure of the maternal circulation from shrinking of the uterus and loss of the stimulus of the growing ovum than to fetal arterial changes. The maternal blood consequently clots more readily and deposits fibrin more freely than in the living placenta. The intervillous spaces are first obliterated around infarcts and upon the fetal and maternal surfaces of the placenta. In this manner the retained placenta becomes extensively consolidated, and its tissues present microscopic characters closely allied to those of infarcts, and differing widely from those of spongy, placental tissue.

The changes in the villi are practically the same as in the middle and inner zones of large infarcts in the living placenta. They undergo atrophy and necrosis, lose their epithelial covering, then their connective tissue, stroma, and blood-vessels, and, finally, their nuclei. In addition, large areas of placenta may become consolidated by the process of nonfibrinous infarction. Extensive fatty degeneration usually occurs in all the consolidated areas, and calcareous deposits are also abundant.

The most frequent cause of the death of the fetus in the earlier months of gestation appears to be some pathologic condition of the decidua, and we must be careful to distinguish between the primary and secondary changes. In a retained placenta of the 5th month or later the compact layer is generally fused with a superjacent stratum, consisting of several rows of villi imbedded in fibrin and blood-clot. Its structure is barely recognizable. The spongy layer, as a rule, is much less altered, but is generally thinned and atrophied, though the characteristic decidual cells are distinct and the vessels often full of blood. The process of fibrinous degeneration never affects this layer except to a very slight degree—a point of importance when we consider that any process tending to consolidate this stratum would inevitably render separation of the placenta difficult.

The amnion always necroses after the death of the fetus, though the changes proceed less rapidly over the placenta than over the extraplacental chorion. The extraplacental chorion and decidua vera also necrose in all cases, but not so rapidly as the amnion, being longest preserved in the neighborhood of the placental margin, perishing soonest in parts most distant from it.

The changes in a retained ovum that follow death may be summed up as follows: 1. Necrosis, commencing at once, of, *a*, the body of the fetus; *b*, the umbilical cord; *c*, the amnion; *d*, the extraplacental chorion and decidua vera. 2. Gradual arrest of the maternal circulation through the placenta by thrombosis of the intervillous spaces. 3. Necrosis of the various divisions of the placental chorion, as they become shut off from the maternal blood. 4. Fatty and calcareous degeneration of the necrosing tissues.

[The foregoing is a valuable addition to the paper contributed by Eden last

year on the development of the placenta, which was reported in the last volume of the *Year-Book*.]

W. E. Fothergill¹ denies that in "placental polypus" and "sarcomatous" or "fleshy" mole placental tissue can remain fresh and comparatively unaltered for many months after the death of the fetus. He believes that after the fetal circulation has ceased no constructive process continues in the fetal elements of the placenta, and he finds no trace of division in either epiblastic or mesoblastic fetal cells of a placenta whose embryo has been dead any length of time. The fetal tissues may increase in size, but only through the swelling of degenerative processes. The placenta has been supposed to grow after the death of the fetus in ectopic gestation, but recent investigation has shown that all progressive changes that occur are in the blood-clot, and that none but degenerative processes occur in the villi.

Diagnosis of the Location of the Placental Attachment by External Palpation.—Tribondani² has been studying this subject at the Clinica Ostetrica of Pavia, examining the uterus of the patients immediately after the expulsion of the fetus to confirm his diagnosis made from external palpation beforehand. He announces as the result of his experience that the location of the placental attachment can be accurately determined by the following indications: 1. It is attached to the posterior wall if the tube and round ligaments are found on the anterior surface of the uterus, converging toward the top; if the anterior surface is rather flat, and if the beat of the fetal heart, the parts of the fetus, and its movements can be clearly distinguished from the front. 2. It is attached to the front wall if the tubes and the round ligaments are found on the sides of the uterus parallel to its vertical axis, if the anterior wall is very convex, and the fetal heart and movements, and the fetus itself, are not easily distinguished from the front. 3. When the placenta is attached to the fundus the latter is remarkably convex, almost hemispheric, and the points of attachment of the tubes and ligaments are much below its edge. 4. When the placenta is attached to the side wall the uterus is very prominent on that side, and the attachments of the uterine adnexa are found much higher on that side.

Placental Transmission of Disease.—E. H. Grandin³ asserts that there is but one acute disease which a woman is not able to transmit to her child in utero, and that is anthrax. There is, however, but one undoubted case on record of transmission of tuberculosis. This is not unexpected when we remember that markedly tuberculous women are not prone to conceive. As to how the transference of disease from mother to child is effected, the theory that fits known facts, and which we must at the present day accept, is that which credits the leukocytes with the process. Let a healthy woman become diseased, and at once the leukocytes in her blood-system carry the infection to the intervillous spaces. Here they are met by the barrier against disease established by the healthy placenta which contains healthy leukocytes with the property of resisting the entrance of disease-germs. The phagocytic action of these healthy leukocytes comes into play, destroys at once the leukocytes bearing disease, and the fetus is protected. Let the woman, however, be diseased at the time of conception, or let her become so very shortly afterward, and we have at the outset a diseased placenta, or one which becomes diseased as it is forming. Such a placenta either contains no healthy leukocytes, or else those with but feeble resisting-powers. Disease may, therefore, be readily transmitted to the fetus.

Etienne¹ records the examination of a fetus which had been aborted in the fifth month of pregnancy from an 18-year-old mother on the 29th day after she had been seized with typhoid fever. The spleen and intestines of the child showed no signs of the disease, and the placenta was healthy. A careful culture-examination of the blood from the right side of the heart and from the spleen, liver, and placenta revealed an abundance of typhoid bacilli. The fetus, Etienne believes, had died of typical acute blood-poisoning from a large dose of the bacillus before the occurrence of any local change.

Partus Serotinus.—Reckoning from the cessation of the last menses, the first feeling of life, and the objective signs, Szasz² reports a case in which gestation lasted 330 days. The child was normally developed and 49 cm. long. Ross³ records a pregnancy lasting 311 days. The condition of the child at delivery coincided with these figures. Wigodsky⁴ reports the case of a patient who carried her child 11 months. She was 28 years old and a multipara. The beginning of her last menstruation was Sept. 7; life was felt first toward the end of January; labor occurred on Aug. 13. The pregnancy was normal, but labor was somewhat protracted on account of the large size of the shoulders (18.5 cm.). Forceps were used and an encephalic fetus was delivered alive.

THE DIAGNOSIS OF PREGNANCY.

The diagnosis of pregnancy by the changes in the microscopic appearance of the urinary phosphates is discussed by W. E. Parke.⁵ This means of early diagnosis was first suggested by W. B. Gray in 1887, who claimed that he could form an absolute diagnosis within 20 days after conception. Parke has studied about 75 specimens of urine of women known or thought to be pregnant, and he concludes that the change in the urinary phosphates pointed out by Gray occurs in a very large percentage of pregnant women, but that it is not equally pronounced in the urine at the same period of gestation in different women, nor at consecutive examinations of the urine of the same woman. When recognized, however, it forms a strongly presumptive evidence of pregnancy, and is recognizable very early, and is, therefore, of greatest value when other signs are of the least value, or not present at all. Moreover, a diagnosis of probable pregnancy can be made without a physical examination or without exciting the suspicion of the patient. The normal triple phosphate is more or less of a stellate figure, and markedly feathery. Sometimes the stella is segmented, and one leaflet stands alone. Whether we see it in bold relief as a star or dismembered as a solitary leaflet of the same, the feathery character is always to be remarked on both sides of the center fiber of each leaflet. As soon as conception occurs, or within 20 days thereafter, the feathery portions of the stella or segment thereof begin to disintegrate. This process may advance from the apex toward the base of the crystal, or it may declare itself by destroying progressively the feathery continuation of one-half the leaflet, the center fiber of the same determining and defining its boundaries. Past the middle of the seventh month the phosphates begin somewhat to approximate their original form and general character, and at the accouchement can scarcely be differentiated from the normal. If the fetus should perish during the gestation, the phosphates at once recover their normal character in all respects. To prepare the urine for

examination take about $1\frac{1}{4}$ in. in a small test-tube and add about $\frac{1}{3}$ as much of Tyson's magnesian fluid; this will throw down the triple phosphates in 15 or 20 minutes, and furnish the necessary material for microscopic examination. *Tyson's fluid* is composed of 1 part each of ammonium muriate, aqua ammonia, and magnesium sulfat, and 8 parts of distilled water.

HYGIENE OF PREGNANCY.

Care of Pregnant Women.—Pinard¹ calls attention to the fact that it is very important that women should be kept at rest toward the end of pregnancy. Hard work is an evil both for the mother and for the child. He has made a comparison of cases of women who sought relief at the Lying-in Hospital, usually after the first pains occurred, and those of women carefully nursed in a refuge for the pregnant. The average weight of the Lying-in Hospital children was 3010 gm. That of the children born after the mothers had been at least ten days in a refuge was 3290 gm. A maximum average of 3366 gm. was reached in cases in which the mothers had resided for some time in the wards of the Baudelocque Lying-in Hospital. Pinard remarks, however, that there were more primiparæ in the refuge and more multiparæ in relatively better circumstances in the hospital. Preliminary rest was found to have a particularly good influence on the duration of labor. Out of 1000 women who worked till labor began, 482 only were delivered on the 280th day of gestation. On the other hand, 660 of the women who had rested were delivered at or after the same date.

PATHOLOGY OF THE FETUS AND OF THE FETAL APPENDAGES.

Malignant Deciduoma.—Cases of this rare and interesting condition have been recorded by J. Cock² and Lönnberg and Mannheim,³ the latter reporting two cases. Cock, suspecting septic infection in her case, employed the antistreptococcic serum, without, however, beneficial results. A comprehensive study of this neoplasm has been made by H. R. Spencer⁴ and Newman Dorland.⁵ Spencer tabulates 40 cases, while Dorland reports 52 cases, including all authentic reports up to date. Spencer remarks that the disease appears to be almost entirely confined to multiparæ, and in some cases there had been a long interval between the last two pregnancies. He regards deciduoma malignum as a distinct pathologic entity arising from the products of conception. Dorland remarks that the trend of opinion is toward the fetal origin of the disease, the fetal epithelial covering of the placenta—the so-called syncytium—probably first becoming involved in the degenerative process. The growth must be regarded as the most malignant of all forms of malignant tumors, as is demonstrated by its early and exceedingly rapid development, the great tendency to recurrence and to the formation of metastases, and the high mortality-record. In 59.6% the symptoms manifested themselves either at once after labor or within 4 weeks' time. In 78.97% death occurred within 6 months of the appearance of the symptoms. Thirty-eight of the 52 cases died of the primary condition or from a recurrence of the growth, thus giving an absolute mortality for malignant deciduoma of 73%. In only one instance did the tumor occur in a colored woman. Metastases were noted in 70.76%.

⁴ Quart. Med. Jour., July, 1896.

⁵ Univ. Med. Mag., July, 1897.

These secondary deposits were found in the following situations in the order of their frequency: lungs, 78.37% ; vagina, 54% ; spleen, kidneys, and ovary, each 13.51% ; liver, broad ligament, and pelvis, each 10.8% ; brain, 5.4% ; and the colon, right iliac fossa, diaphragm, tenth rib, gluteal region, abdominal wall, bladder, peritoneal cavity, mesenteric glands, prevertebral glands, face, stomach, pancreas, left labium, and abdominal lymphatics, each 2.7%. Only twice did the tumor appear in primiparæ. Once it followed a tubal gestation in a single girl of 17 ; 12 times it occurred after abortions ; 17 times it followed labor at term ; and 20 times it occurred subsequently to the discharge of a hydatidiform mole.

Cervical Pregnancy.—Trotta¹ reports the case of a woman, aged 40, who aborted at 2 months in her first pregnancy. She had a myoma upon the anterior wall of the uterus, which shut off the cavity of the womb from the cervix. The uterus was extirpated because of the tumor, and on examination it was found that the condition present was virtually an extra-uterine pregnancy, the decidua developing above the tumor in the cavity of the uterus, while the ovum had lodged below within the cervix. [The rare condition called "cervical pregnancy" was present in this case.]

Umbilical Cord.—A. C. Wood² records a very interesting and rare condition of the cord, namely, the so-called *mesocord*, further complicating an anencephalic birth. The cord, inserted centrally as usual, was adherent from this point to the margin of the placenta ; the blood-vessels radiated from the central point of insertion (see Plate 1).

Lefèvre³ describes 151 cases which he has collected from literature in which the cord lost itself in the membranes some distance from the edge of the placenta (*relamentous insertion of the cord*). The condition is most frequent in twin pregnancy. It exposes the fetus to dangers during pregnancy as well as in labor. It may involve premature rupture of the membranes during gestation ; no other reason could be found in at least 6 cases. Membranous insertion of the cord may cause premature labor, and Lefèvre believes that this anomaly of the funis explains certain cases of hydranmios and fetal dropsy. In labor Lefèvre finds that some cases of premature rupture of the membranes is due to membranous insertion, but it appears that this is not so frequent an accident in labor as in pregnancy. Membranous insertion is a predisposing cause of prolapse of the funis ; in 2 out of the 151 cases the fetus was killed during labor through this anomaly, but it must be remembered that in both the death was due to pressure on the membranous insertion, and in no instance to tearing off of the cord. It would seem, in fact, that a labor-pain would not cause the fetus to tear off a cord of this kind, though it is easy to understand how it may cause great danger from pressure.

The Amnion.—D. S. Robinson⁴ records a case of supplementary amniotic sac which preceded the normal sac and protruded from the vulvar orifice. Examination after the delivery of the placenta showed that the accessory sac had been developed from the amniotic sheath of the cord ; its capacity was about 2 liters.

Maternal Impressions.—Contributions on this interesting subject have been made by G. E. Gilpin,⁵ L. Driesbach,⁶ W. T. Councilman,⁷ J. I. Smith,⁸ A. C. Hatfield,⁹ J. J. Parker,¹⁰ and W. F. Batman.¹¹ Councilman claims that

Mesocord from a case of anencephalus: A, central implantation of the cord; B, distal extremity of the mesocord (A. C. Wood).

there is no scientific foundation for the belief in the so-called maternal impressions, and that no proof exists that they can have any effect on the developing embryo. All malformations seen in man are found in the lower mammalia, on whom the influence of impressions cannot be supposed to be of much importance; and they are also found in birds.

Fetal Monstrosities.—An unusual number of rare and exceedingly interesting specimens of fetal malformation have been recorded during the year. These include the following: Bäcker,¹ a fetus papyraceus of 2 months' development; H. F. Lewis,² a case of miiencephalus; F. H. Allen,³ a case of cyclopia; C. Douglas,⁴ and Brayn and Stuck,⁵ each a case of hemicephalus; Newman Dorland,⁶ a case of diprosopus; A. Brothers,⁷ A. C. Dutt,⁸ F. Bolster,⁹ and S. Mellor,¹⁰ each a case of anencephalus; Dujon,¹¹ a case of syncephalus in a sheep; I. Miller,¹² a case of exencephalia with supplemental sac; W. J. C. Coulthard,¹³ 1 case, R. H. D. Mahon,¹⁴ 2 cases, and J. L. Kerr,¹⁵ 2 cases of anencephalus; C. N. Ballard,¹⁶ a case of exencephalus; E. H. Root,¹⁷ a case of monomphalic ischiopagus; M. V. Ball,¹⁸ a case of notoencephalus; K. Maydl,¹⁹ a case of inclusio fetalis abdominalis; Lop and Pujol,²⁰ a case of miiencephalus or retroflexion of the fetus; Chailons and Desfosses,²¹ a case of hemimelus; A. Stern,²² a case of perodactylus symmetricus in a female child 6 years of age; E. A. Tucker,²³ 2 cases of intra-uterine amputation; M. Günsburg,²⁴ a case of paracephalus in a quadruplet birth; W. Bradley,²⁵ an unusual succession of monsters, the patient giving birth first to a 7 months' anencephalic fetus; 18 months later to a full-term anencephalic fetus with a cystic tumor extending from the edges of the bones of the base of the skull; it started from the top of the forehead, forming three folds, and hanging down the back to the middle of the dorsal region; it was covered with fine hair and was soft; 3 years later a third anencephalic fetus was born at the 7th or 8th month; C. G. Grant,²⁶ a case of ectocardia, the child living for nearly 6 hours; S. K. Church,²⁷ a case of exomphalos, living for 36 hours; Joachimsthal,²⁸ a fetal malformation resulting from advanced extra-uterine pregnancy; in addition to marked distortion of the extremities there was a large meningocele; L. Wendling,²⁹ a case of hydrorrhachis; and J. H. Raymond,³⁰ a case of congenital irreducible umbilical hernia occurring in a double uterus. In Ball's case the fetus presented on the posterior portion of the head a huge tumor larger than the head itself, which contained the cerebral hemispheres; the child lived for about 15 minutes after birth. Sangalli's case showed projecting from the mouth of a female fetus a large mass of rudimentary connective and epithelial tissue, containing cells in process of transformation into bone-corpuscles and muscular fibers, both organic and striated;

there were also scales of bone and formless tracts of pale and red muscular fibers. The head of Günsburg's case resembled a fleshy malformed mass, broad in its upper and narrow in its lower part. The occipital bone was absent, and the facial portions of the frontal bones also. The eyes, mouth, and ears were absent; the nose was normal. In the middle part of the face and from prominences corresponding to the zygomatic bones two muscular masses passed downward and ended by converging in the region of the clavicles. Similar muscular masses passed from the posterior part of the head to the back. The sternum was absent, and in its place was a thin membrane, under which one could see the organs of the thoracic cavity. The upper limbs were deformed. The forearm ended in three eminences resembling fingers. The abdomen showed a fissure through which a portion of the intestine was prolapsed. Dorland's case (see Fig. 31) was one of *diprosopus tetraphthalmus*

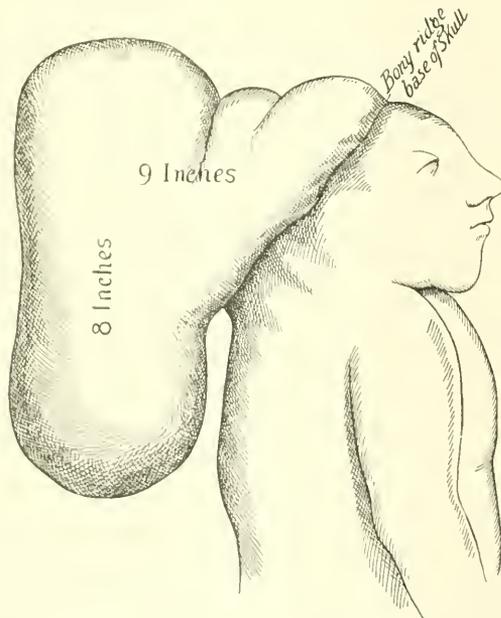

FIG. 30.—Bradley's case of cystic anencephalus. From a sketch taken at the time (Brit. Med. Jour., Jan. 9, 1897).

with four eyes but only two ears—referred to him by his brother-in-law, Dr. J. B. Thompson, of Siam. The child survived 15 days, dying eventually of inanition induced by inability to retain the nourishment taken, the milk introduced through one mouth being regurgitated through the other, thus proving the existence of a common esophagus opening into the two oral cavities. In Allen's case the nasal bones were absent, while the orbits were united, thereby forming a large, quadrangular eye, situated near the center of the face; a fleshy teat hung over it. The child survived 30 minutes. Lewis has collected 22 cases of iniencephalus, including his own.

Olano¹ performed an autopsy upon a well-formed woman, aged 39, who had died after 4 days of labor-pains and an unsuccessful attempt to deliver the child by forceps. The fundus of the uterus was just under the liver. It con-

¹ St. Louis M. and S. Jour., Apr., 1897.

tained a well-formed female fetus with the head downward, which measured 68 cm. (27 in.), and weighed 10,000 gm. (26 pounds). The mother had had 3 normal and 2 premature confinements. The woman was said to be much beyond term.

Councilman¹ quotes some interesting observations as to the frequency of malformations: Peusch has found that malformations are more frequent in

FIG. 31.—A diprosopic monstrosity (Dorland, in Univ. Med. Mag., Nov., 1896).

illegitimate than in legitimate children. All malformations are more frequent in females than in males. In 100,000 births Peusch has found 454 simple malformations, 61 single monstrosities, and 2 double monstrosities. There is a considerable difference in the species of animal in the frequency with which malformations are found. They are more common in the hog, cat, and cow than they are in the horse and goat. In general, malformations are due to excess of development, defect of development, or to the persistence of embryonic conditions. They are especially apt to occur in those parts of the body in which there is the greatest complexity in development.

¹ Boston M. and S. Jour., Jan. 14, 1897.

THE PATHOLOGY OF PREGNANCY.

The Pernicious Vomiting of Pregnancy.—J. Fabre¹ notes a case of uncontrollable vomiting in a primipara, 18 years of age, who had previously suffered from anemia and hysteria. The vomiting began at the fifth month of pregnancy, and had continued up to 8½ months, with increasing weakness. The fetal heart was not to be heard, yet the vomiting continued, and medicinal means were of no avail; it was therefore decided to induce premature labor, and Krause's method (introduction of a bougie into the uterus) was employed. On the day before this was done the patient was so weak as to require injections of caffeine and ether, and of 200 gm. of artificial serum into the subcutaneous tissue of the abdomen. Twelve hours after the introduction of the bougie into the uterus a dead female fetus was delivered by forceps. The vomiting still continued, and the patient died 12 hours later. The only lesions found at the necropsy were those of recent gastritis. [The case is interesting, for the death of the fetus was not followed by a cessation of the vomiting, a circumstance probably due to the fact that here pregnancy was not the sole factor, but had superadded to it the pathologic state of the stomach.]

Kehrer² reports the case of a hysteric woman, aged 21, who not long after marriage aborted at 4 months. During this brief pregnancy she had been greatly troubled with nausea and vomiting, which were not relieved by narcotics. She soon became pregnant again, and at once began to suffer severely from nausea. After various remedies had been tried, including the application of a solution of silver nitrat, an effort was made to end the nausea by partially dilating the cervix with the finger. While very brief improvement followed, no permanent cure resulted. The patient's condition became so serious through weakness, loss of flesh, and failing strength that it was determined to empty the uterus. With a view to bringing on labor-pains, Kehrer tamponed the os and cervix with strips of sterile gauze soaked in glycerin. The nausea immediately stopped, and a period of several days, in which the patient was free entirely, followed the use of the tampon. After a short time the symptoms reappeared, when the tampon was again employed with a similarly successful result. Kehrer was able by this method to carry the patient along in pregnancy until the 33d week, when labor was induced, and she was delivered of a living child. The infant was at first partially asphyxiated, but speedily revived, and became normal in strength and weight.

Rech³ reports a case illustrating the successful use of basic orexin in the vomiting of pregnancy, and thus confirms the favorable report of Frommel published in 1893. Rech gave the drug in doses of 4½ gr. in capsules, 3 times daily. The first and second doses were not retained, but after the third dose the vomiting ceased. With the exception of a burning sensation in the mouth no ill-effects were observed. In the case reported nuxvomica, bromids, chloroform, tincture of iodine, and cocain had been employed without success.

Valvular Cardiac Disease.—L. Demelin⁴ observed 64 cases of cardiac disease among 5162 cases of labor in the service of Tarnier. These 64 women had passed through 162 pregnancies, in 107 of which there was no serious accident or symptom attributable to the heart, a percentage of 66. The accidents that can be attributable to the heart-lesions are classified as follows: dyspnea (notable or grave), 23 cases; bronchitis, 3; syncope, 7; edema (marked), 7; albuminuria (cardiac), 12; gastrohepatic accidents, 2; epistaxis

¹ Marseille Méd., Aug., 1896.

² Ibid., No. 37, Aug. 15, 1896.

³ Centralbl. f. Gynäk., No. 15, 1896.

⁴ L'Obstét., Jan. 15, 1896.

and hemoptysis, 5; uterine hemorrhages of pregnancy, 9; postpartum hemorrhages, 7.

Two of the mothers died, a mortality of only 3%. This small mortality, as compared with that given by other obstetricians, he attributes to the fact that, as a rule, the heart is not examined unless serious, often fatal, heart-symptoms exist; and many mild cases of true cardiac disease go through pregnancy and childbirth unobserved. One of the fatal cases was due to uremic accidents; the other occurred in a rachitic patient with a fatty degenerated heart. He relates 2 cases in which the patients became cyanotic, with much-embarassed heart and respiratory action, yet recovered. One of these, dangerously ill with her first parturition, passed through a second without a bad symptom. The fetal mortality was 15 out of the 162, including 4 abortions and 11 deaths of premature infants.

The cardiac lesions were as follows: mitral insufficiency, 22 cases; mitral stenosis, 6; double mitral, 3; aortic, 2; aortic and mitral, 4; myocarditis, 2; adhesive pericarditis, 1.

He draws the following therapeutic deductions: "The mere finding of a valvular souffle is an insufficient motive for intervention. Conception, childbirth, and nursing are possible and even perfectly easy among those with cardiac disease.

"All essentially depends on 2 grand conditions: (1) the anatomic-physiologic state of the myocardium; (2) the anatomic-physiologic state of the large emunctories (liver and kidneys).

"The artificial termination of labor, even the interruption of pregnancy, is demanded in grave cases. But when menacing accidents appear more or less far from term, and without a spontaneous tendency to the expulsion of the fetus, the following therapeutic means should be followed in turn: (1) medical and dietetic means; (2) bleeding, whose powerful action ought not to be misunderstood or neglected; (3) artificial interruption of pregnancy in the gravest cases." *Bornet and Grimodie*¹ mention the occurrence of a perfectly spontaneous form of abortion in pregnant women with heart-disease, and they also believe that hydrorrhœa during gestation is a localized form of cardiac dropsy.

*Jaccoud*² relates a case in which a patient, the subject of chronic heart-disease, passed through 3 childbirths and 1 miscarriage without distressing cardiac symptoms. After the fourth pregnancy, however, she began to suffer from symptoms of cardiac break-down. [Pregnancy is always liable to cause serious disturbances of the cardiopulmonary circulation and to throw additional work on the heart. Patients who suffer from mitral lesions, which rapidly affect the lesser circulation, frequently manifest toward the fifth or sixth month gravidocardiac symptoms, as dyspnea and hemoptysis. It is yet obvious that a diseased heart up to a certain point may suffer no inconvenience from pregnancy. A too hard-and-fast line must not be drawn in advising or withholding consent to marriage. The wishes and ideas of the patient must be considered, and also the depressing and injurious effect upon the heart of withholding consent. The degree of the lesion and the absence or presence of gravidocardiac symptoms should be noticed, the latter forming a decided bar to marriage, though the effect of treatment upon this condition should determine the final decision. The occupation and surroundings of the patient and the possibility of her taking prolonged rest, if necessary, should be considered. A milk-diet is of great importance,—2 or 3 liters should be taken daily from the second or third month of pregnancy. This is a powerful aid to the circu-

¹ Bull. et Mém. de la Soc. Obstét. et Gynéc. de Paris, Apr., 1897.

² Sem. méd., Sept. 11, 1896.

lation by reason of its diuretic action, and not only are the gravidocardiac symptoms warded off, but the appearance of albumin in the urine is prevented.]

Pregnancy and the Thyroid Gland.—Bignami¹ reports the case of a patient who passed through her first pregnancy without trouble, but a bronchocele developed during the second, and the thyroid gradually returned to its original size after delivery. During the third pregnancy the swelling reappeared, and there were much constitutional disturbance, dyspnea, and dysphagia. The patient died suddenly in the 8th month, and neither tracheotomy nor Cæsarean section could be performed. There was no necropsy. [Pregnancy has a bad effect on all bronchoceles, but there is a true or special bronchocele of pregnancy which does not develop until gestation commences, and disappears or diminishes after delivery, to return at the next pregnancy. It is always vascular, and as dangerous symptoms may set in the induction of premature labor is often advisable.]

Albuminuria and Nephritis in Pregnancy.—[The albuminuria of pregnancy holds, with grave valvular lesions, the foremost place in the pathology of pregnancy, as the ever-increasing literature of the subject indicates.] T. C. Allbutt² believes that the opinion that the renal complications of pregnancy are due merely to mechanical pressure is erroneous. In the first place, he claims that pressure by the enlarged uterus upon the renal veins is not readily produced; again, complete thrombosis of the renal veins is not followed by renal symptoms which are averted by collateral circulation. Moreover, swelling of the legs and other signs of venous obstruction are more frequent as pregnancies increase in number, whereas albuminuria and eclampsia are evils of the primipara. Again, other large tumors, as fibroids, do not produce serious kidney-disorders, though disturbances of micturition and even pressure on the ureters, followed by dilatation of these tubes, and even by pyelitis, may occur. In pregnancy there is little evidence of serious pressure on the ureters, and dilatation of these tubes is rarely a complication. The *puerperal kidney* differs from the *cardiac kidney* in that it is not as hard, is often pale, and presents signs of acute degenerative processes penetrating its tissues. It would seem that two poisons at least are concerned in the production of the disease, the one leading to convulsions, the other to coma. In some not infrequent cases the two acting together produce convulsions followed by coma. It is now generally conceded that there is a toxin as yet unseparated in healthy urine. It is not urea, uric acid, kreatinin, nor potassium chlorid. Thudichum thinks that it lies in the coloring-matters of the urine. Allbutt thinks it most probable that the toxin is absorbed from the bowel, for it is less in amount in a fasting animal, in hibernation, and in the urine after sleep. The point of formation of the toxin is also unknown, but it is probable that the liver is at fault, as is suggested by the frequency of liver-disease in pregnant women. Saft³ believes that the condition is caused by an autointoxication by some product of tissue-change, as is the origin of the *molimina graviditatis* and of the nervous disturbances of the pregnant state. Eklund⁴ states that if the urine be found to contain albumin the patient should be ordered hot baths, flannel underwear, rest in the recumbent posture, mild diuretics and laxatives, beef-tea with parsley, seltzer water with boiling milk, milk-food, boiled fruit, weak coffee, tea, and chocolate, and compound licorice-powder. It is a matter of great importance that the pregnant woman should learn to procure for herself daily evacuations of the bowels, especially toward the end of pregnancy and in beginning labor. For this purpose dietetic means should be employed chiefly,

¹ Wien. med. Bl., Nos. 4 and 5, 1896.

² Lancet, Feb. 27, 1897.

³ Arch. f. Gynäk., Bd. li., No. 7, 1896.

⁴ Edinb. Med. Jour., Dec., 1896.

but in case of failure mild aperients should be used, as cascara, senna, frangula, compound licorice-powder, and enemata of salt and water. Of the very greatest importance during pregnancy, and especially during the puerperal state, is the care of the kidneys, the avoidance of all that would tend to increase the functional activity of these organs, the maintenance of equilibrium, and the proper division of labor between the skin, digestive apparatus, and the kidneys. If any organ can bear a greater exercise of function, it is the skin, and next in order of tolerance the intestinal tract; the lungs are far more sensitive, but the kidneys most of all. If possible, no puerperal woman should be permitted to leave her bed until her urine is free from albumin.

E. H. Grandin¹ especially emphasizes the value of hot saline irrigation of the intestines in case of uremia either complicating labor or some operative procedure. The strength of the solution should be about 1%, and the temperature of the water in the receiver about 118° F. From 8 to 10 gallons of water should be allowed to flow into the bowel, the gravity syringe being hung at least 6 feet above the head of the patient. This should be supplemented by the use of eroton oil and hypodermics of glonoin, $\frac{1}{2}\frac{1}{5}$ gr., repeated $\frac{1}{2}$ -hourly until the physiologic effect has been secured. This drug offers the readiest of all means for relaxing the spasm of the renal capillaries.

Mynlieff² insists that when a woman with chronic nephritis becomes pregnant the induction of abortion is indicated on account of the immediate peril of the patient (which increases as pregnancy advances), the certain continuance of the morbid process in the kidneys themselves, the great tendency to flooding and abortion, and the small prospect of the development of the fetus to term. Mynlieff dwells on the responsibilities of the physician who is called in when pregnancy is advanced. The induction of premature labor may then be undertaken at a time which seems most favorable for saving the fetus—that is to say, a little delay may be allowed; but the history of previous pregnancies must be duly considered, and if it is found that the fetus tends to die at a certain date in pregnancy that date must be anticipated. In any case the life of the mother must be considered first; hence, up to the last, immediate interference is usually the safest course. The same principle is often best for the fetus when viable, as it may die suddenly earlier than in previous pregnancies.

Sevitsky³ describes a case in which he noted symptoms of uremia in a primipara 1 month before delivery. On the 2d day after labor the patient became semicomatose and perfectly blind. The urine was found to contain casts and was highly albuminous. Notwithstanding this no convulsions occurred, and the patient made a rapid recovery. From this Sevitsky concludes that uremia alone does not cause puerperal convulsions.

Pregnancy and Labor after Nephrectomy.—Cases are reported by Schramm⁴ and E. Tridondani.⁵ Schramm's patient was a workingwoman, aged 25 years, who had borne 2 children. She requested the removal of a tumor in her right side which was increasing in size and causing suffering. This proved to be a hydronephrotic kidney, which was removed, the patient making a good recovery. Three years after she asked her physician's advice regarding marriage, and, as her general health was good and the remaining kidney performed its function well, a possible pregnancy did not seem necessarily dangerous. This subsequently occurred and was endured safely, the urine being abundant and containing no casts or kidney-epithelium, but albumin only. The patient was delivered in spontaneous labor of a healthy

¹ Am. Medico-Surg. Bull., Sept. 26, 1896.

² Der Frauenarzt, Jan. 1, 1896.

³ Ann. de Gynéc. et d'Obstét., Aug., 1896.

⁴ Berlin. klin. Woch., No. 6, 1896.

⁵ Ann. di Ost. e Gin., July, 1896.

child, and made a good recovery. But 2 similar cases (Fritsch, Israel) are recorded.

Tridondani's case was of more than usual interest. A patient, aged 29, came into the Maternity at Pavia suffering from symptoms resembling those of intestinal obstruction, accompanied with pain on micturition and scanty urine. She was in the 8th month of pregnancy, and to the left side of the uterus was a fluctuating tumor. Under treatment, the symptoms improved, and the woman was spontaneously delivered of a male infant. Three months later the abdomen was opened and a cystic kidney (the left) was removed. Recovery was complete. Since then the patient has had 3 pregnancies. In none of the 3 were there any abnormal symptoms. There was no edema, and the urine was normal in quantity and quality. The labors were at term and non-instrumental. The placenta and membranes in each case were healthy, and the puerperium was normal. The infants were born alive, were healthy, and had a weight and size above the average. The author concludes, from a study of this and the 3 other reported cases, that pregnancy occurring in a woman with one kidney does not interfere with her health; that the absence of a kidney does not disturb the progress of gestation, labor, and the puerperium, and that the product of conception does not suffer. He does not, therefore, agree with Schramm, who advises that a woman with a single kidney should not marry, or, if married already, should not become pregnant. It is noteworthy that in the above case the liquor amnii was increased in amount; but it is doubtful whether this was a consequence of the absence of one of the mother's kidneys.

Mental Disease in Pregnancy.—Geo. H. Savage¹ classifies the insanity of pregnancy into—(a) mental disorders occurring in the early or later months of pregnancy; (b) insanity of labor; (c) associated with febrile disorder at the establishment of milk-secretion; (d) occurring within the first two weeks subsequent to labor; (e) between two and six weeks subsequent to labor; (f) insanity of lactation and that of weaning.

Savage does not believe that there is a special, definite form of insanity deserving the name of "puerperal mania." The predisposing causes are similar for all the forms of the disorder, heredity being the most important factor. First pregnancies, especially if after the age of 30, are considered more dangerous than earlier pregnancies. Illegitimacy has a doubtful influence. The induction of premature labor as a cure for insanity Savage believes to be far from justifiable in every instance. Within the first two weeks after delivery maniacal symptoms are most common with puerperal insanity; whereas, if developed later, melancholia is more frequent. Savage questions the advisability of the marriage of neurotics, especially if of a pronounced hysteric tendency, because of the danger involved in childbearing by such persons. The term "puerperal insanity" may be ascribed more justly to a group having sepsis as the etiologic factor. The questions involved as to the treatment have reference to the etiology, the use of hypnotic drugs, the removal from home to more favorable surroundings, or the placing of the patient in an asylum.

Chorea Gravidarum.—An interesting case of major chorea gravidarum is reported by W. E. F. Finley.² The patient was a primipara, illegitimately pregnant at 5 months. She had had one previous attack of minor chorea, had had rheumatism, and belonged to a neurotic family. Her expression was idiotic, and she emitted peculiar laughing sounds from time to time, owing to the involuntary contraction of the chest-muscles. She was unable to drink, as the greater part of the liquid ran out of her mouth; her tongue was much swollen and very dirty; from the right side of it she had bitten a piece as

¹ Brit. Gyn. Jour., xliv., p. 559, 1896.

² Brit. Med. Jour., Oct. 17, 1896.

large as a shilling, and from the other side one the size of a sixpence. The involuntary movements continued day and night, so that she never got sleep. When put into bed her head was dashed about, sometimes with great violence; the violent motions of her legs threw off the bed-clothes, and at times she herself was thrown from the bed. Iron, iodin, arsenic, bromids, and chloral were all ineffectual, as were also opium and hypodermics of morphia. Labor was induced under chloroform, but on the following day the patient suddenly collapsed and died within an hour.

Peripheral Neuritis in Pregnancy.—G. Elder¹ has recently seen two cases of peripheral neuritis, both in multiparæ; both came on about the sixth month. The symptoms began with tingling and shooting paresthesiæ, which gradually increased until the shooting-pains and feelings of pins and needles were very severe and disturbed health. In both they were chiefly in the hands, but in one of the cases also in the feet. Sensation was affected in both cases to some extent, but there was little or no paresis, although, owing to loss of sensation, no fine work requiring careful coordination could be done by the hands. In neither case could any other cause of neuritis be discovered—alcohol, diphtheria, influenza, pneumonia, albuminuria, glycosuria, typhoid, and lead being excluded. Both began to recover immediately after delivery, and recovery was pretty rapid—in one case in three or four weeks, in the other in three to four months. There could be no doubt, he thought, that the gravid state was the exciting cause of the neuritis. The number of cases of peripheral neuritis, evidently due to pregnancy, reported were very few (he could only find eight cases in all); and nearly all of these had been preceded by severe vomiting, and all had been very severe cases. He was inclined to believe that the cases of peripheral neuritis in pregnancy of a mild type must be very much more common than one would expect from the number of cases reported. That vomiting was not necessary to produce the condition his cases showed, and it was just possible that the vomiting might be due to the same cause as the neuritis, and to be only a concomitant symptom. The neuritis was evidently toxic in origin, though there was no evidence as to what the exact nature of the poison was. Some recent writers were of opinion that some of the cases of peripheral neuritis found during the puerperium had really commenced during pregnancy. If the symptoms got very severe, it would be one's duty to terminate the labor, as after delivery recovery sets in. [Solowjeff and Polk have each reported a fatal case of peripheral neuritis in pregnancy. Remembering this fact, that the disease may prove fatal, one must be prepared to induce labor before the disease has advanced too far, for as soon as the uterus is emptied there is naturally a tendency to recovery.]

The Influence Exerted by Pulmonary Disease in the Mother upon the Health of the Fetus.—Chambrelet,² in discussing this subject, states that in order to explain disease or death of the fetus in cases of maternal pulmonary affections classical authors invoke particularly three causes: the coughing-efforts of the mother, which provoke abortion, asphyxia and its action upon uterine contractility, and hyperthermia and its role in premature labors. Chambrelet has proved, by a series of experiments, that the influence of these three causes is very mediocre, if not entirely absent, and that it is necessary to take into consideration another factor which the older teachers did not recognize—namely, poisoning of the fetus by the bacilli and their toxins. He has demonstrated that if, after having infected the lung, the pneumococci, streptococci, staphylococci, and the bacilli of tuberculosis should penetrate into the circulatory system of the mother and thus produce a generalized infection,

¹ Lancet, July 25, 1896.

² Bull. de l'Acad. de Méd., Sept. 22, 1896.

they will traverse the placenta, and thereby reach the fetus, which they in turn will poison. The proof of this is that he has found in the brain, heart, lung, and peritoneal serosa of the fetus the same microbes as were in the lungs and blood of the mother.

Retroversion of the Pregnant Uterus.—This interesting and serious complication of pregnancy has been studied by M. Cameron¹ and Chaleix and G. Fieux.² Cameron believes that in the majority of cases the condition is probably due to previous displacement, but that it occasionally arises acutely from a strain or a fall. Overdistention of the bladder is more frequently an effect than a cause, but once retroversion has taken place an overdistended bladder will tend to aggravate the condition and prevent its cure. In fatal cases death has occurred from the manipulations, or from necrosis of the tissues. The symptoms enumerated in those cases that terminated fatally were: (1) retention of urine; (2) febrile symptoms; (3) bearing-down pains at the pelvic outlet, with anxiety and great restlessness; (4) delirium; (5) intermittent pulse; (6) coldness of the extremities, moribund sweats, and convulsions; (7) in a number of cases rupture of the bladder. He reports a case of pregnancy of 4 months, in which the uterus was retroverted, the bladder being enormously distended. Eighty ounces of urine were drawn off. On the next day blood appeared in the urine; and later a blood-cast of the ureter, some 15 in. in length, was withdrawn. Ten days later abdominal section was done, and the bladder opened and cleared of blood-clots. The bladder then contracted, and it was possible to reach the uterus. By combined pressure from below through the vagina and traction through the abdominal wound from above the incarcerated uterus was pulled out of the pelvis. The patient made a good recovery, blood disappeared from the urine, and she was delivered, at full term, of a large, healthy child.

Chaleix and Fieux report 3 cases of retained dead fetuses in retroflexed uteri. In the first case the embryo, perishing in the third month of gestation, was expelled 8 months later. It was then of a peculiar greenish color. The second patient had the symptoms of missed abortion at about the sixth or seventh week of pregnancy, and 3 months later expelled the small ovum intact. The third patient expelled an embryo in the fourth month of gestation, 1 month after its death. The authors advance the theory that in extreme retroflexion, with a sharp angle of flexion at the cervical junction, geniculation of the uterine arteries occurs; also that geniculation and compression of the utero-ovarian arteries take place at the sharp border of the broad ligaments, both of which factors lead to the death of the fetus by diminishing blood-supply to the uterus.

Missed Abortion.—In addition to the foregoing cases occurring in and due to retroflexion of the gravid uterus, additional cases of so-called missed abortion have been recorded by P. G. Griffith,³ F. R. Eccles,⁴ Biot⁵ (3 cases), and Graefe.⁶ Griffith's case was probably one of twin-pregnancy, with death of one embryo at 4 months and its discharge 2 years after the birth of its twin. Graefe states that he has not yet been able to arrive at any certain information as to the etiology of these cases from microscopic examination, although he has personally observed 11 cases and collected 59 reported ones. Retrograde metamorphosis in the ovum is evident after prolonged retention. The mucous tissue becomes converted into more or less rigid connective tissue, but may even be preserved in places or show patches of growth after months of retention. The more the

⁵ Canad. Pract., July, 1896.

⁶ Münch. med. Woch., Nov. 4, 1896.

fruit may be developed at the time of its death, the greater the danger for the mother. The uterus should be emptied as soon as the diagnosis has been established. If this be before 5 months, the uterus may be emptied by dilatation under ether and clearing the uterine cavity with the finger. If the diagnosis be made later than 5 months, premature labor should be induced.

Carcinoma of the Cervix in Pregnancy.—[The rarity of this complication is shown by the fact that in 42,000 cases of pregnancy observed in 3 great obstetric clinics only 22 cases of carcinoma were found.] G. H. Noble¹ has collected 166 cases of carcinoma of the pregnant uterus occurring since 1886, and from the data thus afforded an attempt is made to arrive at some conclusions as to the best methods of treatment. In cases of early pregnancy, when the disease has not yet extended beyond the cervix, vaginal hysterectomy should be performed at once; but if pregnancy is too far advanced to permit of extirpation by the vaginal route, he considers that it is better to perform Freund's operation rather than waste time in emptying the uterus and subsequently extirpating the organ, thus reduced in size, through the vagina. He finds, however, that statistics show that vaginal hysterectomy, when performed in the early weeks of the puerperium, does not appear to be attended with any additional risks. At full term Cesarean section followed by total extirpation is the ideal operation if the fetus cannot be born through the natural passages; but if there is any extension of growth into the parametric tissue, the Cesarean section alone should be done. [He gives no information as to the relative frequency of operable and inoperable cases occurring during pregnancy, but it is probable that in the majority of such cases we could not hold out much hope of a permanent cure after a radical operation. Neither of the above-mentioned authors makes clear the line of action to be adopted when the pregnancy has advanced to the sixth or seventh month, and the carcinomatous infiltration has already passed beyond the limits of the cervical tissue.] As J. Sinclair² suggests, in cases of advanced carcinoma at full term the fetal and maternal mortality is very high. If operative measures be adopted for the purpose of extracting the child through the vagina, there is great danger of tearing the cervix or uterus, and also of septic infection. Experience appears to point to the following conclusions with regard to cases at term: (1) spontaneous delivery if possible, even though labor be prolonged, gives the best result for the mother, but the fetal mortality is very high; (2) if the disease be so far advanced that delivery cannot take place without operative interference, the Cesarean operation gives the best result for both mother and child. [Generally speaking, when the disease is not too far advanced the operation of total extirpation should be performed without delay, whatever the period of pregnancy may be. Within the first 4 months of pregnancy the uterus may be extirpated by the vaginal route unemptied; but later it is necessary first to induce abortion, and then, 2 or 3 weeks later, to proceed to vaginal hysterectomy. If septic endometritis follows the abortion—which, when the growth is in a sloughing condition, is not uncommon—the uterus should be extirpated forthwith. Beckman has collected 17 cases in which the unemptied pregnant uterus was removed, within the first 4 months of gestation, by the vaginal route, for carcinoma of the cervix, without a single fatality.]

Traumatism and Operations during Pregnancy.—Villa³ has amputated a chronically inflamed cervix during pregnancy, with a good result in curing the local disease and without interrupting the gestation. In another case reflex disturbances were so severe that abortion occurred, although the

¹ Am. Jour. of Obst., June, 1896.

² Med. Chron., May, 1896.

³ Ann. di Ost. e Gin., No. 4, 1896.

local treatment was limited to glycerin-tampons and lotions. He has also sutured a torn cervix in pregnancy, without abortion. S. Sutton¹ has removed from one patient a large cyst of the broad ligament and from another both ovaries and tubes during pregnancy, without the induction of abortion. The second patient subsequently gave birth to twins. Mouchet² performed a double ovariectomy in the third month of gestation without untoward results. J. D. Jones³ records a case of strangulated ovarian cyst complicating pregnancy. Twenty-six days after the operation she miscarried at the sixth month. A. C. Butler-Smythe⁴ delivered a woman at term, the pregnancy being complicated by an ovarian cyst, which spontaneously ruptured 19 days after labor without and ill effects. [The treatment of this complication—ovarian cyst in pregnancy—is preferably by abdominal section. In cases that are allowed to go to term the prognosis is not so good. Litzmann records 24 deaths in 56 labors (43%); Jetter gives the death-rate at about 30%; Heiberg found in 271 cases that 25% of the mothers and 75% of the children died. Ovariectomy gives a very low mortality for the mother—1% or less; while a large proportion of the cases advance to term, and thereby the fetal mortality is lessened.]

F. W. N. Haultain⁵ reports 8 patients in whom pregnancy was complicated by uterine fibromyomata, with 2 deaths. He concludes that fibromyomata of the uterus tend to cause sterility by preventing conception and tending toward abortion, should they be so placed or have attained such dimensions as to cause symptoms of their presence in the non-pregnant condition. As regards diagnosis of pregnancy when fibroids also are present, this is often difficult, the tendency being for the pregnancy, on the one hand, by softening these growths, to change the normal "feel," while, on the other, the irregular hemorrhages due to the fibroid tend to mask the ordinary symptoms of pregnancy. Though in a large number of instances the course of pregnancy is in no way influenced by the coexistence of fibroids, their presence considerably increases the risks of pregnancy by complicating labor in preventing ready expulsion of the ovum and predisposing to severe hemorrhage. The prognosis depends on the site and size of the tumor. Thus, when subperitoneal, unless the growth be of sufficient dimensions to cause severe pressure on surrounding organs, or is incarcerated in the true pelvis and thereby obstructs the passages, little or no inconvenience is, as a rule, to be anticipated. Even in these cases, however, retrograde changes in the tumor—that is, suppuration and necrosis—may occasion fatal consequences. With the interstitial and submucous varieties the association of pregnancy must be considered of grave import.

Bossi⁶ stated before the Obstetric Society of France that he had observed 14 cases of fibroids complicating pregnancy. In 5 cases premature labor was brought on, and in 4 of these the tumors disappeared entirely. In the remaining 9 cases, in which labor was normal, the tumors all disappeared during or after labor. Budin recalled an instance in which a lawsuit had been brought against G. Thomas, of New York, by a woman whom he had been treating a long time for a fibroid. She became pregnant and the tumor disappeared. She then sued the doctor for malpractice, claiming that she had been treated for a tumor which had never existed. Dorland has met recently two instances of fibroid complicating pregnancy, in both cases the tumors, which were situated in the anterior uterine wall, disappearing during the puerperium. In one case a transverse presentation was produced, and in the other preparations were made for a Cesarean section; the tumor ascended, however,

⁵ Practitioner, No. 337, p. 38, July, 1896.

⁶ Sem. méd., No. 19, p. 148, 1896.

during the progress of labor, and the delivery was spontaneous. A. Vander-veer¹ reports 2 cases of uterine fibromata complicating pregnancy, both being operated upon and both recovering; and F. L. Burt² records another successful case.

Pregnancy in a Cretin.—C. W. Townsend³ reports the unique case of a cretin, 7 months pregnant. She was born in Eastern Mass., of American parentage, and was 38 years old. She was 43½ in. in height, and weighed with clothes and in her pregnant condition 65½ pounds. Her catamenia began at the age of 22 years. She was an idiot, and her small size and thickened features presented the characteristic appearance of cretinism. She had, of course, a small pelvis. Cesarean section was performed at full term, July 26, 1896, at the Boston Lying-in Hospital by Dr. Edward Reynolds. The mother made a good recovery. The infant was fairly developed, showing no signs of cretinism. It was a male, weighing three pounds and ten ounces. It was very feeble and lived only four hours.

Antepartum Hemorrhage.—J. B. De Lee⁴ gives as the most common causes of *obstetric hemorrhage*, named in the order of the usual time of occurrence, the following: abortion; rupture of a vulvar varix; placenta prævia; premature detachment of the placenta; rupture of a fetal blood-vessel with the membranes in cases of velamentous insertion of the cord; postpartum hemorrhage; puerperal hemorrhage. He reports one case of accidental hemorrhage (premature placental detachment) ending in recovery, and one of placenta prævia with a horseshoe placenta.

G. L. Brodhead⁵ also reports 4 cases of premature separation, only 1 recovering. Budin⁶ relates the history of 2 cases of antepartum hemorrhage in which the blood came from a rupture in the circular sinus of the placenta. In neither case was the placenta situated in the lower uterine segment, nor was there any reason to believe, as the result of careful examination of the surface, that any separation had occurred before the child was expelled. A black clot in each instance was traced directly up to and into the interior of the ruptured circular sinus. [The possibility of antepartum hemorrhage being sometimes due to this accident had formerly been suggested by Jacquemier and Matthews Duncan, but no clinical facts were brought forward to support the hypothesis until quite lately. At the present moment there are 22 cases on record of hemorrhage due to rupture of the circular sinus. It must be remembered that the so-called *circular sinus of the placenta* is situated at the periphery of the placenta, and does not generally form a complete circle, but is interrupted at various points. In caliber it is about equal to the little finger, but in some cases it is imperfectly developed. The walls of the sinus are very thin, which may explain the fact that rupture sometimes occurs. The blood may accumulate in the uterus between the membranes and the uterine wall, or it may escape externally—more often, perhaps, some escapes and some is retained. It is only after the labor is over and the placenta is examined that the cause of the hemorrhage can be definitely ascertained. The prognosis and treatment are much the same as in cases of hemorrhage due to partial detachment of a normally implanted placenta.]

Placenta Prævia.—Cases of interest are recorded as follows: B. Loughrey,⁷ placenta prævia centralis, with twin pregnancy, both children surviving for a short time; C. Pierson,⁸ partial placenta prævia, delivery by version, with

¹ Med. News, Dec. 12, 1896.

⁸ New Orl. M. and S. Jour., July, 1896.

inversion of the uterus, which was the seat of a fibroid tumor; replacement by manipulation; C. A. Thomman,¹ placenta prævia centralis, with masculine pelvis; podalic version was performed with craniotomy of the after-coming head; and T. B. Nariman,² 7 cases of placenta prævia in 1100 cases of labor. Führt³ tabulates the statistics he obtained from midwives in Koblenz with reference to cases of placenta prævia occurring in their practice. The material embraced 50 mothers and 53 children. A physician was present in 44 of these cases. Of the 50 mothers, 19 (38%) died, 2 before delivery, 2 during delivery, and 15 after delivery. Of these last, 4 died from loss of blood, 6 from septic infection, 4 from the effects of previous hemorrhage, and 1 from an unknown cause. Of the 53 children, 32 were born dead and 10 others died in the first 9 days. Only 11 (20.8%) outlived a month. In 12 cases (2 of them fatal) the first hemorrhage appeared just before labor-pains. In 38 cases between the first hemorrhage and labor there was an interval of days, weeks, or even of months, during which time the physician, or sometimes the midwife, tamponed the vagina. Führt believes that many of the mothers might have been saved if the physicians had followed the two cardinal principles that ought to govern these cases: 1. As soon as a diagnosis of placenta prævia is made labor ought to be induced; 2. Only that form of treatment is advisable which stops the hemorrhage and rapidly dilates the cervix, so that the doctor may be by the bedside until the child is delivered. This is especially necessary in the country, where it may take hours to get a physician. These ends are best accomplished by an intrauterine colpeurynter with continued traction upon its tube, followed—as soon as dilatation permits—by podalic version.

ABORTION.

Interesting cases are recorded by C. E. Purslow,⁴ J. McCaw,⁵ and C. D. Spivak.⁶ In Purslow's case the fetus, about 6 in. long, was enclosed in the intact amniotic sac with the liquor amnii; there was no trace of the chorionic or placental tissue on the outer surface of the amnion, and the fetus could be plainly seen through the walls of the sac. Two similar cases have been recorded, one from France and the other by Dorland. Spivak's case was remarkable in that there occurred a delivery at term after 10 previous consecutive abortions. McCaw's patient was septic before the advent of labor, which was presumably due to the septic condition.

Schwab⁷ declares that quinin is an undeniable oxytocic, acting directly upon the uterine muscular tissue and making the uterine contractions stronger, longer, and more frequent, but at the same time preserving their physiologic condition—*i. e.* they remain intermittent. It acts rapidly in from 20 to 30 minutes. It is indicated when uterine contractions are insufficient or inertia exists during the dilatation of the cervix, and when the health of mother or child is threatened, especially when the membranes have ruptured and delivery must be hastened.

Daniel⁸ reports the case of a 37-year-old 18-para, who has aborted in the last 16 pregnancies at between the 4th and the 7th months. The first child was born in 1880, and the second in April, 1882; both are grown and healthy. In 1882 the husband became a house-painter, and soon after developed lead-colic, followed by paralytic symptoms. Frequently he would give up his

⁸ Jour. d'Accouch., May 17, 1896.

work for months, but would be obliged to resume it for a livelihood. In 1884 the wife aborted, and 15 abortions have followed. Her health seemed to improve during the first one or two months of pregnancy. Suddenly she would be attacked by a nervous rigor, with a sensation of fear. In the morning the breasts would be found flaccid, and within a week the dead fetus would be expelled. The patient would feel well in a few days again. She seemed free from any of the symptoms from which her husband suffered, and had not been subject to either tubercle, syphilis, or alcoholism.

Syphilis as a cause of abortion is discussed by J. A. Ouimet.¹ While abortion among syphilitics is more or less frequent at all periods, it becomes more so as the 7th month approaches, the maximum of frequency being between the 6th and 7th months. Almost all observers attribute the cause of abortion to the fetus itself, which is usually dead and often macerated. The belief to-day is that the influence of the father is far from being as marked as that of the mother. Syphilis in the father, however, certainly has an effect upon pregnancy.

Crosti² believes that abortion during the first 8 or 10 weeks is caused by changes in the ovum, and not by any pathologic conditions of the maternal structures. In 3 cases he has observed that when the ovum is thrown off immediately after the death of the embryo the capillary vessels in the chorionic villi are atrophic, while the villi themselves are well preserved, and the epithelium covering them appears perfectly normal, being nourished as before from the decidua. From these observations (atrophy of the capillaries and persistence of the epithelium) the author concludes that abortion is due to the ovum, for if fetal death came through the maternal organism the epithelium of the chorion would be the first structure affected.

Berry Hart,³ in a short paper on the nature and diagnosis of so-called *fleshy mole*, discusses the symptoms and pathology of this condition. By the term "fleshy mole" is meant "a form of abortion in which part of the aborting ovum, usually at or about the second month, is retained for many months, and is ultimately discharged in a much altered condition." As is well known, the altered appearance depends chiefly on hemorrhages between the chorion and decidua. Hart regards the condition as a rare one. The first factor in the production of a fleshy mole is the death of the fetus, and this is followed by shrinking of the chorionic sac and blood-extravasation among the villi—that is to say, between the chorion and decidua serotina and reflexa. As a result of the hemorrhages, numerous small, rounded protrusions are seen when the interior of the sac is examined. The fetus may entirely disappear, or may be represented by a small, shrunken remnant. In most cases moles of this kind are expelled within 6 months of conception, but in some cases they have been retained until the 11th month; but Hart has never met with any recorded case in which retention has exceeded this period. The diagnosis of cases of this kind is not easy, and in some instances is impossible.

Treatment of Abortion.—[But little progress in the treatment of abortion has been noted during the year.] In the line of prophylaxis, W. F. Metcalf⁴ suggests that the rhythm of the body of the uterus is controlled by the hypogastric and ovarian plexuses of the sympathetic, and that pathologic conditions in the rectum, bladder, breasts, or other portions of the body may increase this rhythm, as may also cathartics and other drugs, and mental emotion. The nerve-supply of the cervix is largely cerebrospinal, from the third and fourth sacral; it has no rhythm and guards the opening against the expulsion

¹ La Clinique, Dec., 1896.

² Centralbl. f. Gynäk., No. 9, S. 263, 1896.

⁴ Physician and Surgeon, Oct., 1896.

of the uterine contents. Extensive laceration of the cervix may destroy this function, and to guard against a recurrence of abortion such tears should be repaired. He recommends in threatened abortion the administration of fluid extract of *viburnum prunifolium*, as does also M. Gutierrez.¹ In cases of incomplete abortion A. M. Stuart² proposes the following method of treatment: after thorough antisepsis of the vulva and vagina, a Bozeman's intrauterine douche is introduced through the internal os, and a hot creolin solution allowed to flow through; then all loose clots and débris are removed by the dull curet; the cavity is again washed, and the process repeated until nothing remains but the firm decidual tissue which clings to the uterine wall; finally, the uterus is packed from the fundus to the external os with iodoform-gauze, and the patient is given quinin, strychnin, and repeated doses of ergot. The inert uterus is stimulated to contract, and the blood, unable to escape, distends the cavity and flows in between the decidua and uterine wall, dislodging the former. In treating post-abortion retention of the placenta Chalceix-Vivie³ regards enrettage as the only process that will meet all the indications of that condition.

EXTRAUTERINE PREGNANCY.

[An unusual number of interesting cases of ectopic pregnancy have been reported during the year, and a large number of papers of more than ordinary merit have appeared from the pens of leading obstetricians and gynecologists.] Among the cases of **tubal pregnancy** deserving special mention are the following: W. G. Macdonald,⁴ 7 cases with 2 deaths; B. Holmes,⁵ a right tubal gestation, the operation being followed by a fecal fistula and ultimate recovery; Thibault,⁶ an aborted right tubal gestation; W. B. Chase,⁷ a case of secondary right-sided subperitoneal and intraligamentous ectopic gestation, resulting fatally [this is apparently an undoubted instance of intraligamentous gestation, the existence of which has been questioned by many authorities]; J. C. Stinson,⁸ 7 cases of tubal gestation, 1 unruptured, with 2 deaths; E. S. Bailey,⁹ a tubo-abdominal pregnancy of the right side; A. H. N. Lewers,¹⁰ a left tubal pregnancy, with profuse hemorrhage, cured by intravenous injection of salt-solution after abdominal section; S. E. Wyman,¹¹ right tubal gestation; W. T. Lusk,¹² right tubal pregnancy, simulating appendicitis; A. S. Warthin,¹³ a case of left-sided ectopic gestation associated with tuberculosis of the tubes, placenta, and fetus—the umbilical cord, fetal organs, and placenta showed areas of tuberculous degeneration; T. A. Helme,¹⁴ 4 cases of ruptured tubal pregnancy, all recovering; R. H. Spencer,¹⁵ 1 successful case with operation; A. H. N. Lewers,¹⁶ a ruptured right tubal pregnancy, with a tubal mole (*i. e.*, an ovum situated in the tube degenerated into a mole) which was the direct cause of the rupture and hemorrhage [this is interesting in that it shows that the death of the ovum and its degeneration into a mole are not necessarily followed by a condition of safety to the patient]; E. S. Boland,¹⁷ 5 cases of tubal pregnancy, all recovering; A. Brothers,¹⁸ a ruptured right tubal

pregnancy, developing shortly as an abdominal pregnancy; E. Collins,¹ a fatal case of right tubal gestation, in a woman of 25; R. H. Fetherston,² a fatal case of interstitial pregnancy; W. Balls-Headley,³ a case of fimbrioperitoneal ectopic fetation; M. D. Mann,⁴ 2 cases of ruptured tubal pregnancy, resulting fatally after vaginal operation; W. G. Wylie,⁵ 4 tubal gestations, all recovering; A. J. McCosh,⁶ 15 cases of extrauterine gestation, 1 resulting fatally, and 2 being secondary abdominal pregnancies; F. Henrotin,⁷ a case of early rupture of tubal pregnancy, with profuse hemorrhage (80 oz.), with recovery; J. D. Malcolm,⁸ a right-sided tubal pregnancy, with extensive bowel-adhesions; A. J. Smith,⁹ a ruptured right tubal pregnancy; H. Gage,¹⁰ 7 cases, 1 resulting fatally; and T. F. Prewitt,¹¹ 6 cases, 2 resulting fatally.

Cases possessed of more than usual interest are the following: Leopold,¹² a case of uteroabdominal pregnancy at term, the placenta remaining attached in the uterus; E. A. Ayres,¹³ a case of tuboabdominal pregnancy, with delivery of a living fetus at the 7th month, the patient subsequently dying; Denis,¹⁴ an abdominal pregnancy of 12 years' standing, the fetus not being calcified nor saponified, the child dying at the 10th month; Menchard,¹⁵ a twin ectopic gestation at 6 months, one fetus in the tube and the other in the abdominal cavity, the tubal fetus being flattened and of about the size of 3 months; S. C. Gordon,¹⁶ a case of tuboabdominal pregnancy at the 5th month, with a living fetus at the time of operation; W. J. Means,¹⁷ a case of secondary abdominal pregnancy after term; P. Tytler,¹⁸ a ruptured interstitial tubal pregnancy treated successfully by suture of the fissure; T. F. Prewitt,¹⁹ a unique case of extrauterine pregnancy occurring twice in the same Fallopian tube; R. Ludlam,²⁰ a case of extrauterine gestation with the placenta in utero, and the fetal sac within the Fallopian tube; E. Ekstein,²¹ a case of advanced extrauterine pregnancy of 6 years' standing, the fetus being between 6 and 7 months old, and partially mummified; and H. G. Wetherill,²² a case of extraperitoneal ectopic gestation, advanced to term, the fetus being macerated and the subject of double talipes varus.

J. B. Sutton²³ records a curious case of tubal abortion. On entering the peritoneal cavity he found a clot the size and shape of the dark outline in Fig. 32, lying in the fold of omentum. It was removed. Beneath it lay a second clot of precisely the same shape, but much larger. On removing this a third clot was found in the rectovaginal fossa of twice the dimensions, but of exactly the same shape as the other clots. A rounded, hard body was felt in the left tube. The clots were in shape reniform; the exterior of each was laminated like the blood in the wall of a sacculated aneurysm or in the sac of an old hemocele of the tunica vaginalis testis, but the central parts consisted of ordinary clot. The hard body in the tube was a "mole," and on microscopic examination yielded many chorionic villi in cross-section. The ostium abdominale was widely patent and the ampullary wall thick, succulent, and entire. The case was one of "incomplete tubal abortion," but peculiar in this respect:

as the blood collected and distended the tubal ampulla it firmly clotted and was then discharged with pain through the tubal ostium into the rectovaginal pouch. The "delivery," so to speak, of each clot coincided with three definite attacks of "pains" which occurred at monthly intervals. [The only record which is in any way parallel is by Noble. In a case of tubal abortion the blood-clots in the pelvis "were coiled up as though they had been ground through a sausage-machine." This was due to the blood clotting in the tube, and the clot was then forced out as a sausage-shaped mass by the continuance of the bleeding. The shape of the clot represented in the illustration is exactly that assumed by the ampullary section of the Fallopian tube when in the condition of hydrosalpinx.]

A case of inguinal hernia containing a pregnant Fallopian tube is reported

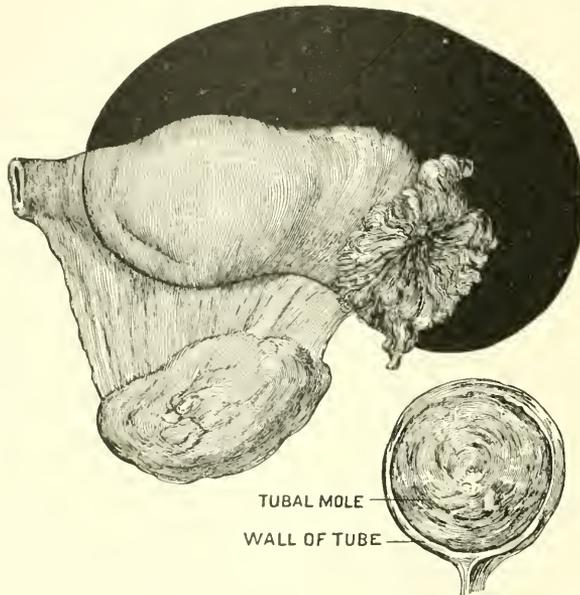

FIG. 32.—Figure of a gravid tube. The dark outline represents the shape and size of the smallest clot. It also shows the shape of the ampulla of the tube when distended (Lancet, Feb. 13, 1897).

by Jordan.¹ The woman had undergone several operations for pyosalpinx and vesicovaginal fistula. The pyosalpinx had ruptured into the right broad ligament, the pus finding its way under Poupart's ligament, where it had been evacuated, leaving a scar. The patient had been seized with severe abdominal pain and repeated vomiting, and suspecting pregnancy had visited the clinic for examination. Upon admission she appeared very anemic, with a pinched face and rapid pulse. Above the scar in her right side was a swelling as large as a fist and tympanitic on percussion. Below the scar was another tumor smaller in size, and nonreducible. A third was found to the outer angle of the scar corresponding in position to the internal inguinal ring. This was the size of an apple, soft, irreducible, and painful on palpation. High rectal enemas were administered, and resulted in neither stool nor flatus. Purgatives were not retained. Operation was decided upon 2 days after admission on account of increasing severity of the symptoms of intestinal obstruction. An incision was made parallel to Poupart's ligament, showing a hernial sac containing a large

¹ Münch. med. Woch., No. 1, 1897.

mass of blood-clots, a fetus about 3 months old, the uterine adnexa, and coils of intestine. The wound was cleansed as much as possible and tamponed with gauze. The vomiting continued, and death occurred the following day. It was found at autopsy that the intestinal obstruction was caused by numerous adhesions which were beyond surgical relief.

Ovarian Pregnancy.—[Some authorities deny the possibility of the occurrence of ovarian gestation in the human female, although it occurs as a natural phenomenon in some of the ovo-viviparous osseous fishes, as sharks and rays.] J. Oliver¹ records an interesting case, as follows: the patient was aged 39 years and had been married 12 years; she had had one child, who was born 11 years ago. She began to menstruate at the age of 16 years, and since the birth of the child the discharge, which usually lasted 5 days, had recurred regularly every month until Dec., 1894. In that month and in Jan. and Feb., 1895, there was complete amenorrhea. On March 10, 1895, a substance was passed which appears to have been deciduous membrane. The expulsion of this membrane was effected with but little pain, and was accompanied by a very small quantity of blood-colored discharge. With the exception of this slight discharge of blood on March 10, there was complete amenorrhea in March, April, May, June, and July. On Aug. 26 there was a copious discharge of blood, which persisted for about 12 hours only. Fourteen days later—*i. e.*, about Sept. 9—there was during one day a slight discharge of blood. In October and November there was again complete amenorrhea. On Dec. 25 the menstrual discharge made its appearance and continued to flow for 2½ days, and thereafter it reappeared regularly every 4 weeks until May 14, 1896, when abdominal section was performed. In Jan. and Feb., 1895, she complained a good deal of abdominal pain, but thereafter she experienced but little discomfort and was able to get about as usual, sometimes walking even 3 or 4 miles in one day. The following physical signs were noted on April 18, 1896: the abdomen was prominent and was occupied by a swelling which was located more toward the right than the left side. This swelling, which was almost solid, extended upward from the pubes for 8½ in., and measured transversely at the umbilical level 8½ in. Here and there nodular projections were felt on its right upper half. The girth at the umbilical level was 29¾ in. Auscultation detected no sounds over the tumor. Neither breast was full, but colostrum was obtained readily from both. On vaginal examination the cervix was found to be located somewhat toward the right side of the pelvis; it was not soft and the os was not open. The body of the uterus lay behind and was independent of the abdominal tumor. On May 14, 1896, the abdominal cavity was opened. The omentum and small gut were extensively and firmly adherent to the tumor. After freeing these structures the tumor, which originated in the right half of the pelvis, was found to possess a well-defined pedicle. The pedicle was ligated after the manner of dealing with an ordinary ovarian cyst, and the sac containing fetus and placenta was removed intact. The left ovary was apparently healthy. The tumor, which was the right ovary, was found to be a closed sac containing a full-grown fetus with its cord and placenta. The fetus was covered with inspissated sebaceous material, but there was no fluid in the tumor. No breach in the right Fallopian tube could be detected, either at the time of operation or afterward. The patient made an uninterrupted recovery.

Of even greater interest than the foregoing is the case recorded by H. Ludwig.² The patient had previously been delivered at term of 5 healthy children, 3 of whom were still living. She became pregnant for the sixth time,

¹ Lancet, July 25, 1896.

² Wien. klin. Woch., July 2, 1896.

and on Feb. 20, 1896, labor-pains began. In 6 hours she was delivered of a healthy girl, which presented by the vertex. It was evident that another child remained. Five days later she was admitted into Chrobak's clinic. On examination a living child could be mapped out in the abdomen. The puerperal uterus was about the size of a man's fist, and the appendages on the right side were normal. On the left side a short, thick cord could be felt extending into a tumor which filled the left iliac fossa. By the vagina this tumor was felt pressing down into Douglas's pouch, and the child's head could be made out in the pelvic excavation. The lochia were normal. Abdominal section was performed. The ovum was found attached to the left side of the uterus, from which the placenta appeared to grow. The vascular relations were so intimate that removal of the sac without the uterus was impracticable. The sac was opened and a healthy, well-developed male child extracted, who cried lustily. An elastic ligature was placed on the uterus at the level of the internal os, and uterus and appendages were removed. The cervical canal was cauterized, and the stump treated extraperitoneally. Recovery was delayed by a right-sided pneumonia, but the mother and child left the hospital well at the end of a month. The right tube and ovary were perfectly normal. The left tube could be distinctly traced into a tuboovarian ligament about half an inch wide. The ovarian ligament proper lost itself in the upper part of the sac; from the free end of the tube an ovarian fimbria led into the sac, of which the outer layers appeared to be formed by the remains of the ovary. The sac consisted of 2 parts, one of which, closely attached to the left side of the uterus, was solid, while the other, situated externally, was membranous, and had contained the ovum. The former consisted mainly of a normal placenta, which received from the uterus 2 large vessels—artery and vein; the latter corresponded in its relations to a greatly enlarged ovary, and showed on its surface a number of cystic protrusions—ovarian follicles. Microscopic examination showed the presence of ovarian tissue covering the whole of the membranous portion of the sac; it contained true ovarian tissue, a large number of follicles, and 2 corpora fibrosa. The placental tissue was normal in structure. [The essential points in the diagnosis of ovarian pregnancy have been stated by Veit as complete presence of both tubes and one ovary, the other either being absent or forming part of the sac-wall, while at the same time one ovarian ligament must run into the sac. All these requirements were satisfied in this case, the diagnosis being clinched by the histologic findings.]

Symptoms and Diagnosis of Extrauterine Gestation.—In discussing the present status of ectopic pregnancy, W. G. Macdonald¹ states that *tubal abortion*, or the expulsion of the developing ovum from the fimbriated extremity of the tube into the abdomen, may occur at any time between the second and eighth week of gestation. It is neither a complete discharge into the abdomen nor incomplete, being arrested in the fimbriated extremity, and gives rise to the so-called tuboovarian or tuboabdominal pregnancies. [This is not to be accepted as the inevitable cause of gestation here situated, which may be primary.] Hemorrhage into the membranes of the ovum may occur while it is as yet within the Fallopian tube, and lead to fetal death and the development of a tubal mole. Bleeding more frequently destroys the fetus than the mother in the first four months of gestation. The contention that all ectopic pregnancies continuing until viability are developed between the folds of the broad ligament is not borne out by conditions found on the operating-table or in the laboratory. C. B. Penrose² classifies tubal pregnancy as follows: it is *infundibular* when the gestation begins in the infundibulum or in an accessory

¹ Jour. Am. Med. Assoc., July 25, 1896.

² Univ. Med. Mag., Oct., 1896.

tube-ending. This variety has also been called *tuboovarian*, because in time the gestation-sac may become adherent to the ovary and be bounded by both tube and ovary. The pregnancy is said to be *ampullar* when it begins in the ampulla of the tube; this is the most usual seat of tubal pregnancy. It is called *interstitial* when it begins in the interstitial portion, or in that part of the tube which is in immediate relationship with the uterus. C. S. Bacon¹ remarks that Wyder's proposition to curet the uterus in order to obtain uterine decidua for microscopic examination, which was made a few years ago, and which it was hoped would prove a great addition to our diagnostic resources, has been somewhat disappointing. The failure to find in every case characteristic decidual tissue is probably due to the occurrence of degenerative changes in the uterine decidual membrane which are not yet fully understood. The various descriptions of this membrane do not correspond in all respects. The investigations of Dobbert are among the latest, and his results agree substantially with those of Langhans and others in showing three layers—the superficial compact layer of decidual cells without glands, the middle spongy layer with dilated gland-spaces and little connective tissue, and the deeper layer comprising the bases of the glands and comparatively unchanged connective-tissue cells. After spontaneous expulsion of the decidual membrane only patches of the inner layer are found. The transformation of the uterine membrane into a decidual membrane takes place more rapidly when the fetus is located near the uterus, as in interstitial pregnancy. The change may not be as great in an ampullar pregnancy of 3 months as in an interstitial pregnancy of 1½ months.

According to J. Oliver,² a fecundated ovum may develop in some structure in the pelvis outside the uterus, and may even arrive at maturity without exciting any symptom different from that of an ordinary pregnancy, there being throughout this period complete amenorrhea. External hemorrhage is, however, so frequently observed in association with ectopic pregnancy, whether the ovum is enabled to complete its development or dies at a more or less early period of its existence, that it constitutes a common symptom of the disorder. In tubal pregnancy it is probable that the bleeding comes from both the uterus and the tube. When the blood is derived from the Fallopian tube it may make its appearance externally as early as the 20th day after impregnation. During the evolution of an ectopic pregnancy the uterus usually becomes somewhat enlarged, and membranous shreds or pieces are occasionally expelled from this organ, together with more or less free bleeding. As early as the tenth or twelfth week these deciduous membranes may be expelled, but independently of their existence blood may be poured out by the vessels of the uterus as early as the sixth or seventh week.

L. E. Frankenthal³ has made an extensive study of extrauterine pregnancy occurring twice in the same patient. He is of the firm opinion that in the human female impregnation occurs normally in the tubes for the following reasons: 1. Living spermatozoa have been found in the tubes; 2. The customary site of impregnation in mammals has been proved to be in the tube; 3. The ovum is impermeable after it has graduated the outer third of the tube; 4. The motion of the cilia in the tubes is toward the uterus; 5. That of the muscular fibers is toward the fimbria; and 6. The motion of the uterine cilia is toward the tubes. Impregnation occurring in the tube, any mechanical obstruction or certain pathologic conditions will prevent the advance of the ovum to the uterus. As regards repeated extrauterine pregnancy, he reports 1 case and has collected 12 others.

² Lancet, July 11, 1896.

³ Am. Gyn. and Obst. Jour., Sept., 1896.

Treatment of Extrauterine Gestation.—[But little new has been suggested in the line of treatment.] As C. N. Smith¹ very aptly remarks, in free intraperitoneal hemorrhage, while heart-stimulants, notably strychnin, should be freely employed hypodermically, the greatest stimulus to the heart is the distention of its cavities by blood, or a fluid of similar density. To produce and maintain this stimulation the infusion of normal salt-solution is strongly indicated; this, however, should never be infused into the circulation until the bleeding vessels have been secured. The hemorrhage having been arrested, the salt-solution may be used, and then the removal of the tube and cleansing of the peritoneal cavity can be done. In advanced cases of tubal gestation after extraperitoneal rupture the most satisfactory and clean procedure, and the one especially indicated in an early operation, is the stripping of the placenta and membranes from the sac, ligation of bleeding points, and quilting together of the layers of the broad ligament. If the hemorrhage cannot be controlled by ligation, the sac should be stitched to the edges of the abdominal incision and packed with iodoform-gauze. If the placenta is situated below the pelvis, has an extensive and firm attachment, and its separation promises to be attended with severe hemorrhage, the sac may be stitched to the edges of the incision, the fetus removed, and the placenta left *in situ*. The sac must then be packed with iodoform-gauze, and extreme precautions must be taken to prevent infection of the placenta, which must be removed on the fourth or fifth day, at which time hemorrhage will usually be slight. After the fourth month in these cases operation becomes most formidable. Von Herff² concludes from his study of these cases that in removing ectopic gestation-sacs which are complicated by adhesions it is important, whenever possible, to ligate the uterine and ovarian arteries. An attempt should then be made to shell out the sac, beginning at the periphery of the placenta, using clamps and ligatures to control the bleeding. The aperture left should be tamponed with gauze. In rare cases the site of placental attachment must be compressed by a running-stitch; compression of the aorta must be employed, or removal of the uterus with the application of clamps to the bleeding vessels. Gauze-packing is especially valuable when oozing exists or secondary bleeding is feared. W. G. Macdonald³ has suggested the following method: preliminary ligation of the ovarian and uterine arteries on the side from which the placenta receives its blood-supply; then the placing of a Mickuliez tampon of sterile gauze over the placenta, establishing pressure-atrophy; then preliminary suture of the abdominal walls, the sutures to be tied after the removal of the tampon and placenta; such a tampon may be safely left for three days, and then removed with the placenta and the sutures tied.

F. Henrotin⁴ remarks that a question of vital importance is that of operating during profound shock. In these cases the surgeon is called upon to differentiate between temporary fainting from moderate loss of blood and profound shock from excessive hemorrhage. The fainting woman is unconscious during swoons, but rallies from time to time, this being indicated by the variable pulse, slight flushes passing over her face, which shows little anxiety, her body-heat being variable, and the lowering of the head being quickly followed by amelioration. The woman suffering from rapidly progressing, uninterrupted hemorrhage to the point of exsanguination, after the first swoon remains conscious; her pulse steadily becomes weaker until it can no longer be appreciated; her face, which betrays extreme anxiety, is permanently blanched; her body remains constantly cold, and lowering of the head produces but little

¹ Am. of Gyn. and Pediat., Aug., 1896.

³ Loc. cit.

² Zeit. f. Geburtsh., Bd. xxxiv., H. 1.

⁴ Am. Jour. Med. Sci., Nov., 1896.

change; she cannot speak above a whisper, and is very still unless she has reached the stage of delirium that immediately precedes death. This differentiation cannot always be absolutely made, as the fainting woman may pass into profound shock from repeated hemorrhages.

Vaginal section for extrauterine pregnancy is discussed by H. Kelly and F. Henrotin.¹ Kelly reports 13 cases so treated, with good results; one patient, comatose when operated upon, died a few days later of nephritis. Cases suitable for this mode of treatment are those that rupture in the early months, including, therefore, the vast majority of all cases. Vaginal puncture and drainage are not a suitable plan of treatment (a) in an unruptured extrauterine pregnancy, (b) in a recently ruptured one, or (c) in advanced extrauterine pregnancy. The most suitable cases are those in which a succession of ruptures has occurred, each time adding to the accumulation of clots in the abdomen. In doing the operation, if the sac is well closed off from the peritoneum, it is a help in bringing away the blood-clots to wash it out at intervals with a normal salt-solution, after which drainage is secured by a strip of plain or washed iodoform-gauze, which is left in for 3 or 4 days. The dangers of the operation are (1) the possibility of a mistaken diagnosis, (2) the risk of opening the peritoneum, (3) the risk of a fatal hemorrhage, and (4) the liability to sepsis through the open vaginal vault. Henrotin prefers this operation for unruptured cases in multipare with large vaginae, in addition to the other indications already given. Especially would he select for this operation patients who are already septic; the dangerous element in the case—hemorrhage—is here to a very great extent eliminated, and by operating through the vagina infection of the peritoneal cavity is prevented. [Vaginal section for whatever cause cannot be recommended for very obvious reasons, notable among which are the danger of sepsis and the inconvenience from lack of room].

CORNUAL PREGNANCY.

H. Briggs² reports a case of pelvic hemocele due to rupture of a pregnancy in a rudimentary uterine horn. Operation was followed by cure. He remarks that a cornual pregnancy is liable to any of the diseases or accidents of the normal or ectopic pregnancy. Given a well-developed uterine horn and pregnancy, a natural labor may result; the uterine horn may be styled in all respects a normal horn. Given an ill-developed uterine horn and a pregnancy within it, the obstetric dangers are increased. It is well known that pregnancy in a rudimentary horn has the same tendency to rupture as tubal pregnancy, though the rupture usually has taken place at a later period of gestation in the former than in the latter. His patient had a bifid uterus; the left horn carried a male child till a natural labor at full term closed the pregnancy; the right horn was rudimentary; its pregnancy was, like a tubal pregnancy, abruptly terminated by intraperitoneal rupture. Between these two events there was an interval of 15 months. The uterus, developmentally, was of the type *uterus unicolis cum cornu rudimentaris*. There are 4 known varieties of rudimentary horn: (1) solid throughout; (2) a small tube throughout; (3) solid at both ends and hollow in the middle; (4) patent toward the Fallopian tube, but solid next the other horn. Briggs' case was of the fourth variety. [C. Webster has collected, from Kussmaul, Sanger, and Himmelfarb, 34 cases of pregnancy in a rudimentary uterine horn. In 24 of them rupture occurred and caused maternal death by intraperitoneal hemorrhage.]

LABOR AND THE PUERPERIUM.

Statistics.—Among the interesting statistics from large institutions mention should be made of the reports of R. C. Norris¹ and H. D. Fry.² In the Preston Retreat there were during the year 245 deliveries without a maternal death. Since Norris assumed charge of the institution there have been 745 deliveries with 1 maternal death from chronic nephritis. In 9 cases of the last 245 deliveries a moderate amount of albumin was found. There were 2 cases of grave kidney insufficiency and 1 of eclampsia; there was 1 case of placenta prævia centralis, 3 of twin pregnancies in primigravidaë, and 8 of minor degrees of pelvic contraction, in only 2 of which was the conjugate diameter below 9 cm. There was 1 complicated labor due to ventrofixation; and 3 cases of prolapse of the umbilical cord, in all of which the cord was pulseless at the time of examination. In 9.8% the temperature in the puerperium did not rise above 99° F.; in 81.8% the maximum rise was 100° F.; in 8.9% the temperature was above 100° F. not longer than 24 hours; and in 9.3% it remained above 100° F. for varying periods longer than 24 hours. Four of the cases were due to septic absorption. One case of puerperal insanity was noted and cured in 5 weeks' time. There were 6 cases of aspiration-pneumonia in infants, with 2 deaths. There was no case of ophthalmia neonatorum. In 5 female infants a bloody discharge from the genitals was observed. At the Columbia Hospital of Washington there were 252 deliveries during the year, with 2 maternal deaths from uremia, giving a mortality of $\frac{7}{100}$ of 1%. There were 3 twin pregnancies; 5 cases of uremic poisoning; 1 of excessive secretion of urine; 7 of moderate pelvic contraction. Forceps were employed 6 times, or in 2½% of the cases. There was 1 case of placenta prævia partialis; 1 of subcutaneous emphysema after labor; 1 of partial premature separation of the placenta; 34 of malarial complication in the puerperium, the attacks being mild and yielding readily to quinin; 6 of puerperal sepsis, 1 being treated by the antistreptococic serum. Of the private statistics, the most interesting are those of W. J. Cree³ and A. Worcester.⁴ Cree reports 330 cases, among which were 165 male children and 186 female children; 3 twin pregnancies; 85 primiparæ; 245 multiparæ; 1 brow presentation; 5 breech presentations; 3 face presentations; 1 footling and 4 transverse. Forceps were applied 65 times; 8 times in high position and 57 times in the low. The largest child weighed 14 pounds; the smallest, 4 pounds. The longest umbilical cord was 42 in.; the shortest, 8 in. True knots were found in 2 cords. There were 3 cases of placenta prævia and 1 of premature separation of the placenta. Thirty-one perineæ were ruptured. There were 1 maternal and 20 infantile deaths; 1 case each of patulous foramen ovale, bisexual organs, spina bifida, hydrocephalus, and supernumerary little fingers. Worcester records 200 cases, 124 of which were normal as regards labor and the puerperium; 64 were primiparæ; 9 cases were premature births, 4 of these being induced. In 37 cases operative assistance was given; 7 times podalic version was performed; in 30 cases forceps were used. There were 2 twin pregnancies; 3 cases of fatal uremia; and 1 fatal case of pulmonary embolism.

Asepsis in Labor.—[The value of asepsis in obstetrics is recognized the world over, and yet the amount of puerperal sepsis recorded and the large amount unrecorded show a deplorable ignorance or carelessness that is unjustifiable. The subject is one that cannot be too thoroughly ventilated, and the

³ Physician and Surgeon, Feb., 1897.

⁴ Boston M. and S. Jour., Oct. 8, 1896.

papers that are constantly appearing from able hands are ever welcome.] Among those who have contributed articles are G. K. Johnson,¹ R. Braun v. Fernwald,² C. E. Skinner,³ H. L. Williams,⁴ C. Godson,⁵ E. P. Davis,⁶ H. B. Bashore,⁷ and C. S. Bacon.⁸ Bacon refers to the mortality records of Chicago, which show that puerperal fever kills in that city more women in the prime of life than any other cause except consumption. Godson reports from the City of London Lying-in Hospital for a period of 10½ years (July 1, 1886–Dec. 31, 1896) 4608 confinements, with 11 deaths, a mortality of 1 in 419, or 2.387 per 1000; in the last 5 years among 2392 deliveries there was no death in which septicemia bore any part. Davis remarks that there are 3 sites after labor at which sepsis may occur—the pelvic floor and perineum, the cervix uteri, and the placental site. After normal labor in a healthy woman the wounds in the cervix and floor are but slight, and are cleansed by the amniotic liquid and blood-serum of the lochia; an occlusion antiseptic dressing is all that is required in such cases. If intrauterine packing is required, iodoform- or bichlorid gauze may be used. Skinner is in favor of vaginal douches of 3% creolin during the puerperal period as a prophylactic measure, using for the purpose a fountain-syringe, well sterilized. He claims that the patients using these douches do not complain of the feeling of soreness in the genitals that is so troublesome to many when they are not resorted to. [We feel that such douching is unnecessary, except when indicated by febrile reaction.] He would also urge early evacuation of the bowels—within 24 hours after labor—to remove the feces and contained microorganisms, and thereby avoid ptomain-absorption. Fernwald remarks that an intrauterine douche should not be given for every elevation of temperature, but ulcers of the vagina or cervix should be looked for and treated if they exist. Iodoform-pencils are of no value for insertion into the uterus after washing it out, and vaginal tampons should never be used. In some cases it is well to swab out the uterine cavity with tincture of iodine.

Anesthesia in Labor.—At the Pirogoff Congress in Cracow Hr. Bukoemski⁹ read a paper on the alleviation of pain in normal labor. After careful consideration he concluded that alleviating remedies do not retard labor, they never do harm, and are sometimes of great service. By the tokodynamometer (ether 45 cases and chloroform 8 cases), he determined that when ether is used the pulse and respiration are unchanged. The labor is shortened, albumin is never seen in the urine, the uterine contractions are more powerful, and involution is improved. Ether is a reliable and non-dangerous drug that does not require accurate dosage. Chloroform rather retards labor, but is not injurious to either mother or child. Ether deserves the preference. Both are good and reliable.

Savitsky,¹⁰ as the result of 17 years' experience, recommends antipyrin enemata as an obstetric anesthetic. He administers 1 gm. every 2 to 6 hours, occasionally combining the drug with opium (from 15 to 25 drops of Russian tinctura opii simplex, which contains 1 part of opium to every 10 parts). The pains are always relieved in 15 or 20 minutes after the first dose. Frequently the patient soon falls asleep, which is especially beneficial in cases of spasmodic uterine pains and tetanic contraction of the os; hemorrhage also diminishes. No untoward accessory effects were ever observed by the author.

J. P. Reynolds¹ deplors the unwarranted disuse of ether in the late stage of labor. Instead of conducing to flooding, he claims that the due use of ether saves the mother's courage and strength, and that it preserves uterine contractile power, and thus lessens the risk of hemorrhage. [Anesthesia in labor is of service in a selected class of cases. The routine use of ether or chloroform must be decried as a growing evil; but it would, on the other hand, be dogmatic and inhuman to forbid the anesthetic when there exists some indication for its use, as in dry labor with uterine exhaustion, or in an overwrought nervous individual.]

Posture in Labor.—T. W. Harvey² enlarges upon the influence exerted by various positions in the different stages of labor. In the second stage he claims that the posture of general flexion is the most effective. In case there is deflection of the long axis of the fetal ellipse either laterally or in front the woman should be placed on her back in the semi-recumbent position, whereby the uterus is straightened; pressure upon the fundus during the pain will then assist in the expulsion of the child. A change of position will also free an incarcerated lip of the cervix. The knee-chest posture in occipitoposterior cases will often aid in securing rotation if practised early.

Contraction-ring.—Barbour³ regards *retraction-ring* as a much more accurate and suggestive term than *contraction-ring*. Further, it is wrong to look for this ring in the pregnant uterus; all we find there is a suggestion as to the *place where it will probably develop when retraction has occurred in labor*. The term *retraction-ring* suggests its nature better than *contraction-ring*. Contraction is temporary, and will only be found in a frozen section from a patient who has died during a pain. Retraction is permanent, and will always be registered in a frozen section. Further, it is to retraction that its clinical significance belongs. It is to the fact that one portion of the uterine muscle has become permanently shortened and thickened at the expense of the lengthening and thinning of the part below it, and the consequent risk of rupture in the same portion, that this change in labor comes to be of importance, as was first pointed out by Bandl.

Fatty Degeneration of the Uterus during Pregnancy.—L. M. Bossi⁴ found the process of fatty degeneration of the muscular fibers of the uterus in active progress in 3 human uteri, 1 removed at the eighth month of pregnancy and the other 2 at term. He inquires whether this is the physiologic condition, and, if so, whether it may not explain the wonderful rapidity with which involution of the uterus after labor normally takes place. It may be asked, further, whether in this fatty degeneration there exists an explanation of some cases of inertia uteri in labor. Bossi has attempted to investigate the subject by the experiments on animals of tying the uterine blood-vessels, but does not regard the results as applicable to the human uterus.

Deflection and Rotation of the Pregnant and Puerperal Uterus.—R. M. Murray⁵ remarks that it is a well-known fact that the uterus, growing under the influence of pregnancy, tends to incline more frequently to the right than to the left side of the body. In from 70% to 80% of all cases the uterus inclines to the right side, while in about 20% to 30% it inclines to the left or lies more or less mesially. In addition to this, it undergoes a rotation of more or less degree about its vertical axis, so that one border comes forward and the other recedes. It has, further, generally been believed that in all cases in which the uterus inclines to the right side of the body the rotation is

¹ Boston M. and S. Jour., Oct. 15, 1896.

³ Edinb. Med. Jour., Nov., 1896

⁵ Edinb. Med. Jour., Feb., 1897.

² Med. Rec., Nov. 7, 1896.

⁴ Ann. di Ost. e Gin., Dec., 1896.

such that the left ovary advances, and conversely that in left-sided inclination the right advances. If the uterus expands absolutely symmetrically, it is the only hollow viscus that does;—the bladder, stomach, intestines, heart, all rotate during distention, and de-rotate when relaxed; and we may safely assume that the uterus does likewise. Admitting the rotation, we have available an easy explanation of the tendency to deflection or deviation from the middle line which is so universal. For with rotation about the vertical axis there must result a redistribution of the mass of the viscus round that axis. In the unrestrained condition in which the uterus lies in the pelvis this will result in a displacement to one or other side, depending upon the direction of the rotation. Thus, when the uterus rotates so as to bring the left side forward and toward the middle, the uterus will incline toward the right, and when the rotation is in the opposite direction the inclination will be to the left. Murray believes that some relationship exists between left-sided rotation after labor and occipitoposterior position, since in 26 cases of this position the deviation was noted in 18 cases. Schroeder and Schatz give it as their opinion that the side of the uterus which corresponds to the child's back rotates forward, and presumably will deviate accordingly. They would seem to imply that the position of the child was the cause of the deviation, but the grounds on which they do so do not seem quite clear.

Mechanism of the Engagement of the Head in Head-presentations.—[It seems somewhat strange that any room for difference of opinion should still exist as to the common way in which the head presents at the brim. Pinard and Varnier, basing their views on careful clinical and post-mortem research, have seen reason to dissent from the belief that it is the anterior parietal bone that habitually presents, especially in cases of contracted pelvis. Naegele long ago taught that in cases of moderate flattening of the pelvis the head, which lay with its long diameter in the transverse diameter of the brim, became tilted so that the sagittal suture approached more nearly to the promontory of the sacrum, and thus the anterior parietal bone was consequently the presenting part. Pinard and Varnier believe that both in normal and abnormal pelvis the fetal head, before it passes through the brim, is not syndelic—that is to say, it is so inclined that the sagittal suture is nearer to the symphysis pubis than it is to the promontory of the sacrum, and that therefore the posterior parietal bone is lower than the anterior. They further hold that the passage of the head through the brim is due to the gradual correction of this lateral inclination, the anterior parietal bone gradually descending until the head is syndelic—that is to say, until the plane of the child's head corresponds with the plane of the pelvic cavity; but this does not occur until the head has reached the lower part of the pelvic cavity.]

R. de Seigneux¹ gives the results of a series of observations. The position and movements of the head during its passage through the brim were carefully watched in 80 cases. In 43 of the cases the posterior parietal bone presented, the sagittal suture lying nearer to the symphysis than to the promontory of the sacrum. Although this does not fully bear out the wide generalization of Pinard and Varnier, it shows that the presentation of the posterior parietal is infinitely commoner than was generally believed. Among these 53 cases the pelvis were all normal except 5, and these only exhibited a moderate amount of contraction. The presentation was found to be syndelic in 19 cases, and during the descent the circumference of the head remained parallel to the plane of the pelvic cavity until the floor of the pelvis was reached. The anterior parietal bone presented only 18 times, although this is

¹ Rev. méd. de la Suisse romaine, May-June, 1896.

the presentation which Naegele and his followers regarded as the usual one both in contracted and normal pelvis. At the outlet of the pelvis it should be noticed that in all cases, irrespective of the original mode of presentation, if rotation has not already occurred, the head is inclined so that the anterior parietal bone presents. This fact was long ago pointed out by Matthews Duncan. De Seigneux's observations show that the head may present at the brim in 3 different ways, without leading to any difficulty in its passage through the brim. The nature of the pelvis has no influence on the kind of presentation, but this appears largely to depend on the inclination of the uterus to the plane of the brim. Thus, in primiparae, in whom the abdominal walls are firm and elastic, the axis of the uterine cavity lies behind the axis of the pelvic brim, and therefore the head presents by its posterior parietal bone; whereas in multiparae, in whom the laxity of the abdominal walls permits the uterus to fall forward, the anterior parietal bone is the presenting part. The figures further show that when the posterior parietal bone presents this one rides over the anterior, and when the anterior parietal bone presents it rides over the pos-

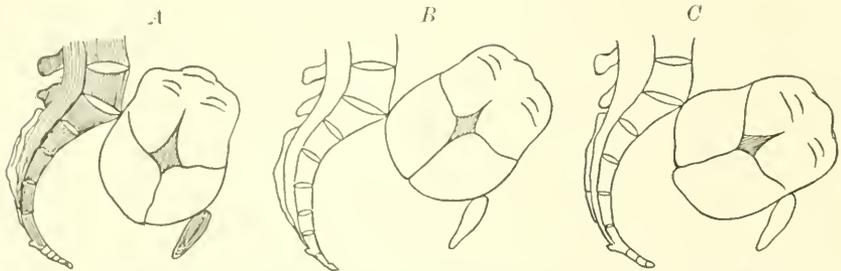

FIG. 33.—A, presentation of posterior parietal bone; B, synclitic presentation; C, presentation of anterior parietal bone (Rev. méd. de la Suisse romaine, May-June, 1896).

terior. When the presentation is synclitic, and there is therefore no inclination of the head in either direction, the parietal bones do not overlap.

Palpation of the Shoulder.—Fabre¹ has studied the relation of the anterior shoulder to the changing positions of the fetus during pregnancy. He says, first, that it can be found with rare exceptions. In 139 patients examined with reference to this point he failed to recognize the shoulder in 5 only, and in these by reason of hydrammios or multiple fetation. One thing that aids in locating the shoulder is the fact that it is found at the level of the fetal heart. By the situation of the anterior shoulder the examiner can determine the degree of engagement, of rotation, and of inclination of the head. Supposing, for example, that the head is normally flexed and is not laterally inclined on the trunk; the distance from the biparietal diameter to the top of the head is 5 cm.; from the biparietal diameter to the bisacromial diameter is (since no lateral inclination of the head is admitted) 8 cm. If it be found by mensuration with the calipers that the height of the shoulders above the symphysis is 13 cm., then the vertex lies at the level of the pelvic brim; and if the shoulder is 8 cm. above the pubic bone, the equator of the head is at the superior strait. Again, owing to torsion of the neck of the fetus the anterior shoulder lies on the same side of the mother with the occiput. In a left anterior position the shoulder is at the left of the median line, and conversely. Fabre's observations have shown that at the end of the 8th month the fetus lies in the posterior more frequently than in the anterior position. During the 9th month the occiput gradually glides forward, toward one of the

¹ L'Obstét., May, 1896.

anterior quadrants of the pelvis. Fabre has demonstrated the fact that the head descends synclitically by finding the same distance between the center of the sagittal suture and the anterior shoulder during the labor as after the birth. In contracted pelves, on the other hand, the measurements have shown asynclitism. [These studies bear an interesting and important relation to the results of de Seigneux, as just related.]

Mechanism of Placental Delivery.—According to Ahlfeld,¹ the theory of placental expulsion now credited to Schultze was first taught by Baudelocque. Rigby and Duncan declared that the mechanism of Baudelocque is artificial, resulting from traction on the cord, yet the views of the latter authority are generally accepted in Germany and in France. No demonstration of the Baudelocque-Schultze theory, however, had been offered till the author's investigations in 1881. He then showed that expulsion by the fetal surface was the normal method, and presentation by the margin was an exceptional one, due to irregularity. Fehling and his pupils, Zinsstag and Ziegler, who still adhere to the views of Duncan, refer deliveries by the fetal surface to supposed traction on the placenta developed during the expulsion of the fetus. This assumption is easily disproved by everyday observations. The cord is not drawn tense during labor in normal conditions. Against the contention of Fehling, moreover, are the facts that the placenta could be separated from the uterus by traction on the cord only so far as the passage of air or liquid behind the placenta would permit; that the insertion of the cord is not always central; that central inversions of the placenta occur even in marginal and in velamentous insertions.

Duncan teaches that the placental separation begins at the margin, and affirms that the free border is perceptible by the touch at the os uteri, but he does not say how many observations of this kind he has made. Again, the introduction of the hand into the passages disturbs the normal mechanism of placental separation and is not a reliable method of investigation. Ahlfeld made observations in 121 confinements, with the following results: placing a *serre-fine* on the part of the placenta that first presented at the vulva, the *serre-fine* was found at the middle of the fetal surface, after expulsion, in 71% of cases, at the border in 16%, on the uterine side near the border in 10.5%, and on the membranes in 1.9%. In 85 out of 122 cases (twins occurring once) the membranes covered the uterine surface, in 32 they were on the fetal surface, and in 5 they were between the two situations. Duncan, as an argument for his theory, invokes the assumed fact that hemorrhage does not occur when the placenta descends by its border. But Zinsstag himself has shown that the loss of blood is greatest in these very cases. In 160 confinements he observed hemorrhage exceeding 1000 gm. 34 times. In 24 of the 34 cases the placenta presented according to Duncan. In 50 cases of hemorrhage noted by Ziegler the placenta was expelled 5 times *a la* Schultze, and 45 times by the method of Duncan. Schultze's theory was sustained in 2 cases of Cesarean section observed by Ahlfeld. The placenta bulged at its central portion, the border still remaining adherent. On lifting the edge with the finger blood spurted out from the retroplacental accumulation.

Parturition during Paraplegia.—A. Routh² reports a case of labor in a multipara with complete paraplegia below the level of the 6th dorsal vertebra. Labor was painless and required but 12½ hours for its completion. The only sensation of the patient was a "tight feeling" at the epigastrium during the pains. Involution and lactation were normal. The case proves: 1. That the act of parturition is partly automatic and partly reflex, these actions cor-

¹ Zeit. f. Geb. u. Gynäk., Bd. xxxiii., H. 3, 1896.

² Lancet, June 12, 1897.

responding in the main to the first and second stages of labor respectively; 2. That direct communication with the brain is not essential to coordinate uterine action, though the brain seems to have a controlling influence upon the pains, helping to make them regular with well-defined intermissions; 3. That direct communication between the uterus and the lumbar enlargement of the cord, through the medium of the sympathetic ganglia, between the first and third lumbar, is probably essential to the regular and coordinate contraction and retraction of the uterus, as occurs in normal parturition; 4. It seems also probable that the uterus is able automatically to expel its contents as far as the relaxed part of the genital canal even when deprived absolutely of spinal influence, spinal reflexes being then necessarily absent; 5. Lactation is not solely due to nervous influence, but partly to chemie changes in the blood.

Nonligation of the Umbilical Cord.—M. B. Kellar¹ enters a plea for this method of treatment of the funis which he has used in more than 2000 cases with good results. He claims that ligation is unnecessary because it is not required at the birth of any other animal, and because there is no danger of hemorrhage without ligation. He asserts that ligation is injurious because it is at times the cause of secondary hemorrhage; because it interferes with desiccation of the cord, and favors ulceration of the navel, fungoid excrescence, umbilical phlebitis, erysipelas, jaundice, and pyemia, and by preventing a normal escape of blood produces hepatic hyperemia and congestion of the portal circulation.

Involution.—Important studies of the process of involution have been made by McCann² and T. B. Stevens and W. S. A. Griffith.³ McCann's method consisted in measuring with a tape-line from the middle of the fundus uteri to the pubes, taking this at the same hour and with the bladder and the rectum of the patient empty. Septic cases were excluded. Of 37 primiparæ the uterus was found in the true pelvis in 29 before the 13th day. Of 21 multiparæ the womb had entered the pelvis in 13 before the 13th day. Conditions which favored prompt involution were full-term labor, involution being delayed after premature labor, normal or excessive length of the labor, and the parity of the patient, as after repeated labor involution is slower. Contrary to what is commonly held, McCann could not find that lactation furthered involution, but rather predisposed to anemia, which delayed it in many cases. Women who had no secretion of milk whatever often had the most complete involution. Prolonged lactation produced *superinvolution*, a distinctly pathologic condition. He also observed that involution proceeds most rapidly during the first week of the puerperium. After-pains, in these cases, have no effect on involution, but are abnormalities in involution, caused either by retained clots or placental remains, or without known cause, resembling dysmenorrhea.

The measurements of Stevens and Griffith are both vertical and horizontal through the abdominal walls, the vertical being the one to be relied upon, as the transverse are very difficult to obtain. The top of the symphysis pubis is taken as the fixed point from which to measure the height of the fundus uteri. A common "foot" rule is used, the end being pressed against the upper border of the symphysis. The top of the fundus being found, the finger makes a tangent with it and the rule. The distance from the symphysis can then be read on the rule in inches. The bladder and rectum should be empty; the uterus in the median line and anteverted. The uterus should be in a state of contraction at the time of measurements; the measurements should be taken at the

¹ Pacific Med. Jour., Jan., 1897.

² Brit. Med. Jour., No. 1856, 1896.

³ Tr. Obst. Soc. of London, vol. xxxvii., part iv., 1895.

same hour each day. An ordinary temperature-chart can be used to show the curve, by making the 100° line represent the pubes, and each degree above represent one inch. The sources of error are—1, distention of the bladder; 2, distention of the rectum; 3, distention of the small intestine; 4, prolapse of the uterus; 5, retroversion of the uterus; 6, abnormally high uterus; 7, unusual bulk of the uterine muscle; 8, excessive lateral obliquity of the uterus. The pathologic conditions that interfere with the involution of the uterus, and therefore with the descent of the fundus, are—1, retention of portions of placenta and membrane, blood-clots, and lochia; 2, putrid decomposition within the uterus. According to the average chart, the rate of involution is represented by a fall of 2 in. during the first 6 days. After the eighth day the rate of involution is very slow. The average height above the pubes on the first evening is $5\frac{1}{4}$ in. On the fourteenth day the average height is 2 in., the variation being from 1 to 3 in. It has not been possible to obtain the exact day that the uterus sinks behind the pubes, as most of the cases leave the hospital on the fourteenth day. In one case, on the eighteenth day, it was 1 in. above the pubes. The measurements were taken morning, noon, and evening, and it was found that there were a morning rise and an evening fall, the curve indicating that involution did not progress as rapidly during sleep as during waking hours. The curve in primiparæ was lower in every case by $\frac{1}{2}$ in. than in multiparæ. Age exerted the same influence; the older the woman the higher the curve. In cases of retained products and clots, curetting and intra-uterine washing exerted a marked effect in reducing the curve. With regard to lactation, in those cases in which there was complete absence of lactation the progress of involution was rapid. If lactation was performed, involution was rapid the first few days, diminishing rapidly later. Prematurity of labor delayed involution. Prolonged labor delayed involution for the first few days.

The Excretions of Parturient Women.—Neumann¹ reports the results of his study regarding the excretions of parturient women. His conclusions agree in the main with Winckel's, and show that the excretion of sulfates is lessened during the first 10 days of the puerperal period, being inferior to that usually observed in a healthy adult. The reason for this is found in the fact that such material is voided in the lochia and to some extent by the formation of milk. He also endeavored to estimate the amount of fecal waste which such patients eject during this time. He found that, like the soluble material, less than normal is passed for the first 10 days of the puerperal period. In one instance in which the patient failed to have the bowels thoroughly emptied before labor a very great increase above the normal was noted. He calls attention from this to the practical necessity of having the rectum thoroughly empty before parturition begins.

Effects of Lactation on Menstruation and Impregnation.—L. Remfrey² concludes that of nursing-women 57% only have absolute amenorrhea; 43% menstruate more or less, but 20% have absolute regularity. Impregnation does not take place so readily during lactation as at other times; but this is not true to such an extent as has been imagined. If absolute amenorrhea is present during lactation, the chances of impregnation occurring are only 6 out of 100. If menstruation occurs during lactation, the chances are 60 in 100. The more regular a woman is during lactation the more likely is she to become pregnant. During a menstruating lactation the changes in the uterus are presumably similar to those connected with the ordinary monthly periods, and the mucosa forms a nidus for the ovum. In the woman who does

¹ Arch. f. Gynäk., Bd. lii., H. 3, 1896.

² Tr. Obst. Soc. of London, 1896.

not suckle at all the menses appear, as a rule, sometimes in the first 6 weeks after delivery.

Statistics of Lactation.—[Statistics on this subject are called for, as they throw much light on the health and strength of women in different regions.]

Buchmann¹ observed 126 lying-in women in the obstetric wards of the Halle clinic from February to May, 1895, inclusive. He wished to ascertain the proportion of cases in which the mother was able to suckle her child. Out of the 126 cases, 83 (or 65.9%) had sufficient milk when discharged between the tenth and twelfth days. The percentages recently reported from Bâle and Stuttgart are much lower.

Wieden² reports from the Freiburg Maternity that out of 525 women in childbed only one-half could suckle thoroughly during the first two weeks, 99 secreted no milk, 49 had imperfect nipples, 46 had fissured nipples, and 44 had insufficient secretion of milk. Only 33 suckled without unfavorable complications. The development of the nipple bore a direct relation to the value of the breast as a secretory organ.

MATERNAL DYSTOCIA.

Pelvic Contraction.—New classifications of deformed pelves are offered by Dohrn³ and Dorland.⁴ Dohrn proposes the following classification, which combines the two systems of classifying by form and by causation: I. *Deformed pelves of normal shape*: 1. Generally contracted pelvis; 2. Abnormally large pelvis. II. *Deformed pelves of abnormal shape*: 1. *Flattened pelves*—(a) Simply flattened pelves: (α) Pelvis plana deventeri, (β) Simple flattened pelves from congenital double dislocation of the hips, (γ) Simple flat rachitic pelvis; (b) Generally contracted flattened pelves. 2. *Deformity from bending of the bones*: (a) Bending of the bones due to osteomalacia; (b) Bending of the bones due to rachitis. 3. *Oblique pelves*: (a) Obliquity due to skoliosis; (b) Obliquity from failure of proper use of one leg; (c) Asymmetry of the sacrum. 4. *Transversely narrow pelves*: (a) Congenital transversely narrow pelves; (b) Kyphotic transversely narrow pelves. 5. *Failure of union at the symphysis*. 6. *Spondylolisthetic pelves*. 7. Deformities due to *exostoses*, *hyper trophy* of normal bony prominences, *early fractures*, or *neoplasms* of the pelvis.

Dorland's classification is founded on a clinical basis, the pelves being grouped according to the diameter which is most concerned in the contraction. He groups as follows: I. *Anteroposteriorly contracted pelves*: 1. Simple flat pelvis; 2. Spondylolisthesis; 3. Spondylolizema. II. *Obliquely contracted pelves*: 1. The rachitic pelvis; 2. The coxalgic pelvis; 3. The skoliotic pelvis; 4. The osteomalacic pelvis; 5. Naegele's, or the obliquely ovate pelvis; 6. The oblique pelvis due to traumatism (fractures, luxations)—the *sitz pelvis*. III. *Transversely contracted pelves*: 1. Robert's pelvis; 2. The kyphotic pelvis; 3. The kyphoskoliotic pelvis. IV. *Generally contracted pelves*: 1. The justminor pelvis; 2. The masculine, fetal, funnel-shaped pelvis; 3. The generally contracted and flat pelvis.

[The *relative frequency* of pelvic contractions has been thoroughly studied by a number of observers in this and other countries. No accurate knowledge on this point can be obtained by measuring only cases operated upon, thus omitting the large class of difficult labors often followed by fetal death or maternal injury. Routine examination of women attendant upon clinics or ma-

³ Centrallbl. f. Gynäk., No. 16, S. 417, 1896.

⁴ Manual of Obstetrics, p. 534.

ternities is essential in arriving at positive conclusions.] J. W. Williams¹ gives the result of his examination of 100 women to determine the pelvic condition present. He designates as contracted only those pelves that presented an oblique conjugate of 11 cm. or less, with an internal conjugate of 9 cm. or less; pelves with shortening of 2 cm. or more. In 2 cases pelves slightly larger than the limit were included in the list, because labor was difficult, 1 case requiring high forceps, the other difficult breech-extraction. In the 100 women 15 had contracted pelves; 4 were rachitic flat pelves; 5 were generally contracted; 1 was coxalgic oblique; 1 was transversely contracted, of the male type. These women were white in 8 cases, and negroes in 7. Eleven of these were born in America. When these cases were reported 13 had been delivered, 7 spontaneously, and 6 by operation. At the recent Congress at Geneva² the discussion upon this subject was briefly as follows: Fochier had examined 120 pelves postmortem in the anatomic rooms of the medical faculty of Lyons. He found 27 of these contracted, 1 of them in a remarkable manner, a percentage of contracted pelves of $21\frac{6}{100}$. Among these, 22 were flattened, 10 being simple flat pelves and 12 irregularly flattened. The remainder were rachitic. His clinical observation included 630 pregnant women examined during 1895, among whom were found 120 contracted pelves, $20\frac{16}{100}\%$. Of these, 42 were simple flat pelves, 58 flat rachitic, and 20 generally contracted pelves. All pelves were considered rachitic in which there was a history that the patient had walked later than the average infant. The frequency of transverse presentations in the obstetric clinic at Lyons had led to an effort to find an explanation for this in the peculiar shape of the pelvis among these patients. It was found that in these cases a peculiar flattening of the pelvis was present, which seemed to be an adequate cause for this phenomenon. Rein, of Kiew, Russia, gave the results, gathered from different Russian clinics, of the examination of 54,000 pregnant patients, among whom were found 2005 pelves whose true conjugate was $9\frac{1}{2}$ cm. in flat pelves and 10 cm. in those generally contracted. He could find but 457 cases of markedly contracted pelves. Sufficient deformity to require Cesarean section was exceptional. In the Caucasus rachitis is rare, while in other portions of Russia almost all contracted pelves are rachitic. In the clinic at St. Petersburg but $\frac{6}{100}\%$ of patients examined had contracted pelves. In Russia the most frequent contracted pelvis is the simple flat, and then the generally contracted. Of the 54,000 patients, $1\frac{5}{100}\%$ had simple flat pelves and $1\frac{5}{100}\%$ had generally contracted pelves. But 4 cases of osteomalacia were reported. Kufferath, of Brussels, had recorded pelvic measurements for 10 years in 5000 women, making the same measurements with each. He found 75 contracted pelves, of which 71 were flat, with a true conjugate of less than $9\frac{1}{2}$ cm., while 4 were generally contracted with a true conjugate of not less than 10 cm. As regards treatment, he divided his patients into 4 classes. In the 1st the true conjugate was from 9 to 11 cm.; delivery was effected by the forceps or version, and rarely by symphysiotomy. If the child was dead, the forceps or embryotomy was employed. In the 2d class the true conjugate varied from 9 to 7 cm. Premature labor was induced at $7\frac{1}{2}$ months. If version or forceps failed at term, symphysiotomy was employed. In the 3d class the true conjugate was from 7 to 5 cm. Labor was induced at $7\frac{1}{2}$ months, and symphysiotomy practised if necessary. If the child was at term and the true conjugate from 6 to $5\frac{1}{2}$ cm., Cesarean section was chosen. In the 4th class the true conjugate was less than 5 cm., and abdominal section was employed. Fancourt Barnes, of London, reported the results of the examination of 38,065 pregnant women, among whom were found 150 flat

¹ Bull. Johns Hopkins Hosp., No. 65, 1896.

² Am. Jour. Med. Sci., Nov., 1896.

pelves, with a true conjugate less than $9\frac{1}{2}$ cm., and 45 pelves symmetrically contracted, with a true conjugate of less than 10 cm. Treub, of Amsterdam, gave the results of 22,955 labors. Among these patients 816 contracted pelves were found. Of these, 657 were flattened, with a true conjugate of less than $9\frac{1}{2}$ cm., while 159 pelves were symmetrically contracted, with a true conjugate of less than 10 cm. No cases of osteomalacia were found. In treatment, Treub had employed the supine posture, or Walcher's position, with success. Pestalozza, of Florence, had examined 7962 patients, of whom 2437 had pelves somewhat contracted; 993 of these patients had such slight pelvic contraction that interference was unnecessary. The most frequent forms were rachitic, symmetrically contracted, and simple flat pelves. In 50 cases an irregular contraction was present. One case of osteomalacia was among the number. Among other operations 3 symphysiotomies and 14 Cesarean operations were performed. The maternal mortality was 8 in 1391 clinic patients, and 95 infants. The most frequent contracted pelves were observed in the south and in the vicinity of Naples. The inhabitants of the north and middle portions of Italy were less often afflicted with disease causing pelvic contraction. Lusk, of New York, reported that in the United States pelvic contraction is exceptional among Americans, rachitis and osteomalacia being practically unknown. Pawlik, of Prague, gave the results of the examination of 29,615 pregnant women in the Austrian Empire: $5\frac{9}{10}\%$ of these patients had flat pelves, $1\frac{9}{10}\%$ symmetrically contracted pelves, and $\frac{14}{100}\%$, or 41 patients, had osteomalacia. Morisani, of Naples, among 2769 labors, found deformed pelves in $4\frac{47}{100}\%$. Among these were 50 rachitic pelves and 13 osteomalacic. Most of the rachitic pelves were found in patients from the vicinity of Naples. The osteomalacic cases came from the villages at the foot of Vesuvius, and 3 of these patients had been born in Naples.

Knapp¹ in 4289 cases observed at the University of Prague from 1891 to 1895 found 105 cases of contracted pelvis. Flat and generally contracted pelves, without demonstrable evidences of rachitis, preponderated over the rachitic forms. Osteomalacia was observed in 5 cases. In the 105 cases there was a maternal mortality of 0.95% and a fetal mortality of 31.43%.

The *treatment* of labor in moderate pelvic contraction was discussed at the 64th annual meeting of the British Medical Association at Carlisle.² In discussing the relative advantages of forceps and version R. M. Murray stated that the forceps present obvious advantages from the point of view of the safety both of the mother and the child. Thus as to the mother, we have (1) avoidance of risk of uterine rupture, (2) avoidance of intrauterine manipulation, and (3) diminished risk of infection; and, as to the fetus, (1) avoidance of traction on the neck, and (2) avoidance of compression of the cord. In justomino pelves the question of turning does not arise, forceps being the only proper operation. In flat pelves version is almost universally recommended, while only recently has the accuracy of this view been questioned. Murray had already shown that the diminution in the cranial capacity produced by compression of the forceps is compensated by a vertical expansion, and not by a transverse one. Accordingly, he holds that the explanation of the inefficiency of the ordinary forceps in a flat pelvis is due, not to complications arising from their grasp of the head, but to waste of force arising from error in the line of traction. He therefore urges the use of axis-traction, offering for this purpose the rods devised by himself to be applied to ordinary forceps. He claims these points for axis-traction in flat pelves: (1) the forceps can be applied without difficulty to the anteroposterior diameter of the head

¹ Arch. f. Gynäk., Bd. 51, H. 3, S. 483.

² Brit. Med. Jour., p. 1281, Oct. 31, 1896.

and in the transverse or roomy diameter of the pelvis; (2) the grasp of the head, while sufficient to prevent slipping, does not materially compress the head; (3) no amount of practical compression of the head in this direction is capable of causing the least expansion of the biparietal diameter; (4) the mode of grasp favors the development of the Naegele obliquity, and this follows the natural mechanism of delivery in such cases; (5) as compared with version, forceps avoid intrauterine manipulation, traction on the neck of the child, and also the risk of delay during compression of the cord. He has delivered living children in this manner when the brim was not more than 3.25 in., and in one case when it measured 2.75 in. C. E. Buslow agreed with Murray, except that he believes version would sometimes succeed when forceps failed. W. E. Fothergill believed that version in flat pelvis had nothing in its favor except its antiquity. He had successfully delivered by axis-traction forceps 6 women in whom the conjugate varied from 3 to 3½ in. A further advantage of forceps besides those mentioned by Murray is that forceps can be applied at any time, however long, after the rupture of the membranes.

R. V. Braun¹ suggests the use of thyroïdin in contracted pelvis in order to produce undersize of the fetus.

Puerperal Eclampsia.—The *pathology* of eclampsia has been studied by P. Leusden² and J. W. Byers.³ According to Leusden, there are two forms of puerperal eclampsia. In the one there is found postmortem evidence of acute nephritis added to congenital defects in the kidney, and in the other the so-called nephritis of pregnancy. He regards puerperal eclampsia as the result of a blood-poison from derangement of the function of the kidney. The giant-cell emboli found in the lungs of puerperal subjects appear to have nothing to do with eclampsia; neither have bacteria, nor disease of the placenta, nor necrosis of the liver. Byers especially emphasized the part played by the fetus in the pathology of the disease. He has verified Winkel's observation that when the fetus dies during pregnancy, even in the case of a woman who presents the premonitory symptoms of eclampsia, the danger for the mother is entirely overcome or very much diminished. The extreme view that all cases of eclampsia are the result of renal disease is being abandoned. The following facts are distinctly against the renal theory of causation: 1. Now and then a case is encountered in which no albumin has ever been present, and in some fatal cases the kidneys are quite healthy; 2. All obstetricians have seen women with chronic renal disease become pregnant and never develop convulsions; 3. The certainty of the occurrence of eclampsia is not proportionate to the intensity of the albuminuria; 4. It is very rare for convulsions to occur in acute disease of the kidney apart from pregnancy, except in cases in which the renal affection is associated with some specific disease like scarlatina, when there is *already* a poison circulating in the blood; 5. Sometimes women die comatose in eclampsia, and yet the amount of albumin present has never been more than a trace. The theory of blood-poisoning or toxemia as the cause of eclampsia is supported by the following arguments: 1. It covers all the cases whether albumin is present or not; 2. The clinical history of eclampsia is that of a toxemia; 3. The postmortem appearances. According to Zweifel, multiple thromboses are invariably found in the liver, lungs, and brain in all fatal cases of eclampsia, and certainly indicate the existence in the circulation of some blood-coagulating product of organic change.

Veratrum viride holds its own in the *treatment* of this disease. According to J. C. Edgar,⁴ it is second only to chloroform in value, provided the pulse

¹ Centrabl. f. Gynäk., No. 27, S. 722, 1896.

² Centrabl. f. innere Méd., No. 17, 1896.

³ Lancet, Jan. 2, 1897.

⁴ Med. Rec., Dec. 26, 1896.

be strong as well as rapid; when the pulse is weak morphin hypodermically and chloral per rectum are better. *Veratrum viride* reduces the pulse-rate and temperature, relaxes the cervical rigidity, and causes prompt diaphoresis and diuresis. C. D. Hurt¹ says that it is suited to the treatment of eclampsia, whether antepartum or postpartum, unless chronic disease or excessive anemia be present. On the other hand, S. Marx² questions its true curative and therapeutic worth in cases demanding its use, and W. W. Potter³ says it is dangerous, uncertain, and deceptive in action. Marx has seen terrible convulsive seizures when the pulse was 60 and alarmingly feeble. [The benefits that generally follow its use are so marked that we are safe in urging its employment in all suitable cases.] Exclusive milk-diet as a prophylactic measure has come into general favor. Potter says it is one of the surest ways to control progressive toxemia. This will also serve to flush the kidneys and thus favor elimination. Marx urges a dietary consisting of milk, buttermilk, kumyss, or matzoon, with the addition of plenty of water. A. Charpentier⁴ remarks that every pregnant woman with albuminuria should be put on an exclusive milk-diet. Ferré⁵ regards the milk-treatment to be most efficient from a prophylactic point of view in the treatment of puerperal convulsions, although it does not necessarily cause the other alarming symptoms besides the convulsions to disappear. He has never seen convulsions in a patient subjected for over a week to milk-diet, nor any other trouble of a toxic origin. The alleged disappearance of albuminuria, on the other hand, does not necessarily occur. Ferré speaks with equal decision on this point, declaring that he has never seen so much as an appreciable diminution of albumin even after prolonged milk-diet. The same is the fact with the edema. The above facts are emphasized because he is aware how some obstetricians have very naturally given up milk-diet on account of persistence of albuminuria and edema. Such a step is a mistake, for if the treatment be continued labor will proceed without any convulsions coming on, though the legs remain swollen and the urine albuminous.

There was an important discussion upon eclampsia at the International Congress of Obstetrics and Gynecology⁶ in Geneva. Charles, of Lüttich, considered eclampsia a complex disorder. While the reflex element is very pronounced, still the part played by toxins is no less significant. After referring to the auto-intoxication evident upon examining the various excretory organs, he stated that these retained poisons might result in dyspnea, carcinoma, and paralysis without the development of convulsions, and these cases he would style "imperfect or incomplete eclampsia." While albumin is present in the urine in most cases, it is by no means the inevitable cause of this condition. Among the cases observed by this speaker, the mortality in 151 had been $24\frac{4}{100}\%$ for mothers and $41\frac{8}{100}\%$ for the children. He had observed the usual predominance of primipare in this complication. Charpentier urged the most thorough examination of the urine of each pregnant patient. Upon slight indications of albuminuria and diminished excretion he would limit the patient's diet strictly to milk, relying largely upon this for the prevention of eclampsia. In the actual presence of convulsions, if the patient was robust and cyanotic, he would bleed. He would also give chloral with milk through a stomach-tube. The inhalation of chloroform and the subcutaneous injection of normal saline solution are of value. If the patient was not robust and little cyanosis had developed, he would content himself with the use of chloral. In most

⁶ Centralbl. f. Gynäk., No. 39, 1896.

cases labor came on spontaneously, and delivery followed without assistance. If birth do not end spontaneously, version or forceps are indicated. If the child have perished, craniotomy should be chosen. He did not believe in rapid and forcible dilatation of the birth-canal, but would wait until such could be accomplished without violence. The induction of labor or abortion is rarely indicated in his experience in this condition. Cesarean section could only be performed amid the most favorable surroundings and in rare cases. Halbertsma considered the most important question in the treatment of eclampsia to be whether the obstetrician should wait for the occurrence of labor, or whether he should interfere at once. In serious cases in prolonged labor, when the patient was more than the average age and the pelvis was contracted or multiple pregnancy present, he would actively interfere. He believes that Cesarean section is indicated at the termination of pregnancy in the presence of convulsions. He also urged incision of the cervix in suitable cases. Veit had little confidence in many methods proposed, because he did not think the pathology of the affection sufficiently well established to furnish indications for treatment. He would hasten labor by every safe method, would administer morphin in large doses, and try to obtain profuse perspiration. He did not advise operative treatment in these cases. Byers, of Belfast, had found that morphin tended to lessen the acute catarrhal process in the lungs, which often hastens a fatal issue in eclampsia. He urged the vigorous use of eliminative treatment. When the conditions are favorable he would deliver promptly under chloroform. He urged the importance of rest, milk-diet, purgatives, and warm baths in preventing this complication. In the discussion upon the views previously advanced Tarnier expressed his great confidence in milk-diet as prophylaxis. He would use this not only with patients who had albuminuria, but with those who showed during pregnancy headache, sleeplessness, and other nervous disturbance. In his clinic from the year 1838 to 1887 the maternal mortality was 37%. From 1889 to 1891 he treated eclampsia with chloroform, chloral, and bleeding, with an increase in the mortality to 38%. His present treatment consists of bleeding, purgation, the use of chloroform and chloral, with rigid milk-diet, milk being given by a stomach-tube if necessary. Under this treatment the mortality had diminished to 9%. Since January, 1896, no case of eclampsia had developed in his clinic. Pamard emptied the uterus in these cases as rapidly as possible. He had found that chloroform could be used if necessary for 48 hours to prevent convulsions.

Audebert called attention to the importance of icterus as a prognostic symptom in these cases. In 34 eclamptic patients 4 had icterus, and of these 4, 3 perished.

Queirel, of Marseilles, had but 27 cases of eclampsia in 1200 labors. He ascribed this small number to the employment in his clinic of a milk-diet in all cases in which elimination was deficient.

Morisani, of Naples, drew attention to the fact that the death of the fetus is followed by the cessation of eclamptic fits and also of albuminuria. In the fourth and fifth months of pregnancy he would treat these cases by appropriate medicines. At the eighth month he would hasten labor with every possible means. He would employ incision of the cervix if necessary.

In closing the discussion, Charpentier urged that the effect of drugs be tried in each case before recourse be had to operation. When the conditions are favorable he would promptly use forceps or do version. When dilatation was not sufficient for either of these procedures he would wait and employ medicinal treatment, hoping that the death of the fetus would lessen the convulsions. He believes that the finger and hand should be employed for rapid dilatation.

H. M. Jones¹ urges the value of pilocarpin in eclampsia, and Appleby² that of guaiacol locally. J. P. Reynolds³ prefers prolonged etherization in eclampsia to the use of chloroform. [The depressing influence of ether upon the kidneys would seem to contraindicate its employment in this condition.] J. T. McShane⁴ makes a strong plea for the revival of venesection as a specific for puerperal eclampsia. [Venesection cannot be called a specific, but is of immense value in the plethoric type of cases.] Potter⁵ claims that if there is high arterial tension—vasomotor spasm—glonoin in full doses is valuable; while Marx⁶ also urges the free exhibition of nitroglycerin hypodermically. [In the operative treatment of eclampsia Dührssen's method of cervical incision does not grow rapidly into favor. Halbertsma's method of Cesarean section is only justified when there exists some insuperable mechanical obstruction. Mechanical dilatation of the cervix and the immediate extraction of the fetus appear to be the popular methods of the day, and if properly performed they are safe and efficient.]

Rigidity of the Soft Parts.—Instances of cervical dystocia are recorded by Clivio⁷ and Jefferiss.⁸ Jefferiss's case was one of total occlusion of the os uteri, relieved by puncture and digital dilatation. Clivio's case was one of cicatricial stenosis, the result of a previous operation for carcinoma. Dilatation was accomplished by incisions and the use of the Tarnier dilator, the fetus being extracted after craniotomy. Clivio discusses operations for the relief of carcinoma, and cites the opinions and experiences of twenty or more different authorities, reaching the conclusion that, in cases of carcinoma of the vaginal portion of the cervix in women who have not reached the menopause, hysterectomy is to be preferred to high amputation of the cervix. When pregnancy complicates carcinoma of the cervix, radical treatment, even if it does endanger the life of the fetus, is to be preferred to a partial operation or to the expectant plan of treatment based on the hope of saving the child.

Perineal Laceration.—G. Coronilas⁹ describes the following method by which he has been enabled to shorten labor, diminish pain, and prevent lacerations of the perineum. After proper antiseptic precautions the accoucheur's hands, and the perineum, vagina, and os uteri, are anointed with the following ointment: cocain, 3 gm.; antipyrin, 3 gm.; vaselin, 50 gm. Four fingers of one hand are then passed within the vaginal orifice, and semilunar movements are made, first on one side and then on the other, so as to dilate the perineum. After three or four such powerful movements the fingers of the other hand are introduced and the performance repeated. When the requisite degree of dilatation is achieved, the fingers are passed into the vagina until the index, middle, and ring fingers touch the os uteri, and the same movements made, the perineum being pushed outward with the palmar surface of the hand. A. Milne-Thomson¹⁰ records a central perineal rupture occurring in a young primipara, the tear not involving the sphincter ani nor the fourchet; the child weighed 6½ pounds. Lambertenghi¹¹ also records a case occurring in a primipara of 17 years. He appends a tabulated report of 91 cases of this abnormality, and various conclusions are drawn from this table. As regards the causation, some writers have sought it in an exaggerated curve of the sacrum, in an abnormal shape of the sacrum, in undue rigidity of the sacroiliac joints, in a very long and high pubes, in retrocession

of the pubic arch, and in abnormal approximation of the ischia. Others have thought that a very long perineum or an abnormally closed condition of the vulva was a potent factor. Some assert that irregular uterine contractions, which destroy the normal dilatation of the birth-canal, are an important factor. As regards the prevention of this accident, insertion of the fingers into the rectum and pressing the head strongly upward have been found efficient by some observers. Others modify the force of uterine contractions by the use of an anesthetic. Episiotomy and the use of forceps have been successful in some hands. In the 91 cases quoted but 1 death occurred, and this was indirectly the result of accident. Under anti-septic precautions and with immediate suture the prognosis for recovery is excellent.

Tumors in Labor.—Sevitsky¹ records a case of labor at term in which the fetal head was arrested by a dermoid tumor of the right ovary. The head was brought to the outlet by forceps, while the tumor, bulging through the anus burst the rectal wall. Its contents were emptied and the fetus then easily extracted, but it was dead. Finally the cyst was drawn down and amputated, the rectal wall being carefully sewn up. There was bad flooding during the third stage of labor, and the patient died in 33 hours of pelvic peritonitis.

Labor after Suspensio Uteri and Vaginofixation.—[The frequency with which backward displacements of the uterus occur, and the increasing use of surgical measures to relieve them, give an especial interest to the report of pregnancies occurring after the various operations for ante-fixation.]

C. P. Noble,² Grusdew,³ and Dorland⁴ have made a thorough study of the effects of these operations upon subsequent gestations and labor. Noble relates two cases of labor occurring in his own practice in which very grave difficulties were encountered, in one case necessitating the performance of a Porro operation. The cause of the obstruction was in both cases the same, and resulted from the fact that the anterior uterine wall and fundus had been fixed by sutures in such a manner that, when the uterus began to enlarge as pregnancy advanced, the fundus and anterior wall were folded on each other so as to form a tumor which occupied the brim of the pelvis. The posterior wall was in both of these instances dangerously thinned as the result of overstretching. The author was led to make a large number of inquiries among American obstetricians; but, curiously enough, could obtain no further evidence that ventrofixation of the uterus led to difficulties during labor. The conclusions he arrived at as the result of his investigations were: (1) that women subjected to this operation are less apt than others to become pregnant; (2) that pregnancy and labor are, as a rule, uncomplicated; (3) that inertia uteri is not infrequently met with; (4) that serious or insuperable obstruction to labor may be produced if the fundus and anterior wall of the uterus are imprisoned below the point of attachment between the uterus and abdominal wall. Noble points out that the operation for ventrofixation of the uterus is performed in different ways by different operators, and that on the method employed depends the presence or absence of difficulties at any subsequent confinement. He believes that the sutures should pass through the upper part of the anterior uterine wall, and that care should be taken that the line of attachment is not too broad or too firm. He alludes to the difficulties in delivery which have been met with after vaginal fixation of the uterus, and considers that from the obstetric standpoint the results have been disastrous. Grusdew reports the results of 123 operations of this character. In 50 of the cases a ventral, vesical, or ventrovesical fixation was performed, in 41, Alexander's operation, and

¹ Ann. de Gynéc. et d'Obstét., Aug., 1896.

⁴ Univ. Med. Mag., Dec., 1896.

in 32, vaginal fixation. In no case of abdominal fixation did relapse occur. Four of these patients became pregnant, one of them after 16 years of sterile matrimony. There was no unusual symptom during the pregnancy, except in one instance. In one case, at operation the uterus was found to be adherent to the inflamed right tube, which was removed. The uterus was then fastened right and left with silkworm-gut to the recti muscles, and with catgut to the vesical peritoneum. Beginning with the second month of pregnancy, there was occasional pain in the right side and straining at micturition. At the end of the fifth month examination by catheter showed the bladder to be situated in the pelvis, underneath the uterus, and extending well to both sides. The urine was perfectly clear. Two of these four cases had normal labors. In the other two pregnancy was not completed at the time of report. Alexander's operation was performed upon 41 women, of whom the subsequent history could be ascertained. It is worth noting that the ligaments were shortened a good deal, in most cases from 3 to 5 inches. There was a recurrence of the posterior displacement in 3 cases, in 1 of them only after labor. Pregnancy occurred in 23 of the patients operated upon, resulting in 5 miscarriages and 18 deliveries at term. One of these was with forceps. Several of the patients complained during pregnancy of more or less pain in the operative scars. Four of the patients treated by vaginal fixation became pregnant. Three of those upon whom Mackenrodt's operation was performed finished the pregnancy normally. In the fourth case the operation recommended by Dührssen, with opening of the peritoneum, had been done. In the second month displacement recurred, and was followed by abortion. In the light of his experience, Grusdew is inclined to reserve the abdominal fixation for those cases in which there are firm adhesions, or in which disease of the adnexa is suspected, preferring for all uncomplicated cases Alexander's operation. The vaginal operations are less advisable, in his opinion, because the strong attachment of the uterus to the vaginal wall is apt to disturb pregnancy, and if that goes on to term relapse is not uncommon. Of course, these objections are most potent in young married women.

Dorland has collected from medical literature every reported case, normal and otherwise, of pregnancy following ventrofixation up to December, 1896, numbering 179 instances. Of this series, in 120 cases, or 62.03%, a normal gestation was noted; in 111 cases, or 62.01%, labor was absolutely normal; in 68 cases, or 37.98%, both gestation and labor were normal; and in 111 cases, or 62.01%, some abnormality was noted, either in gestation, in labor, or in both. Pain more or less severe was experienced in the line of abdominal incision either during gestation or in labor in 16 cases (8.93%); excessive vomiting in 4 cases (2.23%); high position of the cervix at or above the pelvic brim in 10 cases (5.58%); threatened uterine rupture in 9 cases (5.02%); uterine inertia in 5 cases (2.79% of the cases of pregnancy and 22.79% of the cases of dystocia); abortion in 15 cases (8.37%); premature labor in 10 cases (5.58%); gestational disturbances in 15 cases (8.37%); and dystocia in 22 cases (12.29%); abnormal presentation of the fetus in 9 cases (5.02%); ear-presentation once (0.55%); breech-presentation twice (1.11%); transverse presentation 6 times (3.35%), an unusually large percentage of this malposition of the fetus. Version was required 9 times, and forceps 11 times, or in 50% of the cases of dystocia; 3 times Cesarean section was required (1.67% of the pregnancies), and retained placenta was noted in 3 cases. The fetal mortality was 17.87%, and the maternal 1.67%. Lindforst¹ records a case of twin pregnancy after ventrofixation. When 15 years of age the girl, before

¹ N. Am. Pract., Apr., 1897.

she began to menstruate, suffered from prolapsus uteri, the immediate result of lifting a heavy bundle of hay. The prolapse was complete, but she took no means to return the organ for several years. Then she entered a hospital and had what was termed anterior and posterior kolporrhaphy performed. The uterus remained in place but a short time, and 2 years later she came under the observation of the author. The prolapsus was complete, and the mucous membrane was much indurated and hypertrophied. The external os was so small that it could scarcely be detected. The uterus was suspended by the method of Leopold, and a perineorrhaphy by Tait's method. The patient made an uneventful recovery; the uterine sutures, of silkworm-gut, were removed on the 14th day. Eleven months later the patient was again seen and found to be in good condition and pregnant 7 months. The fundus uteri was found 3 finger-breadths above the umbilicus. The cicatrix of the abdominal wound was enlarged in length and breadth and distinctly pigmented. In the middle of the cicatrice the fixed point could be distinctly seen. The bladder was drawn up high, but caused her little inconvenience. Shortly before term she entered a lying-in hospital in labor. The liquor amnii escaped early and the head engaged, but the cervix remained tense and unyielding. The woman's strength began to fail, and it became necessary to deliver. Accordingly, the author made 3 deep incisions in the cervix and delivered with forceps. Another sac then pressed down in the vagina, and it was found to contain another fetus. A profuse hemorrhage occurred from the cervix, and it was necessary to resort to saline injections; but the patient quickly recovered, and passed a normal puerperium. Both children lived, and it was found that the uterus remained in position. The author attributes the difficulty in delivery to the indurated cervix. He does not advise ventrofixation for retroversion.

Successive Pregnancies in a Double Uterus.—Consolas¹ reports a labor in a primipara of 28 years, in which at the time of delivery he found 2 vaginal passages, each leading to a cervix. The left cervix was dilated with the amniotic sac. The right was closed. From the left the delivery occurred without complications, but with the aid of forceps. A second pregnancy occurred, which he also attended. In this he found that the left uterus was empty, the right being the seat of pregnancy. In neither delivery was the septum torn that divided the 2 parts of the vagina.

Delivery in the Moribund.—Decio² publishes a table of 18 labors in which women apparently in a dying condition were delivered *per vias naturales*: of these, 6 children, including 1 pair of twins, seem to have lived. Five were born dead. The remainder expired soon after delivery. Turning after various methods was exclusively the means employed in all of the cases. In 6 the mothers were suffering from eclampsia; of these, 5 recovered, including the twin labor case. Three had cerebral apoplexy; of these, 2 recovered. Two with advanced phthisis survived for a few weeks. Four were flooding from placenta prævia; of these, 3 were saved. One with pulmonary congestion recovered. One bleeding from an internal wound was saved, and 1, injured by a fall, died. Decio has also collected 19 cases of Cæsarean section performed upon dying women. All were graver cases than those in the table, and all died. In 13 cases the child was alive; 1 labor was of twins, making 14 children saved. In only 2 was the os more or less open.

Rupture of the Uterus.—Fatal cases are recorded by J. Saxl,³ Cullingworth,⁴ J. C. MacEvitt,⁵ P. A. Colmer,⁶ and Sherwood Dunn.⁷ Recoveries after

⁷ Pacific Med. Jour., July, 1896.

uterine rupture are recorded by MacEvitt,¹ C. H. Roberts,² J. N. Upshur,³ and Burger.⁴ Burger's was a remarkable case of rupture of the uterus in cross-birth. As the patient could not be taken to a hospital and assistance could not be obtained, Burger could do nothing more than make version and extract the fetus. After delivering the placenta the mother's intestines protruded through the rent in the uterus. These were replaced and the hand kept in the uterus until it contracted firmly. The rent in the uterus was tightly closed by its firm contraction, and but little hemorrhage followed. The patient did well until the sixth day, when her husband, while drunk, had intercourse with her violently. She recovered, however, from this and was delivered of a living child 9 months and 6 days after. The placenta was adherent to the site of the former rupture and was delivered manually. A year later the patient died of hemorrhage from adherent placenta before the midwife in attendance could summon a physician.

MacEvitt⁵ states that some ruptures are progressive and cannot be recognized until the completion of the disaster. Emphysema at the level of the hypogastric region caused by air in the connective tissue is a symptom not always present; when found it indicates a fatal termination. Roberts states that the child always dies when it escapes into the peritoneal cavity.

Inversion of the Uterus.—Cases of this rare accident are reported by H. S. Kilbourne,⁶ J. W. Walker,⁷ G. T. Harrison,⁸ G. Fowler,⁹ W. Lindley,¹⁰ and D. J. Brown.¹¹ Brown suggests as points of diagnosis between *inversio uteri* and uterine polypus the following: 1. The circular, not lateral, implantation of the pedicle; 2. The opening of the tubes upon the inferior portion of the tumor; 3. The special sensibility, sometimes accompanied by special contractility, that it offers to pressure and to acupuncture; 4. The half reduction that can always be made in inversions, never in polypi; 5. The absence of the uterus from its ordinary place, ascertained by rectal and vesical examination. As regards prognosis, Crosse says that one-third of the women with puerperal inversion of the uterus die either immediately or within a month.

FETAL DYSTOCIA.

Multiple Pregnancy.—A. Valenta¹² refers again to the extraordinary case of plural pregnancies reported by H. X. Boër in 1808. The patient was aged 40 years, had suffered from epileptic fits, and during a married life of 20 years had given birth to 32 children in 11 pregnancies. Twice she gave birth to quadruplets, 6 times to triplets, and thrice to twins. Twenty-six of the children were boys, 6 were girls. Twenty-eight were born alive and 4 dead. Her first pregnancy was at the age of 14 years and resulted in quadruplets. The mother herself was one of quadruplets, and her mother had a family of 38 children, and died in the puerperium after giving birth to twins. There was a hereditary history of plural births on the father's side, he being himself a twin.

Interesting cases of twin-pregnancy are reported by C. W. Branch,¹³ with hydramnios—about 220 oz. of water; Chambrelent and Chemin,¹⁴ with hydramnios, the 1st fetus presenting unilateral fusion of the two kidneys, the 2d

forming an omphalosite peracephalus; J. D. Todec,¹ a living and dead fetus existing together in utero for 1 or 2 months prior to confinement; J. S. Wight,² 1 fetus being developed to 7 months and the other to 5 months; the children were both female, there was a single chorion with 2 amnions, both of which were intact, and a common placenta (*uniorial twins*); and C. C. Henry,³ the mother being in a state of uremic coma for 40 hours, with convulsions and serious brain-disturbance, but ultimately recovering, and the twins being healthy. Kalnikoff⁴ reports the case of a woman whom he delivered of a twin 3 days after the spontaneous birth of its brother. He also removed both placentae. The puerperium was normal and both children lived.

A. L. Bailey⁵ records 2 cases of triplets, in one instance the children all being male, and in the other instance all female. Dorland, in Aug., 1896, saw a woman in her 8th month of pregnancy, who 3 weeks later fell into labor while on the street and was admitted to a hospital, where she gave birth to triplets, two boys and a girl.

C. C. Henry⁶ and M. Günsburg⁷ report instances of quadruplets. Günsburg's case was a peasant woman, 20 years of age, in the 4th month of her 1st pregnancy. Three of the fetuses were normal, the 4th was a monstrosity (see p. 460). Henry's case was a woman 39 years of age, in her 6th pregnancy, who went to term. There were 4 placentas with membranous connection, but no vascular communication; their combined weight was 3 pounds; the aggregate weight of the babies was 16 pounds, as follows: 1st, $3\frac{3}{4}$ pounds; 2d, $4\frac{1}{4}$ pounds; 3d, $3\frac{3}{4}$ pounds; and 4th, $4\frac{1}{4}$ pounds. Two were stillborn, and one eventually survived. [P. Charbonnier⁸ gives the proportion of quadruplets to single births as 1 in 400,000; Puech, 1 in 2,074,306; Plenk, 1 in 20,000. The combined tables of Descaner, Spengler-Ploss, Sichel, and Veit, including nearly fifty million births, give the number of quadruplets as about $2\frac{1}{2}$ to the million; in Switzerland, between the years 1881 and 1893 there was one instance in 1,108,092 births. During the last $2\frac{1}{2}$ years a few authentic instances have been recorded, notably one by Bousquet,⁹ one by Pergamin,¹⁰ and one by Stahl.¹¹

R. A. Hibbs¹² reported a case of quintuplets before the Obstetric Section of the New York Academy of Medicine at its May meeting. The patient had had 6 children previously, and had enjoyed good health up to the time of the present pregnancy. Three months before labor her physician noted that the abdomen was unusually distended. On April 29, at about the 8th month of pregnancy, she was taken in labor. In a few minutes the membranes ruptured and a child presented by the feet and was delivered. In a few minutes more a second child presented by the head and was delivered. Fifteen minutes later the third child presented by the feet and was delivered. The fourth presented by the feet and was delivered. The fifth also presented by the feet and was delivered. All were boys. Three of them lived only a few days, and the remaining two were living in May, when Hibbs saw them. There was only one placenta with the five cords attached.

As regards the management of twin labors, Stephenson¹³ concludes that multiple pregnancy is abnormal, and hence more dangerous than usual labor. He believes that different principles should govern these cases from those

which experience has recommended in the treatment of single pregnancies. He would consider the delivery incomplete when the first child was born and the second had not been expelled. With regard to the second twin, the risks are much greater than in single pregnancy for both mother and child, and hence interference must be practised. As regards infant mortality in twin labors, it is on the average $2\frac{1}{2}$ times greater than in single births; inasmuch as twins are usually smaller than the average child and their expulsion more easy, there must be other reasons that bring about the increased mortality. When the element of time is considered, it is found that $\frac{3}{4}$ of the cases end within the first $\frac{1}{2}$ hour without material assistance; 1 in every 4, however, requires artificial aid. The mortality of the second $\frac{1}{2}$ hour after the birth of the first child was 4 times greater than that of the first $\frac{1}{2}$ hour. If the duration of labor be prolonged a $\frac{1}{2}$ hour, the life of the second child is greatly imperilled. It is found that in the first-born of twins, if the head presents, the mortality is greater than in single births; but if the breech or foot presents, the conditions are much more favorable. In the second-born of twins the mortality in head-presentations is almost double. In the cases collected, where the second child was either transverse or in footling presentation, not a single one of these children was lost. To sum up the mortality by presentations, $90\frac{5}{10}\%$ of children lost were in head-presentations; $9\frac{5}{10}\%$ in breech; while there was no mortality in transverse and footling births. The practical conclusion of these studies lies in the fact that so soon as the first child is born the second should be immediately extracted by the feet. In this way the mortality for mothers and children will be rendered as little as possible.

Excessive Size of the Fetus.—A. E. Gallant¹ records a case of dystocia due to disparity between the size of the head of the fetus and the circumference of its shoulders (44 cm.—17 $\frac{1}{4}$ in.), the occipitofrontal circumference being 33.5 cm. (13 $\frac{1}{8}$ in.). In addition the mother was excessively obese, weighing 220 pounds, the pelvic fat interfering with the distention of the vagina. In 4000 deliveries at the Sloane Maternity the largest child measured 43 cm. around the shoulders.

Fœtus Papyraceus.—Bäcker² recently demonstrated at Buda-Pesth a fœtus papyraceus. The mother was a primipara, aged 28, and was delivered at term of a well-developed female child, nearly 19 in. long, weighing 6 lb. 12 oz. On the placenta was the chorion, which bore a second amniotic cavity containing the fœtus papyraceus. This blighted embryo appeared to have reached the 2d month of development. Bäcker preserved the membranes and the placenta as well as the fetus in a 4% solution of formaldehyd: they remained perfect, free from shrinking or opacity.

Goldberger³ reports a remarkable twin-labor. The waters broke and a fœtus papyraceus, amongst the smallest recorded in literature, escaped. It was $\frac{9}{10}$ in. long, and weighed 5 $\frac{1}{4}$ gr. The bones showed very well. The other twin, fully developed (delivery being at term) was born apparently without trouble. It had symmetric defects in the skin of the abdomen, about the level of the 12th rib in the anterior axillary line. The right was as big as a thalerpiece, the left was smaller. The edges were irregular, and from them radiated shiny, reddish cicatricial lines. These scars proved that the defects were not due to injury during labor. The base of each "defect"—a fetal ulcer, in fact—was granulating subcutaneous tissue, with scabs at certain points. Both were healed at the end of a fortnight.

Extraordinary Retention in Utero of the Fetal Head.—

¹ Med. Rec., Sept. 5, 1896.

² Centralbl. f. Gynäk., No. 28, 1896.

³ Ibid., No. 30, 1896.

Toth¹ records a case in which the attending physician pulled so vigorously upon the breech of an 8-months' fetus that its neck parted and the head remained in utero, despite all his exertions to remove it. The mother, a young tertipara, recovered with some fever, and enjoyed good health for a year. During this time, irregular hemorrhages and foul-smelling discharge continued, followed by the occasional discharge of bones. At the end of 16 months the cervix was dilated, and the large bones of the skull, which remained, were removed. They were extensively adherent to the uterus, and the free hemorrhage which followed their removal was controlled by tamponade. The patient made a quick recovery.

Dystocia due to Fetal Retention of Urine.—O. Saintu² reports the case of a woman upon whom it was decided to induce labor at about the 8th month on account of a contracted pelvis. Saintu delivered the head, shoulders, and thorax with ease, but the rest of the labor was conducted with great difficulty on account of immense distention of the fetal abdomen. The child did not urinate until the next night, when it passed a large quantity of urine, and catheterization removed more. The child died the next evening. At the autopsy the bladder was found to extend to the ensiform cartilage above, and laterally to the sides of the abdomen. The urethra was perfectly patent.

Breech Presentation with Extended Legs.—W. S. A. Griffith and A. W. W. Lea read a paper on this subject before the London Obstetric Society on Jan. 6, 1897. Seventeen cases were briefly described and the following conclusions arrived at: 1. The extension of the legs in incomplete breech presentations may be either primary or secondary. 2. In the primary variety, which occurs before labor has begun, the breech engages readily in the brim, and the diagnosis can be made. 3. In the secondary variety the extension occurs during labor. This form is more frequent than the primary. 4. This complication is more frequent in primiparæ, namely, 70% of the cases. 5. The prognosis, with regard to the child, is not worse than is that in pelvic presentations in general. 6. Cephalic version is advantageous before labor is advanced. It is not usually possible in the primary, but may be so in the secondary variety. 7. Most cases are delivered naturally. 8. Prophylactic reduction of the leg is required only in exceptional cases. 9. It is probable that flexion of the leg on the thigh is preferable to bringing down the leg into the vagina. 10. If aid is required in the lower part of the pelvis, the soft fillet will usually effect delivery.

OBSTETRIC OPERATIONS.

Induction of Labor.—Kossmann³ considers that the accidents that have occurred in the induction of labor by the injection of glycerin were caused by the drug being used in large doses for hygroscopic purposes, and not with the more physiologic purpose of stimulating the unstriated muscle. He has used glycerin injections in 2 cases with marked success. He concludes that the injection of 5 c.c. of glycerin into the cervical canal will bring on strong pains without leading to nephritis or any other ill-effect. It is free from the danger of infection which attends injection into the uterine cavity. The introduction of a colpeurynter into the vagina serves to keep up the pains when they have been started, and, therefore, makes further injection of glycerin unnecessary. Kossmann regards this method as being, next to simple vaginal douches, the most harmless method of inducing labor. T. A. Helme⁴ does

¹ Centralbl. f. Gynäk., No. 24, 1896.

³ Therap. Monatschr., June, 1896.

² Jour. de Méd. de Paris, July 12, 1896.

⁴ Lancet, p. 936, Oct. 31, 1896.

the same thing, injecting into the cervix, however, $1\frac{1}{2}$ ounces of pure glycerin.

Stieda¹ contributes an interesting paper upon the employment of elastic bags in inducing labor or abortion. He distinguishes two methods, in one of which the bag is placed within the cervix, while in the other it is carried above the internal os into the lower uterine segment. In connection with this treatment he employed frequent hot douches to soften the parts and promote dilatation. He describes in detail 5 cases in which labor was induced in this manner. In all, a living child was born, while the length of the induced labor varied from 9 to 24 hours, the average being 15 hours. In the case of several of these patients this was a much shorter labor than had occurred previously. In some cases it was necessary to use specula in introducing the bag, but in most this was not found essential. When it was desired to hurry labor traction was made upon the supply-tube through which the bag was filled, and the distended bag was slowly drawn through the cervix; when haste was not desired the bag was allowed to remain until expelled. The precaution was taken to force air out of the bag before its introduction and to fill it with sterile water. In addition to the induced labors, Stieda narrates 3 cases in which he induced abortion by the same method. Here he was equally successful, the abortions being concluded in about 7 hours, the use of the bag being necessary for between 1 and 2 hours. In cases in which traction was made upon the bag the pelvis of the patient was raised so that the traction was exercised downward and backward in the axis of the pelvis. The same method was employed successfully in a case of submucous myoma of the uterus in which the patient declined operation and in which the cervix was dilated; tenaculum-forceps were applied to the tumor, and traction made upon the forceps for 12 hours. At the end of this time it was possible to remove the tumor by enucleation.

Forceps.—A. D. Wilkinson² gives the following indications for the use of the forceps: 1. In all pelves in which the diameters are [slightly] below the normal measurements. 2. When the head is in an immovable position, with the chin fixed over the symphysis pubis. 3. When the head is in the superior strait, with the chin to the front. 4. When the head is locked at the pubis, but when flexion is imperfect and fixation of the frontal part of the vertex is the result. 5. When the face is fixed anteriorly, with the chin locked. 6. When the face is fixed laterally. 7. In transverse and oblique positions of the head. 8. When the head is laterally rotated and deeply fixed in the pelvis. 9. In great narrowness and rigidity of the soft parts, when the hand cannot be introduced, or when the fingers soon become exhausted on account of the constriction. 10. In too large heads—as hydrocephalus [this is doubtful]. 11. In placenta prævia and eclampsia. 12. When the extractive methods have been tried and proved insufficient. 13. When the fetus is dead. 14. When the head has been torn from its trunk.

[It is very remarkable how slowly any improvement, although a very real one, makes its way in this country. It is not too much to say that the advantages of axis-traction forceps have been definitely proved by theoretic and practical demonstration, and yet the number of physicians who use these instruments form but a very small proportion of the whole.] S. Milne Murray³ describes a new modification of his well-known forceps which permits of traction in the pelvic axis being made with still greater scientific accuracy. He points out that the ordinary axis-traction forceps only allow of traction being

¹ Monats. f. Geb. u. Gynäk., Bd. v., H. 3, 1897. ² West. Med. Rev., Oct. 15, 1896.

³ Edinb. Med. Jour., Sept., 1896.

made in the pelvic axis when the pelvis is normal, but that when the axis of the inlet is more vertical than usual, as in the justoinior pelvis, or more horizontal than usual, as in the flat pelvis, some of the force employed is lost unless provision be made to allow the line of traction to be varied to suit the requirements of the altered canal. Of course, in cases of abnormal pelvis, if ordinary forceps are used, the line of traction is still more faulty than with axis-traction forceps, and in order to do away with this "angle of error" he has devised a pair of forceps which will permit the line of traction to be altered to suit any given case of pelvic deformity. The forceps are identical with those used in the ordinary axis-traction instrument, and the traction-rods are jointed to them in the usual manner. These rods run down the back of the handles, and at a point halfway down they turn backward at a right angle, forming two horizontal bars $4\frac{1}{2}$ in. long, with graduations $\frac{1}{2}$ in. apart. A perforated block with a handle attached by a joint is slid along these horizontal rods and can be fixed at any point by a screw. By means of a sector which moves with the handle that position of the block on the horizontal rods

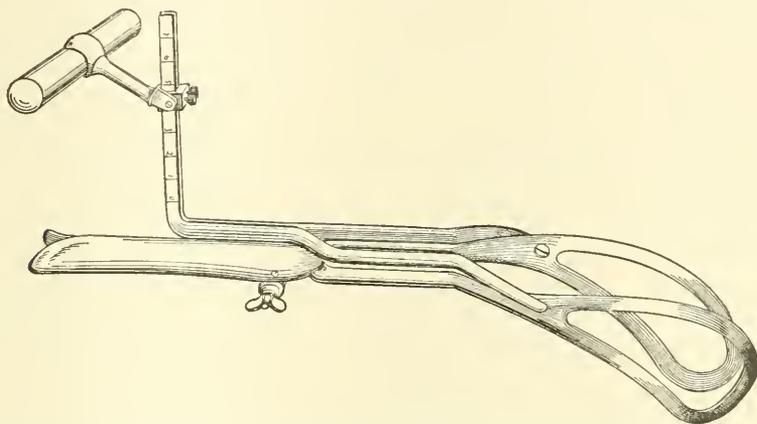

FIG. 34.—Murray's forceps with adjustable axis-traction (Edinb. Med. Jour., Sept., 1896).

can be determined which is necessary in cases in which the pelvic inclination is normal; but if the axis is more vertical than usual, the block is moved forward nearer to the handles, and if the axis is less vertical, it is moved backward away from the handles. By this means we can insure that in all cases the line of traction corresponds with the axis of the pelvis.

Murray¹ also advocates the use of forceps in cases of flattened pelvis in which the head presents transversely in the pelvic brim. He states that the choice of version in these cases has been based upon the belief that the forceps, applied in the anteroposterior diameter of the head, tend to compress it anteroposteriorly, and to cause a bulging of the transverse or biparietal diameter. This would increase the difficulty of extraction, as the biparietal diameter is already brought into relation with the smallest diameter of the pelvic brim. He doubts the truth of this belief, because he has shown by experiment that when the head is grasped over the occiput and forehead that the occipitofrontal diameter may be compressed $1\frac{1}{2}$ in. without increasing the biparietal. A vertical and not a transverse expansion results. The various segments of the cranium slide under each other in a telescopic manner. To

¹ Brit. Med. Jour., No. 1870, 1896.

succeeded in delivering the fetal head presenting transversely in the brim of a flattened pelvis the forceps must not only grasp the head in its anteroposterior diameter, but must also make traction downward and backward in the axis of the pelvis. The head naturally passes through the brim, in these cases, by an exaggeration of Naegele's obliquity, by which the posterior parietal eminence pivots against the promontory of the sacrum, while the anterior moulds itself against the pubes. Murray stated that he had delivered living children when the anteroposterior pelvic diameter was $3\frac{1}{4}$ in., and even as little as $2\frac{3}{4}$ in.

[The value of the Walcher position in pelvic contraction and forceps-operations is becoming more recognized.] W. E. Fothergill¹ finds that in about 30 cases measured by him the average increase in the diagonal conjugate gained by this position was 1 cm., the claim made by Walcher. He concludes that in high-forceps cases, and after perforation, the position saves—(1) the strength of the operator, (2) pressure on the head, (3) pressure on the symphysis, (4) pressure on the perineum by the forceps. In cases of difficulty at the brim not needing forceps, and in breech cases, the position saves—(1) exertion to the uterus and abdominal muscles, (2) pressure on the head, (3) pressure on the pubic symphysis. In all cases, with or without forceps, in which the perineum is in danger, extension of the legs at the hips is of advantage in relaxing the integument and subjacent structures at the vulvar orifice.

Version.—Mensinga² performs podalic version with the patient upon her abdomen. He claims for this method the following advantages: the outlet of the pelvis is directed above with the patient prone, giving the operator much more room for the insertion of the hand. The operator's hand and arm are in the position of pronation, giving a better use of the muscles and tactile sense. This posture also widens and opens the uterus and vagina, whereby the contraction-ring disappears. There is also less risk of bruising the soft parts. The patient has a pillow under the chest, her head being turned to one side, while the operator sits beside her, using either hand for version. By this posture two dangers are minimized: tearing the uterus from the vagina and air-embolism. Patients suffer less in this posture. [Version should always be done under anesthesia, and we cannot see any marked advantage to be derived from the foregoing procedure.]

Craniotomy.—Hergenhahn³ tabulates 46 cases of perforation of the after-coming head. In 25 of these the cranium was opened through the foramen magnum; in 2 the opening was through the neck; in 9 through the occiput; in 3 by means of the smaller fontanel; in 4 through a lateral fontanel; in 1 through the parietal bone; and in 2 by means of the base of the skull. In 29 cases delivery was accomplished by traction on the breech; in 9 the sharp hook was inserted in the opening of perforation for purposes of demonstration. In these cases rupture of the uterus occurred once; the cervix was torn 8 times; minor lacerations were not infrequent. The mortality was 5 in the 46 cases; 1 from eclampsia; from previous septic infection, 2; from hemorrhage and infection (ruptured hematoma of the vulva) and from repeated attempts at delivery and mutilation before admission to the hospital, 2. Hergenhahn found that craniotomy should be undertaken in suitable cases as soon as the fetus has perished. The head should be firmly fixed, after version, at the pelvic brim and steadied by an assistant. The cranium should be opened by some form of scissor-perforator through whatever portion is

¹ Brit. Med. Jour., No. 1870, 1896.

² Centralbl. f. Gynäk., Nov. 23, 1896.

³ Arch. f. Gynäk., Bd. li., H. 2, 1896.

most available. The patient is then put in Walcher's position, the finger of the operator is put in the fetal mouth, and by combined traction the brain is expelled and the head moulded and delivered. The prognosis in cases requiring this operation depends on the condition of the patient before operation, many of them having been lacerated and infected by previous attempts at delivery.

Additional cases are recorded by C. E. Purslow¹ and G. F. De Silva,² both of whom advocate perforation through the mouth. De Silva gives as the advantages of this method: 1. Safety and the ease with which the object can be accomplished without injury to the maternal parts, which often occurs when perforation is done behind the ear; 2. So much force is not required as in piercing the mastoid bone; 3. It easily breaks up the base of the skull. Purslow gives as its disadvantages: 1. The brain-matter will not flow so readily through the opening, but this can be easily overcome by passing the tube of a Higginson's syringe through the hole, and washing out the brain; 2. The pressure of the perforator on the roof of the mouth tends to cause extension of the head, in which case the mechanism of the delivery of the head may be interfered with, or the perforator may pass through the maxilla and into the orbit, not entering the cranial cavity at all, and even injuring the uterine wall.

Symphysiotomy.—[The wave of reaction has begun, and the operation is limited now to but a very narrow scope, largely because of the difficulty in its performance and because of its higher mortality than that of Cesarean section.] Cases are recorded as follow: Donald,³ 3 cases; Swift,⁴ the first case performed in Boston or its vicinity; Heinrichs,⁵ 1 case, recovery being retarded by a fistula which led to the symphysis, and opened near the mons veneris; it was accompanied by necrosis of the severed bones; ultimate recovery occurred with firm union at the pubis; F. R. McCreery,⁶ a case, followed by a fistula and slight separation of the symphysis, with ultimate good recovery; E. P. Davis⁷ and G. M. Boyd,⁸ each 1 successful case; E. A. Ayres,⁹ 1 case, the patient dying on the 33d day of pneumonia.

Hansen¹⁰ reports the case of a quartipara whom he delivered 3 years after a delivery by symphysiotomy. The patient had a contracted pelvis, with a conjugate of $3\frac{1}{4}$ in., and was delivered at her first confinement after great difficulty of a dead fetus, which had presented transversely. The second delivery was completed by symphysiotomy, the fetus presenting by the vertex but not engaging at the pelvic brim. Two years later she aborted at the third month, and a year after she presented herself to Hansen in an advanced stage of pregnancy. The general condition was good and locomotion normal, and she continued to perform her daily work. Upon examination it was found that the pubic bones were separated sufficiently to admit the tip of the little finger between them and that there was a marked motion between them in walking. Three weeks later she fell into labor. The fetus presented transversely and soon became impacted in the pelvis, but labor was easily terminated by version. After delivery the pubic bones were found to be separated more than $1\frac{1}{2}$ in. A firm pelvic bandage was applied. Five weeks later the woman was able to walk a quarter of a mile without discomfort. At the time the case was reported the bones were separated about $\frac{1}{2}$ inch.

¹⁰ Hospitals Tidende, p. 597, June, 1896.

W. Pooth,¹ following the suggestion of Frank, has performed artificial widening in 3 cases of contracted pelvis, inserting a piece of bone between the ends of the pubic bones to keep them separated. The operation is performed through a transverse incision across the symphysis. A piece of each pubic ramus and the anterior part of the symphysis are chiselled off, forming a plate about 3 cm. long and $1\frac{1}{2}$ cm. broad, and including nearly half the thickness of the bones. The posterior part of the symphysis is then separated and the child extracted. The ends of the pubic bones are freshened, and the new plate inserted and fastened by sutures, thus holding the ends of the pubic bones apart about 3 cm. In the 3 cases reported there was complete bony union at the symphysis and no pain or inconvenience of any kind in standing or walking. The diagonal conjugates before and after the operation were, respectively, as follows :

Before, $9\frac{1}{2}$ cm.	After, 11 cm.
“ $8\frac{3}{4}$ cm.	“ 10 cm.
“ $8\frac{3}{4}$ cm.	“ $10\frac{1}{2}$ cm.

Cesarean Section.—Cases are recorded as follows : W. R. Wilson,² a successful Säger operation, in a colored girl of 14 years, with an undeveloped nonrachitic pelvis ; Strebel,³ 10 Porro operations from Wyder's clinic at Zurich, with 1 maternal and 1 fetal death ; Béchet,⁴ 1 successful Säger operation ; Varnier and Delbet,⁵ and Pinard and Ségond,⁶ each 1 successful Porro operation, the first for complete retroflexion at term, and the second for advanced pelvic contraction ; Sinclair,⁷ 1 successful Säger operation ; C. N. Van de Poll,⁸ 3 successful operations upon the same woman, the last by Porro's method ; S. A. Bontor,⁹ and J. B. De Lee,¹⁰ each 1 successful Säger operation ; A. H. Buckmaster,¹¹ and G. M. Boyd,¹² each 1 successful Porro operation. Cases of postmortem Cesarean section with delivery of living children are recorded by Erdheim¹³ and H. S. Stearns,¹⁴ while Dührssen¹⁵ records a vaginal Cesarean section in a woman who had had vaginal fixation of the uterus. The operation consisted in opening the vault of the vagina and the uterus, performing version and extraction. Mother and child recovered, the puerperal period being but little longer than the usual one. The operation consists in enlarging the vagina, if necessary, by perineal incision, freeing the uterus from the tissues about the cervix, rapid incision of the posterior and anterior lips of the cervix as high as the internal os, followed by version and extraction. After the removal of the placenta the uterus is pulled down, tamponed, and the lines of incision sutured. If indications for removal of the uterus exist, this can be performed with facility.

Hirst,¹⁶ recognizing the fact that Cesarean section may be forced on the general physician in an emergency at any moment, has given a detailed description of its technic for his guidance. If there be time to make arrangements, a period of about 2 weeks before term should be selected. It is unnecessary to excite labor-pains beforehand. The patient should be given a full hot bath 2 days before operation, and should be kept in bed. Admin-

ister the following pill 3 times a day : \mathcal{R} Strychnin, gr. $\frac{1}{20}$; digitalis, gr. $\frac{1}{2}$; quinin, gr. 2. M. Secure movements of the bowels daily by 2 drams of Rochelle salt every evening. Examine the heart, lungs, and urine.

Day before Operation.—(1) Diet : gruel for breakfast, soup for dinner, milk-toast for supper. One glass of milk at 10 A. M., 4 P. M., 9 P. M. (2) Medicine : 5 P. M., afternoon before operation, 10 gr. of sulfonal in half a glass of boiling water cooled down to a temperature that permits of its being drunk, if the patient is nervous and has been sleepless ; 9 P. M., half an ounce of Epsom salts in a tumblerful of water. *Evening before Operation.*—(1) Cleanse the abdomen as follows : sterilize for 20 minutes at 240° F. one soft-bristled brush, absorbent cotton, half-dozen towels, gauze, binder, and a long gown. (2) The nurse's and doctor's hands are prepared as for operation : remove rings, scrub with brush, hot water, and tincture of green soap for 10 minutes, clean the nails with a nail-file, scrub the hands and arms with benzene and then with alcohol, immerse the hands and arms in bichlorid solution (1 : 1000) for 2 minutes ; then put on the gown. (3) The abdomen from the ensiform to the symphysis and from flank to flank is scrubbed with a soft-bristled brush, tincture of green soap, and hot water for 10 minutes, paying special attention to the navel and pubis. Wipe the razor with cotton and alcohol, shave the pubis, then scrub thoroughly with alcohol. Cover the abdomen with sterile gauze and apply the binder. *Morning of Operation.*—Give a cup of beef-tea at 7 A. M. The hands of the nurse are cleansed as described ; the articles are resterilized as described. The same cleansing of the abdomen is repeated as described, with the addition that before the alcohol-scrubbing the abdomen is scrubbed with benzene. Wring out a sterile towel in 1 : 1000 bichlorid solution and cover the abdomen with the towel. Put over it a thick layer of sterile cotton. Apply the binder. Catheterize the woman just before anesthesia with a sterile glass catheter in an aseptic manner. Give a vaginal douche of one quart of 1 : 4000 mercuric chlorid solution, followed by a little sterile water. If the bowels have not opened freely, give an anema,—a pint of soapsuds and a dram of turpentine. *The Operation.*—With a large scalpel make a free incision from 2 inches above the umbilicus to just above the symphysis. Enlarge the abdominal opening downward as low as possible with scissors. While an assistant makes the wound gap deliver the womb from the abdominal cavity. The assistant now approximates the edges of the abdominal wound as closely as possible around and above the cervix, at the same time squeezing the latter with outspread hands. Incise the uterine muscle to the extent of an inch with a few rapid but light strokes of the knife, taking care not to wound the membranes. With a rapid movement of the left arm and hand tear the uterine wall down to the internal os. Rupture the membranes, detach the placenta if it be in the way, and push it aside. Seize the child by the most accessible part and deliver. Drop the child with the placenta attached into a sterile sheet spread out over the outstretched arms of an assistant, whose duty it is to revive the child if necessary, and cut the cord. Then follows an easy hysterectomy : ligation of the ovarian arteries and arteries of the round ligaments ; application of clamps ; cutting of the broad ligaments ; preparation of the peritoneal flaps ; amputation of the womb ; ligation of the uterine arteries ; and over-sewing of the stump, which is dropped. The abdominal wall had better be closed by the beginner with close-set interrupted sutures.

PATHOLOGY OF THE PUERPERIUM.

Puerperal Sepsis.—C. J. Cullingworth¹ calls attention to the fact that there is an undiminished mortality from puerperal sepsis in England and Wales, and that notwithstanding the general spread of the Listerian method. In the pathetic statistics given one sees the mortality greater in the decade, 1885–95 than in the previous one, 1875–85, and this worse than 1865–75. The disease has been almost completely banished from the lying-in hospitals; hence the trouble must lie in the methods of obstetricians at large. [A more earnest incentive to prophylaxis in puerperal sepsis cannot be imagined than this startling fact.] Kortright² contributes a paper on the puerperal mortality in Brooklyn. He finds that during 1895, 224 women died of puerperal causes in the city of Brooklyn; of these, 76 deaths were due to puerperal sepsis. The largest number of these cases occurred during the winter months—a fact often observed by others. Many of these deaths were among persons employing midwives instead of physicians. The writer concludes from his study that the puerperal death-rate is lower among Americans than among foreigners and their children. Septic infection is more often fatal where midwives are habitually employed. Kidney-failure is most frequently observed among those who use alcoholic drinks.

Hirst,³ in speaking of the etiology of puerperal sepsis, dwells upon the importance of a careful study of the bacteriology of the vaginal secretions. He remarks that the vagina becomes infected almost immediately after birth. In a normal condition it contains no pathogenic bacteria, and has strong germicidal powers, which serve to guard a woman against infection. These powers depend, as far as our present knowledge goes, upon the presence of a special bacillus and upon the products of its life-processes; upon the leukocytosis due to chemotactic action; upon phagocytosis; upon the germicidal powers, perhaps, of the anatomic elements of the vagina, of the cervical mucus, and of the bloody discharge during menstruation and the puerperium. During and after labor mechanical safeguards of the most effective kind are furnished against infection. These are the discharge of the liquor amnii, washing out the vagina; the passage of the child's body; the descent of the placenta and membranes, and the bloody discharge which follows. Moreover, should the vagina exceptionally contain pathogenic bacteria, they are likely to be in a condition of diminished or absent virulence, in which state they will not be productive of disease unless the tissues with which they come in contact are reduced in vitality. Bearing these facts in mind, it would seem that the common practice of relying upon vaginal douching for disinfecting the vagina before labor is faulty, not to say foolish. It has been clearly demonstrated that the injection of an antiseptic fluid into the vagina will not destroy pathogenic germs there, and will, moreover, rob the woman to a certain extent of the safeguards against infection that nature provides for her.

E. S. Jackson⁴ says that puerperal fevers can only be exactly classified when we can classify the various bacteria to which they owe their origin. Among causes, he insists we must admit autoinfection, since the vagina often contains these bacteria; generally, however, they are introduced from without from lack of antiseptic precautions. The most rapidly fatal cases are due to streptococci; staphylococci seem to be less virulent. The gonococcus seems to produce tubal suppuration and pelvic peritonitis rather than high temperatures and general peritonitis, and chronic rather than acute cases. Faulty sanitation

¹ Lancet, Mar. 6, 1897.

² Brooklyn Med. Jour., No. 2, 1897.

³ Univ. Med. Mag., Oct., 1896.

⁴ Intercol. Med. Jour. Austral., Feb. 20, 1896.

can hardly cause puerperal sepsis, though it may render the system less resistant. Remy¹ speaks of the relationship existing between meconium and sepsis, and insists that the membranes should never be ruptured before complete dilatation of the os without very special reasons. When the waters escape and meconium is mixed with the liquor amnii, the uterine cavity is soiled. If labor be prolonged and antiseptic precautions impracticable, the fluid mixture decomposes rapidly and septic infection becomes certain. Remy distinguished the above conditions in 7 labors under his observation. The mortality was 42%. Antiseptic precautions are, therefore, especially needed in cases of premature rupture of the membranes.

Saft² believes that prophylaxis against puerperal infection should consist in diminishing internal examinations as greatly as possible, and in observing absolute antisepsis. G. W. Dobbin³ reports a fatal case of puerperal sepsis due to infection with the bacillus *aërogenes capsulatus*.

As to the question of puerperal self-infection, Jewett⁴ refers in particular to the relation of pus-producing germs primarily present in the body of the pregnant woman to childbed sepsis, and draws the following conclusions: 1. There is no clinical proof that puerperal infection can occur from normal vaginal secretions. 2. All childbed infection in women previously healthy is by contact. 3. Prophylactic vaginal disinfection as a routine measure is unnecessary, and even in skilled hands is probably injurious. 4. Its general adoption in private practice could scarcely fail to be mischievous. 5. In healthy puerperæ, delivered aseptically, postpartum douching is also contraindicated. 6. A purulent vaginal secretion exposes the woman to puerperal infection. 7. In the presence of such discharges at the beginning of labor the vagina should be rendered as nearly sterile as possible. 8. Concentrated antiseptic solutions should not be used, and the process should be conducted with the least possible mechanical injury to the mucous surfaces. 9. In case of highly infectious secretions the preliminary disinfection should be followed by douching at intervals of 2 or 3 hours during the labor. 10. The safest and most efficient means for correcting vicious secretions is a mild antiseptic douche, repeated once or more daily for several days during the last weeks of pregnancy. 11. Clinically, the amount of discharge, its gross appearance, and that of the mucous and adjacent cutaneous surfaces usually furnish a sufficient guide to its treatment. 12. Probably unclean contact within 24 or 48 hours is an indication for prophylactic disinfection.

Puerperal Purpura Hæmorrhagica.—T. W. Schafer⁵ reports the case of a primipara who was delivered by forceps under aseptic conditions. On the fourth day she developed a temperature of 104°, attended with rigors. There was no pain in the abdomen nor tympanites. Examination revealed an exudate near the right broad ligament. Purpura hæmorrhagica appeared suddenly in the lower extremities, below the knees, during the third week following parturition. The attack lasted 2 weeks, the spots alternately appearing and disappearing during final days. Treatment was empirical, in connection with that of the existing pelvic condition.

Puerperal Herpes.—Lutaud⁶ describes 5 cases of acute pyrexia occurring between the second and fifth days after confinement or abortion, in each of which the febrile attack terminated by an eruption of facial (usually labial) herpes. In each case the attack was ushered in by rigors, the pyrexia was

¹ Rev. Méd. de l'Est., Mar. 15, 1896.

⁶ Jour. de Méd. de Paris, July 12, 1896.

severe, rising to 103° to 104° F., and in each case, after the appearance of the herpes, the patients rapidly recovered. Lutaud calls attention to the disquieting nature of these symptoms and their liability to be confounded with those of grave septic infection, and suggests that when strict antiseptic precautions have been taken in the conduct of labor or abortion, and no local condition can be found to account for the subsequent rigor or pyrexia, it may be well to remember that the explanation of these phenomena may sometimes be found in the occurrence of the herpetic disorder described.

Treatment of Puerperal Sepsis.—[Serumtherapy of puerperal sepsis has commanded a vast amount of attention during the year, and thus far has not given the desired results. In fact, it appears to be a very doubtful method of procedure.] The most interesting debate was that before the Obstetric Section of the College of Physicians of Philadelphia, on March 18, 1897. Hürst reported 3 cases in which the serum gave no results. He stated that the older plans of treatment will answer in $\frac{2}{3}$ of the cases, in which, if the serum were used, the results might be attributed to it unjustly. Norris reported a case successfully treated with the serum; G. E. Shoemaker a case in which it failed; E. P. Davis, 1 case in which it gave excellent results, and 2 cases in which it failed; and Baldy a case of acute puerperal lymphangitis and phlebitis in which he attributed the death to the use of the serum. J. B. Shober gave a statistical report of 21 cases, with 4 deaths, a mortality of 19.04%. In the discussion A. C. Abbott remarked that the earlier the period at which the serum is injected the more likely are favorable results to ensue. He thinks that the opinion that Marmorek's serum is specific for all conditions resulting from the invasion of pyogenic streptococci is unwarranted. E. E. Montgomery was of the opinion that one should not confine himself alone to the use of antitoxin, but should employ all agents which past experience has demonstrated are beneficial in the condition. In cases in which the poison is not due to the streptococcus the antitoxin is contraindicated and would be prejudicial, since one would be adding another poison which may be sufficient to destroy the patient's life. A bacteriologic examination should be made in every case of sepsis. R. C. Norris remarked that the serum should not be considered as a cure-all any more than should the curet. It probably has but a limited field of usefulness. Dorland, from a study of the literature of the subject, had concluded that the serum-treatment has not met with a flattering degree of success. The unfavorable results may be attributed to the following three obstacles that must be overcome: 1. The *difficulty in ascertaining in any given case the precise variety of septic infection that may be present*. In cases of mixed infection it is reasonable to believe a favorable result should obtain only upon the administration of a mixed serum. 2. The *intensity of the infection* in any given case must be taken into consideration, and the treatment by means of the serum regulated thereby. The morbid effects of the infection must increase *pari passu* with the degree of virulence, and upon this factor will depend the amount of blood-alteration present. The general rule is that the earlier the treatment is instituted the better will be the results obtained. The serum, then, should be administered until the desired effects are produced. 3. Another cause of failure must be attributed to the *inability of the blood to regain its proper constitution after grave disorganization has been brought about through the presence in it of the toxins of the germ and of the germ itself*. It stands to reason, therefore, that in all the cases in which the serum-treatment is employed it should from the very first be supplemented by the use of some such remedy as nuclein, which will restore to the blood its nucleinic acid, and thus its defensive properties, whereby it may

successfully resist the further action of the poisonous element. Hirst¹ says that although the antitoxic serum for puerperal sepsis be prepared with the greatest care, there is a possibility that it may contain dangerous toxins, and that the treatment may be more dangerous than the disease. There is a streptococic infection so virulent that the antitoxin will be of no avail, no matter how strong it may be. There is an undeterminable time in streptococic infections when the serum will be used too late. The antistreptococic serum has no antagonistic power over other pathogenic microorganisms. It is not easy to determine during life whether the infection is pure or mixed, though the majority of puerperal infections are due to streptococci. Therefore, the use of the serum must be more or less empirical. Finally, the clinical results of serumtherapy for puerperal infection have not been at all encouraging. Hirst thinks that the plan of treatment for the artificial production of hyperleukocytosis is much more promising. Hofbauer² reports the results of employing Horbaczewski's nuclein in 7 cases of puerperal infection, with favorable results in some cases.

Bar and Tissier³ have employed the serum in 16 cases, 7 of whom died. In most of the cases this treatment was combined with intrauterine irrigation and curettage. In 1 case the authors attribute the death to the serum; they point out that it is absolutely necessary to make a bacteriologic examination of the uterine discharges before using the serum. In addition to the foregoing, the following cases treated by serum-injections have been recorded during the year: J. D. Williams,⁴ 6 cases, 1 resulting fatally; Reddy,⁵ 1 successful case, in which the treatment was followed temporarily by hematuria; Gaulard,⁶ 2 cases, 1 resulting fatally, the death being attributed to the use of the serum; W. Edmunds,⁷ 1 successful case; R. R. Law,⁸ 1 successful case; T. H. Moorehead,⁹ 1 successful case; P. Coleman and T. G. Wakeling,¹⁰ 1 successful case; J. Adam,¹¹ 1 successful case; G. H. Mapleton,¹² 1 successful case; C. Coombs,¹³ 1 fatal case; C. E. Douglas,¹⁴ 1 case in which the serum had no effect, the patient ultimately recovering under other treatment; Letrain,¹⁵ 1 successful case; A. Veitch,¹⁶ 1 successful case; S. C. Fowler,¹⁷ 1 successful case; A. J. Sharp,¹⁸ 1 successful case; H. L. G. Leask,¹⁹ 1 successful case; McKerron,²⁰ 3 cases, 1 resulting fatally; Chaleix,²¹ 1 fatal case; Ballance and Abbott,²² 1 successful case. At a discussion on this subject at the Paris Obstetric Society, 39 cases were reported by Charpentier²³ treated by the antistreptococic serum, with 22 recoveries and 17 deaths. In only 25 cases was the disease confirmed by bacteriologic examination. Of these, in 16 the streptococcus alone was found, and 9 recoveries are recorded; in 8, streptococci in combination with staphylococci or bacterium coli, with 4 recoveries; while in 1 case the Löffler bacillus was noted. Dubrisay related a case of puerperal fever in which the fever developed on the third day, and pure cultures of streptococci were obtained from the cervix. After 4 daily injections of Marmorek's antistreptococic serum the lochia were found free from streptococci, although the tem-

perature did not fall till 4 days subsequently. Shortly after the last injection the patient had an alarming attack of dyspepsia.

Pozzi¹ suggested another method of serotherapy, consisting in intravenous, followed by hypodermic injections of sterilized water containing sodium chlorid in the proportion of from 7 to 10 in 1000 at a temperature of 104° F.; of this solution from 2 to 5 liters may be injected in the 24 hours. The *rationale* of this treatment is that, in the first place, by raising the intravascular pressure it increases the patient's power of resistance; in the second place, time is given to the blood-making organs to produce new blood-corpuscles for phagocytosis, and to the kidneys to eliminate the toxins.

Kahn² reports his results in the treatment of septic puerperal endometritis by the intrauterine injection of steam. The apparatus consists of a kettle heated by an alcohol lamp, to which are attached a thermometer and a hose terminating in an intrauterine applicator having a hollow stem or handle. The thermometer should register 200° C. before the steam is used. He is accustomed to begin with steam at a temperature of 100° C. for 2 minutes, then allowing the temperature to rise to 115° C. for 1 minute. The higher the temperature of the steam the better is the result. Very little complaint of pain is made by patients; in some cases uterine contractions caused after-pains. In cases in which pieces of placenta or membrane have been left within the uterus they must be removed, either by the fingers or curet, before the steam is used. An intrauterine douche is usually employed for 2 or 3 days after the use of the steam. Kahn concludes that the steam increases the sensitiveness of the uterus, stimulates contractions, causes the foul odor of the lochia to disappear, and in no instance have bad after-results been observed. The advantages claimed for this method are its efficiency in destroying bacteria within the uterus, and also its favorable effect upon the general condition of the patient by stimulating the circulation of the blood and lymph.

Baldy³ records a case of abdominal section for puerperal septicemia. He remarks that in general it may be said that when there is a puerperal salpingitis with resultant pelvic peritonitis, without pus being present, it is permissible to delay operation, keeping the patient under observation. In puerperal cellulitis, that variety in which the infection has found its way from the uterine cavity through the lymph-channels and blood-vessels into the surrounding connective tissue, the problem is a more difficult one. If the tubes and ovaries be distended with pus, abdominal section and removal of the offending organs are indicated; a large proportion of the infiltrated area is thus reached, and drainage of the remainder is favored. Another equally difficult group of cases includes those in which no disease of the pelvic peritoneum, tubes, or connective tissue is demonstrable by examination, and yet absorption of septic material is taking place from the uterus. When intrauterine douches and the application of carbolic acid and gauze-packing fail to relieve the symptoms hysterectomy should be promptly performed. R. R. Kime⁴ claims that hysterectomy for puerperal infection has but a limited field of usefulness, as in septic metritis, multiple abscesses in the uterine wall, and thrombophlebitis, if it is possible to be positive in the diagnosis. In doubtful cases he claims that drainage is to be preferred. [The surgery of sepsis puerperalis is a mooted question, and no hard-and-fast rule can be given for all cases. The matter was thoroughly discussed in the last number of the *Year-Book*, and the stand then taken is applicable to-day.]

Gonorrhœa in the Puerperium.—A most important contribution on

¹ Sem. méd., July 3, 1896.

³ N. Am. Pract., Sept., 1896.

⁴ Canad. Pract., Aug., 1896.

this subject is made by A. H. Burr,¹ who dwells upon the fact that many cases of sepsis depend upon a previous infection with gonorrhœal virus. These cases frequently present symptoms of rheumatoid arthritis during the pyrexia. The majority of males (Ricord estimated 80% for France, and Noeggerath believed the same ratio held good for New York City) have been affected at some period of life with gonorrhœa, and Noeggerath held that 90% of males so affected remained uncured, and of every 100 women who had married men formerly affected with gonorrhœa hardly 10 remained well. Prince reported that 60% of the blind in Jacksonville, Illinois, were the victims of ophthalmia neonatorum.

Postpartum and Puerperal Hemorrhage.—In speaking of the prevention of postpartum hemorrhage Atthill² believes that, to be of any use, ergot should be given for several hours before the termination of labor. He concludes that when ergot and strychnin are given previous to the termination of pregnancy in women having a marked tendency to postpartum bleeding, that this bleeding is prevented; that when so given in ordinary doses no injurious effect on mother or child is observed, but that the commencement of labor seems somewhat delayed. Such practice makes the involution of the uterus more perfect, and hence avoids postpartum disease. Unless the uterus is already acting, this treatment will not bring on premature labor or induce abortion; in cases of threatened abortion ergot and strychnin act as uterine tonics, preventing abortion if the ovum be not blighted; if, however, the ovum be dead, this treatment tends to secure its complete expulsion. [The use of strychnin in this way can be commended; we would hesitate, however, to recommend ergot in any condition prior to or during labor.]

Tarnier³ stated that the treatment of postpartum hemorrhage was largely diversified and depended upon an accurate diagnosis. All hemorrhages after labor are not of the same origin, but may be classified under two heads: (a) hemorrhages from the cervix or vagina; (b) hemorrhages from the uterus itself. Treatment differs in the two classes of cases. In the former, the diagnosis being made and the vaginal tear recognized, it is seen that the uterus is small, hard, and retracted, and there is no necessity to bring about its contraction. Local compression at the point of injury for a certain period will suffice to arrest the hemorrhage. Sometimes it is not possible, on account of the presence of considerable quantities of blood, to find the bleeding spot in the vaginal fundus, and it is then best to tampon the vagina as carefully as possible.

Schaeffer⁴ agrees with those who distrust gauze as a material for uterine tampons in cases of flooding. It often acts, he claims, as a capillary drain, and takes up much blood. He now uses non-absorbent gauze, prepared by impregnating it with gutta-percha. It can be mixed with iodoform or airol. By rolling it up into a ball it can be passed into the uterus, which it distends without absorbing any more blood. As a tampon the gutta-percha gauze retains its elasticity. E. S. Bishop⁵ urges the importance of compression of the aorta as a rational and efficient means of checking postpartum hemorrhage. If this is done, the hemorrhage is at once absolutely stopped, and without needless hurry the secondary measures can be employed to empty the uterus of clots in order to bring about firm contraction. The ulnar surface of the closed hand should firmly compress the aorta against the spine, while the other hand is free to compress the uterus. T. Laird,⁶ however, remarks that such com-

⁶ Ibid., Dec. 19, 1896.

pression shuts off so many important vessels that it is practically stopping the blood-supply to half of the body, and he would substitute pressure upon the vessels that supply the uterus near the point where they enter that viscus. He does this by introducing the right hand into the womb, while with the left hand he compresses the uterine and ovarian arteries against it on either side, the fingers grasping the left side and the thumb the right. [Herman's method of manual compression is safer and easier of performance.]

Paraplegia after Parturition.—Two cases of this exceedingly rare complication are recorded by J. R. Leeson.¹ Both patients had neurotic tendencies, both labors were precipitate, and both patients had adherent placenta which had to be artificially removed; in neither case was the bladder or rectum affected. Both cases lasted about the same time, the severer symptoms persisting for about a week, and both recovered slowly and entirely. The paralysis in both cases was probably due to overstimulation and subsequent temporary exhaustion, the shock of the precipitate labor being considerably increased by the prolonged and severe intrauterine irritation necessarily attendant on the removal of the adherent placenta.

Puerperal Osteomalacia.—J. Ritchie² remarks that the pain and muscular weakness which are noticed in the early stages of this disease often lead to a diagnosis of rheumatism or disease of the spinal cord. The fertility of the patient is not diminished—in fact, some have even asserted that it is increased. Ritchie divides the treatment into medical and surgical. Phosphorus and bone-marrow may in some cases lead to a cure. Oöphorectomy cannot be said to produce a definite result, as a relapse may sometimes occur after the operation. The rapid disappearance of the pain after the operation is very noteworthy. If the patient is pregnant, the operation should be postponed until after delivery, unless the disease is progressing very rapidly. There is no evidence that better results follow hysterectomy than oöphorectomy.

Puerperal Thrombosis.—Cases of puerperal pulmonary thrombosis are recorded as follows: T. R. Atkinson,³ 1 fatal case occurring 2½ months after delivery; Zweifel,⁴ 1 fatal case on the 12th day after delivery; Lackie,⁵ 1 fatal case on the 12th day of the puerperium; and P. von Tiesenhause,⁶ 3 fatal cases, the only instances met with in 25 years in the St. Petersburg Maternity in 50,000 labors; in all 3 cases the symptoms appeared when the patient first left her bed after labor, in one on the 4th, in another on the 6th, and in the third on the 7th day. Von Tiesenhause regards whiteness of the lips, followed later by a cyanotic color, as a very characteristic symptom. [Reported cases of this complication show that it occurs most often before the 14th day after birth. It usually follows exertion, and is sometimes not fatal when thrombosis is but partial, in many cases accompanied by peripheral thrombosis also. Beyond immediate stimulation with ammonia and ether nothing can be done for serious pulmonary thrombosis. When a puerperal patient becomes easily faint and breathless she must be kept upon her back, all exertion absolutely avoided, and her nourishment carefully administered. Mental exertion and shock are also potent factors in causing this complication.]

Cases of gangrene of the leg in puerperal women are reported by T. Oliver,⁷ 2 cases; and E. R. Rouse,⁸ 2 cases, both recovering after amputation. In Oliver's first case right brachioptegia with transitory difficulty of speech

occurred 14 days after a normal confinement, and was succeeded by popliteal thrombosis and consequent gangrene of the foot and leg. Amputation above the knee was followed by recovery. In the second case pneumonia appeared 4 days after confinement, and a few days later endocarditis was discovered, followed by embolism of the right popliteal artery. The leg was amputated above the knee, and death occurred 19 days later from pneumonia and exhaustion.

Puerperal Polyneuritis.—Cases are recorded by E. G. Cutler,¹ Köster,² G. Elder,³ W. H. Wells,⁴ J. H. W. Rhein,⁵ and A. Kennedy.⁶ Elder points out that in many instances there is a distinct history of fever during the puerperium; such cases are undoubtedly septic in origin.

Pathology of the Breasts.—A case of true *agalactia* is recorded by J. I. Edgerton,⁷ the patient's breasts never showing any engorgement, involution of the uterus and the puerperium being otherwise normal. Her mother and sister had shown the same peculiarity in their pregnancies.

Lactation-atrophy of the uterus is treated of by Vineberg.⁸ He states that a true process of atrophy goes on quite independently of even relative debility or anemia. In women who remain feeble after labor or become weak from any cause, external or internal, and in patients who are anemic before pregnancy, the uterus tends to remain large. Subinvolution is, and has long been recognized as, a morbid condition. Vineberg finds that when involution goes on to its full completion the uterus is reduced to a size smaller than that of the non-parous organ. *Postpuerperal superinvolution* is principally seen in nursing-women, and from this circumstance has been termed "lactation-atrophy." It is normal and desirable and is temporary, becoming permanent under rare and unfavorable circumstances. When the lying-in woman cannot suckle, the medical attendant should try to bring about superinvolution. Vineberg believes that this course will save her from the development of a host of maladies due to subinvolution.

PHYSIOLOGY AND PATHOLOGY OF THE NEWBORN.

Variations in Weight in the Newborn Child.—Schaeffer⁹ reports his investigations upon this subject in the Heidelberg clinic. His material was 592 healthy infants, observed on the 7th to 14th day after birth, 94 of them being studied daily. It was found that but 14½% of these children had made good by the 7th day their initial loss in weight, while 41% had made good the loss or exceeded it by the 14th day. 44½% weighed less 2 weeks after delivery than when born. The lowest weight was seen upon the 3d day, and the greatest gain from the 10th to the 12th. The greatest variation was seen in boys rather than in girls. Young and slender primiparæ gave birth to the lightest children, showing the least tendency to increase in weight. The same was true of mothers who had worked hard during pregnancy, or had been ill. Well-nourished women between the 20th and 29th years of age gave birth to the heaviest children. The character of the mother's recovery from childbirth had little to do with the weight of the child. The development of the father and the peculiarities of race affected the weight of the child considerably. A reason for the loss of weight in the first few days was

⁹ Arch. f. Gynäk., Bd. 52, H. 2, 1896.

found in the consumption of tissue to maintain the body-warmth. In the first 3 days, when but little fully formed milk is obtained, the excretion of uric acid is greatest. So soon, however, as milk-diet becomes established the quantity of urea increases in the child's urine. Premature children showed greater variations in weight and temperature and in the excretions. The children of tuberculous and syphilitic mothers failed to gain in weight. Icterus resulted from the consumption of tissue to maintain body-warmth. It was furthered by a lack of water in the organism and was often observed in weak, premature, or sick infants. It was also seen in cases in which the meconium was slow in coming away. Artificially fed children increase far less in weight than do those who nurse.

Infantile Syphilis.—An interesting case of post-conceptual syphilitic infection toward the end of pregnancy is recorded by E. Welander.¹ [This is also known as **placental or intrauterine** infection, and is the least common method of transmission of the disease.] Cases are also recorded by A. Post.² Couetts³ finds a syphilitic mother much more potent in infecting than a syphilitic father. Marasmus and congenital atrophy of the secretive and absorptive surface of the intestinal tract are considered among the most important symptoms of inherited syphilis. While first symptoms commonly appear in the second month, they may be delayed 12 months. Visceral diseases (enlargement of the spleen and liver) are found in most cases; bone-lesions are less often observed; pain is often absent in syphilitic epiphysitis; suppuration is rare, and is usually seen in the long bones in children old enough to walk. Couetts has found inherited syphilis very feebly contagious, while acquired syphilis is actively so. Jolly⁴ reports the case of an infant, 19 days old, who died of purpura hæmorrhagica, in whom autopsy showed intestinal ulceration and lesions characteristic of congenital syphilis. Other possible causes of these phenomena were carefully excluded in making a diagnosis.

Albers-Schönberg⁵ gives the results of his studies in the diagnosis of fetal syphilis in the Leipzig clinic. He finds, in common with others, that the mere appearance of sanguinal maceration is not proof that the fetus perished from syphilis. Considerable increase in the weight of the liver and spleen, with increased weight of the placenta, indicates syphilis. On microscopic examination the blood-vessels of the placenta are much encroached upon by an abundant growth of connective-tissue cells. Gradual occlusion of the vessels and anemia and fatty degeneration result.

Melæna Neonatorum.—Swoboda⁶ narrates a number of cases of infants dying with passive hemorrhages from the nose, mouth, and intestine. In a number of these postmortem examination revealed the lesions of congenital syphilis. In others septic infection occasioned by the gonococcus was the primary cause of the bleeding. In others a meningitis had developed without the lesions of syphilis. No cause other than a mechanical one from pressure upon the head, or excessive coughing or straining, could be found for the condition. He also reports several cases of bleeding from the nose in infants, in which bacteriologic examination showed the presence of the bacillus of diphtheria as a cause. [His interesting paper serves to illustrate the fact that melæna is a symptom only, whose cause must always be sought before the pathology or treatment of a given case becomes evident.]

Icterus Neonatorum.—Knöpfelmacher⁷ has studied the icterus of the

¹ Nordiskt Medicinskt. Arkiv, Mar., 1896.

⁷ Ibid., No. 43, 1896.

newborn, and the relation which the condition of the red blood-cells bears to this phenomenon. His conclusions are essentially as follows: in the first weeks of life the number of red blood-cells is not influenced by a condition of icterus. Variations in the number of red corpuscles depend upon changes in the quantity and quality of the blood-plasma. The resisting power of the red corpuscles at birth seems to be fully that possessed by these cells in the adult, and does not seem to be lessened by icterus, however intense. The microscopic examination of the blood of the newborn in these cases shows, during the first days of life, no sign of erythrocytes; but, on the contrary, gives only indications of a vigorous building-up of red blood-cells. [The conclusion of these studies is, in general, that the condition of icterus in the newborn does not influence essentially the red blood-cells.]

Asphyxia Neonatorum.—Schultze¹ draws attention to 2 conditions requiring treatment in asphyxia of the newborn, in which different methods of treatment are indicated and in which it is most important that a differential diagnosis be made. In the first condition the child is blue, its heart is beating, and but a mild stimulation of its skin-reflexes is required to bring about respiration. Sprinkling the chest with cold water is quite sufficient in most of these cases to cause efforts at breathing. In the second class of cases the asphyxia is profound, and the medulla has become so paralyzed that its powers of reflex stimulation are wellnigh exhausted. The most efficient method of rousing this nervous center consists in rhythmic alterations in the vascular tension of the great vessels and the heart. This is best brought about by swinging the child by Schultze's well-known method for 8 or 10 times at intervals of 1 minute, and afterward placing the child in a warm bath. Schultze thinks that the employment of this method produces quite as much result by varying the vascular tension as it does by forcing air into the chest.

G. C. Barker² records a shoulder-injury resulting from this method, the *infraspinatus* and *teres minor* muscles being ruptured.

Calliano³ describes a new method of artificial respiration which he has practised with success in cases of asphyxia. The patient is placed in Sylvester's position, and the arms are then drawn up so as fully to expand the thorax, and then fixed above and behind the head by tying the wrists together. In this position respiration is induced by simply pressing with the hands on the thorax some 18 or 20 times a minute. The advantages claimed for this modification of Sylvester's method are: (1) its greater simplicity; (2) the much smaller amount of labor required and lessened fatigue of the operator; (3) the absence of danger from contusion of the shoulder-joints; (4) the ease with which such a method could be taught to and practised by uneducated and untrained people.

Obstetric Paralysis and Injuries to the Child during Labor.—Walton⁴ has found, in dissecting the brachial plexus of the newborn infant, that the plexus is in close apposition to the sharp, inner edge of the clavicle. The suprascapular nerve leaves the plexus much higher up, passing outward and backward to the suprascapular notch. Walton believes that this nerve is independently stretched in the separation of the head from the shoulder during birth, the distal point of fixation being the suprascapular notch or the outer edge of the suprascapular spine. It is observed that the muscles supplied below the spines of the scapulæ are most often injured; the rotation of the head, which brings the occiput under the pubes, brings the plexus forward against the clavicle also, shortening the distance from the emerging point of

¹ *Centralbl. f. Gynäk.*, No. 37, 1896.

² *Lancet*, May 8, 1897.

³ *Gaz. degli Osped. e delle Clin.*, Aug. 16, 1896.

⁴ *Boston M. and S. Jour.*, No. 26, 1896.

the plexus-root from the spine and also the suprascapular notch. [So far as statistics are available they bear out what Walton has stated. The paralysis usually affects the arm upon the side opposite to that to which the occiput was directed during labor, in the first position paralysis of the right arm being most often observed.] As regards prophylaxis, Walton suggests that the second stage of labor be made as short as possible.

Hiebaum¹ refers to a case of labor in a dutipara at the 8th month of pregnancy in which podalic version was resorted to on account of placenta prævia. The child could not be revived, and was found to have suffered a fracture of the occiput and of the vertebral column. On incising the tentorium nothing could be found of the cerebellum but quite a small fragment; the remainder was found suspended in the form of white particles like sand in about 20 c.c. of bloody serum in the left pleural cavity. Schultze² notes how in many cases of children suffering from mental or nervous diseases it has been found that at their birth labor was difficult or at least prolonged.

Ritter's Disease.—Dorland³ reports a case of this curious and exceedingly rare dermic condition of the newborn. The fact that another child in the family had suffered from scarlatina during the later months of gestation, and the well-recognized predisposition of the fetus in utero to acquire the zymotic diseases, are strong reasons for believing that there was in this instance an association between the two diseases. The treatment of the dermatitis should consist in the application of some emollient ointment, as of ichthyol, resorein, or boric acid, protection of the denuded surface with cotton, and the administration of good milk and tonics, with proper attention to hygiene.

GYNECOLOGY.

By J. MONTGOMERY BALDY, M. D., AND W. A. NEWMAN
DORLAND, M. D.,

OF PHILADELPHIA.

Principal Features of the Year's Work.—The intimate relationship that exists between the nervous system and the sexual apparatus of woman is becoming more clearly appreciated, and the discussion upon this interesting feature of gynecology is probably one of the most important steps that has been taken within recent years in this department of surgery. The baleful influence of gonorrhœa in the male is also being brought more prominently before the profession, and the importance of regulating prostitution, not in the woman only, but also in the male, cannot be too highly emphasized. Organotherapy in gynecology cannot as yet be said to hold a very prominent or suggestive place. It is, however, of interest to note the results of experimentation in this line, as in the treatment of uterine fibroids, the phenomena of the menopause, and the various ovarian neuroses. Rectal exploration, as the examination of the urinary tract, is a comparatively new field of study, and will probably develop into just as valuable means of diagnosis as has the latter. The question of bicycling for women is still *in statu quo*, and the arguments for and against constitute most interesting gynecologic reading. Except for the further development and refinement of technic, gynecologic surgery has undergone no radical change. There may be noted a slight inclination of popular favor toward the vaginal route of pelvic exploration, but as yet this has not become pronounced.

PRELIMINARY AND GENERAL CONSIDERATIONS.

Neuroses and Neurasthenia in Women.—A very valuable discussion on the relations of nervous disorders in women to pelvic disease¹ was held at the College of Physicians of Philadelphia Feb. 3, 1897. From the standpoint of the neurologist, S. Weir Mitchell dwelt upon the subjects of epilepsy, insanity, and hysteria. Epileptic attacks are apt to return at the menstrual period with greater frequency than at others, but in no cases seen by him have ablation of the ovaries and termination of menstruation cured an epilepsy. He has never sanctioned such operations when the appendages were sound. Temporary cessation of epileptic attacks is common after operations or changes of environment and habits of life. The insanities of women present a somewhat different case. In women insanity of various types occurs in which the menstrual period is sometimes the originative and sometimes the determinative cause of the mental disease. Because an insane woman is usually worse at her period is no reason why the flow should be stopped by operation any more than that this measure should be resorted to for epilepsy.

¹ Univ. Med. Mag., Mar., 1897.

That the climacteric puts an end to these disorders is an old delusion; in fact, the change of life is quite as likely to make them worse. A great many aggravated cases of hysteria show disease of the pelvic organs, which is so apparent as to make recovery after removal of the ovaries and tubes seem probable. A large percentage of these cases are not made better by operation, but, on the contrary, are often made worse. He is inclined to think that postoperative traumatic insanities are more common after pelvic operations than after others, and this insanity he believes is due to the anesthetic. C. K. Mills remarked that pelvic disease or disturbance is sometimes due to mental or nervous disease. Thus, during the progress of melancholia menstrual disorder or even amenorrhœa is not infrequent. A true epilepsy, a true hysteria, or a true melancholia is never absolutely caused by pelvic disease. Neurasthenia, however, in some instances seems to be directly traceable to pelvic disease. Gynecologists should become familiar with certain cases of obsession or monomania, in which pain is referred to perfectly healthy organs. The pains are psychic—in the head, and not in the pelvis. He recalls 3 distinct forms of mental disorders subsequent to pelvic operations: (1) a form of acute mania, (2) delusional insanity, and (3) a form of querulous melancholia. Wharton Sinkler said that operation was not resorted to so often now as formerly in neurotic women. A deplorable number of such operations have been done, with poor success. In Paris, since 1883, 40,000 ovariectomies or hysterectomies have been performed, and during that time about 500,000 were done in all France. Of 300 cases of operation for the relief of neuroses and psychoses collected by Krämer, in 100 the result was doubtful or unfavorable. If pelvic disease exists, it often aggravates all nervous symptoms; but in many instances the mental disorders and ovarian neuralgic pains seem to be rather the result than the cause of the existing nervous disease. F. X. Dereum believes that pelvic disease is concerned in but a small percentage of the cases of neurasthenia and hysteria in women. Such potent etiologic factors as neuropathic heredity, improper education, overwork, the worries incidental to household duties, the care of children, the daily frictions of life, are too often overlooked. How little local organic disease of itself acts as a factor in the causation of hysteria is shown in the case of uterine carcinoma, in which neurasthenic and hysterical symptoms are notoriously absent. In the male neurasthenic and hysterical conditions cannot be ascribed to pelvic disease. If pelvic disorders are concerned at all in the production of neurasthenia, it must be the spurious or symptomatic form (*neurasthenia symptomatica*). If the pelvic organs really play a rôle in the etiology of neurasthenia and hysteria, it is largely because gynecologists have created that rôle. Among the symptoms presented by hysterical women the one deserving especial attention is the so-called ovarian tenderness or inguinal pain, most marked on the left side when pressure is made. This in reality is situated in the skin and tissues of the abdominal wall, and not within the pelvis, as can be demonstrated by placing one finger on the spot externally and one in the vagina, the finger-tips being approximated. In his opinion operations upon the pelvic organs should be limited to actual diseases, as pyosalpinx and malignant affections. J. H. Lloyd remarked that modern science has almost entirely abolished the idea that hysteria has its seat in the uterus. He does not agree with Mills, however, that hysteria can never be caused by pelvic disease. It is conceivable that it might be started by a diseased ovary, an ovarian tumor, extensive cervical lesion, or lesions of the pelvic floor. It must be recalled, however, that the operation of castration in the female is sometimes followed by grave hysterical troubles, in such a case the very operation designed for relief becoming in turn an exciting cause of

still more profound trouble. Another aspect of the case is the fact that some serious nervous condition may arise in cases of real pelvic disease. Thus, a patient may undergo a perfectly proper operation, and may develop insanity as a result of it. This insanity may take the form of melancholia or that of confusional insanity, and there is probably some septic condition that is the primary disturbing cause in these cases to produce the mental condition. B. C. Hirst remarked that a neurasthenic woman, her family, or her physician, will almost surely impute the nervous symptoms of the patient to disease of the sexual organs. A large majority of neurasthenic patients (four-fifths) give an entirely negative result on pelvic examination, except for the ill-development of the sexual organs which is such a constant accompaniment of a feeble nervous system in women. In a small minority of neurasthenic cases the nervous disorders do seem to have had their origin in some pelvic lesion, and slowly disappear when the pelvic disease is cured; but it is usually necessary to unite with the gynecologic treatment a "rest-cure." E. E. Montgomery, while admitting that not infrequently we find patients treated for pelvic lesions in whom the symptoms are thereby aggravated, said that, on the other hand, we find many cases who are subjected to rest-treatment without effective result, for the reason that there is a local lesion which manifests itself as soon as the patient resumes her normal relations. This neglect of consideration of the pelvic lesions seems to be more marked on the part of neurologists. A woman suffering from a mental disease is, at least, entitled to a careful pelvic examination, and any pelvic lesion found should receive appropriate treatment. C. P. Noble remarked that arrested development is the fundamental cause of many cases of nervous diseases simulating diseases of the sexual organs in women. Women with such imperfect development have an unstable nervous system, and are not vigorous or normal women. Many of them have had chlorosis in girlhood. He has seen very marked functional disease of the nervous system caused by operations on the pelvic organs. Remarks prejudicial to operative treatment act by suggestion upon neurasthenic and hysterical patients; neurologists should bear this in mind. G. E. Shoemaker takes it for granted that reputable gynecologists are not given to removing healthy organs for nervous symptoms or for pain only. J. M. Baldy¹ remarked that if it be concluded that in a given case of hysteria pelvic disease does not enter further than as one of many groups of symptoms, the case belongs more properly to the neurologist. He regards cases of hysteria as rare which are dependent exclusively upon abnormalities of the sexual organs, but believes that anatomic changes and abnormal irritation of the sexual organs are conditions especially fitted to cause hysterical manifestations. In true hysteria it is folly to resort to surgical interference. If one symptom in such women is cured, another takes its place; ovarian pains are replaced by painful stumps, backaches continue, and the general nerve-reflexes are increased by the addition of the depressing nerve-storms of the menopause.

Gonorrhœa in Women.—According to B. Gordon,² gonorrhœa in women manifests itself in the following forms: vulvitis, Bartholinitis, urethritis, vaginitis, metritis, perimetritis, parametritis, salpingitis, oöphoritis, and peritonitis. Sometimes the disease extends from the urethra, causing gonorrhœal cystitis, ureteritis, and nephritis. Also gonorrhœal proctitis, arthritis, phlebitis, endocarditis, pleuritis, meningomyelitis, and conjunctivitis are met with. Albuminuria is said to be observed quite frequently in the acute form of the disease. Neisser³ calls attention to the difficulty of formulating a positive

¹ Phila. Polyclinic, July 18, 1896.

² Med. Rec., Nov. 21, 1896.

³ Arch. f. Dermat. u. Syph., Bd. 37, H. 1 and 2, 1897.

diagnosis as to the gonorrhœal origin of disease of the adnexa, although this is not so in inflammation of the external mucosa, the secretions of which escape externally. He urges the importance of making a rectal examination. The so-called "creeping" gonorrhœa of women, caused by gonococci of lessened virulence, has no well-proved existence. Even from the most chronic cases extremely virulent gonococci can be obtained. Sanger,¹ taking up the subject of residual gonorrhœa in women, states that after the disappearance of gonococci in the secretions certain manifestations may remain. The period during which gonococci may persist is not known. It is evident from examination of relatively fresh tubal and ovarian abscesses that in these closed spaces the gonococci do not long survive. It is possible they may disappear from the mucosa of the external genitalia, since lesions are often found in whose discharges gonococci are not discoverable. Sanger gives a rather elaborate description of these residua of gonorrhœa, including among others a macular vulvitis and sclerotic adenitis, urethritis, periurethritis, kolpitis, endometritis, metroendometritis, and salpingitis. He holds that the greater number of rectal strictures are of gonorrhœal origin. Bumm² denies that gonococci lose their virulence, and holds that infection from an old case, if planted on healthy mucosa, produces an acute attack. He states that the gonococci may persist and remain virulent in the genital tract for 5 or 10 years. He still believes that the gonococcus is a pure mucous-membrane parasite, remaining in chronic cases quite superficial, and only exceptionally penetrating into other tissues and acting as the ordinary pyogenic microorganisms do.

Schultz,³ during the year 1895, carefully examined 174 patients from the venereal department of a hospital for the gonococcus. The organism was sought for in the vulva, vagina, urethra, cervix, uterus, duct of Bartholin's gland, and rectum. Microscopic examination was the only method employed. The examination for gonococci was made many times in each case. He concludes that to make a diagnosis the clinical symptoms are not sufficient, but the proof is found in the presence of the gonococcus. Gonococci were found much more numerous in the urethral than in the cervical secretion, and therefore urethral gonorrhœa is of greater importance; infection most frequently takes place from the urethra. It results that when there is cervical gonorrhœa or adnexal disease gonorrhœa of the uterus is not always present. As regards other microorganisms contained in the cervical canal and uterine cavity, he agrees with the investigations of Stroganoff, that the hyaline mucus of the canal and uterine cavity is free from bacteria. In the writer's opinion the treatment should be prophylactic and local.

Of the earlier symptoms of gonorrhœal, as well as of nonspecific, salpingitis, E. M. Madden⁴ contributes an interesting paper, but advances nothing new.

Macular kolpitis, according to Sanger,⁵ is characterized by dark-red spots disseminated over the walls of the vagina and the cervix uteri, more particularly where there are neither folds nor papillæ. In *chronic gonorrhœal granular kolpitis* granulations are found in the same regions, at the apex of which the red color is more intense, and which are distinguished from the nodosities of acute granular kolpitis of pregnancy by their being smaller and harder than the latter. These are best treated by applications of a 50% zinc chlorid solution. For gonorrhœal vaginitis Schultz⁶ advises local treatment. For cervical gonorrhœa he employs intrauterine injections, never using more than 8

⁴ Lancet, Aug., 1896.

⁶ Ibid.

minims and allowing the excess to escape. The best injection, he says, is a 10% solution of silver nitrate; with this treatment the secretions soon become hyaline and diminish in quantity, and the gonococci disappear. The treatment is not contraindicated in chronic, but in acute inflammatory disease of the adnexa. Colic results only in those cases in which the external os is stenosed. [This is not a universal experience. Uterine colic is very prone to result from the use of silver nitrate injected intrauterine, stenosis or no stenosis.]

Both Neisser¹ and Gordon² especially recommend the salts of silver (argentamin, argonin, argentum nitricum, actol, itrol), hydrargyrum oxycyanatum, and ichthyol, in the local treatment of the disease. The silver salts destroy the gonococcus, and while penetrating deeply into the tissues do no harm to them. Canova³ believes there is no remedy so promptly curative as ichthyol. He uses injections of 0.5% in water with the most satisfactory results. De Smet⁴ has obtained excellent results from the use of formalin, washing out the vagina with a 2-3% solution. Piéry⁵ recommends the use of nascent carbonic acid in gonorrhoeal vaginitis.

Rectal Gonorrhoea in Women.—Baer,⁶ among 191 cases of gonorrhoea in women, noted 67 in which the rectum was involved, gonococci being found in the discharge from the bowel. While infection may result directly from unnatural coitus, the writer believes that in the majority of cases it is due to contact of the vaginal discharge with the rectal mucosa, especially in women with deep perineal lacerations. Infection through thermometers or rectal tubes is doubtful. Few of the patients presented any marked local symptoms, unless there was an ulceration at the anal orifice. These complained of burning pain during defecation, with discharge of pus and blood. Condylomata and eczema were rare. On inspection the rectal mucosa was seen to be deeply congested, the folds swollen and glistening, with erosions which bled easily and were covered with pus. A deep ulceration was found only once, and proctitis in 2 cases. The treatment consisted in irrigation of the rectum twice daily, through a speculum, with a 3% solution of boric acid, followed by mercuric chloride 1:8000, in order to destroy the gonococci, half a liter of each being used. The erosions were touched with argentamin, 2% solution. Ichthyol suppositories were also used with good effect.

The Rectum and the Female Reproductive Organs as Related in Disease.—J. P. Tuttle⁷ urges the importance of careful examination of the rectum in cases of obscure and intractable pelvic disease; also in diseases of the digestive tract and lower portion of the spinal cord. Certain cases of pyosalpinx and uterine displacement are characterized mainly by rectal symptoms. Tumors of the uterus, especially fibroids of moderate size, frequently make themselves felt at first through rectal symptoms. Prolapse of the ovary often presents marked symptoms of rectal disease, such as dull aching in the back and sacral region, pain at and following defecation, congestion of the rectal mucosa, constipation, and sometimes hemorrhoidal tumors. The effects of pelvic cellulitis upon the rectum are little understood by the profession in general. Cripps has called attention to its influence in causing stricture through the production of spasmodic contractions and consequent shortening of the levator ani muscles. The extension of the acute inflammation into the rectal wall, the deposit of plastic material about the gut, its ligaments, and bloodvessels, the adhesions between the rectum and uterus with its appen-

⁷ N. Y. Polyclinic, Sept. 15, 1896.

dages, are all influential in restricting the physiologic action of that organ, and in causing both reflex and organic diseases of it. In all obscure diseases of the rectum, immobility of the uterus, or history of pelvic inflammation, with thickening and inelasticity of the vaginal vault, should have a marked influence upon our procedure. The proper treatment of the results of the cellulitis will in the majority of cases relieve all rectal symptoms. Adhesion of the ovary may be responsible for these symptoms. This organ becomes inflamed, the adjacent peritoneum is involved, and attachment between it and the colon or sigmoid takes place (more properly speaking, the adhesion generally occurs at the mesocolon). If the inflammatory condition be checked at this point, no rectal symptoms of importance will ensue. If, however, the process goes on, bands of adhesive elastic material will be thrown out over the intestine to the mural peritoneum of the iliac fossa, and, when this has been reached, forming a bridge or stricture-band across the intestine which will persistently contract and produce all the symptoms of high stricture of the rectum. Malignant disease of the uterus in its beginning frequently presents symptoms of rectal disease. Diseases of the uterus and its appendages not only simulate rectal disease in producing symptoms referred to that organ, but they sometimes produce actual organic diseases in it. Displacement of the uterus or ovaries, especially prolapse and retroversion, or anteversion with enlarged cervix, and deposit of plastic material from inflammation, are not infrequently the exciting causes of rectal congestion, inflammation, fissure, ulceration, and hemorrhoids. They act first by obstructing the venous circulation of the gut, and, secondly, by exciting a more or less constant spasmodic contraction of the circular fibers of the levator ani and sphincter of the rectum. This congestion and spasm soon lead to hypertrophy of the sphincters, and they then act as a stricture of the anus and produce obstinate constipation with all its consequent rectal, intestinal, and digestive symptoms. Ulceration, both rectal and anal, results from these conditions, and fistula or cicatricial stricture may follow the ulceration. The influence of uterine diseases upon the rectum is no less interesting than that of rectal diseases upon the reproductive organs. Internal hemorrhoids, ulceration of the rectum, prolapse of the third degree, fissure in ano, inflammation and ulceration of the crypts of Morgagni, may all simulate disease of the uterus and its appendages. A. B. Walker¹ emphasizes the value of examination of the sigmoid flexure of the colon, especially for fecal impaction.

AFFECTIONS OF THE VULVA AND VAGINA.

Kraurosis Vulvæ.—Peter² reviews the literature on kraurosis vulvæ, reports a case, and more thoroughly investigates its pathologic anatomy. He writes that Breisky, in 1885, first described 12 cases of this peculiar disease, and gave it the name kraurosis. Breisky observed an atrophic contraction of the skin of the vestibule, labia minora, the frenum and prepuce of the clitoris, the inner surface of the labia majora and the border of the perineum. Often, however, only part (one side or posteriorly) of these structures was involved. The skin of the vulva appeared stretched and the normal folds were obliterated; the kraurotic tissue was small and glistening, and of a dull-gray color, with the surrounding tissue reddish-brown. In all cases the disease developed slowly and unobserved, and itching was a symptom in only 4 of the cases. The symptoms of which the patients complained were mostly

¹ Ann. of Gyn. and Pediat., Dec., 1896.

² Monatsch. f. Geb. u. Gynäk. Bd. iii., H. 4, 1896.

due to the vestibular stenosis. They presented themselves for treatment because cohabitation had become impossible, or because of tears and painful fissures. Since this first paper cases have been reported by Fleischmann (8), Janowski (6), Heitzmann, Ohmann-Dumesnil, Hallowel, and Bartels. The cases described by these authors in no way differed from those of Breisky until Orthmann reported 8 cases (1894) seen in Martin's clinic. These patients complained of burning and vulvar tenesmus; but it was impossible to determine whether these were the result of itching or pain caused by an inflammatory process. The pain was constant and much increased during micturition and defecation.

The disease has been seen at every age after puberty, in nulliparæ as well as multiparæ, and its etiology cannot be concluded either from the history or observation of the progress of the disease. Orthmann found a small round-cell infiltration of the corium, most marked in the deeper portion, extending to the subcutaneous tissue, with a high grade of atrophic change in all parts of the skin. The involution-process was particularly seen in the corium, which was sclerotic. The epidermis, glands, hair-follicles, and blood-vessels were much smaller than normal. The nerve-tissue was unchanged.

The symptoms of which the writer's patient complained differed in no way from those described. Microscopic sections were prepared by hardening in alcohol, sublimate, and Flemming's solutions, and by Benda's method, and suitably stained. From this investigation, which was most complete, the results of each method being described, he concludes that kraurosis vulvæ in its early stage is a chronic inflammatory hyperplasia of the connective tissue, with a disposition to cicatricial contraction, inflammatory edema of the superficial corium and epidermis, and degeneration of the elastic tissue. As a result of this chronic inflammation and new-growth the other elements of the skin are secondarily affected, and because of the degeneration of the elastic tissue the tears and fissures result. He agrees with Orthmann that the nerve-tissue is not involved, but says that it must have been affected in those cases complaining of pain. He believes that kraurosis should be classified with the other diffuse connective-tissue hypertrophies of the skin, to which group, according to Kaposi, scleroderma and elephantiasis arabum belong. All cases reported have been relieved or cured through dilatation, medicinal applications, ointments, and sitz-baths. [As regards the results of treatment, one must bear in mind that it is the almost universal experience that this disease is exceedingly difficult to cure—a cure most frequently falling short of a surgical removal of the parts; even then the results might be more encouraging than they are. In view of these indisputable facts the above statement as to the cure in all cases must be accepted with reservation.]

Pruritus of the Genitalia.—H. Robb¹ remarks that in treating a case of pruritus the main thing is to discover the cause. Thus, there should be examined (1) the external genitals for skin-eruptions; in doing this it will be well to obtain scrapings and examine them with the microscope for parasites. (2) There should next be examined the cervix for signs of leukorrhœa, and to ascertain the general condition of the uterus and appendages. (3) An examination should be made per rectum. (4) Chemical and microscopic examination of the urine should never be omitted. The presence of enlarged sebaceous glands or any signs of malignant disease should be carefully looked for. Hemorrhoids or fissures of the anus should be treated, and the vulva should be kept free from all irritating discharges. The general health of the patient should never be forgotten. When the vulva is dry, too frequent bathing should be

¹ Therap. Gaz., Sept. 15, 1896.

avoided and the surface should be kept moist, being treated, not with evaporating lotions, but with ointments. Suppositories containing codein or opium and hyoseyamus at night will often give the patient relief. Local applications include silver nitrate (2% solution), ointments containing 2 to 10% of salicylic acid, a mixture of chloroform 1 dram to olive oil 1 ounce, solution of carbolic acid (2%), and a solution of morphin acetate (12 gr. to the oz.). Internally, potassium bromid and belladonna tend to decrease irritation of the peripheral nerves. Ruge¹ adds disinfection of the genital region with mercuric chlorid. According to Cumston,² antipyrin is sometimes of service in calming attacks of pruritus. 50 centigrams are given before dinner and the same dose at bedtime. [And yet, after all is said and done, we are forced to admit that in the majority of cases of pruritus vulvæ the cause cannot be definitely settled, and the treatment must of necessity be empirical. And it must be further admitted that not infrequently the cases remain uncured until nature and time see fit to relieve them.]

Vulvitis and Vaginitis.—According to Marfan,³ the complications of *gonorrhœal vulvovaginitis of little girls* may be grouped under three headings: 1. Those by propagation; 2. Those by inoculation; 3. Those by general infection. Under the first group are included bartholinitis, Rocaz observing a case in an infant of 10 months; phlegmonous vulvitis; anorectal gonorrhœa, which is very rare, Horand reporting 4 cases; involvement of the urinary passages, being here confined usually to the anterior portion of the urethra, although very rarely a cystitis may result; infantile cystitis is nearly always coli-bacillary, succeeding to an enteritis or rectitis, the diarrhœic fecal material soiling the vulva and the bladder becoming infected by way of the urethra; involvement of the internal genital organs, uterus, ovaries, tubes, and peritoneum. Metritis exists in a goodly number of cases; isolated salpingitis and ovaritis are rare. Peritonitis consecutive to infantile vulvovaginitis is very grave; Marfan has observed 2 cases; it may be acute and rapidly fatal; very rarely it may be acute and yet be cured; or it may take the form of subacute or chronic adhesive pelviperitonitis. Complications by inoculation from a distance include purulent ophthalmia, which is quite frequent in vulvovaginitis. Generalized gonorrhœal infection (*gonohœmia*) includes gonorrhœal arthritis, or gonorrhœal rheumatism.

A. H. Goelet⁴ calls attention to *senile vaginitis* as encountered after the menopause. If the disease has been neglected, contraction of the cicatricial bands may become so marked as almost to prevent access to the cervix. The appearance of the vaginal mucosa is characteristic in these cases. The rugæ are effaced, and the surface is pale and glistening in spots, with nearly normal mucosa intervening, upon which may be seen minute ecchymoses or apparently elevated, intensely reddened papillæ, consisting of exposed capillary vessels, the epithelium being destroyed. Occasionally the entire mucosa is intensely injected and inflamed, and is coated with an acrid, mucopurulent discharge, mainly derived from the uterus, which is the seat of a senile endometritis. Treatment consists of cleansing with a solution of lysol ($\frac{1}{2}$ to 1%), followed by the application of a bland, non-irritating antiseptic powder, such as markasol (bismuth borophenate).

Trauma of the Vulva.—Three cases of severe hemorrhage following coitus are reported by Chalcix,⁵ one occurring in a "bleeder." C. S. Ford⁶

¹ Berlin. klin. Woch., No. 18, 1896.

² Ann. of Gyn. and Pediat., Aug., 1896.

³ Gaz. hebdom. de Méd. et de Chir., No. 27, Apr. 4, 1897.

⁴ Med. Rec., Oct. 17, 1896.

⁵ Gaz. hebdom. de Méd. et de Chir., No. 45, 1896.

⁶ N. Y. Med. Jour., Jan. 9, 1897.

records a case of fatal hemorrhage from a slight wound of the vulva. The wound was situated at the juncture of the clitoris and labium minus on the left side, a flap of mucous membrane about a third of an inch square being turned back. The patient had been delivered six weeks before, and the injury was received by falling astride the back of a theatre-seat. The veins of the vulva were enlarged as the result of subinvolution.

Vaginal Seborrhœa.—It is stated in the *Wien. med. Blat.* of December 24, 1896, that a writer in the *Allg. med. Central-Zeit.*, whose name is not mentioned, describes under this title what he considers to be a special form of vaginal catarrh which occurs commonly in corpulent women, old maids, and pregnant women. It consists in an excessive augmentation of the normal secretion of the vagina, and the secretion is made up chiefly of whitish, fatlike lumps containing numerous pavement-epithelia. The secretion soon disappears under the use of injections of warm water containing a little sodium bicarbonate.

Vaginismus.—F. W. A. Godfrey¹ states that vaginismus may be due to several causes well recognized and described, such as urethral caruncle, eczema of the vulva, ulcerations of various kinds, painful fissures of the fourchet, vaginitis, and sometimes probably to a neurosis for which a local cause cannot be discovered. In addition, he refers to that more common form due to a hyperæsthetic condition of the hymen or its remains, which may be a cause of intense suffering and distress. Mere removal of the offending papillæ will not suffice for a cure, but the resulting and remaining reflex muscular spasm must be overcome by systematic dilatation.

Vaginal Stenosis and Atresia.—This subject has been thoroughly studied from an embryologic and clinical point of view by E. H. Lee.² He states that of the various forms of vaginal atresia imperforate hymen is the malformation most frequently met with; it is usually congenital, rarely if ever acquired. The operative treatment of this condition when retention of the menstrual fluid has occurred is simple, a crucial incision usually being all that is necessary; should there be an excessive amount of membrane, or the hymen be hard and dense, it may be excised. [The crucial incision should be given the preference when applicable, as it is less likely to be followed by contraction. Vidal and Bockel encircled the margins of the wound with a suture after excision; this is rarely necessary.] In operating two dangers have to be contended with—namely, rupture of the tubes and sepsis. The former is only present when hematosalpinx exists; the latter in whatever portion of the genital tract menstrual fluid may be retained. Rupture of the tubes has been repeatedly observed following drainage of a hematokolpos, the time varying from 4 hours to 10 days after operation; all of the cases terminated fatally, either immediately from shock or subsequently from peritonitis. When dilated the walls of the tubes become very thin and friable, adhesions to the surrounding organs taking place. After evacuation of a hematokolpos severe traction is exerted upon the adherent tubes by the contracting vagina and uterus in their effort to assume their normal location. This, with the direct pressure that is transmitted from the uterus into the tube when the ostium uterinum is dilated, and the abdominal pressure, favors the occurrence of rupture. [This dangerous complication has been so much feared that it has been suggested to drain the tubes before further operative procedure. Hegar and Kalberbach recommended puncture and drainage per rectum, but this method should be condemned, the danger of infection being very great. It should also be considered that the tube, usually greatly displaced, is not

¹ Quart. Med. Jour., Jan., 1897.

² Medicine, July, 1896.

always accessible from this point. Hausmann proposed drainage of the tube by abdominal section, and this method has more to recommend it; by establishing adhesions between the tube and the parietal peritoneum, the general peritoneal cavity may be walled off and the blood drained without danger. The proper and safer method is gradual drainage by aspiration of the unruptured hymen.] Sepsis, the second danger, can, at the present time, be practically excluded, owing to the improved methods of antiseptics.

Imperforate introitus vaginae and *imperforate vagina* are parallel conditions to imperforate anus and imperforate rectum, and may frequently be found associated. The first step in the operative treatment of this condition is to establish a canal between the introitus and the os uteri [if possible]. This is accomplished by dissection through the connective or cicatricial tissue, as much blunt force as possible being used. The canal having been established without opening the bladder or bowel, the most important part of the operation follows—that is, the prevention of contraction. Implantation and transplantation of skin and mucous membrane have been attempted by Küstner, Neugebauer, and others with variable results. Rein considers the transplantation of skin better than implantation, as it is less apt to be followed by contraction. The operative treatment of stenosis, providing it is not extensive, is not as unfavorable as that of atresia, extensive lateral incisions with packing often resulting in complete cure. Should the stenosis be annular, it may be excised, and the mucosa above and below be brought together and sutured; this is, however, apt to result in contraction. The results of operations for complete atresia have been so unsatisfactory that the operation should not be undertaken [except in rare cases].

External acquired stenosis may follow trauma, agglutination of the smaller labia, and kraurosis vulvæ. Atresia caused by the small labia, following inflammatory processes, is usually met with in children; it reaches as far as the urethra, rarely occluding it. The adhesions are not firm, and may be easily divided with the finger or a blunt instrument. The greater proportion of acquired atresias and stenoses are due to childbirth, forming in the puerperium, the result of extensive lacerations of the mucous membrane, puerperal necrosis, infective colpitis, ulceration, and perikolpitis, always followed by cicatricial contraction and adhesions. Stenosis is the usual result, but complete atresia may follow.

Breisky's atresia retrohymenalis, due to adhesions of the mucous folds, is located directly behind the hymen, but is not connected with it. The adhesions are not preceded by any inflammatory or ulcerated condition of the mucosa, and for this reason have been regarded as physiologic by several authors. This form is usually met with in children; it greatly resembles imperforate hymen, having, when pushed forward, the appearance of a fluctuating, bladder-like tumor of soft consistence and bluish color, protruding into the vulva. It usually ruptures spontaneously; if not, the adhesions are easily broken up by the finger or by some blunt instrument.

Vaginitis adhesiva ulcerosa (Hildebrandt) is a vaginitis appearing in old women, rarely forming before the age of 50 and always after the appearance of the menopause. The patients usually give a history of severe labor or of erosions and lacerations of the cervix. The upper third of the vagina is the seat of the disease in nearly all cases. The mucosa is smooth, not swollen, light-red in color, and has a bruised appearance. The epithelial layer is entirely destroyed. The papillæ are swollen, and if irritated by the finger or speculum are apt to bleed. The secretion is sticky, thin, milky, often mixed with bloody streaks; it contains pus-corpuseles and pavement-epithelium. The

diseased portions always show a great tendency to form adhesions with the portio vaginalis; these are usually extensive, covering the portio and obliterating the anterior and posterior vaults. This condition has frequently been observed in postmortem examinations, when the condition during life had not given rise to symptoms. Operative interference is absolutely contraindicated.

Atresia and stenosis may result from constitutional diseases—acute exanthemata, cholera, typhoid fever, erysipelas, syphilis, and tuberculosis. Trauma is an important factor in their etiology, such as impalement, the introduction of foreign bodies, operation on the external genitals, and the effect of astringent and cauterizing agents.

Meyer¹ has published a very complete monograph on vaginal atresia, with no fewer than 216 cases carefully tabulated. He does not confirm Kussmaul's doctrine that ill-development of the lower part of the genital tract with atresia is due to fetal inflammation. It is in infancy and childhood that these inflammations occur, such as vulvitis and local lesions in general infectious disorders. The vagina closes, the tissues heal and look healthy after a time, and it is not till puberty that the damage becomes manifest. Then it is easy to understand how the disease might be wrongly considered congenital. Unilateral hematosalpinx, with inflammatory closure of the vagina, is very often observed, and Meyer holds that there is closure of the tube at the ostium from the same inflammation, due to some infective agent. As the agent can cause septic changes in the blood in the tube, the ultimate rupture of the hematosalpinx into the peritoneum or into some visceral cavity exposes the patient to great peril. This explains the high mortality of atresia vaginae with unilateral hematosalpinx.

In treating the acquired form of atresia, A. Maekenrodt² suggests the transplanting of flaps, obtained from prolapse-operations on otherwise healthy women, to the granulating sides of the artificial vagina in cases of complete atresia. Of course, an attempt to restore the vagina is warranted only when the atresia is an acquired one, or, if congenital, when the uterus and tubes are sufficiently developed to carry on the generative functions. In attempting to restore the vagina in such cases great difficulty is experienced in keeping the granulating wound open long enough to allow the epithelium to extend up and cover the whole surface.

Labial Hydrocele.—F. Elliott³ records a case of hydrocele of the labium.

Vulvovaginal Anus.—Interesting cases of cloaca in women are recorded by F. J. Lutz⁴ and J. J. Keyes.⁵

Hermaphroditism.—B. Lewis⁶ records a case of male pseudohermaphroditism with marked features of femininity, the patient having had an English mother and an American Indian father. "Her" sexual inclinations have been directed toward the feminine contingent, one of whom she eventually married. "She" has menstruated since the age of 18 with a fair degree of regularity; the flow lasts 2 days, and is accompanied with feelings of malaise, and aching in the back, head, and breasts. Intercourse is pleasurable and is accompanied with the oozing from her vagina of a colorless fluid. Her face is smooth and feminine; her figure lacks the outlines of femininity, and there is a total lack of mammary development. The pubic hair grows as in women, with the apex of the pyramid pointing downward and the base upward. The

⁴ Medicine, Aug., 1896.

⁶ Medicine, Oct., 1896.

arms are feminine, the thighs masculine. The penis in flaccidity is $2\frac{1}{2}$ in.; in the state of erection, $4\frac{1}{2}$ in.; its circumference at the glans is $2\frac{1}{2}$ in. The separated halves of the scrotum contain testicles of a size larger than that of many men normally constituted. The vagina is evidently impractical as a vagina; it appears to end as a blind pouch, and no evidence of uterus or cervix is obtained by either digital or ocular examination. The meatus urinarius opens into the roof of the vagina at a point $1\frac{1}{2}$ in. from its orifice. S. Pozzi¹ records a case of a supposed woman having on each side a testicle, a cystic epididymis (or tube), and a rudimentary uterine cornu on the left side forming a hernia in the inguinal canal.

Vulvar and Vaginal Tumors.—Holzmann² describes an unusually large fibroma molluscum, which grew from the right labium majus of a woman aged 37. It had existed for at least 9 years, beginning as a swelling of the

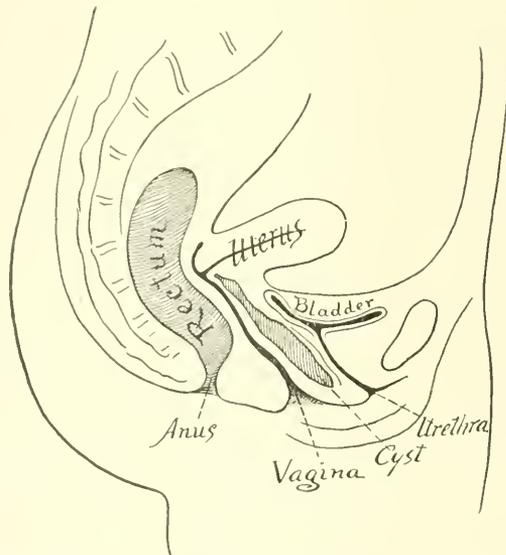

FIG. 35.—Suppurating cyst of the vagina (The Scalpel, Aug., 1896).

labium, which for a time advanced very slowly. Latterly, as is the case with most new-growths, it advanced rapidly, so that it reached to the knee. There was little or no pain, and it was successfully removed. It weighed over 15 pounds.

Turgard³ reports 3 cases of vaginal cyst. The first was a nullipara, 36 years old, who thought that she had a prolapsus. On examination, a tumor the size of a pigeon's egg was found presenting between the labia. This tumor was so freely movable that it gave the sensation of a hernia, but its true nature was determined by rectal and vaginal exploration. With cocain the cyst was excised. The second case occurred in a woman 28 years old, who had had 2 children; during her second confinement her physician discovered the tumor. This was the size of a hazelnut, and was attached to the posterior vaginal wall. It was excised. Its contents were thick and of coffee color, probably of hematic origin. The third case presented a tumor of the vulva. The labia

¹ Bull. de l'Acad. de Méd., July 28, 1896.

² Inaug. Diss., Marburg, 1896.

³ Sem. gynéc., Apr. 7, 1896.

of the left side were distended with a dull, fluctuating mass. Before marriage the patient had had an abscess of the vulvovaginal gland; during pregnancy the mass appeared as described, but disappeared after confinement. After sitting down suddenly with force the present tumor appeared. It was treated by incision and irrigation, and was considered a vulvovaginal cyst, ruptured by the fall, and producing a hematoma.

Hellier¹ reports an unusual case of suppuration in a vaginal cyst. Fig. 35 shows the site of the abscess-cavity between the vagina and the bladder. The author considered it due to suppuration in a vaginal cyst. The patient, an unmarried girl of 17, first came under notice for leukorrhœa, which had troubled her for 2 years. On vulval inspection the physical signs were negative; by the rectum "a soft, elongated swelling was felt in the vagina, reaching from the cervix to the hymen." The vagina was dilated under an anesthetic, and an abscess-cavity was found under the mucous membrane of the vaginal roof and chiefly to the left of the median line. The pus appeared to arise from the os uteri, and was very offensive. Having freely incised the vaginal mucous membrane, the interior of the cavity was scraped and a portion of the cyst-wall excised; the whole surface was then rubbed over with pure phenol and packed with gauze. The patient made a rapid and easy recovery.

To remove papillomata of the vulva Manciere² recommends a mixture of flexible collodion 5 parts, and salicylic acid 2 parts, of which a single drop is to be applied to each wart. At one sitting 8 or 10 may be treated in this manner. On the following day the application is made to a number of others, and also to those previously treated. This is kept up daily until all are gone. The collodion does not affect the healthy tissue.

Perineorrhaphy.—Apfelstedt³ calls attention to the importance of complete approximation of the edges of a recent tear to prevent infection from the lochial discharge. It is important that the stitches should not pass through the rectal wall, as the contents of the bowel might contaminate the wound. A comparatively simple method is described and illustrated. Silk or silkworm-gut is used.

CONDITIONS OF THE CERVIX UTERI.

Profuse Hemorrhage due to a Syphilitic Growth of the Vaginal Cervix.—Wolter⁴ records the case of a patient whose husband had been infected with syphilis 15 years before. The patient had been treated with mercurial inunction for 2 years. She had had 9 children born dead, the last dying during labor and showing but few signs of syphilis. One-half year after the birth of this last child she began to have profuse and prolonged menstruation. The hemorrhage finally became so severe that it caused collapse, and had to be controlled by iodoform vaginal tampons. On the right half of the surface of the cervix there was found a growth which extended into the uterine cavity and bled easily when touched. The patient was given potassium iodid, and after 3 weeks the growth disappeared and the hemorrhage ceased.

Endothelioma of the Vaginal Cervix.—Braetz⁵ describes a case appearing at the Halle clinic for women which he believed to be an endothelioma. A similar case is reported by Amann in the same journal. The patient was 18 years of age and came complaining of leukorrhœa. A tumor 2 cm. in diameter was found growing from the posterior lip of the cervix. It bled easily,

³ Münch. med. Woch., No. 25, 1896.

⁴ Ibid., No. 20, 1897.

⁵ Arch. f. Gynäk., Bd. ii., 1896.

and the tissue was very friable and easily broken off. Kaltenbach removed the uterus by the vagina. Four weeks after leaving the hospital the patient died. The cause of death was not determined, but very possibly resulted from metastasis. The growth was thought to have originated in the endothelium of the lymph-spaces.

Hypertrophy of the Cervix in a Virgin.—Helme¹ describes a case of hypertrophy of the cervix in an unmarried woman, aged 21 years. The fundus uteri was at nearly its normal level, while the cervix protruded from the vulva, a sound passing to the depth of $4\frac{1}{2}$ in. A modified (high) circular amputation was performed for its removal. The stitches were removed on the 9th day and the patient was discharged at the end of the 3d week. When examined 6 weeks after the operation the canal was patent and the uterus measured $2\frac{3}{4}$ in.

Stenosis of the Cervix as a Factor in Uterine Disease.—H. P. Newman² assigns this condition as a causative factor in much of the gynecic disease that abounds. He claims that it is anything but a rare affection, and most instances may be grouped under the acquired form. Many of the so-called congenital cases are merely the persistence of the normal natal condition, and should properly be called acquired. The stenosis may be situated at the external os, the os internum, or it may include the whole extent of the canal. It causes sterility and dysmenorrhea by offering a mechanical obstruction to the spermatozoa, and by preventing the free discharge of the menstrual fluid. In a uterus that seems to have a fairly free outlet at the cervix, the hyperemia that accompanies the monthly molimen may bring the walls of the cervix so closely into apposition that the flow is materially retarded and the secretions more or less retained; this results in endometritis, metritis, salpingitis, and oöphoritis. Much of this improper development may be prevented by proper attention to the environment of young girls during the developmental period of puberty. [The gynecologic teaching of the day is almost the reverse of the teaching of this paper. True stenosis is a comparatively rare disease—it most often exists in the mind of the physician. The supposed evil effects of this condition are in reality small and unimportant. The great harm done in the past as well as the present is that it draws the attention of the physician away from the real causes of the symptoms.]

Trachelorrhaphy.—A. H. Goelet³ employs a knife of peculiar construction for denuding the lips of the cervix in the operation of trachelorrhaphy (see Fig. 36). He claims that the operation can be completed in one-half the time that is usually consumed when scissors are employed, and that the surfaces to be approximated are more regular and even. With the knife each lip is denuded with one stroke, and no trimming is required afterward to remove superfluous tissue. The knife, which is a double-edged, pointed blade, set at nearly a right-angle to a firm shaft and handle, is made to transfix the cervix beyond the plug of cicatricial tissue, and cuts it as it is drawn downward, making a clean denudation. For inserting the sutures he employs a round, full, quarter-curved needle, with a flat, spear-shaped point, which penetrates the dense cervical tissue with ease and never breaks. For suture-material he uses silver wire or silkworm-gut only, believing that catgut or any other suture which is not absolutely impervious should not be used in the cervix. The chief advantage of silver wire and silkworm-gut is that the sutures may be left in the cervix for any length of time until complete union has taken place. Catgut is absorbed or loosens too soon, and is liable to absorb septic

¹ Brit. Med. Jour., Dec. 26, 1896.

² Jour. Am. Med. Assoc., July 25, 1896.

³ Am. Jour. Surg. and Gynec., vol. viii., No. 10, 1896.

matter from the vagina and convey it along the suture tract. Chromicized catgut may be used for superficial auxiliary sutures. [The knife is infinitely superior to the seissors in the performance of all cervical operations—both as

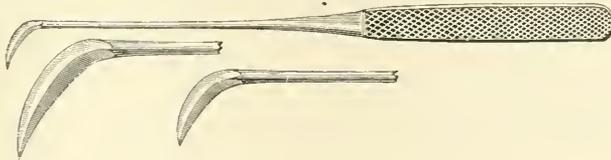

FIG. 36.—Goelet's trachelorrhaphy-knife.

to the result obtained as indicated above and as to the ease of manipulation to the operator.]

W. E. Ashton¹ operates upon all cervical lacerations associated with eversion of the mucous membrane, erosion of the cervix, or cystic degeneration, if local treatment fails, in a reasonable length of time, to effect a cure; also upon all lacerations that are associated with endometritis, uterine retrodisplacement, or subinvolution, if these complications are due to traumatism. [As a matter of fact, the vast majority of cervical lacerations have none of these complications, are entirely harmless to the woman, and need no surgical treatment whatever. The tendency of the day is to attribute too much of the symptomatology to the cervical laceration when most frequently the symptoms are produced by other factors entirely—not infrequently, neuroses.] S. D. West² recommends Schleich's fluid in operation on the cervix in patients unable to take an anesthetic. He injects half a dram into both lips with very satisfactory results.

FISTULÆ.

Spontaneous Healing of Fistulæ in the Female Genital Organs.—Boden³ has searched the literature of medicine for records of cases of fistulæ into vagina or uterus that have healed spontaneously. The result of his effort has an important bearing on the question of operation in such cases, for he was able to collect 235 cases of spontaneous cure. The average duration of treatment before the fistula closed was 3 months, though in some of the cases a much longer period elapsed. The fistulæ were situated as follows in 235 cases: 132 vesicovaginal; 27 vesico-uterine; 3 vesico-enteric; 3 ureteral; 52 rectovaginal; 3 recto-uterine; 9 enterovaginal; 6 entero-uterine.

Vesicovaginal Fistula.—H. A. Kelly⁴ describes a new and very rational method of operating upon large and otherwise intractable fistulæ. He begins his operation by a cut similar to the anterior incision in vaginal hysterectomy; he then separates the uterus and bladder up to but not through the peritoneum of the uterovesical space, carrying the separation widely out on both sides; the edges of the fistulæ are then denuded in the usual manner and stitched together from above downward, thus leaving a transverse wound for union. In the case he describes in the article the ureteral orifices were found in the cicatricial tissue on the edge of the fistula, and it was necessary to pass the ureteral catheters through the urethra and into the ureters before stitching the wound together. These were left in place 3 days without evil effect and the patient made a good recovery.

³ Centrallbl. f. Chir., No. 38, 1896.

⁴ Bull. Johns Hopkins Hosp., vol. vii., Nos. 59 and 60.

W. D. Haggard, Jr.,¹ reports a case of artificial vesicovaginal fistula with subsequent intraperitoneal cystotomy for suppurating papilloma, followed by the formation of a calculus around the dependent portion of a silk suture; the stone was successfully removed and the fistula closed. Baumgartner² records a case of pelvic abscess followed by vesical fistula. [The case is interesting as showing the ability of the bladder to resume its normal condition after the removal of irritating discharges which had lasted over seven years.] The source of the pus was not determined.

Rectovaginal Fistula.—Sécond³ has devised a new method of healing rectovaginal fistule with intact perineum. The operation consists of the following steps: 1. Gradual and thorough dilatation of the anus. 2. Circular incision of the mucous membrane 2 mm. above its junction with the skin. 3. Separation of the vagina from the rectum with the finger, and drawing down of the rectum until the fistula is closed. 4. Resection of the portion of the rectum brought down, and suturing of the end to the skin. 5. Suturing of the vaginal opening.

Intestinovaginal Fistula.—Chaput,⁴ in a case of intestinovaginal fistula in which the knife and thermocautery had many times failed, applied nitric acid to the edges of the vaginal aspect. The thus cauterized surfaces adhered and the fistula closed.

URINARY ORGANS.

Urethra.—*Prolapse of the Urethra in Female Children.*—Attention is drawn to this accident by Broca,⁵ who reports the following case: A girl, aged 6 years, had alarmed her mother through the appearance of blood at the vulva for three days. It was naturally taken for menstruation. The child had been kept in bed for 2 weeks on account of severe bronchitis, with violent coughing; on the day that she arose for the first time the bleeding began. Broca examined the parts, and noted a little red protuberance at the meatus, caused by prolapse of the urethral mucosa. He directed that the everted membrane should be touched with a 2% solution of silver nitrate. The bleeding ceased permanently after the first application, and at the end of 3 days the cure was complete. Broca lays stress on this case, as it shows the extreme importance of early recognition and early treatment of this affection. [In another case the mother suspected rape, but the court ordered a medical examination and the truth was at once made evident. The meatus should be carefully explored in all cases in which blood is found near the child's genitals.]

Tumors of the Urethra.—According to M. Wasserman,⁶ carcinoma of the female urethra is rare. He has recently collected from medical literature 24 cases. As in other regions, epithelioma of the urethra seems to be often connected with some persistent local irritation. Labor, and especially repeated pregnancy, seem to be the principal etiologic factors, but multiparæ are not exempt. Heredity plays no conspicuous part. Four times the tumor was developed between 29 and 38 years; in all the others from 43 to 72 years. Epithelioma develops mostly around the urethra. The urethrovaginal septum is more frequently affected than the upper wall, but in some cases the roof of the urethra, the clitoris, and even the retropubic tissues are invaded. The growth is at first of a deep-red color, more or less hard in consistence, rugose, nodular, with a granular and easily bleeding surface. Later it ulcerates, and yields

⁵ Canad. Pract., July, 1896.

² Berlin. klin. Woch., May 11, 1896.

⁴ Gaz. hebdom. de Méd. et de Chir., No. 41, 1896.

⁶ Ann. de Gyn. et d'Obstét., Apr., 1896.

an ichorous, fetid discharge; then it attacks adjacent parts and forms a large ulcer with cut and indurated edges. In one-third of the cases the inguinal glands are enlarged. The symptoms may be vague at first; later there are painful and frequent micturition, slight loss of blood at the commencement of micturition (sometimes mistaken for menstrual discharge), dull pain in the parts, sometimes lancinating pain radiating down the thighs and toward the abdomen and intense dyspareunia. Rarely a vesicovaginal fistula forms. The treatment consists of free and complete excision of the affected part of the urethra, bleeding being arrested by ligature and by a catheter fixed in the urethra if needed.

C. A. L. Reed¹ records a unique case of melanosarcoma of the female urethra in a single woman 64 years of age, which was cured by urethrectomy. [This is, as far as a reasonably comprehensive research of the literature indicates, the first of the kind to be placed upon record. Sarcoma of even the ordinary varieties, involving the urethra, is exceedingly rare, there being, according to Ehrenderfer, but 2 reported, one by Biegel in 1875, and the other by Ehrenderfer himself. In neither of these cases were melanotic features the distinguishing characteristics.] An absolute cure followed, but the patient died 7 months later from a probable recurrence of the disease in the stomach.

The Bladder.—*Cystitis.*—As regards the etiology of cystitis Kastalskaya,² from a bacteriologic study of secretions from the bladder in 12 cases of cystitis, reports the following results: (1) in 1 case he found the bacillus fetidus liquefaciens mixed with tubercle-bacilli and nonpathogenic cocci; (2) in 5 cases tubercle-bacilli—twice as a pure culture, once mixed with nonpathogenic cocci and bacterium coli immobile, and once with nonpathogenic cocci and the bacillus fetidus liquefaciens; (3) in 4 cases the bacterium coli immobile, twice as a pure culture, once with nonpathogenic cocci and tubercle-bacilli, and once with streptococcus pyogenes; (4) in 1 case pseudobacterium coli commune as a pure culture; (5) in 1 case bacilli with nonpathogenic cocci; (6) in 1 case streptococcus pyogenes with bacterium coli immobile; and (7) in 1 case a pure culture of pseudostaphylococcus albus.

Wertheim,³ at a meeting of the Berlin Obstetric and Gynecologic Society, demonstrated a preparation from a case of gonorrheal cystitis which showed the capillary and precapillary veins filled with gonococci, a condition of gonorrheal thrombosis and thrombophlebitis. The cystitis was secondary to a gonorrheal vulvovaginitis and was associated with an infection of both ulnar joints.

In the prophylaxis of the disease W. D. Haggard, Jr.,⁴ states that the overwhelming majority of cases result from pyogenic microorganisms introduced from without, although the instrumentality of such causes as exposure to cold, retention and decomposition of urine, calculi, foreign bodies, entozoa, neoplasms, tuberculosis, mechanical injuries, croupous and diphtheritic inflammations, and the secondary infection from rupture of an adjacent pus-collection, is unquestioned. Unclean catheterization must stand the impeached sponsor for the majority of the cases. The extension of septic urethritis, particularly gonorrheal, is another source of infection. The rules (modified) for preparing the catheter, and precautions necessary in passing it, in use in the Woman's Hospital in Nashville are as follows: 1. The catheter is to be boiled in boric-acid solution (4%) for 10 minutes; 2. It must be brought to the bedside in the vessel of solution in which it has been boiled. 3. The parts are to be prepared by washing with bichlorid solution (1:3000). 4. The nurse must

¹ Buffalo Med. Jour., Dec., 1896.

² Centralbl. f. Gynäk., No. 33, 1896.

³ Zeit. f. Geb. u. Gynäk., Bd. xxxv., H. 1, 1896.

⁴ Jour. Am. Med. Assoc., May 8, 1897.

scrub her hands with brush, soap and water for 3 minutes; the nails and hands are then scrubbed with the brush and bichlorid solution (1:1000); she must then not touch anything but the catheter before its introduction. The prevention of extension in gonorrhœal urethritis may be secured by daily irrigation of the urethra with a 1:20,000 bichlorid solution, which should be preceded by the instillation of a few drops of a 4% cocain solution.

In the treatment of the disease normal sterilized salt-solution (dram to the quart) is the most useful irrigating fluid. The sovereign remedy in the treatment of inflamed mucosæ is silver nitrate, $\frac{1}{10}$ to $\frac{1}{2}$ %. In obstinate cases of the disease Eseat¹ concludes as follows: 1. A careful examination should be made of the pelvic organs to determine if there is not some extravescical cause for the symptoms. The urethra and kidneys should also receive due attention. 2. After exhausting the usual local methods of treatment (drainage, irrigation, curettage), epicystotomy should be performed, if there are no renal complications. Through the incision the ureters can be catheterized directly, and any diseased portions of the mucosa can be reached with the curet or thermocautery. 3. Vaginal cystotomy is preferable in cases of accompanying renal trouble, or when the patient's general condition is bad. 4. A still more thorough plan of surgical treatment is to follow the epicystotomy and cauterization immediately with a vaginal cystotomy, thus securing perfect drainage. Camero² reports 29 cases of painful cystitis treated according to Guyon's method of curettage, with 19 cures and 10 failures. Camero claims that cystotomy should be reserved for the most serious cases, curettage of the bladder by the urethra often effecting a cure.

Gangrenous cystitis with exfoliation of the bladder-wall is rarely attended by recovery; such a case, however, is reported by C. Warren.³ Under ether "rolls of sloughing tissue" were pulled out by the forceps until a "membrane the size of a small pocket-handkerchief had been extracted from the bladder in a continuous mass." The patient suffered at first from incontinence, but gradually recovered under daily washings out of the bladder with a weak solution of potassium permanganate, and later with a solution of boracic acid. An examination of the specimen removed showed it to be of a character similar to the submucosa of the bladder.

Ureter and Kidney.—*Ureteritis.*—According to E. Reynolds,⁴ *ureteritis* is not an infrequent disease. The most characteristic symptoms are frequency of micturition, which is increased by the erect posture, and especially by standing, and is not wholly relieved by recumbency; and a bearing-down pain, which is increased by standing, but is usually completely relieved by a few hours' rest in bed. Severe ureteritis may lead to a palpable enlargement of the ureter, but the physical signs of the milder degree of the disease, obtainable by vaginal examination, are usually limited to the excitation of tenderness and a desire to urinate, by pressure over the vaginal portion of the affected ureter. This tenderness is usually so closely localized as to be easily overlooked; but when it once has been found, its strict limitation to the situation of the ureter is a diagnostic point of great importance. When the micturition is painful it is always best to examine the bladder at once, since in this class of cases both the pain and, to some extent, the frequency can usually be promptly, though not always permanently, relieved by topical treatment of the bladder. The signs obtainable from cystoscopic examination comprise an alteration of the vesical orifice of the affected ureter or ureters,
