CAMBRIDGE, MASS.: MOSES KING, PUBLISHER.

FRIDAY, JULY 6, 1883.

FIELD-CLUBS AND LOCAL SOCIETIES.

Within the last twenty years there have been a good many experiments made in this country towards the development of science in districts where access to public instruction, in the way of lectures and large museums, was not to be had. Some of these efforts have been successful, but many of them have failed, principally from a want of understanding of the conditions that make success possible. There are few country towns, in this or any other land, where it is possible to maintain an academy patterned on the great societies. Such institutions can only do good when they are sure of the support of many earnest workers, — of men to whom science is a matter of all-absorbing interest. Very few *societies* can be maintained without a system of publication which is very costly, and often of no measure of utility compared with their expense.

To make a society successful there must be a distinct object for it to attain, — one which is well within the reach of such efforts as its members can bestow upon it. The success must be of a tangible sort, — one that is constantly and readily attainable, and in which many can take an active part. In the great societies of the world, this end is honor, or at least notoriety, that may simulate the nobler motive. In a village, a town, or even a provincial capital, neither of these ends can be had with sufficient certainty to secure the talent that is open to temptation. So the local society languishes, or, doing better by itself, dies out altogether.

There is another form of associated action among the lovers of science that escapes the dangers of the more pretentious associations which take the name of society or academy. This is found in the field-club or purely local society, which proposes for itself the study of the problems that lie at the very thresholds of its people. Such associations have already proved wonderfully successful in the old world. They abound in England, and are numerous on the continent. They have found a place in the affections of the people, and a certainty of continued life, where academies have dwindled away.

We do not have to look far into human nature to see why this success has been gained. It is happily natural for men to take more interest in near than in remote things. The primrose by the 'rivulet's brim,' provided it is one's own rivulet, is more interesting than the Victoria regia of far-off wildernesses. The geology of the township where a man lives is more interesting than that of the Colorado cañon, which has never concerned him. So it is that any association for the study of near things has a certainty of support that cannot be secured for any general work in science; and field-clubs which try to promote the study of a township, or at most of a county, are likely to find a support that surprises their founders.

Then, if the proper method be followed by these clubs, there enters into their life an element of the holiday which is very far from the senatorial methods of the more dignified society. Their meetings should be principally in the outer air; for they thus secure the best that the study of nature can give, something of the freshness of woods and field, and the cheerful contact with other fellow-mortals beneath the open sky, — a relation that has a charm that is denied within four walls.

Wherever there is a single zealous student of nature, there is the germ of such an association. He or she can easily gather together a dozen of boys and girls, men and women, who will find in open-air inquiry a rich reward for all the time and force that such activity demands. There should be as little of the machinery of a society as the circumstances will admit: a council of three to five persons to direct the scheme of studies, and a secretary, will serve all the first needs of the association. A few winter-time meetings will find an interest in the discussion of the problems that the neighborhood affords, in the review of work that has been done, and of work there is to do; but the most of the work should be done in the field-meetings.

When there are enough engaged in the work to warrant it, it will perhaps be well to have particular inquiries placed in special hands. Each field-meeting should be for some particular end or ends; and, after the field-work is done, the members should be gathered together, still by preference in the open air, for a discussion of the results obtained.

In those cases where the circumstances admit, it is well for such a society to begin the making of a little museum devoted to the illustration of the field with which they have to deal. The cost of such a collection need not be great; and the utility of the work is very great, provided it be not too much of a burthen to the association. It would best not be undertaken unless the club can see its way to a well-assured income of at least five hundred dollars per annum, beyond the rent of a room where it is deposited. Generally it will be possible in towns of any size, and where public spirit reigns, permanently to secure a room in some schoolhouse or library building, large enough for the needs of the little museum. The walls of a room twenty by thirty will serve for the storage of specimens for many years, and its floor-space will be great enough for meetings in the winter months.

The first thing to be secured is as good a map as can be obtained, on a tolerably large scale, of the region to be studied; for the awakening of the geographical sense of the members is one of the best results that can be obtained by a field-club. In proper time this map can become the place of record of a great deal of fact which cannot be represented by the specimens that may be gathered from the field that it represents.

The five hundred dollars' revenue upon which such a collection should always rest will serve, with due economy, to provide shelves for the collections, to meet the cost of alcohol, bottles, etc., and pay the trifling other charges of the society.

While it is best that the work of such a society should be thoroughly autonomous, — that the motive for its prosecution should come from the people themselves, — it will at times be well to secure the aid of some one specially trained in such problems as its field affords, in the way of suggestions concerning work to be done. Many naturalists will be glad to give aid in this way, either by a lecture, or by written advice. Every field affords problems in geology, botany, entomology, etc., the solution of which is within the limits of the simplest research if it only be patient and truth-seeking in spirit. More of the future of natural history lies in the prosecution of such inquiries than in all the work that can be done in the closet.

Such collections, as soon as they are begun, will at once command the attention of working naturalists. They are sure to be visited and studied; and this interest they arouse will, in itself, pave the way to a quickened life, and better inquiry on the part of the members of the club.

When these societies become numerous enough, — when there are a dozen working in New England, for instance, — it will be well to have a little joint action among them, such as could be obtained by an annual meeting of representatives from them, for the discussion of methods and of problems to be jointly investigated. The interesting experiment of a state meteorological system in Missouri has shown how useful local observers can be in this science. It might be well for the societies to arrange for some common system of observation in this branch. So with each of the sciences: conjoint action would solve many problems that are of the highest interest.

Then, again, there would be a great influence on the extension of science-teaching in the public schools, that would certainly come from the existence of such local societies. The greatest danger that now menaces natural science is, that the parrot system of teaching, so long applied to other branches of learning, will be taken in science-teaching. The presence of a little band of actual inquirers in any town will be the best possible assurance against this. Let the children have some share in the open-air actual study, and the evil of the book-system will surely be mended in part: for its imperfections will be seen.

It will often be possible to organize such a club in immediate connection with the schools of the town where it started. Experience in Europe shows that children readily and zealously engage in such inquiries, and need only a little direction in their work.

However we look at it, we see much to hope from the extension of the field-club system of science study.

THE NATIONAL RAILWAY EXPOSITION.

I.

THE exhibition of railway appliances now being held at Chicago is probably the most complete collection of all the varied apparatus used in every department of railroad working and construction that the world has ever seen; and the management are to be congratulated, that, while little has been omitted to make the show complete, still less has been included which is foreign to the subject of railroads. The exhibits range over a wide field, from uniform-coats to steel rails, railroad officers' desks to revolving snow-ploughs, and from an electric railroad in full working, and earning quite handsome traffic receipts, to George Stephenson's first locomotive, which is shown by an English railway company.

The main questions which are now awaiting solution in the railway world are well represented in the exposition. The cheap transport of heavy freight-trains over steep grades, the conveyance of perishable articles, such as meat and fruit, and the control of the *vis viva* or momentum of trains, are all questions which have to a certain extent been solved; and further developments of these solutions are shown. A locomotive of unprecedented size and power, fitted with a valve-gear of novel construction, which yields excellent results, is shown by the Southern Pacific railroad, and a large number of fine engines are shown by the Brooks and other locomotive works. The exhibition of refrigerator cars is very complete, and most of them appear to be of simple and efficient design. Continuous brakes, applicable to freight-trains, are exhibited; and as some of them appear worthy of careful examination, we shall refer to them later on.

While there can be no doubt, that as regards cheapness and rapidity of construction, general excellence of bridges, locomotives, and cars, the railways of this country are ahead of the rest of the world, the signalling arrangements here, with few exceptions, are rudimentary and inefficient, and render fast travelling a matter of considerable difficulty, if not danger. It is impossible to run a really fast express-train if the signals are ambiguous, and if every level crossing is made a compulsory stopping-place. The saving in time by fast trains can only be fully felt in a great country, where very long journeys are not only possible, but are frequently undertaken; but hitherto this fact has been little appreciated, and people have been content to travel at a slow speed, and put up with frequent stoppages, because the railways were new, the rails roughly laid, and many bridges unsafe at a high speed. But of late years these conditions have been materially changed. The wide-spread use of steel rails, the greater care bestowed on the road-bed, and the introduction of iron bridges of first-class workmanship, have rendered high speed perfectly safe and easy on most parts of good roads in the eastern and middle states; but it is rendered unsafe where switches are so arranged that they may be left open to an approaching train without any signal warning the engineer, or the signals are so formed that the difference to the eye between a clear or all-right signal and a danger or stop signal is slight in snowy weather or under certain atmospheric conditions which render the difference between colors imperceptible, though a difference in form may be perceived.

The exposition is, however, especially strong in signal apparatus; and there can be little doubt that the most important result of the exhibition will be the wide-spread adoption of some of these safety appliances, rendered necessary by the increased number of trains, and the fact that the thicker and more numerous population now demands both safer and faster travelling. The real gain of time to a business-man, obtained by a difference of a few miles an hour in the speed of a long-journey train, is best illustrated by an actual case, — a man in New York who wishes to do a day's work in Chicago. He takes one of the fastest and best appointed trains he can find, — the Chicago limited. It leaves New York at nine A.M., and lands him at Chicago at eleven the next morning, having accomplished nine hundred and eleven miles in twenty-six hours fifty-five minutes, allowing for the difference in time between the two cities. This makes an average speed of 33.8 miles per hour, including all stoppages. But assume, what is surely not extravagant, that as high a speed can be attained on the Pennsylvania or any other first-class American road as on an English main line, and what shape does the problem assume? On one English road, the Great northern, the distance between Leeds and London (a hundred and eighty-six miles and three-quarters) is done in three hours forty-five minutes, including five stoppages; on another, the Great western, the hundred and twenty-nine miles and three-quarters between Birmingham and London is run in two hours forty-five minutes, including two stoppages; and as neither of these routes is particularly level or straight, and both pass through numerous junctions with a perfect maze of switches and frogs, they give a fair idea of what is possible in speed on the railroads of this country. These figures give, respectively, speeds of 49.8 and 47.2 miles per hour. Taking as a fair average forty-eight miles an hour, including stoppages, the journey from New York to Chicago should be done in eighteen hours fifty-nine minutes, or, say, nineteen hours, — a saving of seven hours fifty-five minutes on the present time; so that, if the train were arranged to leave at fifty-five minutes past four in the afternoon instead of nine o'clock in the forenoon, the whole of this time would be saved in the busy part of the day, effectually adding a day to our imaginary traveller's business and dollar-making life.

It may be thought that such a deduction is unfair, as the English style of car is so much lighter than the American; but, as a matter of fact, the average English express-train is considerably heavier than the Chicago limited, and conveys about three times the number of passengers; and, as trucks and oil-lubricated axle-boxes are not yet universal there, the tractive resistance per ton is probably higher. It certainly, therefore, seems not only possible, but feasible, to attain these high speeds in this country, where, owing to the long distances to be travelled, they are more valuable than in England; and the great step towards attaining that end is the adoption of proper and efficient signalling arrangements. All the other steps are achieved: the American passenger locomotive of the present day is perfectly competent to drag a heavy train at a speed of over sixty miles an hour; the cars, as now constructed, can travel safely and smoothly at that speed; and the steel rail, the well-ballasted tie and perfect workmanship of the modern iron bridge, can well support the thundering concussion of an express-train at full speed. But this speed can only be maintained for a few miles at a time if the engineer who guides this train be doubtful whether that dimly-seen signal imply safety or danger, or if the laws of the state bring him to a full stand where his road is crossed by a small corporation with a high-sounding title, which owns one locomotive with a split tube sheet and two cars down a ditch.

To run a fast train, a clear, uninterrupted road is absolutely necessary; and the reason is not far to seek. To move a body from a state of rest to a velocity of sixty miles per hour or eighty-eight feet per second, an amount of work must be performed equivalent to lifting that body a hundred and twenty-one feet. Now, it is apparent to the simplest capacity that it requires a pretty powerful engine to overcome the resistance of a train running at sixty miles per hour without every few miles putting on brakes to destroy this velocity, and then to lift it a hundred and twenty-one feet again to attain speed; the resistance of the air, and the friction of bearings on journals and of flanges against rails, going on all the time. As a matter of fact, showing what severe work this is on an engine, the Zulu express on the Great western railway of England, which is the fastest train in the world, has been repeatedly carefully timed; and it is found, that, though running over an almost absolutely level and straight road, it takes a distance of twenty-six to twenty-eight miles to attain its full speed, about fifty-eight miles and a half an hour.

The adoption of a safe and thorough system of signals, efficiently warning the engineer of a train of any danger in his path, whether from a misplaced switch, an open draw, or a freight-train ahead, may be regarded as of great importance to the American railroad system, in a manner crowning the edifice, and enabling roads to be operated with greater speed, safety, and regularity.

(To be continued.)

THE INFLUENCE OF GRAVITATION, MOISTURE, AND LIGHT UPON THE DIRECTION OF GROWTH IN THE ROOT AND STEM OF PLANTS.

Members of my present botany class have performed some experiments this spring, bearing upon the above caption, which, although not developing any thing new in the interest of the extension of experimental methods in the lower schools, it seems to me may be found worthy of a record in the columns of Science.

Seven balls of moss, about four inches in diameter, were prepared, in the centre of which were planted from fifty to a hundred grains of oats, barley, or corn; in some cases a mixture of two of these grains.

No. 1 was suspended in free air, lighted on all sides. No. 2 was placed on a glass tumbler, in the bottom of which some water was kept, but not enough to rise within two inches of the lowest part of the ball. No. 3 was fitted into the mouth of an inverted bell-glass in such a manner that one half of the ball was within the jar and one half without it. No. 4 was placed one half within and one half without a bell-glass placed in a horizontal attitude. No. 5 was in a tight tin can, the ball fitting it like a stopper, so as to exclude the light and to prevent a circulation of air. One-half of the ball protruded from the can, and the can was inverted. No. 6 was placed in a can similar to that of no. 5; but this was placed in a horizontal attitude, as in no. 4. No. 7 was mounted upon a spindle running through its centre. The spindle was attached to the stem of the minute-hand of an eight-day clock in such a manner that the axis of the spindle was a continuation of the axis bearing the minute-hand of the clock. The spindle was a piece of one-eighth inch brass wire having a strip of tin soldered to one end of it. The tin was perforated with a square hole, exactly fitting the shaft of the minute-hand of the clock. The other end of the wire was filed down to form a small journal, which worked in a hole bored in a lump of solder secured to the end of a wire which acted as a support to the distant end of the spindle. This supporting wire was first bent double, forming a narrow V, and the solder, which served as a box for the journal, dropped in the vertex. The two arms of the V were then bent upon themselves in the same direction so as to form a right angle with the plane of the V. Two holes were bored in the frame of the clock above the dial, but close to it, and the arms of the bent V inserted. The minute-hand was then removed from the clock, and also the washer behind it. The tin shoulder of the spindle was then placed upon the shaft, and the minute-hand replaced; the shoulder serving in the place of the washer, which had not been replaced. It was only necessary to shorten the pendulum a little to enable the clock to record time with its usual regularity.

The results observed after germination were as follows: —

In no. 1 the stems all came out in a clump at the top of the ball, and the roots in a cluster from the under side. The roots, however, after protruding from half an inch to an inch, curved upon themselves, and re-entered the ball, or else withered. In no. 2 the stems all came out at the top, and the roots at the bottom; but the roots in this case continued straight downward into the water, no one of them turning back into the ball. In no. 3 the plants deported themselves in all respects as those did in no. 1, except that the growth was very much more rapid. In no. 4 all of the stems except two came out of the ball into free air: two grew horizontally into the bell-jar. A large cluster of the roots came out of the ball and entered the jar, and continued to grow horizontally, only depending so much as was necessary by their own weight. Others of the roots emerged from the lower side of the outer half of the ball, but soon entered it again. In no. 5 all of the stems came up in the dark, damp atmosphere; and the roots emerged from the lower side of the ball, but re-entered it again, or else perished. Many of the stems (oats in this case) threw out a pair of opposite bodies, apparently secondary rootlets, which grew horizontally, in all cases observed, to a length of about one inch. The color of the stems in this case was a pale yellow. In no. 6 all of the stems came from the ball upward into the light, and very many of the roots protruded horizontally into the can, some of them leaving the ball above its centre. A corn-root extended itself horizontally four inches beyond the surface of the ball, and in that distance was only depressed one-half of an inch. On the corn-roots back of the sensitive tips, the delicate root-hairs were so numerous and long as to give it a resemblance to the hair-brush for cleaning lamp-chimneys. In this ball a number of roots also emerged from the lower side of the ball, but only to re-enter it again, as in the other cases. In no. 7 stems and roots came out together indiscriminately, and from all sides of the ball; the roots, however, after protruding from half an inch to an inch, re-entering the ball or withering. This experiment was twice repeated. In the first case more stems appeared from the side of the ball away from the face of the clock, and the greater number of roots made their appearance on the opposite side of the ball. It was observed in this case, however, that the spindle slanted about two degrees toward the clock. In the next experiment the spindle was made horizontal, and no difference as to place of emerging of root and stem was observed.

These experiments in combination appear to show with clearness the influence of moisture and gravitation in determining the course of the root, and to suggest that the influence of moisture is the stronger of the two.

The emergence of the sensitive tips of the primary roots from the damp ball into the dry atmosphere I suppose Darwin would have explained as the result of the persistence of the impressions in the root behind. The horizontally extending roots in the damp atmosphere, both dark and light, suggest that the response to gravitation in both cases was *nil*. May it not be true that the diageotropism of roots is such in no other sense than that of direction of growth? that it is in reality simply a growing toward the proper amount of moisture? This would appear to explain the oblique direction of secondary branches, and the largely indifferent direction of tertiary ones. The balls in the jars placed in the horizontal attitudes indicate that the stem does not grow simply in a direction opposite to that of the principal root, for they were turned toward each other through an angle of nearly ninety degrees. The two inverted jars show that the stems did not seek a dry atmosphere, for in both cases they grew up into that which was more moist. The inverted dark jar shows that the effect of the impact or absorption of light on the lower half of the ball, and the absence of these effects upon the upper half, did not produce a sufficient contrast to guide the stem into the light; but since, of the two jars placed in the horizontal attitude, only the ball in the mouth of the glass one sent stems into the jar, it seems possible, since other conditions were alike, that light may exert a small influence in guiding the stems from the ground. F. H. KING.

River Falls, Wisconsin, May 17, 1883.

SOME GLACIAL ACTION IN INDIANA.

WITH members of my class in geology, I have been examining the glacial deposits in this vicinity (Montgomery county). Our chief water-course is what is called Sugar Creek, a tributary of the Wabash River, which occupies a valley with a general south-westerly bearing, virtually the same trend which the Wabash has across the state before it makes its sharp bend to the south. Along the valleys of the Wabash and Sugar Creek, there are abundant evidences of a glacier which moved in the direction of the valleys, and is known as the Lake Erie glacier, as it advanced in the direction of the axis of that lake, and so up the Maumee, and across the low divide at Fort Wayne, into the Wabash. Sugar Creek itself has been compelled to bend sharply to the south a few miles to the west of us by the deposits of this old glacier, and has cut its new channel through the soft subcarboniferous sandstone. At one place in this county, where the creek still occupies its preglacial valley, it cuts through what we formerly considered a large terminal moraine, which lies squarely across the valley. Recent floods have swept away some of this moraine, and laid bare the country rock. This rock is found to be smoothly planed, and absolutely covered with glacial scratches all trending N. 20° W., or almost at right angles to the valley of the creek and the course of the former glacier. These scratches of the second glacier are now found in many places throughout the county; and our old terminal moraine proves to be a medial moraine, and bears upon its back a line of huge bowlders with the same northwesterly trend. These facts are recorded here in the hope that they may be of some use in the consideration of a much-vexed question.

JOHN M. COULTER.

Wabash College, Crawfordsville, Ind.

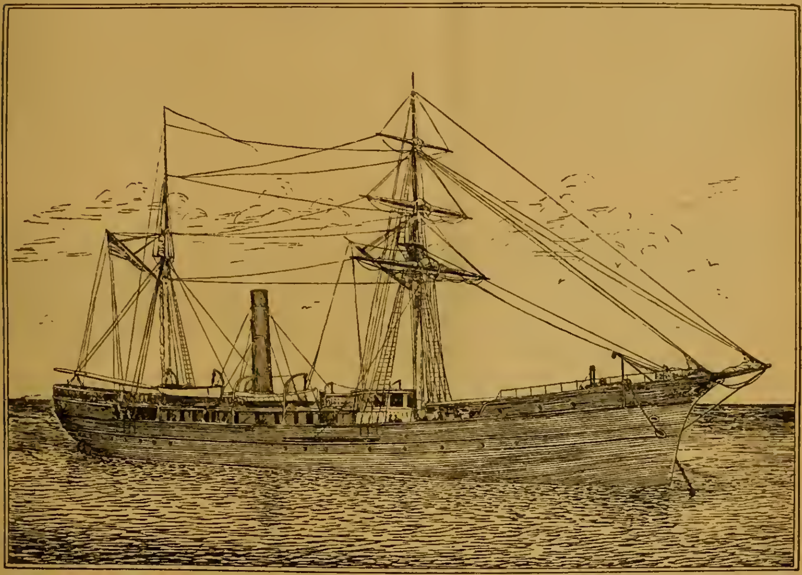
THE UNITED STATES FISH-COMMISSION STEAMER ALBATROSS.

I.

PROBABLY no department of scientific investigation has made greater progress in its methods of work during the past ten years than that of deep-sea research. The successful introduction of steel piano-wire for sounding, and of wire rope for dredging purposes, marks a new era in this class of exploration, for which credit is mainly due to American skill and energy. While claiming so much in behalf of our own country, we frankly acknowledge that the only feasible method of using sounding-wire was devised by one of the best known of English physicists, Sir William Thomson; but his efforts were entirely ignored by the mother government, and first bore fruit on this side of the Atlantic, through the liberality of the American navy.

It is needless in this connection to discuss the rapid development of this system of deep-sea sounding, which has been so fully described by its most zealous advocates, Messrs. Belknap and Sigsbee, of the United States navy. We may be pardoned, however, for recalling the fact, that it was early in 1874 that Capt. Belknap made his famous sounding-voyage across the Pacific Ocean in the U. S. S. Tuscarora, while the Challenger was still plodding its way around the world with its cumbersome hempen rope, one of the Thomson machines being carefully stowed below. Since then Commander Sigsbee has so perfected the sounding-machine, on the proper working of which success with wire depends, that further improvements seem impossible.

The use of wire rope for dredging was suggested by Mr. Alexander Agassiz, under whose supervision it was first put to trial on the coast-survey steamer Blake in 1877. To Messrs. Sigsbee and Agassiz, and the officers of the Blake, is due the greater number of improvements in deep-sea dredges, trawls, and accessories to sounding, which are now employed on the American coast; while the U. S. fish-commission claims priority as to the appliances for moderate depths of water, although many of these are yet to be thoroughly tested in the deeper parts of the ocean.

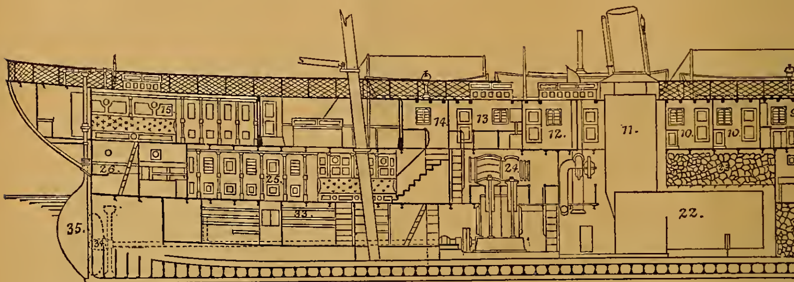


UNITED STATES FISH-COMMISSION STEAMER ALBATROSS.

The great desideratum in marine explorations has always been suitable vessels for properly carrying on the work in all its branches. Our coast-survey, however, is gradually building up a fleet of steamers which are admirably adapted to their special field of surveying and sounding; and several of these, among which we may name the Blake, the Hassler, and the Bache, have already rendered distinguished services in the line of deep-sea dredging and trawling. The latest addition to our exploring-fleet has been the construction of a thoroughly sea-going steamer for the express purpose of investigating our maritime fisheries, in both a scientific and practical manner, by means of every known appliance suited to the work. This new undertaking is but an advance step in the progressive work of the U. S. fish-commission, under the able and judicious management of Professor Baird, and was demanded by the urgent necessity for a more extended knowledge of our off-shore fishing areas. The initiative in this direction was taken some three or four years ago, when Congress sanctioned the building of the steamer Fish Hawk, in the combined interests of fish culture and exploration. Previously, small naval steamers had been adapted to the requirements of the fish-commission as their services were needed; and, considering the pioneer character of their work, they rendered valuable aid.

In associating fish-culture with scientific investigation, some sacrifice had to be made at the expense of one or other of these projects; as no steamer, built to enter the shallow rivers and indentures of our coast-line, could venture with safety to any distance from land. Fish-breeding was at that time considered the more important; and the Fish Hawk, with her shallow draught of water, must confine her operations to the vicinity of the coast; and yet, from a perusal of recent papers in this journal by Professor Verrill, it will be seen that her contributions to biology have been surprisingly great. The Albatross, however, as the new steamer has been christened, will, like her namesake, make her home upon the high seas, chasing schools of fish, or diving beneath the surface with the dredge and trawl.

The Albatross is a twin-screw propeller, rigged as a brigantine, and was built at Wilmington, Del., during 1882, by the Pusey & Jones Company, who were also the builders of the steamer Fish Hawk. She was designed by Mr. Charles W. Copeland, consulting engineer of the U. S. lighthouse board; and her entire construction and subsequent preparation for service have been under the immediate supervision of her present commander, Lieut. Commander Z. L. Tanner, U.S.N. The launch was successfully made Aug. 19; and the work of fitting up the various quarters and of arranging the scientific appliances was rapidly pushed to completion. The trial trip began Feb. 9, 1883; and at the time of writing she is making her first long cruise.



LONGITUDINAL SECTION OF UNITED STATES FISH-COMMISSION STEAMER ALBATROSS.

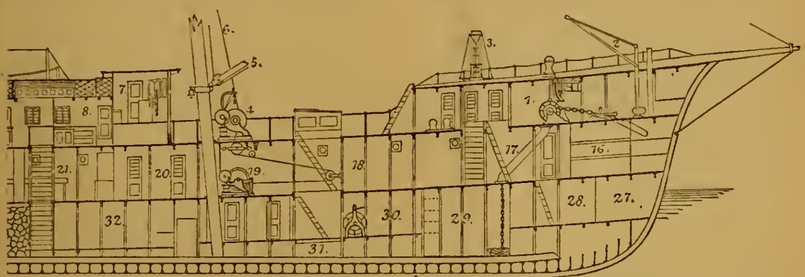
1. Topgallant forecastle; 2. Fish-davit; 3. Sigsbee sounding-machine; 4. Dredging-engine; 5. Lower end of dredging-boom; 6. Dredge-rope; 7. Pilot-house; 8. Chart-room; 9. Upper laboratory; 10. Naturalists' staterooms; 11. Steam-drum; 12. Galley; 13. Upper engine-room; 14. Entrance to wardroom; 15. Poop-cabin; 16. Storerooms; 17. Fore-passage; 18. Berth-deck;

In the construction of the Albatross, several novel features in marine architecture have been introduced; as past experience has proved that the ordinary form of hull is but poorly suited to the work of deep-sea dredging and trawling. The most important modification is at the stern, which has been sharply modelled to enable her to back readily and safely in a seaway, her usual method of propulsion while engaged in this class of work. The rudder and its attachments have also been made of extra strength to withstand the hard service to which they are thereby subjected.

The greatest length of the vessel is two hundred and thirty-four feet; and the length at the ordinary water-line, with a draught of twelve feet, two hundred feet. The breadth of beam moulded is twenty-seven feet and a half. The registered net tonnage is four hundred tons, and the displacement on a twelve-feet draught, a thousand tons. The frame-work and hull are of iron, which also enters largely into the construction of the deck-house. Forward and aft, the iron sides extend to the level of the upper deck to enclose the poop-cabin and top-gallant forecastle, while in the intervening space they form a high protecting rail to the main deck. The deck-house (7–14), which is eighty-three feet long, thirteen feet and a half wide, and seven feet and a quarter high, extends from just forward of the mainmast nearly to the foremast, leaving an ample passageway on either side between it and the rail. The after-part is built of iron, with wooden sheathing; but forward of the funnel it is entirely of wood. followed by the steerage (20), main laboratory (21), engine and boiler compartments (24, 22), which extend into the hold, and the ward-room (25).

The forehold contains the magazine (27), water-tanks, ice-house (29), and a variety of storerooms. Underneath the laboratory is a large room (32) for the stowage of natural history materials: and below the ward-room are the appropriate storerooms for the use of the mess, the navigator, and paymaster.

The poop-cabin (15), on the main deck, is a large, commodious room the entire width of the ship, and extending thirty feet forward from the stern. It contains two state-rooms, a bath-room, pantry, and office, and is conveniently furnished. The ward-room (25) underneath is thirty-eight feet long, and has eight large state-rooms, a bath-room, and pantry. It is



LONGITUDINAL SECTION OF UNITED STATES FISH-COMMISSION STEAMER ALBATROSS.

19. Reeling-engine; 20. Steerage; 21. Lower or main laboratory; 22. Boiler; 23. Coal-bunkers; 24. Engines; 25. Ward-room; 26. Cabin storeroom; 27. Magazine; 28. Magazine passage; 29. Ice-box; 30. Upper hold; 31. Lower hold; 32. Natural history storeroom; 33. Wardroom storerooms; 34. Propeller-wheel; 35. Rudder.

The forward compartment, which is raised about three feet above the general level of the house, is the pilot-house (7), containing a steam quartermaster to aid in steering. Following it in succession are the chart-room (8), upper laboratory (9), four state-rooms (10), steam drum (11), galley (12), upper engine-room (13), and entrance to the ward-room stairway (14).

Below the main deck the vessel is divided into six water-tight compartments by five transverse iron bulkheads, there being also an additional bulkhead which is not closed.

The berth-deck, forward of the collision bulkhead, is cut up into storerooms (16), reached by scuttles from the main deck. Next aft is the berth-deck proper (18), which is forty feet long and the width of the ship, with superior accommodations for a large crew. It is well lighted by a broad skylight overhead in addition to the usual side-ports. These quarters are entirely occupied by the officers of the ship, the civilian scientific staff being accommodated in the four state-rooms (10) of the deck-house abaft the upper laboratory. The latter rooms are better adapted for study than any others on the ship; each having a large, square side-window at the proper height for working with the microscope, should the naturalists desire to conduct their more delicate observations in privacy.

Of most interest to the student are the scientific quarters, which are very capacious, and amply sufficient for all possible needs. They occupy a central position, being thereby removed as far as possible from the extremes of motion caused by rolling and pitching. They extend from just above the keelson to the upper deck, and consist of three rooms on as many levels: the lowest (32) being a storeroom; the central one (21) a general laboratory, or work-room; and the upper one (9) a deck-laboratory for microscopical work and study. These rooms communicate with one another by means of stairways, but are entirely cut off from all the rest of the ship, excepting through the side-doors of the upper laboratory. The two lower rooms are protected fore and aft by water-tight iron bulkheads, reaching to the main deck; and the storeroom, which contains the supply of alcohol, can be made a tight box, and instantly filled with steam, in case of fire.

Light is admitted to the upper laboratory through a skylight, and two windows on each side, and to the general laboratory through three ports on each side, and two deck-lights overhead; but in the storeroom artificial light is necessary. During the day-time, therefore, the working-rooms are sufficiently well lighted for all ordinary purposes; but the system of electric lamps, which pervades the entire ship, reaches its height of development in these quarters, and every few feet of space contains its little glass globe and horseshoe. The effect at night is very brilliant, and work can then go on about as comfortably as in the brightest sunshine.

[*To be continued*.]

SURFACE CONDITIONS ON THE OTHER PLANETS.

IN the *Popular science monthly* for June appeared an article entitled 'Cost of life,' by John Pratt, upon the habitability of the other planets. To his conclusion that most of the larger planets are probably unsuited for habitation by beings like ourselves, I think few astronomers would take exception; but several of his statements as to their surface conditions are apparently at variance with modern observation, and with the results of the application of the principles of mechanics.

As to the light from the planets, he says, "In the first place, as might have been conjectured even before the revelations of the spectroscope, from their great volume of light as compared with their distances from the sun, all of these great bodies [the four exterior planets] are self-luminous." There is some reason to believe that at certain times portions of the surface of Jupiter do shine by their own light, but it is certainly very faint, as otherwise, when his satellites pass into his shadow, they would still reflect some light to the earth. In point of fact, however, even to the most powerful telescopes, they absolutely disappear. As to the three remaining planets, their light is so faint at the best, that any determinations as to their self-luminosity are entirely out of the question. The spectroscope shows us nothing whatever on this subject with regard to any of these bodies.

We are then told, that "the density of Jupiter being about 1.40, and that of the earth 5.48, it follows that the attraction exerted by Jupiter is roughly 300 times that of the earth. A man who weighs 150 pounds on the earth, if transported to Jupiter, would shake the ground with a ponderous tread of 45,000 pounds, or 22½ tons. His own weight would at once crush him into a mere pulp. A hickory-nut, falling from a bough, would crash through him like a minie-ball. Again: water would weigh fifteen times as much as quicksilver. A moderate wave would shiver to atoms the strongest ironclad, etc." Applying the ordinary formula, $W = \frac{M}{D^2}$, — where M, the mass of Jupiter, in terms of the earth, is 313, and D, its diameter, is 11, — we find the weight, W, of an object on the surface of Jupiter, equals $\frac{313}{121}$, or 2½ times what it would weigh here: hence our 150-pound man would weigh just 375 pounds there, and would not be seriously inconvenienced by a whole battery of hickory-nuts, provided he wore his hat. With reference to Mars, he writes, that "the relative mass of Mars being only about $\frac{1}{60}$ that of the earth [it is $\frac{1}{9}$ approximately] . . . our typical man would only weigh about 2½ pounds. . . . An 80-ton locomotive would not propel a train of empty cars. . . . A rifle-ball might be caught in the hand without harm." According to the law of gravitation, the 'typical man' would weigh 66 pounds. Supposing the 80-ton locomotive reduced in weight in the proportion he states, the cars would be so also: therefore, under any such conditions whatever, the 80-ton locomotive would draw precisely as great a quantity of matter there as it would upon the surface of the earth. As to the rifle-ball, its stored energy is proportional to MV^2; that is, it is proportional to its mass, and independent of its weight. But the mass of a body is the same throughout the universe: therefore experiments in catching rifle-balls in the hand on the surface of Mars would be dangerous.

Finally, referring to Mars, he says, "Nothing can be more certain than that there is no liquid in Mars, and no life." As seen through the telescope, the poles of Mars appear of a brilliant white color. When one of the poles is turned towards the sun, the size of the white spot diminishes, and, when it is turned away again, it increases. Some astronomers have imagined these white spots to be snow: in that case, it is difficult to account for the disappearance, unless we suppose that it melts. It therefore seems rather a strong way of expressing it to say that "nothing can be more certain than that there is no liquid in Mars." There are several other points raised by our author which would bear mentioning, one or two on the subject of energy, particularly "a large aspect of the question, which seems to have escaped the attention of thinkers;" but I think the points referred to above will be sufficient for the present occasion. W. H. PICKERING.

COMPOSITION OF THE MESODERM.

UNDER the title 'Archiblast and parablast,' Waldeyer has published a long article (*Arch. mikrosk. anat.*, xxii. 1), in which he reviews chiefly His's views concerning the origin of the connective tissue, blood-vessels, etc.; but he also considers several cognate questions.

His's investigations have been confined to vertebrates, but he apparently believes that his view is also applicable to invertebrates. Professor His distinguishes two distinct groups of tissues, — the archiblastic and parablastic. The former includes all the epithelial, muscular, and nervous tissues, comprising, therefore, the glands, smooth muscles, and neuroglia: the parablastic group comprises all the connective tissues and blood, with which are counted the blood and lymph vessels, and also the leucocytes. The parablast arises beyond the embryonic area proper as cells which grow into the embryonic region. These cells arise, according to His, out of the granules of the white yolk; these granules, from cells in the yolk; which cells are immigrated leucocytes, that enter the ovum while it is still in the follicle of the ovary.

Waldeyer accepts this division, but he differs from His mainly in two points, — first, in excluding the lining of the peritoneal cavity from the list of endothelia, and therefore also from the parablast; second, in ascribing a different origin to the parablastic cells. (As regards the first point, there can be no reasonable doubt that His's account of the origin of the membrane is erroneous: because, 1, the disappearance of the original epithelium, and the new formation by leucocytes of an epithelium on top of it, was, to the last degree, improbable, so that a gross error of observation would be more probable; 2, His was unable to bring forward any definite observations in his favor; 3, his conclusion was and has since been contradicted by the direct observations of others. Waldeyer has done good service in calling general attention to these objections, but the matter can hardly be considered new.)

As regards the second point, we reproduce Waldeyer's own summary (p. 47). In the eggs of all animals which have blood and connective tissue at all, the segmentation of the egg does not continue in the same manner up to the end; but one must distinguish a primary and a secondary segmentation: the first divides the egg, so far as it is capable of segmentation, into a number of cells which are mature for the formation of the tissue, and form the primary germinal layers. A remainder of immature segmentation-cells (in holoblastic eggs), or of egg-protoplasm, which has not assumed the cell-form (in meroblastic eggs), is left over. In either form, this remainder does not directly enter into the germ-layers as an integral component, but undergoes first a further cell-formation, — the secondary segmentation. From the cells thus formed, the parts richer in protoplasm are cut off, and make the primitive parablast-cells; while the part richer in yolk remains only to be used as nutritive material. It will be seen that the essence of Waldeyer's theory is, that a portion of the segmenting egg is retarded by the presence of yolk; and so there are some cells, or, in meroblastic eggs, some protoplasm, which is laggard in development, and does not directly enter into the primitive layers, but becomes the parablast.

The parablast is essentially identical with the mesenchyma of the brothers Hertwig, except that the latter include the smooth muscles in the group. Waldeyer endeavors to justify his theory of the origin of these tissues from laggard cells, but it seems to the reporter unsuccessfully.

There is given also, p. 38–44, a discussion of the relation of the yolk to cleavage, in which the views advanced several years ago by Minot (*Proc. Bost. soc. nat. hist.*, xix.) are brought forward anew, apparently without knowledge of their previous publication by another writer. In the discussion of the origin of the parablast-cells, p. 9–27, it appears that His's view of their origin from the white yolk is definitely shown to be untenable. Incidentally, emphasis is laid upon the fact, that, in meroblastic eggs, the protoplasm of the animal pole sends down processes into the yolk: it is from these processes in the 'keimwall' of birds' eggs that the parablast-cells arise, according to Waldeyer. His article, as a whole, is chiefly a discussion of the literature of his subject. C. S. MINOT.

THE ECLIPSE OF 1882.

AT the present time, when interest is chiefly drawn toward the successes of the astronomers who observed the eclipse of the sun month before last from the small islands in the Pacific Ocean, the results of the eclipse of May 17, 1882, obtained in Egypt, have especial significance. These were briefly stated by Dr. Schuster at a late meeting of the Royal astronomical society. During the progress of the eclipse three photographic instruments were at work: one took photographs of the corona itself; a second was a photographic camera with a prism placed in front of it, that is, a spectroscope without a collimator; and the third was a complete spectroscope. Photographs were obtained in all three instruments. The direct photographs of the corona indicate its variations from eclipse to eclipse, — a matter of much importance in solar physics. If the photographs taken during eclipses in the past twenty years are compared with each other, it will be seen that the corona varies in a regular way with the state of the sun's surface, although there are irregular minor changes. At the sun-spot minimum the corona is much more regular than at the maximum. At the minimum there is a large equatorial extension, and near the solar poles a series of curved rays. At the maximum there is practically no regularity at all: the long streamers go up sometimes in one direction, and sometimes in another; and this last year, near the sun-spot maximum, there was absolutely no symmetry in the appearance of the corona. The transparency of the streamers was most striking. One streamer can sometimes be traced through another, showing that the matter, whatever it is, must be very thin. The rifts start from the solar surface in an entirely irregular way, with a tendency very often toward the tangential direction at the lower parts of the rifts. The photographs extend about a diameter and a half from the sun's limb, and a comet appears on the plates about a solar diameter and a half from the sun's centre. It must have been very bright, as it appears clearly in the photographs. Measurements seem to indicate a small shift in its position during the interval between the first photograph and the last.

Turning now to the photographs taken with the camera and prism in front, — an instrument which gives an image of the prominences as oft repeated as there are rays in the prominence, — the plates employed were sensible to the infra-red as well as violet rays. One prominence gave a great number of lines in the ultra-violet. The fact was brought out in this eclipse, that the brightest lines in the prominences are due, not to hydrogen, but to calcium. Besides these and the hydrogen lines, there is the line D_3 in the yellow, and the C line of hydrogen in the red, and also a photograph of two prominence-lines in the ultra-red. In addition to the prominences, there are visible in the photographs certain short rings round the moon, which mean that at these places the light sent out by the gaseous part surrounding the moon is not confined to the prominences. It is, as would be expected, the green coronal line which chiefly corresponds to one of those rings. This green line, K 1474, is a true coronal line, and is only very faintly traceable in one of the prominences.

In considering the results obtained with the complete spectroscope, it is a striking fact that some of the lines cross the moon's disk, and especially the two lines H and K. This proves that the calcium-lines, H and K, were so strong in the prominences that the light was scattered in our atmosphere, and reflected right in front of the moon.

The prominence-lines are very numerous: thirty such lines appear in the photograph. The hydrogen-lines are there, including those in the ultra-violet photographed by Dr. Huggins; also H and K, and other calcium-lines; and still others, chiefly unknown.

Close to the sun's limb we can only trace a continuous spectrum, a very strong one, going up to about a quarter of a solar diameter. The photographs bear out the distinction between the inner and the outer corona, the former being much stronger in light. The boundary at which this continuous spectrum ends corresponds to the extension of the inner corona. The continuous spectrum is stronger on the side where the prominences are weaker. In the corona we first of all see a very faint continuous spectrum, and in that continuous spectrum one can trace at G the reversal of the dark Fraunhofer lines. In addition, a series of faint true coronal lines can be traced in the outer regions of the corona. We have not traced any known substances in the solar corona. The greater number of the prominence-lines in the ultra-violet are also unknown, but they seem to be present in Dr. Huggins's photograph of the spectrum of α Aquilae.

LETTERS TO THE EDITOR.

**** Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

The relative ages of planets, comets, and meteors.

The theory that the sun was once a gaseous mass extending beyond the most distant planet, and that it has contracted to its present dimensions by the continuous action of gravity, and is still so contracting, is now very generally accepted by astronomers. It is well known, moreover, that the condensation of a gaseous body produces heat, and that the impact of solar matter in consequence of its motion towards the centre of gravity is one cause, at least, — perhaps the principal one, — of the sun's high temperature. The modern law of the conservation of energy affords data for determining the amount of heat produced by the condensation of the sun's mass from one volume to another. It is thus found that the contraction to its present dimensions, from a primitive volume extending indefinitely beyond the orbit of Neptune, would have kept up a uniform supply of heat equal to the present for twenty millions of years.[1] The age of the solar system, however, may be greater or less than this, as the sun's radiation may not have been constant.

In any form of the nebular hypothesis, Neptune is the oldest planet known, and the innermost of the number has had the most recent origin.

A majority of comets probably move in hyperbolas, and visit the solar system but once. Some orbits have been changed into ellipses by planetary perturbation.

For any thing we can know to the contrary, cometary matter has been falling towards the centre of our system in all ages of its existence. Whenever the perihelion distance has been less than the radius of the solar spheroid, the comet's orbital motion must have been arrested, and transformed into heat.

As the limits of geological dates are determined by the strata of the earth's crust, so the superior limits of the age of periodic comets are fixed by the planetary orbits next exterior to their perihelia. Of the comets known to be periodic, the perihelion distances of thirteen are less than the earth's distance from the sun. The ages of all these must therefore be less than that of the earth. In like manner the ages of others are shown to be less than that of Venus, while those of a few are found to be less than the age of Mercury. We may conclude, then, in general, that the ages of comets, as members of the solar system, are less than those of planets.

But as meteoroids, partly at least, are derived from comets, their origin as separate bodies in connection with our system must be still more recent: in fact, meteoric matter is being constantly detached from comets at each successive return to perihelion. The indications of this process were unmistakable in the case of the great comet of 1882, and many meteoroids of the Biela group have been separated from the comet in our own day. Daniel Kirkwood.

Bloomington, Ind.

First use of wire in sounding.

Professor Verrill is quite right in supposing that I was unaware that any report of the sounding expedition of Walsh had been published. A casual reference to Walsh in the 'Depths of the sea' led me to inquire,

[1] A contraction of the radius equal to a hundred and twenty-nine feet per annum would yield the present supply of heat. See Monthly notices of the R. A. S., April, 1872.

through a naval friend, of an officer in the Navy department, unofficially, whether any report had been published. This gentleman was kind enough to make inquiries, and finally replied that he could not find out that any thing had been printed, but that the log-books were at the department On this account I made no further search for printed data; but later, on Commander Bartlett's installation at the Hydrographic office, I mentioned it to him, and he had the goodness to search the log-books, and to send me copies of *all* references to the work with wire, contained in them, from which my note was compiled. Doubtless other note-books might have been used also. In regard to the breaking of the wire, it is specifically stated in the log-book that it parted 'owing to some of the links catching at times on others,' as the line was *paid out* in one or two cases, and in others as it was being hauled in. In another instance it parted 'owing to one of the joints catching upon another joint on the reel.' It is nowhere in the *original log* referred to the heaving of the vessel; and the last entry repeats, 'entirely owing to the short nip of the catch upon the reel.' Having had some experience in sounding in great depths of water with a small sailing-vessel, I have come to the opinion, in which I think most practised hydrographers would concur, that it is impossible that a plumb sound should be obtained from such a vessel under any circumstances likely to occur in actual work. The words quoted by Professor Verrill from Walsh's report show that the latter officer deceived himself; for it is evident, that, if the wire 'served as an anchor to keep the vessel steady,' it could not have been plumb; and, even if it appeared to be so at the surface, what it was below the surface no man could state with confidence, except that it was *not* plumb. A steamer may be kept over the wire, and, with wire properly spliced and heavily weighted, a plumb sound can be had, but not otherwise; and it may be confidently said that *accurate* sounding in deep water dates from the combination of these two factors. I may say, also, that in my note I did not, nor do I now, consider that successful trial of a sounding apparatus has been arrived at, until bottom has been reached, and the signs of it brought up. WM. H. DALL.

Washington, June 23, 1883.

False claims.

It is to be regretted that the pages of a popular magazine of high standing should be made the vehicle of such an advertisement as appears in the *Century* for July, entitled 'Cheap food for the million,' reprinted in the publisher's department of SCIENCE for June 22. Of the merits or demerits of a new food-preservative, of which so many have been brought forward within the last few years, I have nothing to say: the testimony of Prof. S. W. Johnson, cited in its favor, is certainly entitled to respectful consideration. But I wish to call attention to the claim of the inventor of the new nostrum to public confidence on the ground that he is "a fellow of the Chemical society of London, and also of the Geological society, being elected after unusually severe examinations. President Huxley, of the latter society, said that 'no American should boast of an election without a severe struggle.' In evidence of this prejudice towards Americans, the fact that Professor Humiston was given two hundred and fifty questions (five times the usual number) may be cited. He is now superintendent of the company's works," etc.

It is not clear what meaning is to be attached to the words put into Huxley's mouth; but it is a well-known fact that neither in the societies named, nor any others with which I am acquainted, is there any examination whatever required, or are any questions asked. A nomination by three members, one of whom must have personal knowledge of the candidate, and the payment of fees, are the only conditions necessary to membership of the Geological society of London, which has several hundred members upon its lists, including many Americans. In the complete catalogue of all scientific papers published in Europe and America up to 1877 (*Roy. soc. cat.*) we search in vain for the name of the 'superintendent of the company's works.' It is not creditable to the advertisers that the names of illustrious men of science and of learned societies, coupled with erroneous statements and absurd appeals to national prejudices, should be invoked, even indirectly, to recommend their wares. T. STERRY HUNT.

Montreal, June 25, 1883.

MACLOSKIE'S ELEMENTARY BOTANY.

Elementary botany, with students' guide to the examination and description of plants. By GEORGE MACLOSKIE, D Sc , LL D., professor of natural history in the J. G. Green school of science, Princeton, N J., etc. New York, *Holt*, 1883. 370 p. 12°.

SCIENCE is ready to welcome a new text-book, asking only for some particular line of excellence as a warrant of its reason to be. Considering that "this volume aims to supply a readable sketch of botany," and so to treat the subject "as to meet the wants of a large class of readers who wish to know something of the fundamental principles and philosophical bearings of the science without being distracted by technicalities," we think that its readable character and the comparatively sparing use of unnecessary technical terms are among its commendable features. The style is easy, sometimes a little odd in its concatenations, as where "it is said that a monkey first introduced tea to the notice of the Chinese; the English government started its cultivation in Assam, whence the best teas now come;" and in the following paragraph it becomes even sensational.

"Their power of increasing in thickness imparts to roots their capacity for mischief. Their vigor is somewhat surprising. They make their way through dense soil, loosening it so that it becomes soft and spongy. They can split rocks, overturn walls and buildings, stop up sewers, and root up our street-pavements. They effect more injury to man's handiwork than tempest, fire, and war combined. . . . We possess a root hugging an old bottle in irredeemable captivity."

In a well-known passage at the close of one of his books, Darwin likened the tip of a root to the brain of one of the lower animals; and brains, we know, are capable of mischief, and therefore of demoralization. Whether the root which the author is so fortunate as to possess is in dipsomaniac captivity to the bottle it hugs, or whether the bottle is captivated by the caressing root, is not quite clear from the context. And how such dire mischief to man wrought by roots — more injurious 'than tempest, fire, and war combined' — is to be reconciled with creative benevolence, we must leave for the Princeton theologians to settle, and pass on to another topic, that of judicious abstinence from technicalities.

Writers of text-books are prone to employ all the technical terms they can find, especially new-fangled ones which have not yet proved their right or reason to exist by continued usage, or which, though convenient in an original treatise or memoir, and harmless or even useful in a glossary, may be advantageously dispensed with in ordinary scientific teaching. We all know of the painter commemorated by *Punch*, who 'rubbed out a good deal,' and who claimed to 'get his best effects that way.' Many scientific books for students' use might be bettered by the same process. Professor Macloskie has so well resisted the ordinary temptation, or restrained in parenthesis needless terms which he did not like to leave out, — such as *xylem*, Greek for wood, most barbarously Germanized (as if, where a Greek said *xylon* and a Roman said *lignum*, we might not say *wood* when we meant it), — that it may be a little ungracious to complain of his making one or two himself, and making them badly. Where he says, "to avoid confusion, we shall call [the seed-coats] *exotest* and *endotest*," the inference is, that these terms are original. Nor, not to insist that confusion is rather made than avoided by the substitution of new names for well-recognized old ones, we might suggest that the coinage is in a small way pedantic, except that a pedant would not violate what our author in another place terms 'the jus connubii' by hybridizing Greek with Latin. Nor, if we must have such Greek-Latin crosses, would he have truncated them into *quasi* English, which is as bad as a third cross, but have written *exotesta* and *endotesta* in full, vile as the terms are. *Gametic* is certainly new coinage; and the author does not clearly say what he means it to pass for. But it may be gathered that 'gametic affinity' means relationship near enough to allow of interbreeding. We are to say, then, that species belonging to different genera have gametic affinity in the rare cases when they can be made to hybridize; and that certain species strictly of the same genus, which we have failed to hybridize, are devoid of gametic affinity: so the term has no explanatory value whatever.

Some of the borrowed woodcuts are very good; most of the original ones are quite the reverse; and the one which is said to represent a 'tip shoot of pea' is a complete puzzle, after all the enlightenment which the letterpress affords.

Turning over the pages, we now and then come upon statements which dampen any enthusiasm of commendation which a reviewer might wish to express. On p. 16 we read that "cymose flowers are always actinomorphic, being equally exposed to light in all directions." The implication that 'actinomorphic,' i.e., regular, flowers are so because equally exposed to light from all directions is a bit of deductive botany of the Grant Allen school. And the assertion that cymose inflorescence and actinomorphic flowers always go together is by no means true, as witness all Labiatae and a large share of other didynamous flowers. The seed "in Lepidium, on being moistened, darts out mucilaginous threads." Is Dr. Macloskie sure of this, or does he infer that there must be such threads because they exist in various other seeds and seed-like fruits which develop mucilage when wetted? The hypocotyledonary stem "in the pea is short because the seed remains underground." Were it not better to say that the seed remains underground because this initial stem does not lengthen? On p. 82 it is asserted, or at least implied, that root-hairs last all summer long, and may be renewed on a surface that has lost them. To Grant Allen, in the year 1882, is attributed the idea that neutral ray-flowers of Compositae are sterilized members set apart and enlarged for purposes of display. Has Dr. Macloskie met with no earlier exposition of that doctrine?

Not to prolong questioning, let us say, that, for those who are most likely to use this book, it was a good idea to devote a few pages at the close to the derivation of common terms, Latin and Greek root-words, and prefixes, and to help those who do not know the Greek alphabet by writing out the words, as nearly as may be, in Roman letters.

THE GEOLOGY OF BELGIUM.

Géologie de la Belgique. Par Michel Mourlon. 2 vols. Bruxelles, *Hayez*, 1880-81. 317; 16+392 p., illustr. 8°.

This book, a model in its way, will be read with equal profit by the geologist and by the general reader. The geologist will find in it, critically exposed, and in a short and impartial manner, the immense amount of labor and of detail which is scattered in the numerous papers of the Belgian geologists. Any one of ordinary intellectual culture, and interested in Belgium, will find it a clear and readable account of the past history and chief features of the country. Two causes have contributed to make easier the task of the author: the works on the geology of Belgium by d'Omalius, Dewalque, and especially the celebrated 'Esquisses géologiques' of Gosselet, have already pointed out the way to success; and, moreover, the natural disposition of the country allows a very simple grouping of facts.

Both geologically and geographically, Belgium is formed of two distinct parts. The southern half (the Ardennes) is a hilly region, a continuation of the old paleozoic nucleus of Europe, — the so-called Hercynian mountain-range; the northern half (Flandres, etc.) is a flat land or prairie region, and forms part of the great plain of northern Europe, the basin of the North Sea. The Ardennes is a paleozoic district; Flandres, a tertiary one; the triassic, Jurassic, and cretaceous formations forming but a broken belt around the paleozoic masses. All these formations are, however, studied by the author in a complete manner, and their mineralogical, paleontological, and stratigraphical characters successively described. Both their historical divisions and their local extension are given with care.

Beginning with the older rocks, we first meet the Cambrian shales, forming two principal ranges (massifs de Rocroy and de Stavelot). These rocks can be compared to the Ocoe conglomerates and shales of the Appalachian region; they contain the curious interbedded crystalline porphyroids, so well illustrated by de la Vallée Poussin and Renard, whose papers are here summarized in two good plates. The Silurian beds form two small crests extending east and west, through Brabant and Condros, and have supplied fossils of Barrande's second fauna. These beds, like the underlying Cambrian, have a southerly dip. The upper Silurian fauna is not represented.

The folding of the Silurian rocks was the initial cause of the so-called Dinant and Namur devono-carboniferous depressions, or basins. It was followed by a long-continued depression of the area, in consequence of which the accumulation of an enormous thickness of stratified rocks within the great troughs of Dinant and of Namur took place. This downward bending of the earth's crust did not go on continuously, but submitted to some irregularities related to the breaks and numerous stratigraphical divisions of the Devonian formation. The Devonian formation of Ardennes is the most complete and best studied in Europe, through the labors of Dumont, Gosselet, Dupont, and the author. It shows a thick series of four thousand metres of alternating fossiliferous shales, sandstones, and limestones, marine for the chief part, though some beds have furnished Psilophyton and other plant-remains. After the period of the mountain limestone, littoral, brackish water, and finally lacustrine and terrestrial deposits, came in, and the coal continued forming.

A general movement of elevation succeeded towards the end of the coal-measures, and folded all the paleozoic sediments as if they had been crushed from south to north. This thrust had a more violent effect in the Namur than in the Dinant basin. In the former are comprised the celebrated coal-fields of Mons, Liége, and Charleroy, — the chief causes of Belgian prosperity and wealth.

At the close of the paleozoic period, the mountainous region of southern Belgium was formed; and since then it has always been exposed to denudation. South of this mountainous district, the Jura-triassic beds of eastern France now began to accumulate in the Gulf of Luxemburg (Buntersandstein and Keuper, and the Jurassic from the Avicula contorta beds to the middle oölites). These mesozoic seas did not penetrate north of the Ardennes, where the lower cretaceous are the most ancient mesozoic formations.

The cretaceous formations in this district possess great interest, notwithstanding their small geographical extent. The lower beds have furnished the splendid iguanodons of the Brussels museum, and the upper ones are the well-known Maestricht beds. All are chiefly littoral formations; and the so-called tourtias of the middle cretaceous are famous by the variety and richness of their faunas. In the deep and narrow Gulf of Mons, the cretaceous beds are found in a chalky condition, as in the Anglo-French basins.

In the neighborhood of Mons and Landen are found the most ancient representatives known in Europe of the tertiary epoch (systèmes montien, heersien), so well illustrated by Cornet and Briart. The Landenian system has a wider extension, forming, with the other terms of the eocene series, nearly all of lower Belgium. Thus it is to the wide-spread mass of the London clay, which covers the Landenian sands, that Belgium owes its meadows and well-cultivated fields, which extend in an immense plain from the Brabant to the coast.

and from Dunkirk to Ostend. The Bruxellian and Laekenian systems form superficial hills in the neighborhood of Brussels, Gand, etc. The oligocene system shows two principal divisions (tongrian, rupelian), which stretch across the lower part of the river Escaut, where it leaves the eocene districts, through which it flows in the western part of the country. The pliocene formations overlap irregularly the underlying tertiary beds, and extend from Antwerp to Louvain. Many fine fossils have been found in these beds, where Mourlon admits several divisions, — Diestien (in part), Anversien, and Scaldisien. The last chapters of the work treat of the quaternary (diluvien, hesbayen, and campinien) and recent periods.

Though special attention has here been given to the stratigraphical extent and disposition of the beds, the author has treated with equal care of their lithological and paleontological characters, their minerals and fossils, and the useful products they furnish to Belgian industry. It will be enough, to indicate what amount of documents are included in the book, to state that the lists of fossils occupy 240, and the bibliographical lists 144 pages.

DU MONCEL'S ELECTRO-MAGNETS.

Electro-magnets. The determination of the elements of their construction. By TH. DU MONCEL. From the second French edition. New York, *Van Nostrand*, 1883.

The same. Translated from the French by C. J. Wharton. London, *Spon*, 1883.

THE great interest in the practical applications of electricity demands simple treatises on the most economical methods of making electro-magnets. Count Th. Du Moncel has endeavored to supply this want, and has added another treatise to the long list he has already published upon electricity. He disclaims any endeavor to make a treatise on electro-magnets which shall embody scientific theories upon that most difficult of subjects, theoretical magnetism. His desire is to give the mechanician a *vade mecum* by means of which he can construct electro-magnets for operations outside the laboratory. Indeed, this treatise is intended to stand in the same relation to the maker of dynamo-electric machines as a treatise on the practical construction of boilers, minus theories of elasticity, would stand to the constructor of steam-engines. There is need for such a treatise, undoubtedly; for much expense can be saved by a little knowledge where to put the material to the best advantage. Most of the dynamo machines which are before the world at the present time are defective in the arrangement of the wire of the field electro-magnets. Does the treatise of Du Moncel supply this want? The author follows the antiquated French fashion of expressing the resistance of a wire in terms of the length and diameter, without specifying, in many cases, the specific resistance. Thus, instead of ohms, we read so many metres of telegraph-wire; and one must enter into a troublesome arithmetical drudgery to ascertain what is meant. The English edition, published by Spon, states in the preface the relation between Du Moncel's units and the commonly received units of resistance and electro-motive force; but the American edition, published by Van Nostrand, leaves the reader to find out this relation after he has plodded some distance through the treatise.

The two imprints, one by Spon and the other by Van Nostrand, are carelessly edited. Thus, on p. 43 in Van Nostrand, we find an inconsistency between the values of t^2 and A.

On p. 47, Van Nostrand gives

$$ab = \frac{\rho}{e^2}\,0.000506\,\sqrt[3]{\sqrt[3]{P^4f^8}}$$

$$= \frac{\rho}{e^2}\left(0.0225\,\sqrt[3]{\sqrt[3]{P^2f^4}}\right)^2;$$

while Spon gives, on p. 34,

$$ab = \frac{\rho}{e^2}\left(.0225\,\sqrt[3]{\sqrt{P^2f^4}}\right)^2$$

$$= \frac{\rho}{e^2}\,.000506\,\sqrt[3]{\sqrt[3]{P^4f^8}}.$$

We give this as an example of similar mistakes which meet the eye. The question arises whether a more carefully prepared treatise, which would start with the fundamental system of electrical measurements, is not still needed. It is useless for any one to endeavor to become a practical electrician to-day, without a sound training in mathematics as far as the principles of the differential and integral calculus. A genius may arise, but he will know enough to employ a steady plodder who has been steeped in the principles of the calculus. Most constructors who desire to build electro-magnets will find that the exigences of space and material will demand a certain form. Unless they understand the theory of magnetic measurements, they will find the treatise of Du Moncel of little value; for so many and so large approximations must be made, that the final result would not differ much from those obtained by a thumb-rule. We commend to the practical electrician a study of the fundamental magnetic measurements rather than the perusal of treatises of this nature.

LEDGER'S SUN AND ITS PLANETS.

The sun, its planets, and their satellites. By Rev. Edmund Ledger, M.A. London, *Stanford*, 1882. 432 p. 12°.

Of late a considerable number of semi-popular works have appeared on astronomical subjects. They seem to meet a felt want of the community, and have been very successful. We call them *semi*-popular: because, while they are not written for professional astronomers, they are adapted, in their style and mode of treatment, less to the great masses of the business and laboring population than to the educated people who are engaged in various professional occupations. Those, for instance, who are busy in teaching, or with the practice of medicine or law, or who are pursuing geological or biological research (in short, pretty much all who would naturally subscribe for Science), generally wish to keep *au courant* of what is going on in other than their own special lines of work, and are delighted to find what they want, when they can get it in an attractive form.

Mr. Ledger's book is an excellent one of this class. It is less diffuse than Mr. Proctor's essays, and not quite so imaginative. It is narrower in its scope than Professor Newcomb's Popular astronomy, but easier reading, and fuller of detail in respect to the subjects of which it does treat. It makes no special claims to originality, but is accurate and clear, and the style is unpretentious and agreeable. The book is nicely gotten up, and very well illustrated. Altogether, we have no hesitation in pronouncing it a volume well worth reading and possessing.

It is made up of fifteen lectures read in 1881 and 1882 in Gresham college, London. Two are upon the sun, two are devoted to the moon, two to the earth, and two to Jupiter and his satellites. Each of the other planets has a chapter to itself (counting the group of planetoids as one), and there is a chapter entitled 'Ptolemy *versus* Copernicus.' Naturally, the lectures are not all of equal interest and value; but none of them are poor, or could be well dispensed with. The chapters upon Mars and the planetoids strike us as particularly good, and contain information not otherwise very easily accessible. The chapters on the sun and moon are also excellent, though naturally enough, in the main, only an abridgment and compilation from the recent books on these subjects; to which books the author handsomely acknowledges his obligations.

There are remarkably few mistakes in the work: in fact, in reading it over for this notice, we have found none at all, unless we count as such, a blunder in the illustration on p. 147, representing the comparative size of the sun as seen from Mercury at perihelion and aphelion; the difference being represented very much greater than the truth. Speaking of illustrations, the fine Woodbury-type of the eclipse of 1871 deserves special mention, and several of the pictures of Mars and Jupiter are unusually excellent. It is rather a pity that a few pages of tables were not appended, containing the numerical statistics of the planetary system. They would have greatly increased the value of the book for those who wish not merely to read it once, but to keep it on their shelves for occasional reference.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

Flexure of the broken transit.—Professor C. A. Young, after alluding to the fact that the flexure-correction of this peculiar form of transit is not treated of in any of the common text-books on practical astronomy (not even in Sawitsch, who specially describes and discusses the instrument itself), states the theory of the correction to transits of stars observed with the 'broken transit,' which is often so great as to amount to a large fraction of a second of time at the zenith. The constant of flexure must be known, and its effect eliminated, before the collimation error can be determined by reversal of the instrument on a circumpolar star. The correction has the same coefficient with the level-error; and denoting this latter, as usually obtained, by b, the flexure-constant by f, and the pivot-correction by p, the complete formula for the 'level-constant' is $[b \pm (f \pm p)]$. Thus, by flexure, the time of transit of a star is affected by $f \cos z \sec d$. The sign of f changes with the reversal of the instrument, being always plus for eye east, and minus for eye west. Prof. Young gives several methods of determining f: by observing zenith stars in reversed positions of the instrument, by means of the collimating eye-piece and mercury-basin, or a vertical collimator supported above the instrument, and by least-square treatment of equations given by repeated observation of suitable stars in both positions of the instrument. Some forms of the 'broken telescope' transit, especially those with a slender axis, require the addition of terms involving other functions of z than its cosine. Prof. Watson found for a Stackpole transit a flexure-correction of the form $(f \cos z + f' \cos^2 z) \sec d$. But if the axis is reasonably stiff, the second term is never sensible. — (*Sid. mess.*, June.) D. P. T. [1

MATHEMATICS.

Double theta-functions. — M. Caspary gives an account of some of the more elementary theorems concerning the theta-functions of two variables. He proves first, in a very simple manner, that the squared functions can be arranged in the form of a determinant of the fourth order which satisfies all the conditions of a determinant of an orthogonal substitution. He derives also the Göpel relations between these functions and their application to Kummer's surface. A number of other fundamental theorems are also arrived at in a very elementary manner, making the paper a valuable introduction to the study of the double theta-functions. — (*Journ. reine ang. math.*, xciv. no. 1.) T. C. [2

Periodic functions. — M. Hurwitz discusses single-valued $2n$-fold periodic functions which throughout a finite region have the character of rational functions, and which are real for real values of their arguments. More exactly he examines the properties of the periods of such Abelian integrals as belong to a real algebraic form (*gebilde*). By a *real* algebraic form he means the aggregate of all pairs of values of (x, y) which satisfy an irreducible algebraic equation $(F(x, y) = 0)$ whose coefficients are all real. Defining a periodic function by the equation

$$\phi(u_1 + P_1, u_2 + P_2 \ldots u_n + P_n) = \phi(u_1, u_2 \ldots u_n),$$

the complex of quantities P_a is called a period of the function ϕ, a single one of these quantities being called a modulus of periodicity. A period is then real or pure imaginary when the moduli of periodicity which constitute it are real or pure imaginary. The principal theorem arrived at by the author is as follows: let $\phi(u_1, u_2 \ldots u_n)$ denote a single-valued $2n$-fold periodic function which everywhere throughout a finite region possesses the character of a rational function, and which takes real values whenever its arguments are real; then there are always n period-pairs,

$$(P_{1\beta}, P_{2\beta} \ldots P_{n\beta}), (P_{1, n+\beta}, P_{2, n+\beta} \ldots P_{n, n+\beta}),$$

which form together a system of primitive periods of the function, and which are of such a nature, that, for each pair, one of the two conditions following is satisfied: either the first period $(P_{1\beta} \ldots P_{n\beta})$ is real, and the second period $(P_{1, n+\beta} \ldots P_{n, n+\beta})$ is purely imaginary; or the first period is real, and the period $(2P_{1, n+\beta} - P_{1,\beta} \ldots 2P_{n, n+\beta} - P_{n\beta})$ is purely imaginary. — (*Journ. reine ang. math.*, xciv. no. 1.) T. C. [3

PHYSICS.

Liquefaction of nitrogen and carbonic oxide. — S. Wroblewsky and K. Olszewski give a more detailed account of the liquefaction of nitrogen (SCIENCE, i. 970). The gas remained invisible when submitted to a pressure of one hundred and fifty atmospheres and a temperature of $-136°$; but, when the pressure was slowly reduced to fifty atmospheres, the gas was liquefied, presenting a visible meniscus, and evaporating very rapidly. Under the same conditions, the authors succeeded in liquefying carbonic oxide, which formed a colorless liquid with a visible meniscus. — (*Comptes rendus*, xcvi. 1225.) C. F. M. [4

Optics.

Mirage. — In an article entitled "State of the atmosphere which produces the forms of mirage observed by Vince and by Scoresby," Prof. Tait presents some very interesting researches regarding these particular forms of mirage. After an historical note, in which he refers to two valuable contributions to the subject by Wallaston and by Biot, which go far toward a solution of the problem, but have unfortunately fallen into oblivion, he presents his own investigations. His method consists in treating the curvature of a ray of light in the same way as the motion of a projectile; the two cases corresponding when, in the case of mirage, the square of the index of refraction of the air is proportional to the distance from a given horizontal plane.

He finds, however, that, "whatever be the law of refractive index of the air (provided it be the same at the same elevation), all we have to do to find the various possible images of an object at the same level as the eye is to *draw the curve of vertices for all rays passing through the eye in the vertical plane containing the eye and the object, and find its intersection with the vertical line midway between the eye and the object.*" By making suitable suppositions regarding the change of density, he finds that "the conditions requisite for the production of Vince's phenomenon are a stratum in which the refractive index diminishes upwards to a nearly stationary state, and below it a stratum in which the upward diminution is either less, or vanishes altogether." It will be seen that the solution of the problem of atmospheric density and refraction by this means is entirely indeterminate. The supposition of Prof. Tait satisfies the conditions presented by the observations of Vince; but that it is the only law or the true law must be verified by investigations of a different nature.

The method is especially valuable in its inverse form as affording a test of supposed laws of density and refraction in their ability to furnish the various phenomena of mirage. — (*Nature*, May 24.) G. E. C. [5

(*Photography.*)

Concentrated developer in one solution. — Where the photographer intends to travel, and develope on the route, it is very desirable to reduce his chemical outfit to the smallest bulk and to the fewest liquids possible. Mr. G. Cramer, the dry-plate manufacturer, gives the following formula for a developer, which he considers gives the best of results, and at the same time has the advantage of extreme portability.

Stock solution.

Sulphite of soda (crystals)	3 ounces.
Bromide of ammonium	½ ounce.

Bromide of potassium	1½ ounces.
Pyrogallic acid	2 ounces.
Dissolve in distilled water	32 ounces.
Add sulphuric acid (c. p.)	120 minims.
Add aqua ammonia (strongest) . . .	3 ounces.
Add water to make up bulk to . . .	40 ounces.

The sulphuric acid and aqua ammonia should be measured very exactly. Instead of three ounces of crystals, two ounces of granular sulphite of soda may be substituted to produce the same effect. Dilute a sufficient quantity for one day's use as follows: for ordinary purposes, one part in eleven; for very short exposures, one part in three to six; for over-exposed plates, or in all cases where great intensity and contrast are desirable, one part in twenty. This developer may be used repeatedly if it is always returned immediately to the pouring-bottle, which should be provided with a tight-fitting rubber stopper. As long as the solution remains transparent, it is good; but when it looks muddy its use should be discontinued. — (*Philad. phot.*, June.) W. H. P. [6

ENGINEERING.

Mill-engines. — The Southwark iron foundry has constructed for Messrs. Cheney Brothers of South Manchester, Conn., a compound 'Porter-Allen' engine, having steam-cylinders 12 and 21 inches diameter, 2-feet stroke, to run at 180 revolutions per minute. The power is given at 200 horse-power. The ratio of expansion is 16. The expenditure of water was 18.5 pounds per horse-power and per hour. Of this, 11.75 was accounted for by the indicator: the rest was wasted by condensation in the steam-cylinders and by leakage. In these engines the low-pressure cylinder is steam-jacketed, and the exhaust from the high-pressure cylinder passes into an intermediate reservoir, from which the large cylinder is supplied. The reservoir acts as a separator for the water carried in with the steam; and this water is trapped off, and does not reach the low-pressure cylinder. — (*Mechanics*, May 19.) R. H. T. [7

Compressed steel. — Tests have been made at the Watertown arsenal on cold-worked steel made by Naylor & Co. at the Norway steel and iron works, Boston, Mass. The elastic limit is raised from 26,540 pounds per square inch (1,966 kgs. per sq. cm.), in the hot-rolled bar, to 61,000 pounds (4,288 kgs.) in the cold-rolled steel. The ultimate strength is increased from 55,400 pounds (3,895 kgs.) to 70,420 (5,140 kgs.), in one case, and to 81,890 (5,757 kgs.) in another. The results of tests made at the mechanical laboratory of the department of engineering of the Stevens institute of technology are given, showing the increase due to cold rolling to be 70 per cent of the original torsional strength with iron, and over 150 per cent with soft steel. The resilience, or shock-resisting power, was increased, in an average of three tests, nearly 300 per cent in iron, and to double the latter quantity in steel. — (*Ibid.*) R. H. T. [8

Time-fuze for artillery. — Col. Richardson, R.A., finds that all the forms of time-fuzes at present in use are unsatisfactory, since they depend for their accuracy on the length of time during which a given column of composition burns: and this is a matter which is difficult of control at the best. He proposes to take advantage of the rapid and regular rotation of the shell during its flight by which to work a mechanism, which shall liberate a concussion-fuze at any desired moment. — (*Proc. roy. artill. inst.*, April, 1883.) C. E. M. [9

CHEMISTRY.

(General, physical, and inorganic.)

Basic sulphates of copper. — By continued boiling of a solution of cupric sulphate, S. U. Pickering obtained a basic sulphate, to which he assigns the formula $6\,CuO \cdot 2\,SO_3 \cdot 5\,H_2O$. Precipitation in the cold with potassic hydrate gave the basic salt $4\,CuO \cdot SO_3$. — (*Chem. news*, xlvii. 181.) C. F. M. [10

The hydrates of chlorine. — E. Maumenè thinks that the hydrate $Cl \cdot 10\,H_2O$, mentioned by Faraday, does not exist. Maumenè observed the formation of the hydrate $Cl \cdot 4\,H_2O$, which crystallized in cubes, and of the hydrate $Cl \cdot 7\,H_2O$ in well-marked crystals. With an excess of water, the hydrate $Cl \cdot 4\,H_2O$ is converted into the form $Cl \cdot 12\,H_2O$, which forms orthorhombic crystals. — (*Bull. soc. chim.*, xxxix. 397.) C. F. M. [11

Ammoniacal bromides and oxy-bromides of zinc. — When zinc oxide is dissolved with the aid of heat in a solution of ammonic bromide, G. André states that the compound $3\,ZnBr_2 \cdot 3\,NH_3 \cdot H_2O$ is formed. This compound is completely decomposed when boiled with a large quantity of water, leaving only the oxide. The compound $3\,ZnBr_2 \cdot 4\,NH_3 \cdot H_2O$ is formed when the experiment is conducted in the cold. On passing dry ammonia gas into a solution of zinc bromide, it is absorbed, with the formation of the product $3\,ZnBr_2 \cdot 5\,NH_3 \cdot H_2O$. The compound $2\,ZnBr_2 \cdot 5\,NH_3$ results when the ammoniacal bromide $2\,ZnBr_2 \cdot 5\,NH_3 \cdot 2\,H_2O$ is heated. The following oxy-bromides were prepared by methods similar to those which give the oxy-chlorides: $ZnBr_2 \cdot 4\,ZnO \cdot 13\,H_2O$, $ZnBr_2 \cdot 4\,ZnO \cdot 19\,H_2O$, $ZnBr_2 \cdot 5\,ZnO \cdot 6\,H_2O$, $ZnBr_2 \cdot 6\,ZnO \cdot 35\,H_2O$. — (*Bull. soc. chim.*, xxxix. 398.) C. F. M. [12

Artificial hausmannite. — By heating manganous chloride to the point of fusion for several hours, A. Gorgeu obtained crystals, on cooling, which possessed all the properties of the mineral hausmannite. — (*Comptes rendus*, xcvi. 1144.) C. F. M. [13

Formation of sulphides by pressure. — W. Spring submitted finely divided magnesium with the amount of sulphur calculated for one atom to a pressure of sixty-five hundred atmospheres. The product proved to be a homogeneous mass which gave off hydric sulphide when heated with water to 50° or 60°. Zinc sulphide was formed by subjecting a mixture of zinc and sulphur to the same pressure. Iron united with sulphur, forming, probably, a polysulphide. Cadmium gave a yellow powder, from which hydrochloric acid liberated hydric sulphide. Sulphides of aluminum, bismuth, lead, silver, copper, tin, and antimony were obtained by this process. — (*Berichte deutsch. chem. gesellsch.*, xvi. 999.) C. F. M. [14

(*Analytical.*)

Determination of nitrogen. — A new method for determining nitrogen, applicable to all nitrogen compounds, is proposed by H. Grouven. It consists essentially in burning the substance at a bright-red heat in a current of superheated steam. He first applied the process on the large scale to the production of ammonium salts from peat, but has since perfected it as an analytical method. The substance is burned in a boat, and the vapors arising from it are passed over a glowing layer of small fragments of a preparation called by the author 'contact-mass', and then through standard acid, as in the soda-lime method. The contact-mass consists of an ignited mixture of peat, chalk, and cement clay in certain proportions, and must be renewed after about fifty combustions. The advantages claimed for the method are, that combustions may succeed each other rapidly in the same apparatus (constructed of iron, with asbestos stoppers), that large quantities of material (two to three grams) may be used, that no drying or pulverization is necessary, and that it may be combined with an ash determination. Nitrates are dissolved with addition of sugar, sufficient clay is added to make a stiff dough, and the latter is introduced into the apparatus. The method is said to give concordant results, which are slightly higher than those obtained by the soda-lime method. — (*Landw. vers.-stat.*, xxviii. 343.) H. P. A. [15

AGRICULTURE.

Chemistry of 'fairy-rings.' — The formation on pasture-land of so-called 'fairy-rings,' that is, of circles of dark-green grass more luxuriant than the surrounding herbage, has long been supposed to be connected with the growth and decay of fungi, which serve as manure for the grasses which succeed them. The effect has by some been ascribed chiefly to the ash of the fungi, while others attribute it largely to their nitrogen. Two views are possible in regard to the way in which the fungi enrich the soil. They may have the power of attacking those organic and mineral matters in the soil which are not available as food for higher plants, and so of converting them into an available form, or it is possible that they have the power to assimilate free nitrogen from the air, and thus increase the store of this element in the soil. Lawes, Gilbert, and Warington have endeavored to decide between these alternatives by analyzing samples of soil from within, on, and outside of, several such rings. Almost uniformly the percentage of nitrogen in the surface-soil to the depth of nine inches was greatest outside the ring, least within it, and intermediate on the ring. The results of the carbon determinations were similar, but less uniform. The authors conclude that the fungi simply render more available to vegetation materials already existing in the soil; and that, as these materials are taken up and removed in the more abundant growth which follows, the soil is naturally impoverished. This conclusion applies, in the first place, to the nitrogen; but it would seem that it must be equally true of the ash ingredients. Whether there may not also be an evolution of free nitrogen by the fungi, or whether, on the other hand, nitrogen may not be assimilated from the air, are undetermined questions; but the phenomena are explainable without these suppositions. — (*Journ. chem. soc.*, ccxlvi. 208.) H. P. A. [16

GEOLOGY.

Puerco beds in France. — Professor E. D. Cope referred to an analysis by Dr. Lemoine of the marsupial types belonging to the *faune cernaysienne* as having been made considerably later than the speaker's diagnosis of similar forms from the Puerco beds, which belong to the same geological horizon. He claimed, that, as the age of the American formation had been the first to be definitely determined, its name should be applied to the corresponding French deposits. — (*Acad. nat. sc. Philad.; meeting* June 12.) [17

The Allegheny oil-sands. — Mr. C. A. Ashburner stated that he had recently examined the Allegheny oil-fields of western New York, and had been able to determine one or two points of interest both to commerce and to geology. After defining the Bradford and Allegheny oil-fields, the varying horizons of the oil-supply were alluded to. He had determined that the Allegheny oil-sands of New York were not above the Bradford sands of Pennsylvania, but were the same. Investigations extended into Livingston, Steuben, and Wyoming counties, N.Y., established the belief that the sands alluded to belong to the lower Chemung group. Mr. Ashburner further remarked, that, while these sands are doubtless for the most part reservoirs of oil produced in lower strata, some of the material was formed from plants contained in the sands themselves. The oil in Pennsylvania never reaches the reservoirs from above.

Mr. Benjamin S. Lyman stated his belief that the oil always originates in the sand where it is found. — (*Acad. nat. sc.; meeting* June 12.) [18

GEOGRAPHY.

(*Arctic.*)

Northern notes, Atlantic region. — The Germania sailed from Hamburg, June 20, with provisions and instruments for the German expedition at Cumberland Inlet. —— The departure of the Willem Barents in search of the Dutch expedition on the Varna took place as proposed. —— The account recently published of the wintering at Cape Flora, Franz Josef Land, by the Eira party, contains numerous items of interest in connection with the proposed use of this land as a starting-point or base for more northerly expeditions. As might be expected from the insularity of the land, the winter is milder than in the same latitude on the west Greenland coast. The land is probably slowly rising, like most other arctic land. Terraces ninety feet above the sea-level were observed. Resident land-animals, such as reindeer, arctic hares or rabbits, and ptarmigan, there are none. Of wandering arctic animals who live in the sea or on the ice, and are common to the whole frozen region, and sea-birds, there is a certain supply, the former being present the year round, though only male bears occur in winter, and the small auks for two-thirds of the year. The lowest temperature observed was forty-three degrees below zero, Fahrenheit, and this in latitude 80°. —— Tromholt, whose researches into the aurora borealis have proved its connection with electrical discharges from the earth, proposes to spend the winter 1883-84 in Iceland, devoting himself to similar studies with Lemström's apparatus, and on the lines indicated by him. —— The U. S. S. Yantic sailed June 14, from New York, to join the Proteus at St. Johns. Ensign H. G. Dresel, U. S. N., accompanies the Yantic as naturalist. Later advices announce the departure of both vessels from St. Johns for Lady Franklin Bay, June 29. —— The Danish South Greenland expedition has arrived at its field of work, and at last accounts expected to begin operations immediately. — W. H. D. [19

Northern notes, Pacific region. — June 2, the steamship Dakota left San Francisco for an excursion throughout south-eastern Alaska with a large number of excursionists. Similar excursions are planned for July and August. —— The schooner Leo has sailed from San Francisco to Point Barrow, to relieve Lieut. Ray and his party, and to obtain absolute magnetic astronomical and pendulum observations at the station. Returning, Mr. Clarke of the signal-service will relieve the present officer at St. Michaels, Norton Sound, and take charge of the station, which will be the most northern signal-service station then in operation. —— A vessel for the hydrographic exploration of the waters of Alaska, under the auspices of the U.S. coast-survey, is about to be constructed on the Atlantic coast, and sent out *viâ* Cape Horn, it being found that the expense of building her on the Pacific coast would considerably exceed the funds available. —— The last reports from the mines near Juneau, Alaska, are very favorable: the owners of one mine 'cleaned up' $9,000 in April; $80,000 have been refused by the owners of another claim. A number of miners will have preceded Lieut. Schwatka on his journey down the Lewis and Yukon rivers this season, bound to join the Schreffelin party on the Tananah. If these numerous prospectors and adventurers were to record their observations, doubtless much valuable information on other than mining topics might be preserved. —— The rock upon which the steamer Eureka was lost last month proves to be a previously unknown danger. —— The decrease of salmon in the rivers of Oregon and elsewhere has led to much activity in pushing out into the new north-west in search of unpillaged streams. A great many new salmon-fisheries have been established at various points in British Columbia and Alaska. —— The U. S. S. Adams is to visit the island of Kadiak on her summer cruise. —— The authorities of British Columbia have instituted an exploration of the Queen Charlotte Islands with reference to agricultural lands. The north-eastern portion of the northern island has been noted for nearly a century for its attractive aspect. The Hudson Bay company has long had a station at the entrance of Massett Inlet (named Hancock River by Capt. Crowell of Boston in 1791), where potatoes and other vegetables flourish; and the fat and sleek appearance of the cattle has been often mentioned by more recent visitors. The western coast of these islands has hardly been visited by explorers since Ingraham, in 1791, made his sketch-map of the coast. It is high and mountainous as far as known, and, like the south-eastern part of the group, likely to be chiefly valuable for its timber, minerals, and fish. —— The body of a white man murdered by the British Indians has been found near Milbank Sound, concealed near the shore; while two Alaskan Indians, who enlivened a visit to British Columbia by slaying two Chinamen, have been sentenced to be hanged at Victoria, V.I. —— The steamer Pinta of the U. S. navy, which was prepared for police-duty and exploration on the Alaskan coast, and lately pronounced unseaworthy, has been re-examined, and the decision reversed: she will sail shortly *viâ* Cape Horn under the command of Lieut. Uriel Sebree, U.S.N. This voyage will offer excellent opportunities for scientific observations *en route*. —— The U. S. S. Corwin, under the command of Capt. Healy, has sailed under instructions to visit Juneau, and settle certain quarrels between American and British miners there, then to proceed to the Pribiloff Islands to protect the seal-fisheries; after which St. Lawrence Bay, Bering Strait, will be visited, and the presents from the government to those hospitable Chukchis who preserved the lives of the Rodgers party will be delivered, arctic whiskey-smugglers looked after, and the usual observations made. — W. H. D. [20

BOTANY.

Cryptogams.

Notes on Laminariae. — In the fourth part of his Observationes phycologicae, Prof. J. E. Areschoug gives a revision of some species of Laminaria and related genera, including several of the forms found in the United States. He considers that L. platymeris, De la Pyl., is the same as L. Cloustoni, which he places in the genus Hafgygia, to which he considers that L. Andersonii also belongs. — W. G. F. [21

Iowa fungi. — Professor J. C. Arthur gives very full descriptions of twelve species of Iowa Uromyces, including one new species, U. acuminatus, on Spartina. At the end is an index of synonyms and host-plants. — (*Bull. Minn. acad.*, ii.) W. G. F. [22

Injurious Algae. — In a paper on some Algae of Minnesota supposed to be poisonous, Prof. J. C. Arthur gives an account of a species of Rivularia infesting the water of ponds at Waterville, Minn., and supposed to be the cause of death or injury to cattle. He also describes the condition of Lake Phalen, near St. Paul, in which he found several species of Nostochaceae. — (*Bull. Minn. acad.*, ii.) W. G. F. [23

Ohio fungi. — In a continuation of his paper on the mycologic flora of the Miami valley, Mr. A. P. Morgan gives a description of the Hyporhodii, Dermini, Pratelli, and Coprinarii of the region mentioned, including sixty-five species. — W. G. F. [24

Phenogams.

Formation of cystoliths. — Chareyre has examined the development of these bodies with special reference to the source of the materials from which they are produced. He finds that the food-reserve in seeds of Urticaceae is composed of aleuron grains possessing 'globoids;' and yet the calcareous matter forming the globoids, though disappearing at the period of germination, does not contribute to the formation of the cystoliths. Sometimes, when grown upon pure sand, the seedlings exhibit the *pedicle* of the cystolith, but nothing more. Upon chalky soil, or even ordinary earth, the cystoliths appear very soon, — in fact, as soon as the cotyledons are disengaged from the seed-coats. If the seeds are made to germinate in darkness, even if other conditions are favorable, the cystoliths remain in the rudimentary state. Furthermore, in some cases, cystoliths already formed disappear upon keeping the plants in darkness. — (*Comptes rendus*, May 28.) G. L. G. [25

ZOÖLOGY.

Coelenterates.

A new hydroid polyp. — Professor E. D. Cope described an interesting form of hydroid polyp found in large numbers on the bark of submerged trees in Upper Klamath Lake, Oregon. Its coenoecium is a mass of creeping yellowish stems embedded in sarcode. Each zoöid is of an elongate oval form, sessile, and with six rays of equal size, each one-half as long as the body. The zoöids are translucent, but with two oval bodies in the lower half of the body-cavity of a yellow color. These are collected in masses as large as the fist. The length of each zoöid is one millimetre. They did not extend themselves beyond this length, neither did the rays elongate to beyond half the same during the time they were observed. They retracted themselves on being irritated. They do not possess any fringes like the arms of the polyzoa. As the possession of a coenoecium distinguishes this genus from all the fresh-water hydroids, it was proposed to distinguish it as the type of a new genus with the name Rhizohydra, the species being named flavitincta. An attempt to preserve some of the masses of zoöids in alcohol was not successful. — (*Acad. nat. sc. Philad.; meeting* June 19.) [26

Mollusks.

Abyssal mollusks. — The fifth part of the Mollusca of the Lightning and Porcupine expeditions, by Dr. J. Gwyn Jeffreys, has been received. It treats of the Solenoconchia, Polyplacophora, Docoglossa, and scutibranchiate limpets, contains supplementary notes to the preceding four parts, and is illustrated by two excellent plates. The number of species first described herein is not large; but a surprising number of facts as to distribution, synonymy, biography, and external anatomy, are brought together. In adopting a later name than Acmaea for that genus, he observes that in the original description no type or species was mentioned by Eschscholtz, but has apparently overlooked the fact that the same is true of the genus Tectura, by which he would replace Acmaea. —— Parts xv. and xvi. of the preliminary descriptions of the Mollusca of the Challenger expedition, by Rev. R. Boog-Watson, are at hand. They cover the Ranellidae, Muricidae, Scalariidae, and Solariidae in the first, and the Fissurellidae and Cocculinidae in the second part. Quite a number of the species are from comparatively shallow water. Eight new species of Puncturella were obtained from one dredging at a locality north of Culebra Island, near St. Thomas, in the Danish West Indies. One of these is the largest yet known. The common Puncturella noachina Linn. of British, north-east American, and Alaskan seas was obtained in the Straits of Magellan, at Kerguelen Island, and at a station between these two, which seems truly remarkable. The operculum of Nassaria kampyla Watson, and the dentition of a new species of Cocculina from the Philippine Islands, are figured. The teeth closely resemble in general features those of the American species, except that the median tooth is more, and the major laterals less, developed than in the forms obtained by the U. S. fish-commission. The descriptions are in the full and faithful manner characteristic of Mr. Watson's work. — W. H. D. [27

Crustaceans.

Haemoglobin in the blood of Branchiopoda. — Some years ago E. Van Beneden discovered a double system of circulation in some of the parasitic Copepoda like that in many annelids, and described a complicated system of vessels with true walls, filled with a red fluid containing haemoglobin, but no corpuscles, and entirely distinct from the lacunar system with colorless fluid containing corpuscles. P. Regnard and R. Blanchard find a similar system in Apus, and believe that it exists also in some Cladocera and Ostracoda. Chemical examination convinces them that true haemoglobin is present in the blood of Apus, is always combined with oxygen, and plays some part in respiration. — (*Zool. anz.*, May 7, 1883.) S. I. S. [28

Fresh-water Copepoda. — F. W. Cragin enumerates the genera of free-swimming Copepoda known to inhabit inland waters, describes and figures ten species of Cyclops, half of them new, from Cambridge, Mass., and publishes a translation of descriptions in Russia of several species of Cyclops by Poggenpol. Mr. Cragin notes the occurrence of the gregarinian, Lagenella nobilis, in North American species of Cyclops. — (*Trans. Kansas acad. sc.*, viii. 1883.) S. I. S. [29

Insects.

The male genital armature of Lepidoptera. — Considering how important a use has been made of these organs to distinguish species in nearly all other groups of insects, it is a little surprising to see how few lepidopterists have availed themselves of the excellent marks of distinction they afford. Rambur in 1839 (whose writings Gosse in the paper before us entirely overlooks), de Haan in 1842, and recently Buchanan White, are the only European authors who have paid any attention to these organs in butterflies; and Scudder and Burgess stand alone in this country.

In the present paper, Gosse describes and figures their appearance in eleven species of Ornithoptera, and fifty-six species of Papilio, including our own Thoas and Turnus. In one, P. Schmeltzi, he found a slight asymmetry in the armature of the two classes. Gosse gives new names to nearly all the parts. The side-plates, or flaps, which conceal the whole, he terms, as usual, 'valves;' the inwardly projecting armature of the interior of these, the 'harpes;' the beak-like mesial prolongation of the eighth abdominal segment, the 'uncus;' the unpaired appendage lying between it and the intromittent organ, the 'scaphium.' He has done particular service in the care with which he has reproduced the scaphium, — an organ consisting, in the swallow-tails, of chitinous points on a membranous body, and therefore badly distorted in dried specimens. This portion was studied and drawn after it had been made to assume its natural fresh appearance by absorbing a drop of water. The variety and strangeness of form and armature assumed by these parts, and particularly by the so-called scaphium and harpes, is very remarkable. In his naming of these parts anew, Gosse has burdened us with new terms for organs which are abundantly named already; but they will, perhaps, have their advantages, if they do not survive after homologues in other insects are pointed out. In his remarks on these organs in other butterflies, Gosse fails to see the homologies which exist, and which Burgess points out in part in a paper which Gosse appears not to have seen (*Anniv. mem. Bost. soc. nat. hist.*), and Buchanan White as well (*Trans. Linn. soc., Zoöl.*, i. 358). In brief, it may be stated that the organs in butterflies consist, besides the intromittent organ, of simply an unpaired upper organ, and paired lower appendages; both of which are attached, the upper immovably, to the ninth abdominal segment. The upper organ usually takes the form of a hook, and the lower, of claspers. In the Papilionides, however (including in that both swallow-tails and pierids), the dorsum of the *eighth* segment of the abdomen is prolonged posteriorly into a terminal hook overlying and concealing the true upper appendage, and at first readily mistaken for it, as shown in the swallow-tails by White and in the pierids by Burgess. Burgess also shows that false claspers exist in Danais, differing only from true claspers in not being articulated. Bearing in mind the attachment of the different external organs ancillary to generation, their homologies throughout the insects are not difficult to trace.

Buchanan White termed the 'upper organ' of Scudder and Burgess the 'tegumen,' and their 'clasps,' 'harpagones.' The uncus of Gosse (which on rare occasions is wanting in some swallow-tails) is therefore no proper part of the ordinary organs ancillary to generation, but a prolongation of the eighth abdominal segment. The scaphium is the upper organ, or the tegumen, of White; the valves of Gosse, the clasps of Scudder and Burgess or the harpagones of White; and the harpe, merely the armature of the clasp, which is extremely varied and complex, not only in the group where Gosse has so well illustrated it, but also in many skippers: indeed, this bizarre form of armature, both of 'scaphium' and 'harpe,' is a new indication of the alliance between the swallow-tails and skippers. We may further remark, that, if the old genus Papilio is the sooner broken up by the additional help afforded by these new studies, Gosse will have done systematists a real service. — (*Trans. Linn. soc. Lond., Zoöl.*, ii. 265.) S. H. S. [30

VERTEBRATES.

Chemistry and physiology of blood-serum. — In dogs which have been starved for a period of five or six days, and which previous to the commencement of the starvation had been fed for two or three weeks on horse-flesh freed as far as possible from fat, Burckhardt finds a diminution in the total amount of proteids in the blood-serum, the loss varying from 4% to 16% of the original amount of proteids present. Of the two proteids of serum, the quantity of serum-globulin increases during starvation, the increase ranging in his experiments from 22.8% to 66.4% of the quantity present before starvation. Serum-albumen, on the other hand, suffers a marked diminution, from 5.3% to 21.66% of the normal quantity. A calculation of the probable loss of albumen from the blood and lymph on the basis of his experiments, when compared with the amount of urea excreted by dogs, according to Voit, in the first five days of starvation, shows that the quantity of albumen lost from the circulating liquids is much too small to account for the proteid destruction indicated by the urea. Burckhardt made use of dialysis chiefly in determining the quantity of serum-globulin present in serum. The serum-albumen was estimated as the difference between the total proteids and the serum-globulin. He states that Hammarsten's method of obtaining serum-globulin by means of $MgSO_4$ is not reliable. Complete saturation with $MgSO_4$ throws down not only the serum-globulin, but also a large amount of proteid, which resembles serum-albumen, as usually understood, in every respect except in its precipitation by $Mg.SO_4$. — (*Arch. exper. path. pharmak.*, xvi. 322.) W. H. H. [31

Double staining blood-corpuscles. — Dr. Vincent Harris has made a series of systematic experiments on double staining of nucleated blood corpuscles with aniline dyes, and gives in connection therewith a table of the aniline dyes, and their solubility in water and alcohol. A little blood was dried rapidly in a thin layer on a slide, and treated with two dyes in succession. The only entirely successful combinations were the following: rosein and aniline green, fuchsin and methylen blue, fuchsin and Bismarck brown, eosin and resuvin, iodine green and Bismarck brown, Hoffman's violet and Bismarck brown, aniline violet and methylen blue. The greens were not at all permanent. The results were often variable and uncertain. For success the solutions must be quite fresh. The time each dye is allowed to remain greatly affects the results. — (*Quart. journ. micr. sc.*, 1883, 292.) C. S. M. [32

The primitive mouth of vertebrates. — According to Rauber, the gastrula mouth (original blastopore or prostoma) is represented by various parts in vertebrates. In Pretromyzon, sturgeons, and Amphibia it is undivided. In sharks it is divided into two parts; i.e., primitive furrow, and posterior marginal opening. In birds it consists of the primitive furrow and marginal notch of the germinal area, and includes also the various small openings formed at the terminal swelling of the embryo; viz., the neurenteric canal, the passage observed by Gasser in the embryo of the Cochin-China breed of hens, and the break which sometimes occurs between the allantois sack and the ectodermal ingrowth behind the tail (caudal sack).

Rauber also asserts in the same paper that the bilateral outgrowths from the primitive streak of amniote embryos are homologous with the divesticula forming the mesoderm in Amphioxus. — (*Zool. anz.*, vi. 143, 163.) [33

Reptiles.

Venom of serpents. — The constitution of the venom of certain of the poisonous serpents has been examined by Mitchell and Reichert with interesting and somewhat remarkable results. According to them, three distinct proteids may be isolated from the venom of the moccason and the rattlesnake (C. adamanteus). These they propose to call respectively, venom-peptone, venom-globulin, and venom-albumen. The venom-peptone may be obtained from fresh venom, or from the aqueous solution of the dried material by dialysis, or by boiling and filtering off from the precipitated proteids. It is soluble in water, not coagulated by boiling, and readily dialyzable. Its solutions, while answering to all the general tests for peptones, exhibit certain peculiar reactions which distinguish it from the class of peptones as usually understood. The most marked of these specific reactions are its precipitation from aqueous solutions by saturation with potassium hydroxide or sodium chloride, and by the addition of dilute acetic acid. Its solutions possess the poisonous properties of venom, though in a less marked degree, giving rise to putrefactive changes when injected into the living animal.

The solution of the peptone obtained by boiling venom, and filtering from the precipitate of coagulated proteids, breaks up on drying with the formation of two proteids, one of which is soluble, and gives all the reactions of the original substance, with the exception that it is not poisonous. The other is insoluble in water, and likewise innocuous.

If an aqueous solution of venom is allowed to stand for some time, a precipitate occurs which gives the usual reactions of globulins. This substance possesses all the toxic powers of fresh venom.

After the separation of the peptone and globulin, a third proteid remains in solution which is apparently closely connected with the albumens, though the authors have not been able to obtain it in a state of sufficient purity to make decisive tests. It is soluble in water, coagulates below 70° C., and is precipitated from its solutions by weak alkalies and acids. It is probably not poisonous. — (*Medical news*, April 28, 1883.) W. H. H. [34

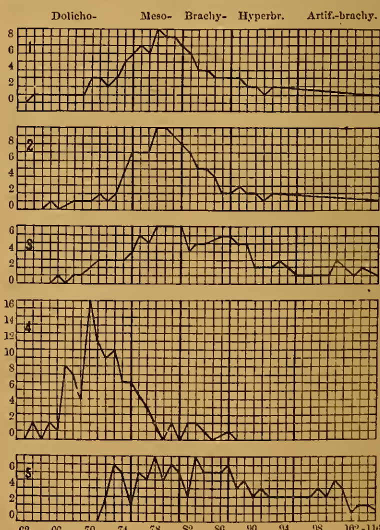
Mammals.

Cutaneous nerves in mammals. — Dr. Harrison Allen has succeeded in tracing nerve-filaments to the larger setae-bearing hair-follicles in mammals as exposed after depilation. He believes that the hair-follicles of the oral, the mental, the supra-orbital and the disto-carpal tufts, as well as those placed on the lateral aspects of the limbs, are in all cases supplied with nerve-filaments, as are the pteryls of birds. In specimens in which the follicles are rudimentary there is a corresponding failure of the nerve, thus indicating a close relation between the two. — (*Acad. nat. sc. Philad.*; *meeting* June 12.) [35

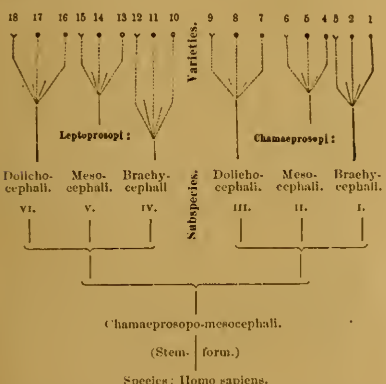
Nerves of the human eyelid. — Von Mises describes the results of his studies. The nerves enter in bundles from the sides as well as from above, and are distributed more or less parallel with the blood-vessels, and form a rich plexus along the edge of the lid. Some details are given as to the distribution of the nerves to the conjunctiva. — (*Sitzungsb. akad. wiss. Wien*, lxxxv., *abth.*, iii. p. 172.) C. S. M. [36

ANTHROPOLOGY.

The autochthones of America. — Dr. J. Kollman of Basel gives his views of American craniology, based on a study of the breadth indices of 1,500 crania, quoted from published measurements, and representing all the countries between Bering Strait and Tierra del Fuego. Five curves are appended,



which reproduce graphically the breadth indices of five groups of American skulls. Curve I. represents 1,292 crania of aborigines of America, whether from ancient Indian burying-places or picked up on recent battle-fields; curve II., 917 North Americans, including the territories of the United States and British America, with the exception of the Eskimo; curve III., 248 Central and South Americans, including the Mexicans on account of their peculiar civilization; curve IV., 127 Eskimo, consisting of all crania from the arctic regions of North America; curve V., 208 pre-Columbians, discriminated from other North Americans by their manner of burial, i.e., mound-builders and stonegrave people. A study of these teaches, 1°. The plurality of varieties in America; 2°. The diffusion of these varieties over the whole continent. As an illustration, the stonegrave people of Tennessee are cited. Their remains are those of a single people, as Mr. Putnam has shown by the correspondence of their customs, and grade of civilization; while the measurements of their skulls by Mr. Carr show a varying proportion of dolichocephali, mesocephali, brachycephali, and artificially shortened crania. A people is an ethnic unity, which, according to the results of craniology, may consist of an anatomical plurality of races; but a race is an anatomically characteristic variety of the human species. Like the Germans, the mound-builders consist of many races, which have combined to an ethnic unity. The term 'race,' as here employed, is equivalent to a sub-species of the species Homo sapiens of Dr. Kollman's system, illustrated by the following diagram.



The varieties are distinguished by peculiarities of the hair: 1, 4, 7, being smooth-haired, indicated by the sign ○; 2, 5, 8, etc., straight-haired, by the sign ●; 3, 6, 9, etc., woolly-haired, by the sign V. So far as is known, only straight-haired varieties have immigrated into America, of the following sub-species: 1. Broad-faced dolichocephali (Eskimo); 2. Broad-faced mesaticephali (Indians); 3. Broad-faced brachycephali (mound-builders); 4. Long-faced brachycephali (ancient Peruvians).

Like the European, the American varieties of the species Homo sapiens have long since passed into the condition of permanent types. The time of elasticity, of the organization of new physically diverse forms, has long gone by. Wherever human remains are found in the glacial formations of Europe, they are as highly organized as to-day. Undoubtedly they represent men of a lower plane of civilization. It is erroneous at every footstep of advance in civilization to infer a new and more highly organized race. Craniology demonstrates that varieties, unchanged physically since the glacial epoch, are continually making their way to higher grades of civilization. — (*Zeitschr. ethnol.*, 1883, 1.) C. A. S. [37

Madagascar. — The vast island of Madagascar, 960 by 300 miles in extent, is unique in its proximity to a continent with which it has such feeble connections. Its population is about 4,000,000; but it is subject to great fluctuations through epidemics, witchcraft, infanticide, intertribal wars, and murders. The peculiar formation of the island effects a tropical, malarial climate around the coast, and a nearly temperate climate elsewhere. All around the island there is a belt of forest, often splitting into two parts, which enclose fertile valleys teeming with people. The natives are the Hovas, of Malay origin, and the Malagasy proper, of African origin, who for the past hundred years have been augmented by importation of slaves from central Africa. The system of government among the negro tribes is purely African in form. Among the Hovas, however, a queen holds sway, through the agency of a prime-minister, who is *ex-officio* husband of the queen. The religion of all the Malagasy is fetishism, with a shadowy recognition of a superior power. They believe in ghost-souls who are capable of good or harm to us, and this belief leads to great respect for the dead. Their beliefs, witchcraft, burials, roads, commerce, and language have been carefully studied by Dr. G. W. Parker, who has communicated a paper on the subject to the London anthropological institute. The island became known to the Portuguese, Dutch, French, and English early in the seventeenth century; although the Arabs traded there long before that. At the beginning of the present century the Hovas became the firm friends of the English, — a connection which has remained unbroken except during the reign of Queen Ranavalona I. Upon the assassination of her son, Radama II., the present system of queens and prime-ministers began.

The languages belong to the class of purely spoken tongues, no one of them having ever been reduced to writing by the natives. The vowels are *ah*, *ay*, *ea*, *ō*, *oo;* the consonant sounds, *b*, *d*, *f*, *g*, *h*, *j*, *k*, *l*, *m*, n, *ng*, *p*, *r*, *s*, *t*, *v*, *z;* the diphthongs are *eye* and *ow*.

The number of consonantal combinations is very small, which occasions many euphonic changes in compounds. The meaning of words and sentences depends little on the tone, but much on accent, position, and the discriminative particle *no*.

Onomatopoeia is common. The grammatic structure is quite regular. A large percentage of the words are traceable to verbal and denominative roots, which are affixed and compounded to an indefinite extent. Gender is indicated by the affixes for male and female, and there is no distinction between animate and inanimate. The numeral system is decimal, and ends with *tapitrisa* (ended are the numbers), the word for a million. There are two moods of the verb,— the indicative and the imperative. There are two classes of personal pronouns,— the inclusive of the speaker, and the exclusive. Other peculiarities in grammar are pointed out by Dr. Parker in an exhaustive dictionary of fourteen dialects, which unite the Malagasy with the Malay stock-language. To account for this anomaly of race and language, Dr. Hildebrand supposes the Hovas to have first settled the island, and to have been overpowered by African marauders, who killed most of the Hova men, and married their wives. The children, learning their language from the mothers, perpetuated at the same time their African blood and their Malay language. But Dr. Parker seriously objects to this explanation. Mr. Keane is of the opinion that the Africans were introduced as slaves, who, while gradually corrupting the blood, would have little effect upon the language. Dr. G. Oppert also commented upon the paper. — (*Journ. anthrop. inst.*, xii. 478.) J. W. P. [38

The flora of ancient Egypt. — The student of anthropology is repeatedly charmed and surprised by the varied and brilliant illumination thrown upon his subject by sister sciences. He is not less pleased to know that quite frequently the light proceeds in the other direction, and that human custom preserves for other sciences their sibylline leaves. In 1881 Emil Brugsch Bey discovered in the vault of a king of the twentieth dynasty a large number of plants contained in the funeral offerings, repasts, and wreaths of the dead. Among these are several species not known to have belonged to ancient Egypt. Mr. G. Schweinfurth, deputed by M. Maspero, has studied these plants, and classified them in the Egyptological museum of Boulak, according to the high personages for whom they were intended. A very extended and interesting account of these labors was communicated to Sir Joseph D. Hooker, together with a set of the wreaths, flowers, etc., described. Excellent illustrations accompany the paper of Mr. Schweinfurth. These objects were exhibited at the annual *soirée* of the Royal society on the 25th of May, and are now on view at the Royal gardens, Kew. — (*Nature*, May 31.) J. W. P. [39

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

STATE INSTITUTIONS.

Missouri weather service, St. Louis.

Weather report for May. — The average temperature for May at the central station has been 63.4°, which is 2.8° below the normal temperature, and 3.5° above the temperature of May, 1882. Since 1837 the May temperature has fallen below that of last month five times. The extremes during last month at the central station were 38.0° and 88.4°; although, in the suburbs of St. Louis, the temperature fell to 36.0° on the evening of the 21st. In 1851 Dr. Engelmann observed a temperature of 29.0° in May, but it was in the early part of the month. The lowest minimum temperatures reported were, 29.5° at Centreville; 31.0°, at Big Creek, Warren county; 32.0°, at Steelville; all other stations reporting over 34.0°. The highest minimum temperatures are reported from Glasgow, 45.0°, and Harrisonville, 47.0°. The highest maximum temperatures reported were, Corring, 91.0°; Miami, 98.0°; Harrisonville and Big Creek, 90.0°. The highest average temperatures reported were, Cairo, Ill., 65.2°; Mascoutah, Ill., 65.0°; Harrisonville, 64.0°: the lowest being at Keokuk, Io., 59.9°; Macon, 60.4°; Louisiana, 60.5°.

The rainfall at the central station was 2.61 inches, which is 2.2 inches below the normal May rainfall at St. Louis. In western Missouri, however, from Harrisonville northward along the Missouri valley, the rainfall has been over seven inches; and a small maximum of over seven inches occurs in the region around Ironton. An area of minimum rainfall of between two and three inches occurs in south-west Missouri, around Greenfield and Lamar, and another occurs along the lower Missouri below Chamois, extending along the Mississippi as far south as Cairo.

On the 13th, tornadoes occurred at various points in Missouri and Kansas, as follows: the town of Oronogo, Jasper county, was destroyed at about 7.40 P.M., two persons being killed, and forty injured. This tornado is probably the one which passed about two miles north of Carthage. Hailstones as large as hen's eggs fell at Springfield at about 10 P.M. Another storm passed two miles south-east of Pattonsville, Davies county, on the same evening. Two tornadoes passed through Kansas City at 5 o'clock, one passing a few minutes later than the other. Several persons were killed, and a great deal of damage was done to property. These whirls were slender whiplike vortices, the diameter at the surface of the earth being only a few feet, although the destructive path was about seventy feet. These storms originated apparently in Wyandotte county, Kan., where they caused great damage. A later development of this storm passed through Macon City, one hundred and twenty miles east-north-east from Kansas City, where a tornado occurred about 8.30 P.M. The track was from one-fourth to three-eighths of a mile wide. Three persons were killed at Macon.

On the 18th, tornadoes occurred in Missouri, Illinois, and Wisconsin. At 7 P.M. a tornado did considerable damage at Berger, Gasconade county, Mo. At about 8.20 P.M. a tornado passed through Wentzville from the south-west, causing great destruction to property, and loss of life, as far as St. Paul, Mo. At about the same time a storm passed from Cottleville, through Elm Point, to Grafton, on the Illinois shore of the Mississippi River.

Hail-storms have occurred as follows: at Big Creek, 10th; Centreville, 9th; eight miles north of Savannah, 3d; Hannibal, 9th; Louisiana, 9th and 10th (and at Springfield and Dover church, near Louisiana, large hail fell on the afternoon of the 18th); Lamar, 3d; Chamois, 9th, — a violent storm of wind and hail at 7 P.M., for seven to ten minutes, the hail completely covering the ground, some stones weighing six ounces. On the 18th, at 5.50 P.M., a dark cloud in the south-west moved to the west with a heavy roaring noise, appearing to spend its force when due west, rain and small hail following.

Killing frosts occurred on the nights of the 21st and 22d. At Big Creek great damage was done to wheat, corn, and fruit. At Centreville, at 9 P.M., on the 21st, the temperature was 32°, and fell later to 29.5°, — the latest frost in sixteen years. Fog prevented damage in the valleys of the Black River, but in the dry valleys every thing was killed. Louisiana, 32° at sunrise on the 22d; Chamois, destructive frost with ice an eighth of an inch thick in a pan of water; Greenfield, heavy frost, which injured foliage of forest-trees so that they looked as though scorched by fire.

White frosts occurred at Hannibal, Greenfield, Mexico, Chamois, 5th; Hannibal, Louisiana, Chamois, Miami, 11th; Ironton, 16th; over the entire state, 21st and 22d, but light in the south-west, where the temperature was about 40°; Mexico, Ironton (33° at 5.30 A.M.), Louisiana, Chamois, Miami, Greenfield, 23d; Sedalia, Centreville, Greenfield (heavy), Ironton, Chamois, Miami, 31st.

ADDENDUM to April report. — At Cairo a heavy shock of earthquake was felt at 2.36 A.M. on the 12th, which lasted thirty seconds. Vibrations, three per second, from south-south-west to north-north-east. An old one-story frame-building, which was occupied at the time the shock occurred, was shaken down and collapsed, the inmates receiving slight injuries.

Iowa weather service, Iowa City.

Weather bulletin for May. — May was remarkably cold, very rainy, with late frosts, westerly and northerly winds prevailing. The mean temperature of the air was nearly five degrees *below* normal. In forty-five years, May has been six times as cold or colder than this year; namely, in 1882, 1867, 1858, 1851, 1850, and 1849. The late frosts about the 12th and 22d were general.

The rainfall was much above normal throughout Iowa, except in middle northern Iowa and down the middle Cedar and Wapsipinicon valleys. The total rainfall was highest along the Mississippi and Missouri rivers, and from Wayne to Polk county: in the regions here specified, the rainfall averaged seven inches. The rain frequency was also high: two of every three days were rainy in most parts of the state.

The principal storm-days were the 8th and 9th, the 13th and 14th, 17th and 27th. On the 9th a very small tornado did slight damage in Linn county, near Norway station: on the other storm-days, Iowa was spared the visitation of tornadoes, which struck, on the 13th, Kansas City; 18th, Racine; 28th, southern Indiana.

While unusually cold and quite wet, the season is much more promising than last year, when May was much colder.

NOTES AND NEWS.

Stephen Alexander, professor emeritus of astronomy at Princeton, died June 26. He was born at Schenectady, N.Y., and was educated at Union college, where he graduated in 1824. Since 1840 he has been connected with Princeton, first as professor of astronomy, and later as professor of mechanics as well. As an astronomer he became widely known.

— Sir Edward Sabine, whose death has been lately announced, was born in Dublin in October, 1788. He studied at the military schools of Marlow and Woolwich, and at the age of fifteen entered the English army. In 1813 he was made captain, and took part in the campaign on the Niagara frontier, commanding the batteries at the siege of Fort Erie, 1814. From 1818 to 1825 he made a number of voyages from the equator to the arctic regions for the purpose of studying terrestrial magnetism, the figure of the earth, and other questions in terrestrial physics. He was with Ross and Parry on the arctic expedition of 1818, and with Parry the following year. He edited a number of translations of scientific books, and published a large number of papers on his favorite studies, having read more than forty before the Royal society, and having contributed many to the proceedings of the British association. From 1827 to 1830 he was secretary of the Royal society, and president for the ten years 1861 to 1871, and president of the British association in 1853. In 1875 the French academy elected him as a corresponding member.

— A few weeks ago (April 26) *Nature* gave a sketch of the life of Spottiswoode. In the number for June 14 we find a regret expressed at his absence, on account of sickness, from the Royal society meeting of that week. On June 27 he died. Born in London, Jan. 11, 1825, he began his education in a private school at Laleham, and then at Eton and Harrow; his stay at Eton being short on account of some experiments with detonating mixtures, in which he was found to be interested. In 1842 he entered Balliol college, Oxford, where, in his last year (1845) as undergraduate, he read with the Rev. Bartholomew Rice. After graduation he held university mathematical scholarships for two years, and for a short time lectured on geometry of three dimensions. But he soon took an active part in the management of the large printing-business about this time resigned to him by his father, and which he largely developed. His scientific work was mainly in mathematics, although of late years he has devoted himself to physics, his recent investigations in electricity being well known. When a young man, he travelled widely, and, among others, published a very lively account entitled "A Farantasse journey through eastern Russia in the autumn of 1856." He also studied languages, both oriental and European, and gave evidence of the thoroughness of these studies in his contributions to our knowledge.

—The Dickson expedition, in charge of Professor Nordenskiöld, which left Thurso May 29, is reported as having called at Reikiavik, Iceland, June 6, and was to sail for Greenland on the 10th. When the expedition started, it was the intention that Count Stromfeldt (botanist), Dr. Arpi (philologist and archeologist), and Mr. Flink (mineralogist) should disembark at Reikiavik, and remain in Iceland for study and exploration. It is reported by recently arrived whalers that the condition of the seas west from Iceland, as regards ice, is at present not unfavorable to the success of the expedition. The Sofia, upon which the party is embarked, is a little iron propeller of less than two hundred tons, capable of a speed of eleven knots, and draws ten feet of water, —a vessel much better suited to her purpose than the unwieldy craft which have been used in many of the English expeditions. It was originally intended that Palander should command the Sofia, but circumstances intervened to prevent this; and the vessel has been intrusted to Capt. Emil Nilsson, who is well qualified by experience, and who will be ably seconded by the well-known Norwegian ice-master, Johannesen. The scientific staff does not comprehend any of the members of the Vega expedition, who are mostly engaged in working up the investigations made on that voyage, but, after Baron Nordenskiöld, is composed of Dr. Kolthoff, entomologist and ornithologist; Dr. Nathorst, geologist and paleontologist; Dr. Berlin, surgeon, botanist, and general biologist; Mr. Forsstrand, taxidermist and preparator; Dr. Hamberg, hydrographer; Mr. Kjellström, photographer. Beside these, there are a harpooneer, two mountain Lapps (in accordance with the suggestion of Professor Fries, to which we have already alluded), and eight or nine picked men, to accompany the party over the inland ice. This party will be provided with fourteen months' provisions in the most compact shape possible. The crew of the Sofia comprises twenty-four men. The party is thoroughly equipped with scientific apparatus, and even includes a flying-machine contributed for trial by its inventor, according to the Swedish papers.

—Among the most interesting of the living animals in the gardens of the London fisheries exhibition are two British-born beavers from the Isle of Bute in Scotland. They were members of a colony established by the Earl of Bute upon his estate of Rothesay several years since. A considerable tract of land was walled in, and beavers were imported from Canada, which soon established themselves, gnawing down the trees, building a dam, and forming a lake of considerable size. The 'beaver wood' is considered one of the most interesting features of the island. Mr. R. B. Matthews writes to the *Field*, complaining, that, in capturing the two beavers to send to the exhibition, the colony has been broken up, the dams destroyed, the houses pulled down, and all the other beavers killed. It is to be hoped that the damage is not so serious as is represented, for the acclimation of the American beaver in Scotland is a task which is not likely to be often attempted.

—The next issue of the Proceedings of the naval institute (vol. ix. no. 3; whole no. 25) will be entirely devoted to an article by Lieut. Edward W. Very, on the development of armor for naval use. The number will thus be a complete work of itself, fully illustrated, and will possess more than ordinary interest in being the only work extant devoted exclusively to the details of armor development. Orders for this number should be sent to the secretary U. S. naval institute, Annapolis, Md., as early as possible. Price $1.

—The extraordinary meeting of the geological society of France for this year is to take place at Charleville (Ardennes) on Sunday, Sept. 2, and the excursions will end Tuesday, Sept. 11.

—The yearly meeting of the Schweizerischen naturforschenden gesellschaft will take place from the 6th to the 9th of August in Zurich, where the national exposition is attracting many people this year.

—G. Valentin, for forty-five years professor of physiology at the university of Berne, died on the 24th of May at the age of seventy-three. He was a native of Breslau. He was formerly one of Louis Agassiz's collaborators; and the fourth *livraison* of Agassiz's 'Monographies d'echinodermes vivants et fossiles', containing the anatomy of the genus Echinus, is by Valentin.

—Past assistant-engineer N. B. Clarke, U. S. N., read a paper on water-line defence and gun-shields for cruisers, at the meeting of the U. S. naval institute (Washington branch) on June 7.

—The bureau of education has issued, as one of the 'circulars of information,' a pamphlet containing the legal provisions respecting the examination and licensing of teachers.

—A contributor's note in the *Atlantic monthly* for June calls attention to the question of the spelling and pronunciation of geographic names, on which several articles have lately appeared in foreign journals. The question is not always settled by adopting local spelling and sound, for in many cases foreign names are well Anglicized, and will so remain; the difficulty is rather in knowing where to begin using the original pronunciation. As we do not say Paree and Bairleen, why may we not say Prāgue and Hāgue, even though we do drop a visible *s* from Calais, and attempt the difficulties of Rouen, Amiens, Chartres, and Blois? As to St. Petersburg, the error of sanctification is not ours, but the Russians', from whom we have taken it. Our mistake, if it be one, is in putting an *s* after Peter, for this seldom occurs in the original. A similar but incorrect addition is often made in Prince Edward Island. The back-and-forth method of naming seen in the German *Vogesen*, which the contributor explains as coming from the original German *Wassigen* (watery), through the French *Vosges*, is found again in the same polyglot borderland in the *Laacher See*.

— The Comision del mapa geologico de España has just published, for the Exposicion de mineria at Madrid, a brief account of the history of the survey from its beginning, about the year 1831, under D. Angel Vallejo, down to the present time. Two maps show the condition of the work in March, 1873, at the beginning of the present system of the survey, and in March of the present year, showing how great an amount of work has been done in the last ten years. Eighteen provinces are finished; viz., Oviedo, Madrid, Santander, Castellon, Albacete, Murcia, Teruel, Cadiz, Zaragoza, Cuenca, Cáceres, Valladolid, Huesca, Avila, Salamanca, Guadalajara, Barcelona, and Valencia. More or less has been published concerning twenty-three other provinces, but their full descriptive memoirs are still to appear; viz., Coruña, Lugo, Orense, Pontevedra, Segovia, Palencia, Baleares, Alicante, Burgos, Logroño, Soria, Alava, Guipúzcoa, Vizcaya, Tarragona, Huelva, Toledo, Badajoz, Cordoba, Ciudad-Real, Granada, Navarre, and Almeria. Seven provinces are entirely unpublished or under study; namely, León, Lérida, Zamora, Málaga, Gerona, Jaén, and Sévilla. A rough draught of the final map, on the scale of 1 : 400,000, is shown in the exposition, upon which all the work done up to date is entered.

— The Belgian photographic association has organized an international exhibition of photography to be held, during the month of August, 1883, in the palais des beaux-arts at Brussels.

— The sixth international congress of orientalists will be held at Leyden, Sept. 10.

— The international congress of societies for the prevention of cruelty to animals will be held at Vienna in September. A number of local societies, among them those of Berlin, Cologne, Munich, Dresden, and Hanover, besides several Spanish Italian, and Russian, have expressed their intention to be represented.

— The British association for the advancement of science meets this year at Southport, Sept. 10.

— Dr. William Lee read before the Philosophical society of Washington, June 2, a paper on medical history as illustrated by medals; Prof. Theo. Gill discussed analogues in zoögeography. The society then adjourned till October.

The Mathematical section of the society adjourned for the summer on June 6. At the last two meetings, Mr. G. W. Hill discussed the planetary perturbations of the moon, Mr. G. K. Gilbert explained the construction of graphic tables for use in connection with his new method of determining heights from barometric data, and Mr. E. B. Elliott gave an improved system of electrical units.

— An excursion to northern Norway and Spitzbergen is projected for some of the students at the Paris École des mines. Two French naturalists will accompany the party, which will charter a steamer directed by a competent arctic navigator for the purpose.

— Professor Fries has proposed the colonization of Greenland by Lapps, on the hypothesis that in the interior, in summer, abundant reindeer-pasture can be found. How the reindeer are to get at it does not seem to have been considered, nor how they are to be subsisted during their travels over the continental ice-sheet.

— Mr. Oliver W. Huntington, assistant in the chemical laboratory of Harvard college, has edited a book of five-place logarithms, which will finally form part of a set of tables mostly for use in chemical calculations, but is now published in separate form. The logarithm tables are well arranged, and very clearly printed. The book is published by Moses King, Cambridge.

— The museum at Oxford, Eng., has lately bought the unique collection of Silurian fossils of Dr. Grindrad of Malvern.

— It is rare to find, at the present time, a scientific memoir in Latin. Aloysius Molina, a student at Pisa, has, however, recurred to the ancient custom, and has published a memoir, 'De hominis mammaliumque cute,' in volume v. of the *Atti della società Toscana.* The opening sentence sufficiently describes the paper: "Expectans dum Ranvierus in lucem perfecte proferat conclusiones omnes suarum investigationum de intima structura cutis, prodesse existimo breviter quae praecipua facta sunt resumere, nonnullas considerationes addens, quas ipse feci dum per duos annos ad Anatomicam Scientiam meum adhiberi studium in Laboratorio Anatomiae Comparativae hujus universitatis." The 'nonnullas considerationes, quas ipse feci' one finds not very numerous, the chief value of the paper being as a summary. A good bibliography is appended.

— Much progress has been made at the Lick observatory during the past year. The dome for the twelve-inch equatorial has been entirely completed in a very thorough manner. It is, without any doubt, the most convenient and complete dome of the size in the country. The four-inch transit-house, and the buildings for the photoheliograph, are in capital working order. They were utilized last December in a very successful observation of the transit of Venus. The walls of the main building are half done, and the cellar for the dome of the thirty-six-inch equatorial is excavated. Many of the original arrangements of the buildings and grounds were only provisional, and these are being replaced by others more substantial and permanent. A brick reservoir containing 83,000 gallons of water (derived from three springs) has been built during the season; another of 20,000 gallons (spring-water), and another of 83,000 gallons (rain-water), will shortly be begun. The roads have been extended. The house for the meridian circle (Repsold) will be begun in a few weeks, as well as a house for the astronomers, and buildings to contain the appliances for heating and lighting the buildings and moving the dome. The end of this season will show great progress.

— The division of entomology of the U. S. department of agriculture has begun the publication of a series of bulletins for the purpose of placing before the public, current matter that would either lose much of its value if kept for the annual report, or find no space in the limited pages of that volume.

Two numbers have been issued. The first includes reports of experiments, chiefly with kerosene, upon the insects injuriously affecting the orange-tree and the cotton-plant. The second includes reports of observations on the Rocky Mountain locust and the chinch-bug, together with extracts from the correspondence of the division on miscellaneous insects.

— The University of Pennsylvania has conferred the degree of M.A. on Professor Lewis M. Haupt, C.E.; and of Sc.D. on Professor Isaac Sharpless, professor in Haverford college.

— At the meeting of the Royal astronomical society, May 11, Professor C. Pritchard of Oxford gave an account of his recent expedition to Cairo, and of the work on which he has for the last two years been engaged; viz., the measurement of the magnitude of the stars visible to the naked eye from the pole to the equator, including at present all those brighter than the fifth magnitude. This work is now complete. He found, that, at Oxford, Laplace's law of alteration of a star's light as measured in magnitude — according to the secant of the star's zenith distance — did not hold good for zenith distances exceeding 65°, and that for stars at lower altitudes the alterations in apparent magnitude were conflicting and not satisfactory. For the purpose of accurately investigating the effect of atmospheric extinction of light under better circumstances, he chose the climate of Upper Egypt, where the atmosphere is uniform and stable, as the proper locality for repeating the Oxford observations, and rendering the research complete. A duplicate set of instruments was left at Oxford in charge of the senior assistant, who observed the same stars with Professor Pritchard at Cairo. The results of both sets of observations are embodied in the formulae, —

Atmospheric absorption
At Cairo $= 0.187 \times$ Sec. Z.D. in magnitude;
At Oxford $= 0.253 \times$ Sec. Z.D. in magnitude.

Thus the whole effect of the atmosphere at Cairo is to diminish the brightness of stars seen in the zenith by about two-tenths of a magnitude, and at Oxford by about one-fourth of a magnitude. At an altitude of about 30°, the stars at Cairo will be brighter than in England by about one-fifth of a magnitude, and consequently many more faint stars are just visible at Cairo than can be seen at Oxford.

— Alexander Melville Bell has written a primer, which will soon be published, for use in elementary schools in teaching the methods of visible speech. The book can be used by any teacher without special training in the peculiarities of the system.

— A correspondent states that the shortest scientific article known to him, and perhaps the shortest ever published, is by William Griffith, in the bulletin of the U. S. fish-commission for 1882, p. 12, under the title 'Result of planting shad in the Ohio River.' The article contains twenty-six words, and occupies two lines.

— At the meeting of the Cambridge entomological club, June 8, Mr. S. H. Scudder discussed the homologies of the male abdominal appendages of butterflies, and Mr. G. Dimmock showed a living Buthus occitanus, and described some of its habits.

— The Argentine government has sent Col. Solá, with a party of two hundred soldiers, to explore the Pilcomayo in its course through the Gran Chaco. The party is accompanied by a delegate of the Argentine geographic institute, whose chief object is to discover the remains of Crevaux, and ransom two of his men who are reported to be held as prisoners by the Indians.

RECENT BOOKS AND PAMPHLETS.

SCIENCE.

FRIDAY, JULY 13, 1883.

THE GOVERNMENT AS A PUBLISHING HOUSE.

We have called attention to the report of Messrs. Ames, Spofford, and Baird upon the distribution of public documents, and noted the propriety of the recommendations made to the government by the committee. If these recommendations were to be carried out, something would be gained; but we have little faith that any real reform would be effected, for the evil lies deeper, and requires more radical treatment.

Ever since the government went definitely into the printing business in 1861, the evil has been growing, until now there is waste, confusion, and public mischief. It is no more essential to government to carry on the large printing business which it conducts than it is for it to manufacture paper. Let us make a distinction. There is a necessity, in the ordinary administration of Congress and the executive department, for a large printing-office in the immediate vicinity; and we are quite ready to grant, as immaterial to our argument, that it is better to have such an establishment, with its manager as a civil officer of the United States, immediately under the control of Congress. There is a vast deal of printing required in the exigencies of the daily business of government, and there is reason for this being done by persons hired directly for the purpose.

There the necessity stops, but the business of the printing-office does not. Costly scientific reports are manufactured year after year, and then published; that is, given away recklessly and with little discrimination. The report of scientific experts, to which we have referred, points out the desirability of a single agency for distribution, which should act upon some systematic plan. We do not object to a policy by which government shall put before the public the results of the surveys and experiments which it is carrying on; but we contend, that, in doing this, it should employ economic agencies already existing, which are far more efficient than any immediate governmental agency can be.

Government should contract with publishers to print and publish its scientific reports. The plan is perfectly feasible. Every copy which the government might wish to give away to public libraries could be bought of the publisher at a cost fifty per cent less, we venture to say, than government now pays for the same work. It would be the publisher's business to make the work known everywhere; and such a work would be far more read than it now is, for it would be made as other books are, and brought before the people intelligently. By such a policy no scientific organization or student of science now in communication with the distributing-office would suffer loss, while a great many people who are accustomed to get their books from booksellers would come into possession, in the most natural way, of this important body of literature.

The effect of such a system would be to contract the business of the government printing-office, and that is an end devoutly to be wished for by every honest citizen who sees the necessity of checking corruption by limiting the opportunities for corruption. The fewer salaried offices this government has, the less chance there is for an abuse of the civil service; and science will gain nothing by asking favors of the machine. There is an excellent opportunity here for the educated classes to enter a protest, and to encourage a reform in administration. We have been demanding that the administration should be conducted on business principles; and the present system by which government prints and publishes books is un-businesslike, extravagant, and in peril of being scandalous.

THE NATIONAL RAILWAY EXPOSITION.[1] — II.

The numerous accidents that have occurred owing to the signals showing 'clear' when the switches were set for a side-track led to the invention of 'interlocking,' which is now used extensively in England, and is being introduced into this country. The term 'interlocking' applies to a system where the switches and signals can be so worked by levers concentrated at one point, that no safety-signal can be given for any track until the switches are properly set for the safe passage of the train; and, when the signal is set to safety, none of the switches can be moved until the signal is again made to indicate danger. The advantages of this system are, that one man can operate a large number of switches and signals, and the interlocking apparatus acts as a check upon him, and renders it impossible for him to commit a mistake and move a wrong lever; and the mechanism is so arranged that a certain definite routine must be gone through in making a safe course for a train. The signals standing at their normal position of 'danger,' the switches are first moved, then they are locked firmly in position: then only can the danger-signal be changed to safety for the passage of the train when all possible conflicting signals or switches are locked, so that they cannot be operated. When a certain track has been prepared for the safe passage of a train, the necessary alteration of switches and signals is begun at the point farthest from the train, and ended at the signal nearest to it, this signal being locked to indicate danger until the track is ready for the train; and the setting of this signal to safety shall lock to danger all conflicting signals not already locked.

The amount of safety secured by the adoption of interlocking apparatus is thus laid down by an English author: "If a man were to go blindfold into a signal-box with an interlocking apparatus, he might, as far as accordance between points and signals is concerned, be allowed with safety to pull over any lever at random. He might doubtless delay the traffic, because he would not know which signal to lower for a particular train; but he could not lower such a signal, nor produce such a combination of position of points (switches) and signals, as would, if the signals were obeyed, produce a collision."

Interlocking has been very generally adopted in England, but hitherto little attention has been paid to the subject in this country; though in some crowded depots, such as Lowell, Wilmington (Del.), and Boston (Boston and Albany railroad), it has recently been introduced with great success.

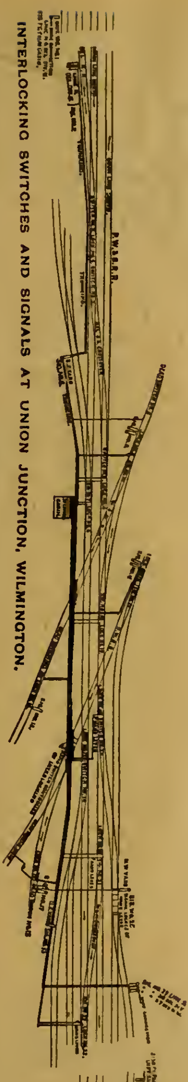
The two principal exhibits of interlocking and signalling apparatus at the Chicago exposition are those of the Pennsylvania steel company and the Union switch and signal company; Mr. George Westinghouse, so well known as the inventor of the break bearing his name, being the president of the latter company. The Union switch and signal company exhibits several distinct methods of working switches and signals controlled by interlocking apparatus. First, the Saxby and Farmer method, which is very generally used in England, and in some station-yards on the continent; Brussels, for example. In this the whole work of moving the signals and switches is effected by the manual power of the signalman. But as this involves considerable physical exertion in places where the levers are numerous, and some of the signals are a considerable distance away, Mr. Westinghouse has introduced a system whereby the signalman only moves valves admitting either compressed air, or a mixture of water and wood, or methylated spirits of wine, to cylinders, the pistons of which perform the actual hard work of shifting the switches and signals. The Pennsylvania steel company shows an American invention, which proceeds on similar lines to the Saxby and Farmer apparatus, attaining, however, the same end by the use of fewer levers. As, therefore, these two systems are very similar, except as regards mechanical details, into which we need not enter here, the following description of the general methods and purposes of interlocking mechanism will apply to both exhibits. The whole question is novel on this side of the water, and will well repay a careful study by all those who are interested in the progress of railroads.

One of the points that has been equipped with interlocking apparatus by the Pennsylvania steel company is shown in the accompanying plan of tracks at the Union Junction of the Philadelphia, Wilmington, and Baltimore railroad, at Wilmington, Del. This junction is one mile west of the passenger-station, at the crossing (at grade) of the Wilmington and northern railroad and of the Delaware western railroad, where the Delaware railroad branches from the main line of the Philadelphia, Wilmington, and Baltimore railroad. Through trains pass this junction at lightning express speed. The main line is protected from crossing roads by dead

[1] Continued from No. 22.

switches on the crossing roads, so that crossing trains running against signals will be turned into a side-track, and cannot, therefore, cross or foul the main line. There are, in all, fifteen switches handled and controlled, and three other switches not handled (owing to the infrequent use, or being required only for hand-drilling), which are also perfectly controlled. Twelve facing point locks and seventeen signals are employed, some of them 2,150 feet from the signal-tower. To operate the above, twenty-eight interlocking levers are used, with two spare levers in the frame for future improvements. At this writing, the apparatus at Union Junction has been in use over one year with perfect success, and it will probably repay any railroad manager to visit it, and study its workings.

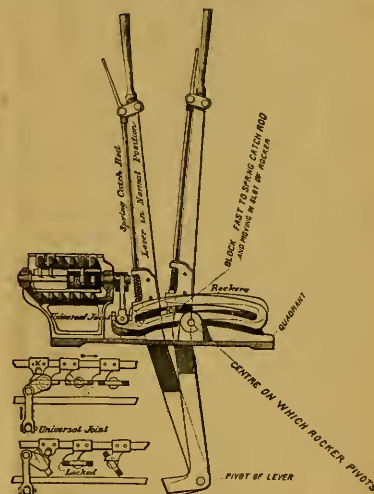
In arranging a yard on the interlocking system, it is important to concentrate the switches so that they can be worked by one man from one machine, where as many as fifty levers operating switches and signals can be conveniently arranged. Provided that the yard is well laid out, it is possible not only to gain greater safety and security in switching and drilling, but a saving in time and labor is effected, as one man who is always on the same spot can perform the



INTERLOCKING SWITCHES AND SIGNALS AT UNION JUNCTION, WILMINGTON.

work of several men scattered about a yard, and having continually to move from one spot to another. The levers should be placed in a house constructed so as to shelter the signalman from the weather, and enable him to have a good view of the whole yard; and the latter object is generally best attained by placing him at some distance above the ground-level, so that his view is not obstructed by passing engines and cars.

The levers, which resemble the reverse lever of a locomotive, are mounted close together in a line, and a name or number plate on each lever shows its use and purpose; and,



to further distinguish the levers, all those operating switches may be painted one color, locking levers another color, and so on. Each hand-lever carries a spring-catch, which secures the lever at either end of the stroke; and the detent, forced down by the spring, and pulled up by the action of the signalman's hand in grasping the handle-end of the lever and its catch, instead of engaging in a notched rack, as on a locomotive, slides in a curved slot in a pivoted bar. This bar, or 'rocker,' is therefore moved about its pivot by the very action of the signalman grasping the lever. Interlocking virtually consists of mechanism attached to this pivoted bar, which renders it immovable under certain circumstances. These controlling circumstances are the positions of certain of the other levers in the frame. To exemplify this, we will take three levers, A, B, and C. If A and B be in such position that a signal given by the movement of lever C will be dangerous or misleading to a train, the pivoted bar connected to lever C is locked, and cannot be moved by any exertion of strength on the part of the signalman; and therefore he cannot even begin to move lever C, and the possibility of giving a wrong signal is put beyond doubt. Similarly, nothing is effected unless the lever completes its stroke. The pivoted bar or 'rocker,' through which the whole work of interlocking is done, moves only at the extreme ends of the stroke of the levers, and then is only moved by the rising or falling of the spring detent. This invention, simple as it seems, is the result of many years' experience, accidents having often occurred through a lazy signalman pulling his lever through part only of the stroke, and thus only partially effecting the locking. This is now impossible; and the *intention* of a switchman to move a lever, expressed by his grasping the lever and so moving the spring-catch, independently of his putting the intention into force, actuates all the necessary locking.

The details of locking-apparatus are somewhat complicated, but the principle is simple. Certain bars carrying lugs or projections are made to slide or move by the movements of the rockers. Certain other bars, which are also moved by the action of one or more rockers, are slotted or pierced with holes, so that, in certain positions, the lugs in the first set of bars can enter the holes in the second set of bars, and, in other positions, the lugs strike against the bars, and cannot be moved. It is, of course, obvious that the arrangement is such as to prevent unsafe or contradictory signals being given, and permit only of safe or harmonious signals; and, by a careful arrangement of the locking-apparatus, it is sometimes possible to make a few movements effect important changes of the switches and signals with a minimum of levers and complication.

It is obvious, that, when switches are worked from a distance, there is a chance of the switch being incompletely closed, owing either to dirt, or a stone, or ice, choking the switch itself, or the switch-rods working it. There is also a danger that the switch-rod might break or become disconnected, and that, though the signalman moved all his levers, and all the locking and unlocking was properly performed in his cabin, yet the switch itself might remain unshifted, or be left half open. To obviate this, the facing point lock was invented. This is a bolt which can only be shot into a crossbar connecting the two rails of the switch when the switch is either properly closed, or wide open. A failure of the switch connections, or an obstruction in the switch, will render it impossible for the bolt to enter the opening to lock the switch; and, as the signalman's lever actuating this lock interlocks with the signal levers, no train can be signalled to approach until the switch is either closed, or wide open, as the case may be, and firmly locked in its proper position. But another danger has to be guarded against: signalmen, to save time, will generally throw a signal again to danger directly the engine of an approaching train has passed; his other levers are then set free, and he can unlock his switch, and actually change the switch, before the whole train has passed, thus probably throwing the rear vehicles off the track, and causing a serious accident. To guard against this, a locking or detector bar is used, which lies near the rail, but clear of a wheel, when the switch is either shut or full open; but directly the switch is moved from either of these positions, the bar moves close to the tread of the rail, and takes such a position that it must come in contact with any wheel approaching the switch. As the bar is made longer than the distance between any two trucks, it follows, that, as long as a train is passing over the switch, one or more wheels of the train must prevent this bar being moved, and, as the switch-lock and the bar are arranged to move together, it follows that the switch cannot be unlocked until the last truck of the last car of a train has passed. The Union switch and signal company adheres to Saxby and Farmer's arrangement of this bar where it moves vertically. The Pennsylvania steel company shifts it laterally. The latter movement is more easily performed, and the bar can serve as a guard-rail; but its movement seems somewhat liable to be impeded by snow falling between the rail and bar.

(To be continued.)

THE WEATHER IN MAY, 1883.

THERE have been two periods of very severe storms, and at many places of tornadoes. The first of these accompanied a 'low,' first noted in Colorado[1] on the 13th. This moved with considerable energy over Colorado and Nebraska. On the 14th, increasing in energy,

[1] It has been found necessary, owing to the smallness of the appropriation, to give up all telegraphing reports west of the Rocky Mountains: hence the charts are made up only to the east.

MONTHLY MEAN ISOBARS, ISOTHERMS, AND WIND-DIRECTIONS, MAY, 1883. REPRINTED IN REDUCED FORM BY PERMISSION OF CHIEF SIGNAL-OFFICER.

it advanced into Ohio. At the morning observation of this date, pressures .5 to .6 inch below the mean were noted in Iowa.

Reports of hail on the 13th, 14th, and 15th, sometimes of astonishing size, have been sent from thirty-six stations, mostly in Iowa, Kansas, Missouri, Indiana, and Illinois. The following is a brief summary of tornado reports. Indiana: Amity, 14th, 7.30 P.M.; Waterloo, night of 14th, only three houses left standing; Muncie, night of 14th; Indianapolis, 14th, 6 P.M. In Kansas: Troy, 13th, 5 P.M.; Muncie, 13th, 4.30 P.M., most violent storm ever known in the county. In Michigan: White Pigeon, 14th, 4 P.M.; Sturgis, 14th, 3.30 P.M., came from south-east. In Missouri: Kansas City, 13th, 4.30 P.M., from south-west, track from a hundred and fifty to two hundred and fifty yards wide, damage $300,000; Cameron, 13th, 5 P.M.; Macon, 13th, 8 P.M.; Pattonsburg, 13th, 5 P.M. In Ohio: Fredrickstown, 14th, afternoon.

The second period was ushered in by a deep 'low' in Colorado on the 17th. At 11 P.M., Washington time, pressures at Yankton and North Platte were 29.16 inches, or more than .7 inch below the mean. On the 18th the 'low' moved into Minnesota, and on the 20th a portion of it moved east into the St. Lawrence valley; while its influence was felt in forming a second subsidiary 'low' in western Tennessee on the same date. The latter moved slowly, and passed off the Atlantic coast on the 24th. Tornadoes are reported as follows. In Arkansas: Eureka Springs, 18th; it cut a path a quarter of a mile wide through a dense forest, and destroyed several buildings. In Illinois: Hillsboro', 18th, 10 P.M., a funnel-shaped cloud moving north-east, the width of destruction, ten to thirty rods; Grafton, a car loaded with stone weighing twenty-one tons was lifted from the track, and the stones were scattered; Chemung, 18th, before 6 P.M.; Chicago, night of 18th; Springfield, 18th, 7.10 P.M.; Pesotum, 18th, 11.30 P.M.; Littleberry was nearly destroyed; Jacksonville, 18th evening, severest storm ever known; Edwardsville, 18th evening, came from south-east, width of track six hundred to eight hundred feet; Tallula, 18th, 9 P.M. Up to midnight of 19th, the number of deaths in Illinois caused by the tornadoes of this date was sixty-three. In Missouri: Moody, 18th, 19th, every house blown down; Berger, 18th, 7 P.M., six houses and one mill destroyed; Oronogo, 18th, 7.40 P.M., six persons killed, $75,000 damage. New York: 21st, one of the severest storms that ever visited Long Island. In Tennessee: Chattanooga, 20th, 4 P.M. In Wisconsin: Janesville, 18th evening; Racine, 18th, 7 P.M., twenty-five people killed, damage $60,000, track five hundred yards wide.

The chart of monthly isobars, isotherms, and wind-directions is given on p. 35. The permanent summer low-pressure area has enlarged a little, and moved only slightly from its position last month. Mean pressures are in general below the normal, except in Florida and the upper Missouri valley. The mean temperature east of the 100th meridian was 3.1° below the mean; highest temperature, 109° at Eagle Pass, Tex., and Yuma, Cal. Illinois and Missouri report damaging frosts on the 22d.

A comparison of floating ice with May, 1882, shows the eastern limit 3° west of last May, but the southern limit is the same. The number and size of icebergs are much less than last year, while there has been no field-ice. The Gulf of St. Lawrence, blocked last year, is clear this.

There were deficiencies in rainfall: Middle Atlantic, .58 inch; West Gulf, 1.50; Rio Grande valley, 2.93; extreme north-west, 1.65; and middle plateau, .69. Excesses: New England, 1.41; South Atlantic, 2.91; Tennessee, .54; Ohio valley, .77; lower lakes, 3.02; upper lakes, .85; upper Mississippi valley, .68; Missouri valley, 3.03; middle slope, 1.09; southern slope, 1.91; northern plateau, .99; North Pacific coast, .86; Middle Pacific coast, 2.33; and Southern Pacific coast, .80. In California the rain has been four times the usual May fall.

A hundred and thirty-nine cautionary signals were displayed, of which 84% were justified by winds of 25 miles or more per hour, at or within 100 miles of the station.

SYMMETRICAL LINEAR FIGURES PRODUCED BY REFLECTION ALONG A RIVER-BANK.

In July, 1882, I noticed on the Magaguidavic River, in New Brunswick, some figures, apparently formed through combination of actual fissures in the rocks at the water's edge, and the reflections of these fissures from the surface of the water, which were not a little remarkable.

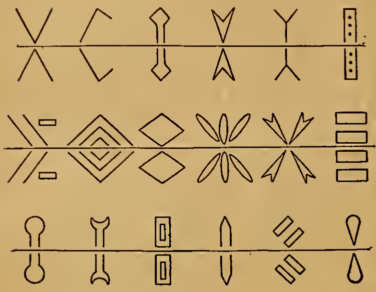
It was late in the afternoon. One thunder-shower had just ceased, and another was about to begin. The sky was somewhat overcast, and the water more or less shaded by the forest which covers most of the adjacent land. The banks of the river are bold, the shore being lined in many places with steep rocks having abrupt faces. Thanks to the lifting of the salt or brackish water by the tides, the boughs of the trees which overhang the river are trimmed off sharply and squarely, as if by shears, at a plane which marks the limit reached by the water of the highest tides. By the same means, the rocks on the strand are kept clear of vegetation; so that there is ordinarily a well-defined wall of bare rock between the water and the trees, even when the tide is high, and the river not far from being full. At the time I am speaking of, there was no wind: the surface of the water was absolutely glassy, and a superb reflection of the foliage of the forest was to be seen in the mirror which the river made. I had just remarked to a chance companion on our little steamboat how difficult it was to distinguish between the water and the land, so completely were the real rocks and trees blended with their reflections, when my attention was attracted by a rock, apparently at the water's edge, which was covered with symmetrical lines and figures. I called out to a friend, who was standing at some distance from me on the deck of the boat, to 'look at the pictured rock,' and, on turning from him to again look at the shore, I perceived that it was not one rock alone that bore figures: there was a long, broad ribbon or dado of similar picturing at the edge of the water, running along the shore between the real trees and the picture produced by the reflection of the trees in the water. I am fortunate in being able to say that my friend saw the picturing on the rock to which his attention was thus hastily directed, for the fact enables me to dismiss the notion that the figures might possibly have been 'subjective' to myself. I had, however, hardly time enough to get a fair view of the picture before a new shower of rain ruffled the water, hid the shore, and drove us under cover.

Beside herring-bone patterns, there were symmetrical lines, bars, and flutings of various lengths, together with figures suggesting short maces, staves, or even spears and arrows, as well as others in the semblance of hieroglyphics. Indeed, the whole effect was very Egyptian-like; while many of the lines recalled those so commonly used of late years for ornamenting furniture, — such lines as are, I believe, technically called 'reeding.'

On thinking the matter over, I was at first inclined to believe that I must have been looking into a great natural kaleidoscope; but, on further consideration and observation, it seems plain that simple reflection — that is to say, duplication by the water-mirror of lines, cracks, dents, or scars upon the rocks — might account for most, if not for all, the appearances I witnessed. I regret that the attitude of mere wonder and admiration into which my mind was thrown should have hindered me for the moment from making a proper critical examination of the figures; but I have been impressed by the conceptions that similar appearances cannot possibly be infrequent when the water of the river is still, and that some of the first rudiments of primitive art did probably originate in efforts made to copy such natural lineations as these.

There is, I believe, an old, perhaps it is an endless, dispute as to whether, in the history of human art, such kinds of ornamentation as herring-bone figures, reeding, and fluting have ever been derived from a direct imitation of natural objects, or whether they have not always arisen from mental conceptions. It has seemed to me that the observation here recorded should bear with considerable force in favor of the view of those students who refer the beginnings of all things to facts of actual observation and experience.

I am well aware that the atmospheric conditions were of somewhat exceptional character at the moment when I saw the picturing; but it is evident that rock-fissures, properly placed as regards a body of still water, will naturally be duplicated by reflection therefrom. There is every reason to suppose that figures analogous to those I witnessed may often be seen where rocks and water meet, and it is hard to believe that they have not been seen frequently by persons favorably situated. There is consequently no improbability in the idea that some of the primitive designs of savage nations may have been copied from them. Different effects would, of course, be produced in different localities, according to the quality and mode of stratification of the rocks, and to the nature of the jointings, seams, and scars which the rocks bear; and it is not unlikely that the rocks on the Magaguidavic River may be peculiarly well fitted for exhibiting these pictorial effects. But the capital fact of duplication by reflection must be common to all localities; and there are probably many places where ornamental figures would be produced by mere force of repetition even of very simple forms; that is to say, by the formation, at one and the same time, of a series of figures comprising many individual reflections, each one of which was similar to all the rest. A general idea of some kinds of forms that may possibly be seen where cracks in rocks are reflected from a body of calm water may be got by drawing figures like those of the diagram which I have selected from a hundred or more that occurred to me. No effort has been made in the diagram to copy the actual appearances seen on the river-bank.



An essentially different style of representation would be needed in order to convey a just conception of the effect of the scene I witnessed. With the exception of the herring-bone figure, I cannot profess that either of the figures of the diagram is like any of those I saw in New Brunswick. It is to be remembered, however, that, whatever the forms may be that are produced by reflection from one particular bank of rock, the same kinds of forms will usually and probably be repeated again and again with the result that a pattern or 'design' will be produced.

I consider myself so little qualified to look up a matter wholly foreign to my usual studies, that I have made no effort to search for records of observations similar to the one here described, though I am strongly inclined to believe that such records must exist. I would say merely, that on again steaming up the Magaguidavic River at a time when a breeze was stirring, and the surface of the water was ruffled, I saw none of the picturing excepting in one quiet nook or cove, where a series of really superb herring-bone figures was produced by reflection from the surface of the calm water of the lines of stratification between the beds of rock, which were here tilted at a considerable angle. Although during this second visit I saw none of the 'reeding,' or of the other kinds of symmetrical figures which had so much impressed me before, the multiplicity of the herring-bones, i.e., the continued repetition of this figure, was specially noteworthy. A peculiar kind of beauty or sense of satisfaction to the eye was thus obtained, which a single figure would clearly not have been competent to give. It is reasonable to suppose, that wherever complete herring-bone figures are formed, as here, by reflection of those lines between the layers of rock which are continuous, and, so to say, perfect, a variety of related or derived figures will be produced by the reflection of lines which are not continuous; that is to say, the reflections from lines that are imperfect in any way, or broken into various lengths, would give rise to hieroglyphic characters in considerable variety, though they might all belong to one common group or kind.

At the time of my second visit to the river, I could see no reason to doubt that the figures might be seen almost any day when the time of high tide, and consequently of a full river, happened to be coincident with the calm moments so common in summer at the hours not far from sunrise and sunset.

As bearing on the question of human imitation, it is of interest to note, that while herring-bone patterns would naturally be produced wherever the lines of stratification of tilted layers of rock are reflected from calm water, i.e., in numberless localities, it is precisely these figures which have been most frequently delineated by savages upon pottery and other implements as one of their earliest artistic efforts.

Excepting the two instances here recorded, I have never noticed any such figures in the course of my own travels, nor have I heard of their being seen by others. I am assured, moreover, by several of the most competent and experienced observers of my acquaintance, that they have never witnessed any thing similar. I expect, however, for my own part, to see such figures from this time forth, when opportunity offers, and I trust that many other persons will do so. It is to be hoped, withal, that some of the more noteworthy effects of this sort may be accurately depicted.

F. H. STORER.

THE AMERICAN SWAMP CYPRESS.

THE following observations on the bald or swamp cypress of the southern states are condensed from the forthcoming second volume of the memoirs of the Kentucky geological survey. They embody the results of certain inquiries which show that this peculiar tree deserves more study than has been given to it by our botanists.

The Taxodium distichum is, as is well known, a common tree in the swamps of the southern states, extending from New Jersey to Texas, and northwardly in the Mississippi valley, to the lowlands of southern Illinois. It has several titles to distinction: it is not only in all its proportions the noblest of all our coniferous trees east of the Rocky Mountains, vying in girth and height with the yellow poplar (the Liriodendron tulipifera of the botanists), but it is by far the most stately all the of trees belonging on the eastern face of the continent. Moreover, it has certain habits which are altogether peculiar to its species, and which constitute it a very exceptional member of the Coniferae.

When this tree grows on the dry ground, or on a surface where the water does not stand during the summer half of the year, it differs in no important feature from its kindred species; but, when it grows in swamps which are flooded during the spring or summer months, the roots form excrescences, which rise so that their crests overtop the level of the water during these seasons. These excrescences are of varying height, their projection above the level of the roots depending on the depth of the swamp-waters during those seasons of growth. These conditions may be satisfied by projections, or 'knees' as they are called, that rise only a few inches above the root, or they may rise to the height of five or six feet above the soil. These knees are sub-cylindrical in form; near the base they are elongated in the direction in which the root extends; above, they give a nearly circular section; at the top they are crowned by a cabbage-shaped expansion of bark of irregular shape, rough and warty without, often hollow within. They are often as much as eighteen inches in diameter. They are so commonly hollow, and of such size, that they are sometimes used by the natives for beehives or for well-buckets, for either of which uses they are tolerably well adapted. A tree of large size, say six feet in diameter, will often have as many as thirty or forty of these knees projecting above the swamp-water which surrounds its base.

Looking closely at these knees, we observe, that, unless they are evidently decayed, they generally have a very porous, spongy bark over the surface of their crests; and the bark on this summit, peeling off from time to time, often exposes a singularly spongy surface, such as we find in the inner bark of the pine-tree when the coarse outer bark is peeled away.

There have been many conjectures as to the function of these knees. It has been supposed that they were in the nature of suckers or branches from the roots, which gave rise to new trees; but, after examining thousands of these knees, I am convinced that they never have this nature. In no case have I seen or heard of any buds appearing on them. The only clew to their function I have obtained in the following way: whenever it happens that the knees become entirely submerged during the growing season, the trees to which they belong inevitably die. Very extensive proof of this point was given by the general submergence of extensive districts during the earthquakes of 1811–13, in the region near the Mississippi, where the cypress-trees over a region several hundred miles in area were killed by a subsidence that brought the water a foot or two below the crests of the knees. In Reel-Foot Lake, in Kentucky and Tennessee, thousands of these long ordinary cypress-boles still stand in the shallow waters, though it is now seventy years since they were killed by the slight submergence of their knees.

The same thing can be seen on a smaller scale in several mill-ponds in western Kentucky, where the change in level of the swamp-water has brought these excrescences below the surface of the water. These facts — viz., the absence of the knees when the tree grows on high land, and the death of the tree when the knees are permanently submerged — lead me to the opinion that the use of these excrescences is to bring the sap while in the roots in contact with the air. That they have this function is made more probable by the fact that their heads, i.e., the parts which always project above the water during the growing season, remain very vascular, and, by a process of desquamation, secure the exposure of the inner bark to the air.

It is evident that this tree affords us a very interesting instance of a specialized structure, that only develops when the plant occupies a certain position. We often find this tree artificially transplanted to the gardens of the western country. It then shows no distinct tendency to form knees, though the surface of the roots show a few short spurs not over an inch or so high.

It is a well-known fact that the genus Taxodium dates back into the early tertiaries. I am not aware, however, that fossil knees have ever been found. We have only to examine the borders of the swamps to see that it cannot, on the uplands, maintain a battle with the contending broad-leaved trees, though in any artificial open place it will grow with singular luxuriance.

It seems to me likely that we have here a very interesting case of a species owing its survival to a peculiar habit of growth. There can hardly be a doubt that the kindred of this Taxodium held an important place on the continent before the development of the broad-leaved trees. It seems not unlikely that it was crowded out on the higher ground, and forced to limit itself to this station which the swamps afford. In these permanent though shallow waters it clearly has an advantage over the broad-leaved forms of trees.

I am not aware that any structures resembling these knees are found among other plants. If it be the fact that they are peculiar to the Taxodium distichum, we have in this species a very remarkable case of a peculiar organ developed for a special purpose.

There is another interesting problem concerning this species. The seeds *seem* to germinate beneath the water. I have seen many young trees growing in what must be permanent swamp, where the soil was buried to the depth of a foot or more. I have long desired to try some experiments on this point, but have not been able to do so. I hope that some observer will undertake the inquiry.

This tree is certain to have a great economic value. Its great size, its favorable position in relation to our great water-courses, its very rapid growth and excellent timber qualities, are all calculated to commend it for use as a constructive wood. There are many million acres of land in the southern states where it could be cultivated to advantage. If kept from competition with the deciduous trees, it will do as well on any moist lowlands as in the actual swamps. Its growth is more rapid than that of any other of our timber-trees; the wood is said to be much stronger than that of any pine; it endures well in the open air without paint, as is shown by the fact that the trunks of trees killed in 1811 still stand undecayed in the swamps near the Mississippi River.

N. S. Shaler.

RECENT BABYLONIAN RESEARCH.

In the Proceedings of the Society of biblical archeology for November, 1882, Mr. T. G. Pinches, the Assyrian scholar of the British museum, reports a discovery of more than ordinary interest. This is an historical notice on an inscribed cylinder, coming from the ancient city of Sippar, and belonging to Nabonidus, the last of the native Babylonian kings. The cylinder was written before Cyrus had captured Babylon, but after his conquest of the Medes. The inscription of Nabonidus, after the usual introductory formulas, relates the reconstruction of several famous temples. The first of these, the temple of the Moon-god at Haran, had been destroyed by the Medes. Being instructed by the gods Marduk and Sin to rebuild it, Nabonidus recalls for this purpose his armies from Gaza, on the borders of Egypt. He informs us that the temple had once before been restored by the Assyrian king Assurbanipal (Sardanapalus), and that he found, while engaged in the work, the inscribed cylinders of Assurbanipal and of Shalmaneser II.

The great historic event referred to in this part of the inscription is the fall of the Median empire before Cyrus the Great. When commanded to restore the temple by the god Marduk, Nabonidus replies that the Medes have destroyed it, and receives from Marduk the promise that they in their turn shall also be destroyed. Nabonidus then relates: "At the beginning of the third year, they (the gods) caused them (literally 'him,' the Median nation) to go out to war; and Cyrus, king of the land Anzan, their (lit. 'his,' i.e., the Median nation's) young servant, overthrew with his small army the Median hosts, captured Astyages, king of the Medes, and carried him bound to his own (Cyrus's) land."

The undoubted value of this passage for the solution of the riddle left us by the conflicting testimony of the Greek writers, as to the relations of Cyrus and the Persians to Astyages and the Medes, is in part impaired by the ambiguous use of the pronouns. It is partly owing to this ambiguity that the translation just given differs from that of Mr. Pinches, who renders: "In the third year, he [the god Marduk] caused Cyrus, king of Anzan, his young servant, to go with his little army; he overthrew the wide-spreading Ṣabmanda [Medes], he captured Ištumegu (Astyages), king of Ṣabmanda, and took his treasures to his (own) land." It is difficult to say whether the words 'his servant' mean servant of Marduk, as Mr. Pinches supposes, or servant (= tributary) of the Median people; but the latter seems, for certain grammatical reasons, more probable. It is also improbable that Nabonidus, a special votary of Marduk, should speak of Cyrus, a foreigner, as a servant of the same deity, although we know that later, perhaps for state reasons, Cyrus was friendly to the worship of Marduk (V. Rawl. 35). It is more probable, that, when Nabonidus mentions Cyrus as 'his small servant,' he means to say that Cyrus was a vassal prince to the Medes. The translation 'him bound' (*kamûtsu*, lit. 'his bondage'), instead of 'his treasures,' is well established (I. Rawl. 13, 24 ff.), and adds not a little to the interest of the passage.

In the cuneiform annals of Cyrus, written after he had captured Babylon, we have this monarch's brief account of the war with Media (*Trans. soc. bibl. arch.*, vii. 155 f.). After a renewed careful collation of this important passage, Mr. Pinches has published the original a second time (*Proc. soc. bibl. arch.*, Nov., 1882). It is unfortunate that the ends of the lines are lost by mutilation of the clay tablet containing the inscription. Following is a translation of this passage: "[Astyages relied upon his troops] and marched against Cyrus, king of Anšan to [capture him?] . . . The troops of Astyages revolted against him, made him prisoner [and delivered him] to Cyrus . . . Cyrus (marched) to Ecbatana, the royal city. [He captured] the silver, gold, treasures (?), (and) possessions (?), which Ecbatana had gotten by plunder and he carried to Anšan the treasures and possessions which [he took?]." This version differs slightly from the one offered by Mr. Pinches, but not as to the revolt of the troops of Astyages, his delivery to Cyrus, and the capture of Ecbatana.

The accounts of Nabonidus and of Cyrus vary somewhat. The language of the former implies a battle in which Cyrus defeated the Medes and captured Astyages, but does not mention a revolt, nor the capture of Ecbatana, the Median capital. The account by Cyrus, being the state annals, is likely to be the more exact, and enters more into detail than that of Nabonidus; but the two are not at all contradictory. All that Nabonidus wished to record was the overthrow of the Median power and the capture of their king, and it was unimportant whether this took place in battle or by mutiny. It may be that he did not know the details of the war, or it is possible that one division of the Median army gave battle, while another mutinied and delivered Astyages to Cyrus. There is an apparent difference in the two accounts as to the date of the capture of Astyages. According to the Cyrus text, this event took place in the sixth year of Nabonidus, while Nabonidus says that it occurred in the 'third year.' It is, however, not clear from what point Nabonidus reckons, — perhaps from the date of his dream.

There is nothing in either of these accounts to show whether Cyrus was in any way connected by birth with Astyages. As to the relation of the countries of Media and Persia at this time, it is clear, from the language of Nabonidus, that Persia was a very small power; and if the word 'his servant' (*aradsu*), as applied to Cyrus, means the servant of the Medes, the conclusion would be that Cyrus was a tributary king to the Median power. This agrees with the statement of Herodotus (i. 107), that Cambyses, the father of Cyrus, was considered by Astyages as of respectable family, but inferior to an ordinary Mede. Nicolaus of Damascus also makes Persia subject to Media (Müller, *Frag. hist. Gr.*, iii. 399, Fr. 66).

It is certain that the mystery surrounding the relations of the Median and Persian courts and people can never be cleared up with the aids hitherto possessed. Nothing but the contemporaneous literature of these peoples themselves, and of neighboring peoples, can ever solve the problem. In another inscription Cyrus calls himself the king of Babylon, son of Cambyses king of Anšan, grandson of Cyrus king of Anšan, descendant of Šišpiš king of Anšan, royal offspring (V. Rawl. 35). This language is, however, not inconsistent with the tradition, so strongly represented by the Greeks, that the Persians were tributary to the Medes. To leave the government of subject nations in the hands of native kings was the rule in the later centuries of the Assyrian empire, and the Medes may well have practised the same policy. It was sufficient that the vassal king sent his yearly tribute, and, on proper occasion, kissed the foot of his master; but further than this was not required, and he was regarded as king in his own tribe or nation.

A word as to Anšan and Anzan. These are geographical terms, — the first a city; the second apparently a land, because preceded by the sign for a country. But since this sign often represents a city also, it may well be that Anšan and Anzan are only two different ways of writing the name of the same place. This seems to be also the opinion of Professor Sayce (*Trans. soc. bibl. arch.*, iii. 475). Probably there was both a city and a country Anšan, or Anzan. But what was Anšan? In the same inscription Cyrus calls himself king of Anšan and king of Persia (Parsu, *Trans. soc. bibl. arch.*, vii. 155, 159). Possibly Anšan, or Anzan, was originally the name of a tribe, city, and district, to which Cyrus and his family belonged.

Another temple which Nabonidus restores is the celebrated temple of the Sun-god at Sippar. Nebuchadnezzar, he relates, had restored this edifice, and had sought for cylinders, but without success. But Nabonidus was determined to find the inscription of the founder of the temple; and his search was rewarded, for, at a depth of eighteen cubits, he came across the cylinder of Naram-Sin, son of Sargon, which no king preceding him had seen for 'three thousand two hundred years.' According to the custom of the kings, he placed an inscription of his own by the side of that of Naram-Sin. As the date of Nabonidus was about 550 B.C., that of Naram-Sin would go back to 3750 B.C. But even at this time civilization must have been far advanced, for Sargon, the father of Naram-Sin (if the same as the Sargon of Agane), had in his library an astronomical work comprising seventy tablets. With this ancient date would agree the statement of Sargon II., king of Assyria 721-705 B.C., that three hundred and fifty princes had preceded him on the throne (Cylinder inscription, l. 45), and the long list of Babylonian kings, numbering, before the tablet was broken, two hundred or more.

A third temple, which Nabonidus restores, is that of the goddess Anunit at Sippar. By digging he found the inscription of the last king who had restored the temple, *Ṣaggašti-Buriaš*, son of *Kudûi-Bêl*, about 1050 B.C. Anunit, goddess of this temple, seems to be the planet Venus as morning and as evening star.

These two celebrated temples at Sippar are mentioned several times in the cuneiform literature. From Berosus, also, we know that the people of Sippar were devoted to the worship of the sun, for he calls the place 'city of the sun' (ἐν πόλει ἡλίου Σιππάροις). It was also, no doubt, as a part of this worship that the people of Sippar, whom the Assyrian king settled in the land of Samaria, burned their children in the fire (2 Kings, xvii. 31).

D. G. LYON.

OCEAN WATER AND BOTTOMS.

THE ocean explored by the Norske Nordhavs expedition, 1876–78, was a part of the North Atlantic lying to the west and north of Norway. The sea-water was especially studied in order to ascertain, if possible, whether the relation subsisting between its component parts varies sufficiently to admit of determining its fluctuations by the most exact analytical methods, and whether, in that case, it were possible to deduce some definite rule regarding them.

As the result of the analyses, L. Schmelck concludes, "The hypothesis which assumes the ocean to consist throughout its entire depth of one homogeneous fluid, in which the most accurate of chemical analyses shall fail to detect dissimilarity of composition, has received from the experiments here described probably stronger confirmation than from any that have gone before them." Some of the most interesting results are tabulated as follows, the first table showing the mean amounts of certain substances in sea-water at various depths, and the second showing the same for different parallels of latitude: —

I.

	Surface.	Bottom.	Intermediate depths.	Mean value.
Specific gravity	1.0265	1.0265	1.0266	1.0265
Chlorine	1.930	1.933	1.934	1.932
Calcium oxide	0.0576	0.0581	0.0577	0.0578
Magnesium oxide	0.2205	0.2207	0.2200	0.2203
Sulphuric oxide	0.2211	0.2208	0.2223	0.2214

II.

	80°–71°.	71°–66°.	66°–62°.
Specific gravity	1.0264	1.0265	1.0268
Chlorine	1.929	1.937	–
Calcium oxide	0.0580	0.0579	0.0577
Magnesium oxide	0.2190	0.2219	0.2205
Sulphuric oxide	0.2208	0.2210	0.2223

The mean value of the salts occurring in sea-water is given as follows: —

$CaCO_3$,	$CaSO_4$,	$MgSO_4$,	$MgCl_2$,	KCl,	$NaHCO_3$,	NCl.
0.002,	0.1395,	0.2071,	0.3561,	0.0747,	0.0166,	2.682.

Hence 100 parts of dry sea-salt contain —

$CaCO_3$,	$CaSO_4$,	$MgSO_4$,	$MgCl_2$,	KCl,	$NaCO_3$,	$NaCl$.
0.057,	4.00,	5.93,	10.20,	2.14,	0.475,	76.84.

The ocean-bottom studied is especially interesting from the amount of present and past volcanic and glacial activity in the lands surrounding it. Here, as elsewhere, depth was found to be the principal factor in determining the character of the deposits. Along the coasts of Norway and Spitzbergen, generally at a less depth than five hundred fathoms, the bottom was found to be covered with a more or less plastic gray clay. Its coarseness or fineness varies considerably; and grains of quartz, as a rule with rounded edges, constitute the chief portion of the mineral particles in it. At the approximate depth of from five hundred to a thousand fathoms, a brown clay is found, forming a transition from the gray clay to the true oceanic deposits.

At nearly all depths below a thousand fathoms, and oftentimes at less depths, is a fine light to dark brown colored deposit containing minute white shells of the genus Biloculina, in size and shape like a pin-head. This shell gives name to the clay, which corresponds approximately to the Globigerina ooze of the Challenger expedition. The ground is taken, that the power of sea-water to dissolve the carbonate of lime of the foraminiferal shells is not owing to the greater amount of carbonic acid at great depths in the ocean; for the observations of Mr. Tornøe showed that the sea-water invariably reacted as an alkali, and hence the carbonic acid could not be free. Again: the latter was found to be about the same in the depths of the ocean as on the surface; while the general uniformity of composition of the sea-water, as shown by numerous investigations, renders it improbable that any deviation in amount of carbonic acid occurs; hence the power possessed by sea-water to dissolve carbonate of lime does not depend upon the greater or less proportion of free carbonic acid.

The bottom of the shallow ocean between Norway, Beeren Eiland, Spitzbergen, and Novaia Zemlaia, was found to be covered with a greenish-gray clay containing but few animal remains. Minute and generally sharp-edged quartz grains were the principal constituent. This deposit was termed the Rhabdammina clay, from a genus of Foraminifera which often abounds in that part of the ocean-bed. This clay, according to Schmelck, originates from the 'decomposition of quartzitic rocks,' especially those of Beeren Eiland.

Off the volcanic island of Jan Mayen, above the six-hundred-fathom line, occurs a deposit of dark-gray sand, and sabulous clay containing fragments of basaltic lava, olivine, augite, etc., which seem to have been derived from the volcanic *débris* of the island.

An important fact bearing on the question of the distribution of *débris* by bottom-currents in the ocean is the statement that "all samples of water brought up from the bottom were perfectly clear, without a trace of floating particles."

The occurrence of numerous stones and pebbles on the sea-floor, as well as not uncommonly a rocky bottom, is of interest. The pebbles decrease in size and number in going from the shore towards deep water. While rare in the deep water south of the 72d parallel, they are quite common in that to the west of Spitzbergen and Beeren Eiland, where drift-ice abounds. Out of three hundred and seventy-five stations, pebbles and fragments of minerals and rocks were dredged at a hundred and twenty-three of them, while at many others no sample of the bottom could be obtained on account of its rocky condition. Of especial interest is the finding of numerous fragments of flint and chalk, a fossil (belemnite) from the chalk, fragments of coal, and some striated stones. Other pebbles and fragments found were marble, limestone, granite of various kinds, sandstone, argillite, quartzite, flint, chalk, granitic veinstone, quartz porphyry, gabbro, basalt, pumice, amygdaloidal rocks; chloritic, hornblendic, quartz, mica, and other crystalline schists; calcite, quartz, mica, hornblende, felspar, asbestos, coal, olivine, augite, coral, shells of various kinds, rotten wood, etc.

Schmelck concludes that organic agency is a subordinate factor in the formation of the floor-deposits of the northern ocean, as is volcanic *débris*, but that the chief portion of the material consists of the solid matter carried out to sea by drift-ice and glacial rivers. M. E. WADSWORTH.

THE NATURAL HISTORY OF IMPLEMENTS.[1]

"WHEN will hearing be like seeing?" says the Persian proverb. Words of description will never give the grasp that the mind takes through actual sight and handling of objects; and this is why, in fixing and forming ideas of civilization, a museum is so necessary. One understands the function of such a museum the better for knowing how the remarkable collection formed by Gen. Pitt-Rivers came into existence. About 1851 its collector, then Col. Lane Fox, was serving on a military sub-committee to examine improvements in small arms. In those days the British army was still armed (except special riflemen) with the old smooth-bore percussion musket, the well-known 'Brown Bess.' The improved weapons of continental armies had brought on the question of reform; but the task of this committee of juniors to press changes on the heads of the service was not an easy one, even when the Duke of Wellington, at last convinced by actual trial at the butts, decreed that he would have every man in the army armed with a rifle-musket. Col. Fox was no mere theorist, but a practical man, who knew what to do and how to do it; and his place in the history of the destructive machinery of war is marked by his having been the originator and first instructor of the School of musketry at Hythe. While engaged in this work of improving weapons, his experience led his thoughts into a new channel. It was forced upon him that stubbornly fixed military habit could not accept progress by leaps and bounds, only by small partial changes, an alteration of the form of the bullet here, then a slight change in the grooving of the barrel; and so on, till a succession of these small changes gradually transformed a weapon of low organization into a higher one, while the disappearance of the intermediate steps, as they were superseded, left apparent gaps in the stages of the invention, — gaps which those who had followed its actual course knew to have been really filled up by a series of intermediate stages. These stages Col. Lane Fox collected and arranged in their actual order of development, and thereupon there grew up in his mind the idea that such had been the general course of development of arts among mankind. He set himself to collect weapons and other implements till the walls of his house were covered from cellar to attic with series of spears, boomerangs, bows, and other instruments, so grouped as to show the probable history of their development. After a while this expanded far beyond the limits of a private collection, and grew into his museum. There the student may observe in the actual specimens the transitions by which the parrying-stick, used in Australia and elsewhere to ward off spears, must have passed into the shield. It is remarkable that one of the forms of shield which lasted on latest into modern times had not passed into a mere screen, but was still, so to speak, fenced with. This was the target carried by the Highland regiments in the low countries in 1747. In this museum, again, are shown the series of changes through which the rudest protection of the warrior by the hides of animals led on to elaborate suits of plate and chain armor. The principles which are true of the development of weapons are not less applicable to peaceful instruments, whose history is illustrated in this collection. It is seen how (as was pointed out by the late Carl Engel) the primitive stringed instrument was the hunter's bow, furnished afterwards with a gourd to strengthen the tone by resonance, till at last the hollow resonator came to be formed in the body of the instrument, as in the harp or violin. Thus the hookah or nargileh still keeps something of the shape of the cocoanut-shell, from which it was originally made, and is still called after (Persian, *nárjíl* = cocoanut). But why describe more of these lines of development when the very point of the argument is that verbal description fails to do them justice, and that really to understand them they ought to be followed in the series of actual specimens? All who have been initiated into the principle of development or modified sequence know how admirable a training the study of these tangible things is for the study of other branches of human history, where intermediate stages have more often disappeared, and therefore trained skill and judgment are the more needed to guide the imagination of the student in reconstructing the course along which art and science, morals and government, have moved since they began, and will continue to move in the future.

[1] Extract from a lecture on anthropology, delivered Feb. 21, at the University museum, Oxford, by E. B. TYLOR, D.C.L., F.R.S. From *Nature* of May 17.

THE INTELLIGENCE OF THE AMERICAN TURRET SPIDER.

AT the meeting of the Academy of natural sciences of Philadelphia, June 19, Rev. Henry C. McCook exhibited nests of Tarentula arenicola Scudder, — a species of ground spider of the family Lycosidae, properly known as the turret spider. The nests in natural site are surmounted by structures which quite closely resemble miniature old-fashioned chimneys composed of mud and crossed sticks, as seen in the log cabins of pioneer settlers. From half an inch to one inch of the tube projects above ground, while it extends straight downward twelve or more inches into the earth. The projecting portion, or turret, is in the form of a pentagon, more or less regular, and is built up of bits of grass, stalks of straw, small twigs, etc., laid across each other at the corners. The upper or projecting parts have a thin lining of silk. Taking its position just inside the watch-tower, the spider leaps out, and captures such insects as may come in its way. Nests had been found at the base of the Alleghany Mountains near Altoona, and in New Jersey on the seashore. In the latter location the animal had availed itself of the building-material at hand by forming the foundation of its watch-tower of little quartz pebbles, sometimes producing a structure of considerable beauty. In this sandy site the tube is preserved intact by a delicate secretion of silk, to which the particles of sand adhere. This secretion scarcely presents the character of a web-lining, but has sufficient consistency to hold aloft a frail cylinder of sand when it is carefully freed from its surroundings. A nest recently obtained from Vineland, N.J., furnished an interesting illustration of the power of these araneids to intelligently adapt themselves to varying surroundings, and to take advantage of circumstances with which they certainly could not have been previously familiar. In order to preserve the nest with a view to study the life-history of its occupant, the sod containing the tube had been carefully dug up, and the upper and lower openings plugged with cotton. Upon the arrival of the nest in Philadelphia, the plug guarding the entrance had been removed; but the other had been forgotten, and allowed to remain. The spider, which still inhabited the tube, immediately began removing the cotton at the lower portion, and cast some of it out. Guided, however, apparently by its sense of touch, to the knowledge that the soft fibres of the cotton would be an excellent material with which to line the tube, she speedily began putting it to that use, and had soon spread a soft smooth layer over the inner surface and around the opening. The nest in this condition was exhibited, and showed the interior to be padded for about four inches from the summit of the tower. The very manifest inference was drawn, that the spider must for the first time have come in contact with such a material as cotton, and had immediately utilized its new experience by substituting the soft fibre for the ordinary silken lining, or by adding it thereto.

LETTERS TO THE EDITOR.

Equations of third degree.

THE second or third terms of any equation may be made to disappear, and we may therefore assume

$$x^3 + Ax^2 + B = 0; \qquad (1)$$

and the solution of this equation must involve the general solution of cubics. Assume

$$x = y^{\frac{2}{3}} - y^{\frac{1}{3}}z^{\frac{1}{3}} + z^{\frac{2}{3}}. \qquad (2)$$

Hence

$$y^{\frac{1}{3}} = \sqrt{x - \tfrac{3}{4}z^{\frac{2}{3}}} + \tfrac{1}{2}z^{\frac{1}{3}}.$$

$$y = \sqrt[\frac{3}{2}]{x - \tfrac{3}{4}z^{\frac{2}{3}}} + \tfrac{3}{2}xz^{\frac{1}{3}} - z + \tfrac{3}{4}z^{\frac{2}{3}}\sqrt{x - \tfrac{3}{4}z^{\frac{2}{3}}}.$$

$$y + z - \tfrac{3}{2}xz^{\frac{1}{3}} = \sqrt[\frac{3}{2}]{x - \tfrac{3}{4}z^{\frac{2}{3}}} + \tfrac{3}{4}z^{\frac{2}{3}}\sqrt{x - \tfrac{3}{4}z^{\frac{2}{3}}}.$$

$$z^{\frac{2}{3}} - \frac{y+z}{x}z^{\frac{1}{3}} = \frac{x^3 - (y+z)^2}{3x^2}.$$

$$z^{\frac{1}{3}} = \sqrt{\frac{4x^3 - (y+z)^2}{12x^2}} + \frac{y+z}{2x}.$$

$$z = \sqrt[\frac{3}{2}]{\frac{4x^3 - (y+z)^2}{12x^2} + \frac{y+z}{2} + \frac{3(y+z)^2}{4x^2}\sqrt{\frac{4x^3 - (y+z)^2}{12x^2}}}.$$

$$432x^6(z-y)^2 =$$
$$64x^9 + 240x^6(y+z)^2 + 192x^3(y+z)^4 - 64(y+z)^6.$$

$$x^9 - 3x^6(y+z)^2 + 3x^3(y+z)^4 - (y+z)^6 = -27zyx^6.$$

$$x^3 + 3\sqrt[3]{zy}\,x^2 - (y+z)^2 = 0. \qquad (3)$$

In (1) and (3), equating coefficients,

$$3\sqrt[3]{zy} = A, \quad zy = \frac{A^3}{27}. \qquad (4)$$

$$-(y+z)^2 = B, \quad y^2 + 2yz + z^2 = -B. \qquad (5)$$

Whence, from (4) and (5),

$$y = \sqrt{-\frac{B}{4}} + \sqrt{-\frac{B}{4} - \frac{A^3}{27}}.$$

$$z = \sqrt{-\frac{B}{4}} - \sqrt{-\frac{B}{4} - \frac{A^3}{27}}.$$

Substituting these values of y and z in (2),

$$x = \sqrt[\frac{2}{3}]{\sqrt{-\frac{B}{4}} + \sqrt{-\frac{B}{4} - \frac{A^3}{27}}} - \frac{A}{3} + \sqrt[\frac{2}{3}]{\sqrt{-\frac{B}{4}} - \sqrt{-\frac{B}{4} - \frac{A^3}{27}}}, \qquad \text{formula } (a)$$

or

$$x = -\sqrt[3]{\frac{B}{2} + \frac{A^3}{27} - \sqrt{\frac{B^2}{4} + \frac{A^3B}{27}}} - \frac{A}{3} - \sqrt[3]{\frac{B}{2} + \frac{A^3}{27} + \sqrt{\frac{B^2}{4} + \frac{A^3B}{27}}}. \qquad \text{formula } (b)$$

In the case of the irreducible case of formula (b), which is similar to Cardan's formula, formula (a) may be used. In such case, only one part, as $\sqrt{-\frac{B}{4}}$, of formula (a) is imaginary, and $\sqrt{-\frac{B}{4} - \frac{A^3}{27}}$ is real; and if the signs of the roots of equation (1) be changed, which is done by changing simultaneously the signs of A and B in equation (1), the converse is true, that is, $\sqrt{-\frac{B}{4}}$ is real, and $\sqrt{-\frac{B}{4} - \frac{A^3}{27}}$ is imaginary. Which shall be the imaginary term is, then, arbitrarily chosen. Hence, factoring preparatory to expansion by the binomial theorem, the coefficient of $\sqrt{-1}$ may be made less than unity when the real term is unity.

A. M. SAWIN.

Evansville, Wis.

Solar constant.

It is feared that the letter of Mr. Hazen (SCIENCE, i. 542) in relation to above topic may not entirely remove the confusion of which he justly complains. It should be premised that there are two units of heat in common use among physicists: the smaller being the quantity of heat required to raise the temperature of one gram of water 1° C.; the larger, the quantity of heat required to raise the temperature of one kilogram of water 1° C. The larger of these units is a thousand times as great as the smaller; and, in ordinary applications, no confusion is liable to arise. In either case, the number of units of heat received by the unit-mass of water is (sensibly) proportional to the number of degrees of rise of temperature.

With regard to the 'solar constant,' two additional units are required, — a unit of surface, and a unit of time. This constant may be defined in general terms to be the number of units of sun-heat incident perpendicularly on a unit-surface, in a unit of time, at the upper limit of the earth's atmosphere; or it is the number of degrees Centigrade a unit-mass of water would be raised in temperature by the sun-heat incident perpendicularly on a unit-surface, in a unit of time, at the upper limit of the atmosphere. The three units here indicated are, of course, arbitrary. But most physicists, following the example of Pouillet (*Comptes rendus*, vii. 24), take the gram, square centimetre, and minute, as respectively the units of mass, surface, and time. With regard to time, there is no diversity, the minute being universally used; but, for mass and surface, some employ the larger units of a kilogram and a square metre, and hence the apparent confusion. To obtain a general expression for the value of the 'solar constant,' let

Q = Quantity of sun-heat incident normally on a unit-surface in a unit of time = solar constant.
S = Area of surface receiving the heat.
T = Time of receiving the heat.
m = Unit mass of water.
n = Number of unit masses of water heated.
t° = Rise in temperature of the mass of water.

Then we have

$$Q \times S \times T = n \times m \times t^\circ.$$

Consequently, when S, T, and n are severally equal to unity, we have $Q = m \times t^\circ$; and, when $m = 1$, $Q = t^\circ$ = rise in temperature of a unit-mass of water = value of solar constant in units of heat.

Now, when the unit of time remains the same, but the units of mass and surface are changed, the value of t° (which measures the solar constant) will be altered, unless both of these units are changed in the same ratio. For, from the equation $Q = m \times t^\circ$, it follows that t° varies as $\frac{Q}{m}$; but evidently Q is proportional to the magnitude of the unit of surface: hence t° varies as $\frac{\text{unit of surface}}{\text{unit of mass of water}}$.

For example: using Pouillet's units, Langley's recent experiments make the solar constant = 2.84; that is, the sun-heat incident normally on one square centimetre, in one minute, at the upper limit of the atmosphere, would raise the temperature of one gram of water 2.84° C., or would heat 2.84 grams of water 1° C. Now, the unit remaining the same, if we assume the unit of mass to be one kilogram (1,000 grams), and the unit of surface to be one square metre (10,000 square centimetres), we should have the value of the constant $t'^\circ = \frac{10,000}{1,000} \times 2.84 = 28.4$ kilogram-units of heat; that is, the sun-heat incident normally on one square metre, in one minute, at the upper limit of the atmosphere, would raise the temperature of one kilogram of water 28.4° C., or would heat 28.4 kilograms of water 1° C.

Moreover, as it requires a definite number of units of heat to liquefy a unit-mass of ice, or to evaporate a unit-mass of water, or to produce a unit of mechanical energy, it follows that this constant may be measured by either of these units.

The exact determination of the value of this constant is a most refined and difficult experimental problem; for it involves the precise estimation of the amount of solar heat absorbed in traversing the earth's atmosphere, or the law of extinction of sun-heat in passing through it: hence it is, that, although several excellent physical experimenters have attacked the problem, their results are not so accordant as would be desirable. The following are some of the results: —

EXPERIMENTER.	DATE.	SOLAR CONSTANT.	
		Gram-units of heat per square centimetre per minute.	Kilogram-units of heat per square metre per minute.
Pouillet . .	1838	1.7633	17.633
Forbes . .	1842	2.847	28.47
Crova . . .	1876	2.323	23.23

Langley . .	1882	2.840	28.40

JOHN LECONTE.

Berkeley, Cal., June 25, 1883.

WARD'S DYNAMIC SOCIOLOGY.

Dynamic sociology, or applied social science, as based upon statical sociology and the less complex sciences. By LESTER F. WARD, A.M. 2 vols. New York, *Appleton*, 1883. 20+706; 7+690 p. 8°.

I.

THIS work of Mr. Ward is composed of two distinct parts. The first gives the outlines of his philosophy, as a basis for his reasoning in the one that follows. The second is a discussion of the causes and consequences of progress, or evolution, in human society. For some purposes it would have been wise to give each part a distinct title, reserving for the last part the one used; but the philosophic system propounded in the first part has evidently been prepared as a basis for the second, and in itself would not be considered by the author as a complete exhibit of his philosophy.

Vol. i. contains: first, an outline of the work, in which the author's purposes are clearly set forth; second, an historical review, chiefly devoted to a discussion of the philosophies of August Comte and Herbert Spencer; third, the cosmic principles underlying social phenomena, in which the outlines of the new system are set forth. Under the general title of 'primary aggregation,' he discusses the constitution of celestial bodies and chemical relations. Under that of 'secondary aggregation,' he discusses biology, psychology, and the genesis of man. Under that of 'tertiary aggregation,' he discusses the genesis of society and the characteristics of social organization. The purpose of this preliminary volume on general philosophy, and of the introduction to the second volume, is tersely given by Mr. Ward himself, as follows: —

"The purpose of the present chapter [chap. viii.], as already announced, has been to accomplish the complete orientation of the reader for the voyage before him. Without this, much that is to come might appear meaningless, or at least lose its point.

"Men think in systems. Most systematic treatises are unintelligible unless followed from the beginning and grasped in their entirety. A fundamental tone runs through them which prescribes the special sense of every line, and which is wholly unheard in isolated passages. The careful reader of such works, without necessarily acquiescing in the author's views, is able at least to comprehend them and to do justice to them." . . .

"In the following argument, now to be briefly stated, and subsequently to be fully elaborated, the statements made in this chapter, as well as those contained in the preceding volume, are to be taken as the basis, or premises, and must be granted 'for the sake of the argument' at least, however unsound they may be deemed in themselves."

Elsewhere the theory is more fully elaborated, that the more complex sciences can be grasped only as the more simple sciences upon which they are based are properly understood, and that anthropologic sciences in general must rest firmly upon physics and biology. Though the reader may differ from Mr. Ward in relation to his classification and conclusions, he will still be interested in the symmetry of his system and the perspicuity of his presentation.

The essential principle running through the treatise is, that progress in society is based upon the struggle for happiness in the same manner as biologic progress is based upon the struggle for existence. It is therefore a new system, in radical contrast with that taught in our schools and enunciated by the majority of publicists of the present day, of whom Herbert Spencer is the chief. For this struggle for happiness the term 'conation' (*conari*, to endeavor) is used, taken from Sir William Hamilton; and he says, "The term 'conation' will be employed in this work to represent the efforts which organisms put forth in seeking the satisfaction of their desires, and the ends thus sought will be designated as the 'ends of conation.'"

Again, the author classifies phenomena as *genetic* and *teleologic*. Genetic phenomena are such as appear in series, with natural antecedents and consequents, unaffected by design or purpose. Teleologic phenomena do not appear in natural series, the antecedents being physical phenomena controlled by design existing in mind, and the consequents being the purposes for which the will is exercised. Throughout the work these two classes of phenomena are clearly distinguished; but it is impossible, in a brief review, to set forth fully the importance of the distinction, as the author himself has done. In general terms, it may be stated that biologic progress is due to the struggle for existence, and involves genetic phenomena; while sociologic progress is due to the struggle for happiness (conation), and involves teleologic phenomena.

"All progress is brought about by *adaptation*. Whatever view we may take of the cause of progress, it must be the result of a correspondence between the organism and the changed environment. This, in its widest sense, is adaptation. But adaptation is of two kinds. One form of adaptation is *passive* or *consensual*, the other form is *active* or *previsional*. The former represents *natural* progress, the latter *artificial* progress. The former results in a *growth*, the latter in a *manufacture*. The one is the *genetic* process, the other the *teleological* process. In passive adaptation the means and the end are in immediate proximity, the variation takes place by infinitesimal differences; it is a process of *differentiation*. In active adaptation, on the contrary, the end is remote from the means; the latter are adjusted to secure the former by the exercise of *foresight*; it is a process of *calculation*."

By the term 'dynamic sociology,' as used by the author, is to be understood a systematic treatise on the forces which impel mankind into social relations, to develop social organization, and to provide and modify the institutions of society. The subject-matter of dynamic sociology, appearing in the second volume, is arranged in the following order, as set forth by the author: —

"The remainder of this work will chiefly consist in the discussion of six terms; and therefore, before entering upon such discussion, it is a primary necessity to furnish rigid definitions of each of these terms.

"For a purpose which will presently appear, we will assign to each of these terms a letter, which will fix their order in a series not admitting of any alteration.

"The first of these terms, which we will designate by the letter A, is *happiness;* the second, which we will designate by B, is *progress;* the third, which we will designate by C, is *dynamic action;* the fourth, which we will designate by D, is *dynamic opinion;* the fifth, which we will designate by E, is *knowledge;* and the sixth, which we will designate by F, is *education*.

"The definitions of these six terms are as follows:

"A. Happiness. — Excess of pleasure, or enjoyment, over pain, or discomfort.

"B. Progress. — Success in harmonizing natural phenomena with human advantage.

"C. Dynamic action. — Employment of the intellectual, inventive, or indirect method of conation.

"D. Dynamic opinion. — Correct views of the relations of man to the universe.

"E. Knowledge. — Acquaintance with the environment.

"F. Education. — Universal distribution of extant knowledge.

"Corresponding to these six terms thus defined, there are six theorems of dynamic sociology, which require to be elaborated and established, and to each of which a separate chapter will be devoted.

"Continuing the literal designations, these theorems are the following: —

"A. Happiness is the ultimate end of conation.

"B. Progress is the direct means to happiness; it is, therefore, the first proximate end of conation, or primary means to the ultimate end.

"C. Dynamic action is the direct means to progress; it is, therefore, the second proximate end of conation, or secondary means to the ultimate end.

"D. Dynamic opinion is the direct means to dynamic action; it is, therefore, the third proximate end of conation, or tertiary means to the ultimate end.

"E. Knowledge is the direct means to dynamic opinion; it is, therefore, the fourth proximate end of conation, or fourth means to the ultimate end.

"F. Education is the direct means to knowledge; it is, therefore, the fifth proximate end of conation, and is the fifth and initial means to the ultimate end."

The remaining six chapters of the work, namely, chapters ix., x., xi., xii., xiii., xiv., treat of these six subjects *seriatim*.

In chapter ix., then, the doctrine is set forth that happiness is the ultimate end of conation, or human endeavor. Here Mr. Ward discusses the nature and genesis of feeling, as the proper basis of a philosophic system involving the interests of man; and he subsequently endeavors to show, that, what function is to biology, feeling is to sociology. And after a discussion of the intellectual method as compared with the physical method of conation, and several collateral subjects, he sets forth the doctrine that degree of feeling is concomitant with degree of organization, and that the pursuit of happiness by man leads to higher physical, mental, and social organization; that, in turn, such higher organization increases feeling, and thus increases pleasure, and thus increases happiness.

Chapter x. is devoted to the consideration of progress as the primary means to happiness, and includes: a discussion of the difference between dynamic sociology and moral science; then a discussion of the growth of the means for communicating ideas, — language in all its forms; then of the arts and industries which are developed in the pursuit of subsistence; then the origin of government and the institutions of government; and, finally, the origin and institutions of religion.

Chapter xi. is entitled 'Action,' — a term chosen in preference to the more common expression, *conduct*. The chapter is chiefly devoted to the discussion of a systematic classification of actions, first, as involuntary and voluntary; and voluntary actions are again divided into impulsive or sensori-motor, and deliberative or ideo-motor. Each of the latter classes consists of two groups; namely, actions possessing moral quality, and actions devoid of moral quality.

It is no part of the author's purpose to treat of action possessing moral quality; although, in order to make clear the irrelevancy of such actions to his discussion, he occupies some space in going over the ground usually covered by writers on ethics. Actions devoid of moral quality are those upon which progress essentially depends, and chiefly that branch which falls under the more general head of deliberative or ideo-motor actions. They are further subdivided into static and dynamic, the former group embracing the great bulk of human activities in the performance of the ordinary duties of life. Static actions of this class do not result in progress, but tend simply to preserve the existing social status. Dynamic actions constitute the really progressive class of actions.

The chief fact which distinguishes dynamic actions from all others is, that they are performed by the indirect or inventive method. All the progress that has taken place in society has been due to such action. However spontaneous such progress may appear, it has, nevertheless, been the result of teleologic methods in adjusting natural phenomena in such a manner that they will accomplish desired ends, — remote in themselves, but foreseen by the intelligence of the developing intellect. The results are the essential elements of human art; and consequently civilization is fundamentally and wholly artificial. Here Mr. Ward introduces a series of illustrations of typical dynamic actions performed in the course of social progress, for the purpose of elucidating the central idea which he desires to embody in the term 'dynamic action.'

Chapter xii. is a discussion of opinion as the direct means to progressive action. As dynamic actions are ideo-motor, such actions must result from the possession by the agent of certain underlying and directing ideas. The truism that 'ideas rule the world' simply means, that opinions determine actions. But in order to produce dynamic actions, — that is, actions which will, in fact, result in progress, — it is essential that the opinions which underlie them be in rigid harmony with objective reality. Dynamic action can only flow from correct opinion.

Opinions must not only be correct, they must be important. Unless important, no appreciable dynamic result will flow therefrom. The most important opinions, or ideas, are arranged under four general heads: first, cosmologic ideas; second, biologic ideas; third, anthropologic ideas; fourth, sociologic ideas. Correct ideas belonging to these four great classes constitute the primary motive power to all human progress.

Chapter xiii. is upon knowledge, — the immediate data of ideas. Opinions cannot be directly reached. They are not subject to the will, either of the party holding them or of any other: they are simply consequents. Obviously, the antecedents of ideas consist in the data possessed by the mind relative to the materials and phenomena of nature. Such data are grouped by the author under the general term 'knowledge.' Knowledge, therefore, must first exist; and, if it exist, no effort need be expended in determining opinion. In this chapter the author shows that the chasm which in fact separates the intelligence of the lowest and the highest classes of mankind is chiefly due to inequality in the possession of the data for thought. He shows that the capacity of the mind is, in any particular class of society, practically equal; that, even in what are known as semi-civilized or barbaric races, the capacity exists for a far greater amount of knowledge than is ever obtained.

Chapter xiv. is on education as the direct means to knowledge. The possession of knowledge, therefore, if it could be secured, would constitute the true means to the proximate end, and thus secure the ultimate purpose. But the human mind is so constituted that it cannot be safely intrusted to secure this end for itself; for the individual cannot understand the necessity for this knowledge, or guide himself wisely in its attainment, prior to its acquisition: that is, the period of acquisition is in the earlier years of the life of the individual, when he must be guided by others. The initial means in the entire series is therefore education, actively considered as a function of society.

The work closes with a condensed but fundamental treatment of the general subject of popular education, in which appears a review of the various theories that have been held, and that still control human action on this subject. He divides the general body of public opinion into five parts, which he denominates 'the five kinds of education.' These are: first, education of experience; second, of discipline; third, of culture; fourth, of research; fifth, of information. The first four of these kinds of education are considered for the purpose of showing, that, however important in themselves, they are insufficient to accomplish the great end of securing an artificial civilization as the product of direct social action. The last of these forms of education, therefore, is the only one which embodies such promise.

The author sees little hope in the imperfect and desultory attempts of individuals to secure this great need in society. To render it of any value, he claims that education must be the systematic work of society in its organized capacity. Ceasing to exert itself longer in vain attempts to secure directly the various proximate ends, society should vigorously adopt this inital means, and concentrate its energies on the work which is clearly practicable, — that of furnishing to all its members the data actually in its possession.

Under the heading 'Matter of education' the author briefly, but without dogmatism, discusses the general theorem that the subject-matter should be a knowledge of nature, — a knowledge of the environment of the individual and of mankind. His treatment of the methods of popular instruction is brief, maintaining that this is merely a matter of supply in the politico-economic sense, which will certainly come as soon as there shall be an adequate demand. He says, "The methods and the teachers have always been as good as the popular notions of education, and they will doubtless continue to be so." The only criterion which he does lay down with regard to method is that it be teleologic. He insists that education, like every other department of civilization, must be an artificial product; that it must be undertaken deliberately, planned by human intelligence, and achieved through human effort.

The author discusses, in a broad and philosophic manner, a great body of questions in which civilized man is deeply interested. He has therefore written for a wide reading; and happily his style, in its essential characteristics, will not repel those to whom it is presented.

GEOLOGY OF SOUTHERN PENNSYLVANIA.

Second geological survey of Pennsylvania. — Report of progress T².— The geology of Bedford and Fulton counties. By J. J. STEVENSON. Harrisburg, *Survey*, 1882. 15+382 p., 2 maps. 8°.

PROFESSOR STEVENSON has made a detailed survey of the district, which has led to but few material changes in the map of the first survey. The descriptions of the structural geology are careful, plain, and easily understood; and the second part of the report, consisting of a day-book of observations along the roads, with reference to outcrops, mines, and quarries, will doubtless prove very useful.

It is well that Professor Stevenson has not completely neglected paleontology in his descriptions of the various formations; but this feature of his report is capable of much improvement, only about sixty species being cited as occurring in a section that extends from the upper coal-measures to the calciferous. The value of his determinations, and the scientific interest of his work, would have been much increased, if care had been taken to collect and determine the fossils found in each group, and lists of them published, together with the localities in which they occurred. It is not meant to infer that Professor Stevenson's determinations are incorrect, but simply that he gives no evidence in support of them. For instance: he says, "Some of these layers contain fossils which are *distinctly Chemung*, none whatever of Portage type being present; but, owing to the weathering, the forms can be identified only generically." The writer does not think he is alone in doubting whether there are any fossils which are distinctively Chemung. At any rate, it would be interesting to know what these genera are. He mentions no fossils in his Hudson River group, and in the Trenton mentions only three forms, which are also very common at the top of the lower Silurian. The director of the survey, in his letter of transmittal, makes the following curious remark, which seems to indicate a peculiar conception of the objects of paleontology. He says, "Paleontologists will find it an easy task to copy out from the index, separately, the whole list of fossil names, and arrange them afterwards to suit their own purposes." Certainly, paleontologists do not want to arrange fossils to suit themselves, but to find out how nature has arranged them. The two maps accompanying the report are of very indifferent quality, as it is difficult, especially over the Broad Top area, to follow on the maps the descriptions in the text. Mr. Stevenson disclaims responsibility for several things in them, which may account for the discrepancies between the text and the maps. Professor Lesley seems to think that the maps may be easily followed by a person familiar with the country; but the maps should have been constructed so that others, also, may be able to understand them. He seems to apply preconceived notions of orography, whether it agrees with the geology as studied in the field or not; and, if the responsibility of preparing the maps rested with the same person who has done the field-work and prepared the text, the result would probably be more intelligible. Mr. Stevenson mentions a bed 195 feet above the Pittsburg coal. This would apparently belong to the upper series, considered Permian in other reports of the survey; but this does not appear to be represented anywhere on the map.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

Eclipses of Jupiter's satellites. — Cornu proposes to observe these eclipses photometrically, comparing the light of the satellite during the time while it is entering or emerging from the shadow with that of an artificial satellite visible in the same field, and made to vary in brightness at pleasure by an adjustable 'cat's eye,' so called. He shows that the moment when the light of the satellite is *half* that of its unobscured condition is the one which can be most accurately determined, and urges that the photometric observations should be so arranged as to give an automatic record. Admiral Mouchez has authorized the application of the necessary apparatus to one of the large equatorials of the Paris observatory.

M. Cornu does not seem to be aware that a very similar, but really more precise, method of observation has been in use at the Harvard college observatory for the past two years. Prof. Pickering, however, very wisely prefers to compare the eclipsing satellite with one of the other satellites, or with an image of the planet, rather than with an artificial star; and he uses polarization apparatus instead of a cat's eye to equalize the brightness of the objects compared. — (*Comptes rendus*, June 4.) C. A. Y. [40

MATHEMATICS.

Theory of functions. — In a series of three memoirs, M. Appell has reproduced in a more extended form a number of investigations which he has recently communicated to the French academy of sciences. The first of the three memoirs treats of uniform functions of an analytical point (x, y); the term 'analytical point' meaning simply the system of values of (x, y) formed by any arbitrary value of x and the, say, m corresponding values of y. The first section of the memoir contains three theorems concerning the development in rational fractions of such functions. In the second section a uniform function is defined, and also the poles and essential singular points (*points singuliers essentiels*, Weierstrass' *wesentliche singuläre stelle*). Functions with a finite number of singular points are then taken up, and a generalization of a known theorem concerning the coefficients in the development of a uniform function is given: viz., if $F(x, y)$ is a uniform function of the analytical point (x, y), having a finite number of singular points (a_i, b_i), and if R_i are the residues relatively to these points; if, further, in a certain region of the analytical point $\left(x = \infty, \ \lim \frac{y}{x} = C_k\right)$, we have $F(x, y) = \sum_{\nu=-\infty}^{\nu=\infty} A_\nu^{(k)} \frac{1}{x^\nu}$, — then we have the relation

$$A_1^{(1)} + A_1^{(2)} + \ldots + A_1^{(m)} = R_1 + R_2 + \ldots + R_n.$$

In this, i has all values from 1 up to n, and k has all values from 1 up to m; m denoting the number of values of y corresponding to a given value of x. After a brief review of some of the properties of the Abelian integrals, the author gives a generalization of a holomorphic function of x in the interior of a circle whose centre is a in terms of ascending powers of $(x - a)$. The subject of functions with an infinite number of singular points is then taken up, and a generalization is first given of Mittag-Zeffler's theorem concerning these functions; viz., if a series of distinct analytical points $(a_1, b_1) \ldots (a_\nu, b_\nu) \ldots$ are such that $\lim. (a_\nu, b_\nu) = (a\ b)$ for $\nu = \infty$, and if $F_1(x, y), F_2(x, y) \ldots F_\nu(x, y)$ is a series of rational functions of x and y which become infinite only in the two points (a_ν, b_ν) and (a, b) respectively, then there exists a uniform function $\Phi(x, y)$ having only the point (a, b) as an essential singular point, and admitting as poles the points (a_ν, b_ν) in such a manner that the difference $\Phi(x, y) - F_\nu(x, y)$ is regular in the point (a_ν, b_ν).

The second memoir by M. Appell is a continuation of the first. In it he considers the decomposition into prime factors of a uniform function of an analytical point (x, y) having only one essential singular point, and also gives a theory of doubly periodic functions with essential singular points. The author examines, first, functions having in a parallelogram of periods a finite number of singular points, and gives an interesting theorem; viz., the sum of the residues of $F(u)$ relative to the singular points situated in a given parallelogram of periods is equal to zero. A general expression is then obtained for a doubly periodic uniform function $F(u)$ having in a given parallelogram of periods only one singular point.

In the third memoir, M. Appell considers the development of functions in series inside an area bounded by arcs of circles. These three memoirs by M. Appell, taken with a memoir by M. Poincaré, which precedes them, and which has already been referred to in these pages, constitute a very valuable series of papers on the modern theory of functions. — (*Acta math.*, i. no. 2.) T. C. [41

PHYSICS.

Acoustics.

Upper limit of audibility. — Pauchon and Bertrand have investigated the question of the effect of the intensity of the sound upon this limit. A siren blown by steam with pressures varying from 0.5 to 1.5 atmospheres gave from 24,000 to 30,000 double vibrations as a limit; but, with certain modifications and a higher pressure (2½ atmospheres), the most acute sound that could be produced by the instrument, due to 36,000 vibrations, was still heard. Metallic rods of different lengths, set into longitudinal vibration in the usual manner, gave the following results: 1. The length of the rod giving the highest perceptible sound is independent of its diameter; 2. For steel, copper, and silver, the lengths are proportional to the velocity of sound in those media. These results disagree with those reached with the siren. The authors find, however, that, if the ear is aided by a resonating trumpet, the limit is slightly raised; that the limit is raised with substances like rosin, producing the most energetic friction; and that the sound, even when too high to affect the ear, still acts on a sensitive flame.

These results of Pauchon with the siren agree with the fact observed several years since by Dr. H. P. Bowditch of Boston, that, with a König's bar of exceedingly large diameter, the limit of audibility is higher than with one of the ordinary size. — (*Comptes rendus*, April 9.) C. R. C. [42

Production of whispered vowels. — Lefort calls attention to the wide range of whispered vowels that can be artificially produced by blowing across resonant tubes or spheres: *ou*, *o* (closed), *o* (open), *u*, *eu*, *e*, *i*, *é* (closed), *é* (open), — all being produced as the capacity of the resonator is diminished. By diminishing the length of an open tube the vowels *â*, *à*, *e*, *eu*, *u*, *è*, *é*, *i*, are successively heard, while *ou*, *ô*, *o*, are obtained by closing the upper end of the tube more or less. — (*Comptes rendus*, April 23.) C. R. C. [43

Transmission of sounds by gases. — Neyreneuf has studied the relative transmission of sound through air, carbonic oxide, carbonic acid, and illuminating-gas. The sound is transmitted through a tube two metres long, containing the gas experimented upon, and the intensity is studied by noticing the distance at which a sensitive flame ceases to be acted upon by it. He finds that air and carbonic oxide have the same transmissive power, air and illuminating-gas give very variable results, and carbonic acid has a much greater transmissive power than air. A table of results for air and carbonic acid is given. — (*Comptes rendus*, April 30.) C. R. C. [44

Experimental demonstration of velocity of sound. — Griveaux arranges a glass tube and a bar of pine wood of equal length, so that the passage of a pulse through either the column of air in the tube or the wooden rod shall move one of two light screws, and so break an electric contact. The current from a battery is divided, and passes into the two coils of a differential galvanometer; the light screw resting on the end of the rod being placed in one circuit, and a similar screw, resting on a membrane closing the end of the tube, in the other. The resistances are so arranged that the needle of the differential galvanometer remains normally undeflected. If a sound is produced by striking a drum, the needle of the galvanometer is deflected in such a direction as to show that the contact is broken by the movement of that screw resting on the end of the wooden rod, thus illustrating the greater velocity of the sound-wave in wood than in air. — (*Journ. phys.*, May.) C. R. C. [45

ENGINEERING.

Electric stop for steam-engines. — Mr. Tate, an English engineer, has combined the Leclanché battery, an electro-magnet, an auxiliary steam-cylinder, and a stop, to the closing of the stop-valve of the steam-engine, if its sudden stoppage should become necessary. It has been applied by Mr. Tate to the driving-engines of his large woollen-mills in Bradford. The mechanism consists of a weighted suspension rod attached to the stop-valve by a bracket, and actuated by a small steam-cylinder, the piston of which is supplied with steam through a valve which is opened by the action of the electro-magnet and the weighted rod. The movement of this auxiliary engine shuts the stop-valve of the engine in a small fraction of the time usually required to close it by hand. The wires of the battery are carried to various parts of the mill, so that the engine can be 'shut down' at any instant, and from any one of a number of promptly accessible points. This arrangement is proposed to be attached to the engines of steam-vessels, the wires being led to the bridge, and to other parts of the vessel where the officers can easily reach the button. — (*London times*, Oct. 21.) R. H. T. [46

Forms of steamers. — Two vessels recently built by the Messrs. J. & G. Thompson have been compared to determine their relative economy as a means of transportation as affected by a considerable difference in proportions. One was 390 feet long, 42 feet beam, and drew 18 feet of water: the second was 375 by 45 by 20 feet. The longer vessel had less fine ends than the broader ship. The former required 5,100-horse power to drive her 15 knots an hour, while the latter only demanded 3,900. At 13 knots, the power demanded was the same for both; but at higher speeds the difference became greater and greater, and more and more in favor of the shorter, broader, but finer ended vessel. The gain to be expected from giving ships greater beam, and, at the same time, finer ends, is expected to be observed in larger and faster vessels. — (*Mechanics*, May 26.) R. H. T. [47

Efficiency of the steam-engine. — Professor R. R. Werner, of the Technical high school at Darmstadt, publishes a paper describing his trial of a compound engine driving a mill in Augsburg. The engine has an indicated power of 132 horses. The cylinders have a proportion of 2.75 to 1; they are steam-jacketed, as is the intermediate reservoir; the ratio of expansion is 14. The boilers carry a pressure of about 7 atmospheres, and the steam supplied contains 3 per cent water. The steam-jackets condense about 11 per cent of the steam, and the cylinders demand about 7 kilograms (15.4 lbs.) of steam per horse-power and per hour, beside that condensed in the jackets. This is about the amount required as a minimum in the best-known English and American engines. In this country, a very similar figure has been reached by Corliss and by Leavitt. — (*Zeitschr. ver. deutsch. ing.*, May.) R. H. T. [48

'Compound' locomotives. — M. Mallet communicates to the French society of engineers a note from M. Borodine, giving the results of experiments to determine the relative economy of the simple and the compound system of engine for locomotives. The engines experimented with were those designed for the railway from Bayonne to Biarritz by M. Mallet. The trials extended over a considerable period of time, and the comparisons were made fairly complete. The result showed the compound system to have an economy of from ten to twenty per cent, according to the conditions under which they are carried out. The variation in the ratio of expansion is very greatly restricted in the compound engine. The use of the steam-jackets with which the engines were provided did not prove to be of advantage. The expenditure of steam was greater when they were in use than when they were shut off. — (*Mem. soc. ing. civ.*) R. H. T. [49

CHEMISTRY.

(Organic.)

Compounds of benzotrichloride with phenols and phenylamines. — When a mixture of one molecule of benzotrichloride and two molecules of phenol is heated gently, O. Döbner finds that the following reaction takes place: —

$$C_6H_5CCl_3 + 2C_6H_5OH = C_6H_5CCl\begin{matrix} C_6H_4OH \\ C_6H_4OH \end{matrix} + 2HCl.$$

The remaining chlorine atom is replaced by a hydroxyl group when the product is heated with water, forming dioxytriphenylcarbinol, —

$$\begin{matrix} (OH) \\ C_6H_5 \end{matrix} C \begin{matrix} C_6H_5OH \\ C_6H_5OH \end{matrix}.$$

By reduction, dioxytriphenylmethan

$$\left(\begin{matrix}H & & C_6H_5OH\\ & C & \\ C_6H_5 & & C_6H_5OH\end{matrix}\right)$$

is formed. An analogous reaction takes place if resorcine is used instead of phenol. The resulting resorcine benzein, by reduction, gives tetraoxytriphenylmethan, —

$$C_6H_5CH\ CH\begin{matrix}C_6H_3(OH)_2\\ C_6H_3(OH)_2\end{matrix}.$$

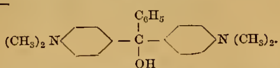
With primary aromatic amines, benzotrichloride united readily. When added to a mixture of dimethylaniline and zinc chloride, it formed malachite green, —

$$\begin{matrix}(OH) & & C_6H_4N(CH_3)_2\\ & C & \\ C_6H_5 & & C_6H_4N(CH_3)_2\end{matrix}.$$

By reduction, this substance gave the corresponding leuko-base, —

$$\begin{matrix}H & & C_6H_4N(CH_3)_2\\ & C & \\ C_6H_5 & & C_6H_4N(CH_3)_2\end{matrix}.$$

The base malachite green was easily decomposed, when heated with hydrochloric acid, into dimethylamine and benzoyldimethylaniline. This reaction points to the following structure for malachite green: —



The action of benzoyl trichloride upon hydroxyl or amido compounds seems, therefore, to be normal to the para position with respect to the amido or the hydroxyl group. — (*Ann. chem.*, ccxvii. 223.) C. F. M. [50

GEOLOGY.

Lithology.

The Potsdam and St. Peters sandstones. — The surface induration of the friable Potsdam and St. Peters sandstones, as determined by macroscopic observations in 1871–73, was brought to the notice of the readers of SCIENCE some time ago (i. 146), while a recent interesting paper by Prof. R. D. Irving gives the results of his microscopic investigations on the same subject. Irving finds, as Sorby had previously, that ordinary quartz grains, formerly rounded and worn, have been built out and supplied with crystal facets from silica deposited later on them. He finds that the induration of the above-mentioned sandstones arises from the deposition of interstitial quartz cementing the grains. The deposited quartz is found to be optically oriented, the same as the enclosed grain, which is distinguished by its cloudiness and worn surface, and frequently by a coating of oxide of iron upon it.

To the deposition of quartz upon worn quartz grains is ascribed the occurrence of quartz crystals in the Potsdam sandstone described in 1882 by Rev. A. A. Young. Credit should have been given by both Irving and Young to Rev. John Murrish for calling attention to the occurrence of quartz crystals in Potsdam sandstone in 1870–72 (*Bull. Wisc. acad.*, ii. 32), especially since Murrish's observations were discredited at the time.

All quartz crystals in sandstone have not this derivation, as the writer showed for the Lake Superior sandstone in 1880, the crystals of which come from old eruptive rocks owing to the decomposition of the matrix. It is pleasant to find my earlier observations on the surface induration of the Wisconsin sandstones, and the formation in them of quartz crystals, sustained by the much more complete and valuable work of Irving, made, as his was, without any knowledge of mine.

Irving holds that the quartz deposited may come from the action of water on the occasional felspar particles in the rock, although sometimes from an external source. He further regards the induration of quartzites and quartz schists as caused by the same deposition of intersticial quartz. — (*Amer. journ. sc.*, xxv. 401.) M. E. W. [51

Antase as an alteration product of titanite. — The titanite in a biotite amphibole granite from the Troad was found by Mr. J. S. Diller to be replaced by a light wine-yellow to honey-yellow mineral, showing, under the microscope, quadratic and rhombic sections. The former are isotropic, and have a well-marked cleavage parallel to their sides; the latter are strongly doubly refracting, extinguish parallel to the diagonal, and have one cleavage parallel to the short diagonal and another to the edges. In order to isolate the substance, the finely pulverized rock was separated into two portions, one of lighter and the other of heavier specific gravity than 2.72, by means of the potassium-iodine-mercury solution. The yellow mineral was found in the second portion, which contained also iron ore, zircon, and apatite. The ore was removed by the electro-magnet, and the apatite by nitric acid. By means of the cadmium-boron-tungstate solution it was shown that the yellow mineral had a specific gravity between 3.6 and 4.5. Some grains were picked out, and found to be insoluble in hot aqua regia.

The mixed zircon and yellow mineral powder gave a reaction for titanium, while the pure zircon would not: hence it was inferred that the mineral contained titanium. Its angles were found to be 98° 24′ and 136° 16′, while the corresponding ones of antase are 97° 51′ and 136° 36′. From its optical, chemical, and crystallographic characters, it was then inferred that the yellow mineral was antase. — (*Neues jahrb. miner.*, 1883.) M. E. W. [52

GEOGRAPHY.

(*South America.*)

The Puno railroad, Peru. — Dr. R. Copeland gives a readable account of a journey over this remarkable railroad from its beginning at Mollendo on the coast, through Arequipa, to Puno on Lake Titicaca, and of his farther travels by boat on the lake, and by stage, beyond to La Paz in Bolivia. The features that attracted his special attention were the deep, narrow valleys followed by the road in its sharp windings while ascending from one pampa level to the next; the broad, flat, barren pampas at great and greater altitudes; and the superb views of the volcanic peaks and ranges of the Cordillera, — Misti, Chaycam, and Pichupichu, eighteen to nineteen thousand feet in height. On the pampa of La Joya (4,100 feet) he saw countless hillocks of pure, sharp sand (*médanos*), in half-moon form, with the curve to the west or windward (see SCIENCE, i. 488). A mirage gave these white hills the appearance of drift-ice in an arctic sea. — (*Deutsch. geogr. blätter*, vi. 1883, 105.) W. M. D. [53

Colombia. — R. B. White, for several years resident in Colombia, and a companion of Stübel and Reiss in some of their expeditions, furnishes a summary account of the more attractive parts of this republic, and of its productions, and chance of development. Several of the rivers that flow northward between parallel ranges of the Cordillera are navigable for small steamers for many miles into the interior, opening districts well adapted to agriculture, and well supplied with timber and mineral products. Above the low plains the climate is healthy. A good share of the world's platinum supply is obtained from the upper valley of the San Juan, and gold occurs in profitable quantity in many of the river-gravels. Brief mention is made of an ascent of the snowy volcano, Puracé; and the extensive view from the Cerro Munchique, nearly ten thousand feet high, west of Popayan, is highly praised. The geological observations on the origin of mountain and valley form do not carry conviction, and the frequent mention of volcanic upheaval and valleys of fracture remind one of the theories of fifty years ago. — (*Proc. roy. geogr. soc.*, v. 1883, 249.) W. M. D. [54

(*Africa.*)

The Kongo. — Dr. Pechuel-Loesche, a member of the German-African expedition to Loango in 1873–76, and later in charge at Stanley Pool while Stanley went to Europe, recently read an address on the Kongo and the neighboring mountains of western Africa before the German geographical congress at Frankfort. The river is remarkable for the rapids all along its course, and especially in its narrow passage through the mountains below Stanley Pool, where it falls nine hundred and twenty-eight feet in some three hundred and forty miles. Of the several falls in this part of its course, only one is vertical, that of Isangila, with a height of sixteen feet. There are two periods of high water, with a rise of twenty feet, when the falls disappear in a uniform rushing flow. The water rises from September to January, falls from January to March, attains its greatest height in the rainy months (April and May), and its lowest level in July and August. Many of the mountain brooks have cut deep channels, and join the main stream on a level; but some of the larger rivers of the interior, flowing over horizontal rocks, have not cut their way so deeply, and, on joining the Kongo, form cataracts. Thus the Luenga falls three hundred feet, and the Luvubi five hundred feet. (This, if correctly reported, is certainly a very abnormal arrangement.) The mountain belt is about two hundred miles wide, rising from a sloping plain at about one thousand feet to rounded and monotonous elevations with a maximum of three thousand feet. The higher land is grassy, with small trees and apparently leafless bushes: the more luxuriant growth of lofty trees and palms is hidden in the valleys. It is these deep and steep-sided valleys that make the rather open upland difficult to traverse. Near the river, the natives have destroyed all the forest-trees, either by burning or cutting. The villages are built on high and bare summits. Dr. Pechuel-Loesche regarded the Makoko (ruler of the stream), with whom de Brazza had made a treaty two years ago (SCIENCE, i. 79), as a local ruler of no general authority. The Makoko's son had reported that his father had ceded no land to de Brazza, and that he had no French flag in his possession. There are four Makokos in this region; and none of them has a right of precedence over the others, or any title to be sovereign of the Bateke population of this part of the Kongo. — (*Proc. roy. geogr. soc.*, v. 1883, 286.) W. M. D. [55

The muatiamvo of the southern Kongo basin. — Max Buchner, the fourth European who has been in this region in the last two centuries, spent half a year at the residence of the 'muatiamvo,' or king (SCIENCE, i. 19), and reports on the peculiar form of his government. The kingdom on the southern side of the Kongo basin, the special field of the German-African explorations, includes an area about as large as Germany. Its population can hardly exceed two millions, and its power cannot compare with that of Mtesa's country, farther east, where an army of a hundred thousand men can take the field. Here the army is not more than one thousand strong at the highest; and Buchner says he could go where he chose with fifty European soldiers, if they were not attacked by that more dreaded enemy, the African fever. And yet, through a large part of south-western Africa, the muatiamvo is the greatest native power. The most notable peculiarity of the government consists in the presence of a second high authority besides the muatiamvo, namely, the 'lukokessa,' or queen: she is not the wife of the king, who has some sixty wives of his own, but is free and independent of him, having her own chief consort, the 'shamoana,' and numerous frequently changing husbands of lower order. Buchner traces the origin of this form of government, and gives a list of thirteen muatiamvos, down to Shanana or Naoesh-a-kat, the present king, and describes the different parts of the kingdom and its neighboring states. — (*Deutsche geogr. blätter.*, vi. 1883, 56.) W. M. D. [56

BOTANY.

Pollination of Rutaceae. — Urban has studied the adaptations for fertilization in a considerable number of species of this heterogeneous order, using living material at the Berlin botanic garden. As few of the genera have been previously studied in this respect, a rather full translation of his tabulated summary is given.

I. MONOCLINOUS SPECIES.

A. *With dichogamous (protandrous) flowers.*

1. Nutation successively places the dehiscent anthers at the point which the receptive stigma occupies later.

a. Style undeveloped in the staminate stage.

α. The filaments rise from their original horizontal position, place themselves against the ovary, resume their original position, and again become erect, but without lengthening; petals plane; self-pollination usually impossible: *Ruta.*

β. The originally short, erect filaments lengthen, curve inwards, and again straighten; petals united below in a tube; close pollination possible by gravitation: *Coleonema.*

b. Style developed in the staminate stage, though not always to its full length; so placed as to oppose self-pollination.

∸ Flowers zygomorphic.

α. The stamens which lie on the lower lip successively bend upward, and, after dehiscence, resume their original position; the end of the style likewise bends up at maturity: *Dictamnus.*

β. The stamens, originally bent upwards, successively straighten at maturity, then bend outward; the style, bent downward when young, straightens when the stigma becomes receptive: *Calodendron.*

≐ Flowers actinomorphic. The filaments successively elongate after dehiscence.

α. In the staminate stage the style is bent horizontally across the ovary; the stamens bend over the pistil successively at maturity, then lengthen, and turn outward between the finally erect petals: *Diosma tenuifolia.*

β. Similar to the last; but the staminodia, and not the petals, become erect, the stamens bending outward but little: *Adenandra.*

γ. After flowering, the style bends outward and downward between the staminodia, the petals remain horizontal, the staminodia lie against the ovary, and, after dehiscence, the fertile stamens resume their original horizontal position: *Barosma.*

2. The stamens nutate but once, and simultaneously. In the staminate stage they are perpendicular, or incline but little toward each other, so that the anthers are in contact at their margin; in the pistillate stage they have bent outward.

a. The anthers fall away when the filaments curve outward: *Ravenia.*

b. Anthers persistent on the bent filaments.

∸ Pollen may fall on the unreceptive stigma, and so effect self-fertilization. Even later this is not impossible, as the wind or gravitation may carry pollen from the reflexed stamens to the mature stigma.

α. In the pistillate stage the style elongates: *Zieria* and *Eriostemon.*

β. With normally developed stigma: *Boronia* (ex parte).

γ. When the style lengthens, the stigma may encounter the anthers of the still erect stamens: *Erythrochiton.*

≐ The viscidity of the pollen, and the situation of the anthers, prevent self-pollination: *Metrodorea.*

3. The stamens do not nutate at all.

a. Self-pollination possible in the pendant flowers after the separation of the lobes of the stigma: *Correa.*

b. The style is surrounded by staminodia in the first stage; in the second stage spontaneous pollination by neighboring flowers may occur if insect-crossing has not been effected: *Agathosma* (ex parte).

B. *With synacmic flowers.*

1. Self-fertilization impossible.

a. With viscid pollen: *Boronia* (ex parte).

b. The stigma surpassing the anthers: *Triphasia.*

2. Spontaneous self-pollination impossible because of the situation of the filaments, but spontaneous crossing between neighboring flowers favored: *Agathosma* (ex parte).

3. Spontaneous pollination of either sort opposed; crossing by insects inevitable: *Crowea.*

4. Spontaneous close fertilization possible; crossing favored: *Cusparia, Choisya, Skimmia* (ex parte), *Murraya, Citrus.*

II. DICLINOUS SPECIES.

Self-fertilization impossible; crossing necessary: *Ptelea, Skimmia* (ex parte). — (*Jahrbuch bot. gart. Berlin,* ii.) W. T. [57

ZOÖLOGY.

Mollusks.

Credit to an American naturalist. — In an official report by M. Bouchen-Brandely, secretary of the college of France, the author states that he has learned by two years of study that the sexes of the Portuguese oyster are confined to separate individuals ; that after this discovery he conceived that it might be possible to artificially fertilize the eggs of this mollusk ; and that, after two years more of experimenting, this attempt has been successful. Americans will be interested to learn that in 1879 an American naval officer, Lieut. Francis Winslow, who was stationed at Gibraltar for a few weeks, determined the unisexuality of the Portuguese oyster, and reared it from artificially fertilized eggs. His results were printed in the *American naturalist* in 1879 or 1880 ; but, as I have no opportunity for reference at present, I cannot give the exact date. — W. K. B. [58

Notes. — In the year-book of the Verein für vaterländische naturkunde in Württemberg, published lately at Stuttgart, Weinland has a paper on the mollusk fauna of the Württembergisch Franken, and Wundt one on the zone of Ammonites transversarius in the Suabian white Jura. —— The second part of the *Quarterly journal of microscopical science* contains a paper by Lankester on the existence of Spengel's olfactory organ and of paired genital ducts in Nautilus pompilius. —— Heude's 'Conchyliologie fluviatile' of Nanking and Central China approaches completion. The ninth and concluding fasciculus will appear during the present year. It is luxuriously illustrated, and printed in large quarto. —— Kuster's continuation of Martini and Chemnitz Conchylien cabinet bids fair to go on, like Tennyson's brook, forever. Lieferung 322 is announced. This work would be much benefited by the total exclusion of the frightful engravings which illustrated the earlier editions and are still pressed into the service. —— J. B. Gassiés, known by his conchological researches in New Caledonia and Southern France, has recently died. — W. H. D. [59

Insects.

American paleozoic insects. — R. D. Lacoe, whose collection of these objects must be one of the largest, if not the largest, in the country, has prepared a list of those hitherto published, including twenty-six genera and forty-eight species of hexapods, five genera and species of arachnids, and nine genera and nineteen species of myriapods, — a total of forty genera and seventy-two species. This embraces, however, three genera and fourteen species still unpublished. The list is purely bibliographical, excepting that it contains careful statements of the place of discovery of the fossils, the name of the finder, and the place of present deposit. About half of the described species have been published within the last five years. — (*Wyom. hist. geol. soc., publ.* 5.) [60

A monstrous caterpillar. — E. H. Jones figures a curious larva of the geometrid moth Melanippe montanata of Europe, which he exhibited at an entomological reunion at the Royal aquarium on March 5. It has the antennae and legs of the perfect insect fully developed, while in other respects a normal larva. It was reared from the egg with a dozen others. Last November this one, then normal, was considerably larger than the rest of the brood,

Abnormal larva of *Melanippe montanata.*

and was noticed as a constant feeder. "On Feb. 15 I was astonished to find that this forward individual had developed the antennae of the imago, but without in any other way altering its larval appearance. For a space of two or three days the antennae were beautifully pectinated, and then the prolegs [thoracic legs ?] of the imago became perfect. . . . Both antennae and legs then gradually shrank and dried until the 20th." — (*Entom.*, xvi. 121.) [61

VERTEBRATES.

Temperature and pulse rate. — By means of his new method of isolating the mammalian heart, Prof. Martin has been able to make an accurate study of the effect of variations of temperature on the rate of beat of the dog's heart when completely separated physiologically from all the rest of the body except the lungs. In the brief abstract of his work which has been published, a short description of the method of operating is given, together with some of the more important results which have been obtained. He finds that in the mammalian heart, as in that of the frog, the rate of beat is gradually increased as the temperature of the blood is raised from 27° to 42° C. The quick pulse of fever can therefore be explained by the direct action of the heated blood on the heart itself, without assuming any special action upon the extrinsic inhibitory or accelerator nerve-centres.

The rate of beat of the heart is found to bear a much more direct relation to the temperature of the blood in the coronary arteries than to the temperature of the blood in the right auricle or ventricle.

An interesting point which comes out of the method of work is, that, although the defibrinated calf's blood used to nourish the heart was repeatedly circulated through the heart and lungs for several hours, it gave no evidence of clotting at the end of an experiment, showing that fibrinogen is not formed in these organs. — (*Proc. roy. soc.*, no. 223, 1883.) W. H. H. [62

Lymphatics of periosteum. — George Hoggan and Frances Hoggan criticise the previous writings on this subject, and give the results of their own studies. They assert that what Budge described as the lymphatics are really capillary blood-vessels. Their own conclusions they summarize as follows : —

1. The lymphatics of the periosteum exist only on the outer surface, or within the outer gelatinous (white fibrous) stratum of the membrane. They never ramify upon the inner or bony surface. 2. When the periosteum is thin, more especially when the animal is old, the whole lymphatic plexus lies free upon the outer surface; but when the periosteum is thick, lymphatic twigs may pass part way through, but they never reach the inner surface. 3. The lymphatics accompany the blood-vessels, as if arranged to drain them. 4. No lymphatics exist on the surface of the great cavities of the bone. "There is thus every reason to believe that the lymphatics never come in contact with the bone itself, and that bone possesses no lymphatics apart from those found within the periosteum, which may be physiologically considered, therefore, as the lymphatics of bone." — (*Journ. anat. physiol.*, xvii. 308.) C. S. M. [63

Fish.

Classification of the Petromyzontids. — The Lampreys have been systematically considered by Gill, and are differentiated into two sub-families: 1. The Petromyzontinae, 'with the suproral lamina median and undivided;' and 2. The Caragolinae, 'with two lateral suproral laminae.' The former embraces six genera, one of which is named for the first time Exomegas, and is intended for the Petromyzon macrostomus of Buenos Aires: the Caragolinae are confined to the southern hemisphere; i.e., Australia and Pacific South America. — (*Proc. U. S. nat. mus.*, iv. 521.) [64

Characters of the Ephippiids. — The family of Ephippiids is distinguished by T. Gill from the Chaetodontids by the bifurcation of the post-temporal bones, and the wide, scaly isthmus extending from the pectoral region to the chin, and separating the branchial apertures.—(*Proc. U. S. nat. mus.*, iv. 557.) [65

Extinct fauna of Idaho and Oregon. — Professor E. D. Cope, referring to the remains of fishes from the middle valley of the Snake River in Idaho and eastern Oregon, stated that bones collected from sections now dry, but which had formerly been portions of lake-basins in the Oregon district, indicated a close relationship with the fishes now found in the remaining lakes and rivers. The number of species of fishes collected from the Idaho beds amounts to twenty-two. They are all distinct from those found in the Oregon basin, and cannot be identified with existing forms, although, with two exceptions, they belong to existing genera. Four of the families of fishes obtained from these beds are not now found west of the Rocky Mountains, except a single species of one of them (Percidae) in California. Of even greater interest was the fact that this fauna includes representatives of the Cobitidae, — a family of fishes entirely absent in the living fauna of North America. The presence of their remains in the Idaho beds indicates a probable former connection between North America and Asia. The names 'Idaho Lake' and 'Idaho deposits' were proposed for the lake and deposits now first described. The formation is distinct from any previously known, and is older than the Oregon lake-deposit. With the exception of fishes, the remains of but few vertebrates were found in the Idaho beds, although the Oregon deposits are full of the bones of mammals and birds. The means of indicating the exact geological position of these pliocene beds, as compared with those of Europe, was as yet wanting. — (*Acad. nat. sc. Philad.; meeting* June 19.) [66

Reptiles and batrachians.

Spermatozoon of newt. — Dowdeswell describes a very minute barb at the tip of the head of the spermatozoon of the newt: it measures 1.5 μ in breadth by 2 μ in length. He looked for it in other animals, but did not find it. — (*Quart. journ. micr. sc.*, 1883, 336.) C. S. M. [67

Nerves of the frog's palate. — Stirling and Macdonald describe fully the palatine nerves of the frog, their origin, and their general and minute distribution. There is a coarse plexus of medullated fibres and a finer plexus of naked fibres, which last innervate the blood-vessels and the glands, besides forming the ultimate ramifications of the nerves. In the course of the former plexus are scattered unipolar cells, each with a straight and a spiral fibre. There are, besides, many details given. This well illustrated and admirably written paper may be specially commended to histologists engaged in laboratory practice. — (*Journ. anat. physiol.*, xvii. 293.) C. S. M. [68

ANTHROPOLOGY.

Australian class systems. — In the Australian division of the tribe the communes are represented by two primary classes, each of which has a group of totem names, which are chiefly names of things animate or inanimate. The two primary intermarrying classes are over a large part of south-eastern Australia called Eaglehawk and Crow. Each group of totem names is a representation of its primary; and, as a general rule, any one of the group may marry with any other of the complementary group. If the primaries are A and B, and the groups, 1, 2, 3, etc., and i, ii, iii, etc., in certain localities, A 1 must marry B i only, and so on. The next change is the subdivision of A and B as in the Kamilaroi, thus: —

$$A\left\{\begin{matrix} a \\ \\ \alpha \end{matrix}\right\} 1,\ 2,\ 3,\ \text{etc.}$$

$$B\left\{\begin{matrix} b \\ \\ \beta \end{matrix}\right\} \text{i, ii, iii, etc.}$$

The effect of this is to remove the woman of the second generation from the possibility of marrying her father. Were this not so, the law 'A (male) marries B (female)' would permit A to take his daughter to wife, the simpler law forbidding the marriage of brothers and sisters only.

Under the form $a + \alpha = A$ and $b + \beta = B$, each half of an original class has marital rights over the women of one particular half of the other class, whose children do not take the class name of the mother, but of the sister class. For example: $\alpha + \beta = b$, who must marry a; and the children of the third generation, by mother right, will be again α and β. Mr. Howitt, who has worked out these systems with great patience, is of the opinion that this subdivision into classes was designed to render impossible those unions which were considered, and are now considered, as deep pollution. He has certainly given the most rational explanation of aversion to mothers-in-law. Under the old *régime* a daughter was of the clan of her mother, and B could marry any A. The law against looking at a mother-in-law, therefore, was to prevent the possibility of marrying her.

Mr. Howitt sums up his labors in the following conclusions: 1. The primary division prevented brother and sister marriage; 2. The secondary, intermarriage between parents and children; 3. The prohibition of intercourse between a woman and her son-in-law prevented connections not to be reached by class rules; 4. These changes were all reformatory in the community. — (*Journ. anthrop. inst.*, xii. 496.) J. W. P. [69

Region of man's evolution. — Mr. W. S. Duncan is the author of a paper upon the probable region of man's evolution, in which the following points are made. Man formed one of a set of families of man-like animals, somewhat similar to the present apes. Since only the lowest members of the Primates have been distributed to the eastern and the western continent, it is probable that the Primates originated within the arctic circle, while the higher groups sprang from the eastern continent: man, therefore, did not originate within the arctic circle, nor in the new world. The Cynopithecidae, since tertiary time, have been spread over nearly the entire eastern continent. The Semnopithecidae have been dispersed over central and western Europe to southern Europe and south-eastern Asia, as far south as Ethiopia. The anthropoid apes have been more circumscribed, but all the genera of living apes are derived from southern Europe and subtropical Asia. As apes existed in Europe and Asia before they reached the tropics, so we may infer that man existed in Europe and Africa before the low types, the Akkas and the Aetas, occupied tropical Asia and Malasia. The present habitat of the apes is not conducive to change: we must look to some region where apes were compelled to change their food and modes of locomotion. The stoppage of the southern migration by vast sheets of water shut up the apes in temperate regions. The crowding of other animals in the same locations sharpened the intelligence of the precursor of man. Here, then, Mr. Duncan supposes the great conflict and transition from man-like apes to ape-like men took place. — (*Journ. anthrop. inst.*, xii. 513-525.) J. W. P. [70

Tylor's lectures at Oxford. — The concluding portion of Dr. Tylor's lectures on anthropology, delivered in the Oxford museum in February (see i. **1055**), is devoted to the history of the growth of practical art. "In considering the claims of anthropology as a practical means of understanding ourselves, we have to form an opinion how the ideas and arts of any people are to be accounted for as developed from preceding stages. To work out the lines along which the process of organization has actually moved, is a task needing caution. A tribe may have some art which plainly shows progress from a ruder state of things: and yet it may be wrong to suppose this development to have taken place among themselves; it may be an item of higher culture, that they have learned from sight of a more advanced nation. It is essential, in studying even savage and barbaric culture, to allow for borrowing." Illustrations are given by Dr. Tylor of this borrowing, one of which is quite amusing. The later Danish travellers among the Eskimo enter very minutely into the description of the tools and dress of these people, before contact with Europeans, meaning the post-Columbian voyagers; but, unwittingly in many instances, they are describing fashions and forms borrowed from the Skraelling ancestors of these very writers a thousand years ago. Another very important point discussed in the lectures is the possibility of national degradation. Dr. Tylor was the first to discover, after the battle between the advocates of 'degradation' and those of evolution, that both were right, and that a proper view of human history must include both vicissitudes over and over again, and the commingling of both in every degree of complexity. Mr. Tylor gives a succinct account of the formation of the Pitt-Rivers collection, now housed at Oxford, and, in commenting upon the evolution of gesture-speech, pays this tribute to our country: "The labor and expense which anthropologists in the United States are now bestowing on the study of the indigenous tribes contrasts, I am sorry to say, with the indifference shown to such observations in Canada, where the habits of yet more interesting native tribes are allowed to die out without even a record." With very great shrewdness the speaker discussed the subject of magic and the benefit derived from even such useless search as that for the 'lost tribes of Israel.' — (*Nature*, May 17.) J. W. P. [71

The North-American Indiana and the horse. — Professor Hovelacque, in his recent work Les races humaines, gives as one of the important characterizations of the North-American Indians the statement that they do not breed horses, leaving it to be inferred from the context that they obtain their supply from wild herds. It may be remarked, that, however general the use of horses is at this time among the Indian tribes of the great plains, an ethnologic distinction based upon any treatment of that animal — a European importation and intrusion — is hardly legitimate. For centuries after the Columbian discovery but a small proportion of the tribes of North America ever saw a horse. The fact that the horse was not known to or used by them in their prehistoric condition constitutes an important element in establishing their position in the ethnic scale, their rise from savagery and barbarism having been retarded by that deprivation. Further, it must be suggested that there is little evidence, apart from the novels of Capt. Mayne Reid and similar authorities, of the existence in North America of herds of wild horses similar to those in South America, sufficiently large to supply the Plains tribes. There were, doubtless, some wild horses, the descendants of those imported by the Spaniards, in a condition to be captured by a past generation; but probably no living Indian has relied upon recruiting his stock from such herds, and his horses have been obtained by the civilized method of purchase or the more convenient process of stealing. The latter expedient has of late years been stopped by the powers of the United States authorities: so some of the tribes have learned to breed from their horses, though as yet the practice is limited by the same want of prudence as is shown in their neglect to provide food and shelter for their ponies. The whole connection of the tribes with the horse simply shows a course of education to a certain extent by a foreign civilization. The statement of M. Hovelacque is therefore as untrue in fact as it is unphilosophic as an ethnic characterization. — J. W. P. [72

EARLY INSTITUTIONS.

Land-holding in South Africa. — Sir H. Bartle Frere gives us an account of the systems of land-tenure among the aboriginal tribes of South Africa, — Bushmen, Hottentots, Kaffirs. Among the Kaffirs, if a man wishes to leave the paternal kraal, he seeks a tract of unoccupied land, and builds a kraal for himself. His wives proceed to cultivate as much land as they please, and the live-stock is turned out to pasture. The settlement descends from father to sons, unless, as often happens, this is prevented by the chief or an enemy. Titles rest simply on force. A man owns the land he occupies as long as he can hold it by his own might, or with the aid of the chief, or the tribe, if this is given. Authority of the chief or elders to resume or recognize possession has not been discovered by Sir Bartle Frere; but he says that it may, perhaps, be discovered by future investigators. — (*Journ. anthrop. inst.*, Feb.) D. W. R. [73

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Naval bureau of ordnance.

Experiments at Annapolis. — By direction of the Naval bureau of ordnance, experiments with the six-inch steel gun were resumed at the experimental battery recently, the chief object being to develop and encourage the home manufacture of steel projectiles. Steel projectiles manufactured by the Midvale steel company near Philadelphia, having different physical characteristics as to toughness, extensibility, etc., were fired at a target consisting of two mild steel five-inch plates strongly bolted together, and backed with twenty inches of live-oak. The first and the second shots broke up; the third pierced the plates, and was stopped by the backing; while the fourth perforated target and backing, and buried itself in a mound of earth beyond the target. This projectile had an initial velocity of 1,983 feet, and weighed 75 pounds. The charge of powder was 32 pounds, and the striking energy per inch of shot's circumference was 108 foot-tons. The results indicate that there will be no serious difficulty in procuring the proper material for armor-piercing shells in this country.

A somewhat remarkable result was obtained with a projectile weighing 52 pounds, and a charge of 33 pounds of powder. The muzzle velocity obtained was 2,323 feet per second, with a pressure of about 13 tons. The ratio of charge to projectile was adopted as being nearly that which will be used in the new ten-inch guns designed by Commodore Sicard. These guns will be manufactured at the Washington navy-yard, and are intended for the batteries of the four double-turreted monitors.

It does not necessarily follow that results equally favorable will be obtained with the ten-inch gun, since the masses of both charge and projectile will be greatly increased. The pressures will doubtless be higher; but these guns will be sufficiently strong to withstand a working pressure of more than 25 tons to the square inch. The indications, however, are, on the whole, extremely favorable to the success of the ten-inch gun.

This experiment is likewise interesting when compared with the record of a six-inch gun constructed by Sir William Armstrong, in which, with an 80-pound projectile and a charge of 55 pounds of powder, a muzzle velocity of 2,297 feet was reached with a pressure of 21 tons. In the latter case the ratio of charge to projectile is 11 : 16, whereas in the former case the ratio is 11 : 17½. It is to be regretted that the size of the chamber of this experimental gun does not permit the employment of a larger charge of powder.

Two six-inch guns, representing the types proposed for the broadside batteries of the new steel cruisers, are now in process of construction at the Washington navy-yard, and will be ready for testing in August. — J. M. B.

U. S. magnetic observatory at Los Angeles, Cal.[1]

Magnetic observations. — There is at present but one self-registering magnetic observatory within the limits of the United States. That observatory is located in Los Angeles, Cal.; and the object of the present article is to present a brief description of the observatory and its work, together with a short account of its origin.

Continuous series of magnetic observations, covering longer or shorter periods, have been made at several stations in North America; but, with two exceptions, they have all been made on the eastern side of the continent. We have a series of observations of five years (1840–45) at Girard college, Philadelphia, by A. D. Bache; six years' observations at Key West, Fla. (1860–66), by the U. S. coast-survey; and a long series, still continuing, at Toronto, Canada (1841–83). We have, further, a series of nearly five years of photographic records taken at Madison, Wis., by the U. S. coast and geodetic survey.

On the western coast the only continuous series of magnetic observations we have, were made by the Russian government at Sitka at the magnetic and meteorological observatory established in March, 1842, and maintained until the cession of Alaska to the United States in October, 1867; and the series of hourly observations at Point Barrow in 1852–54 by Capt. Maguire, R.N. Up to the present time, a great part of these observations have remained undigested and undiscussed.

It was therefore contemplated by the coast-survey, many years ago, to obtain a continuous series of magnetic records from some station on the western coast of the United States; and, with this end in view, an Adie magnetograph of the latest and most approved pattern was purchased in 1860. The outbreak of the war, however, prevented the carrying-out of this plan.

The instruments remained packed until 1878, when a favorable time seemed to have arrived to put it to use. Assistant C. A. Schott, aided by Mr. Suess, then set it up for trial in the basement of the coast-survey office in Washington. Some minor defects of construction were remedied, and the magnetograph set to work in January, 1879. It was kept going for about two weeks on trial, and found to perform satisfactorily. During this time, it was inspected by Superintendent Patterson, and its workings observed by various members of the survey. At the close of this trial it was packed up for shipment to some station in California.

It was found, however, that more money would be required to run the instrument than could be then set apart for this work, and it therefore remained in the coast-survey office.

In response to the invitation of the International polar conference, our government consented, in 1881,

[1] Communicated, with permission of the superintendent of the U. S. coast and geodetic survey, by Marcus Baker, acting assistant in charge of the observatory.

to the establishment of two observing stations in high northern latitudes. Observations, especially of meteorology and magnetism, were to be undertaken; and it was arranged to carry on these observations under the joint auspices of the signal-service and coast and geodetic survey. The executive management of these stations, the selection of observers, etc., were put under the direction of the chief signal-officer. The coast-survey co-operated by furnishing such magnetic instruments as were on hand, and by training, during the short time available for their work, the magnetic observers selected by the signal-office. It is to be regretted that there was not time enough to procure suitable differential instruments for the stations.

Two parties were despatched to the north, — one to Lady Franklin Bay, near the northern end of Greenland, under the charge of Lieut. A. W. Greely; and the other to Point Barrow, Alaska, under the direction of Lieut. P. H. Ray. Both these parties reached their destination in the fall of 1881.

It was the wish of the International polar conference that all the northern stations should be occupied three years; and a special effort was to be made to secure a complete and continuous record from August, 1882, to August, 1883. In the spring of 1882, additional observers were selected by the signal-office to replace any of the former ones that might have become disabled, or to act as auxiliaries, should such be needed. These magnetic observers, like their predecessors, received instruction at the coast-survey office prior to their departure for the north; and a set of differential magnetic instruments, hastily constructed, was sent to Point Barrow.

The spring of 1882 seemed, therefore, a peculiarly favorable time to put the Adie magnetograph to work, and to secure at one and the same time the long-desired series of magnetic observations from the western coast, and a series which would also be available for comparison with those observations made at the International polar conference stations. It was therefore mutually agreed by the signal and coast survey offices to establish a magnetic station at the joint expense of the two offices. In the case of the northern stations, the management was intrusted to the signal-office. The expense of the Lady Franklin Bay station was specifically provided for by act of Congress. The expense of the Point Barrow station was to be borne by the signal-service and coast and geodetic survey jointly. In the new station to be established in California, and which was to be devoted to observations of magnetism only, the management was left entirely to the coast-survey.

At first San Diego was suggested as the site of the new station, it being the place on the western coast of the United States farthest from the northern stations. A somewhat better location, nearly as far south, was, however, finally selected in Los Angeles, Cal.

Plans for a building were prepared in Washington, and forwarded to Assistant J. S. Lawson of the coast and geodetic survey, who proceeded to Los Angeles, and superintended the selection of a site, and erection of a building, in June and July, 1882.

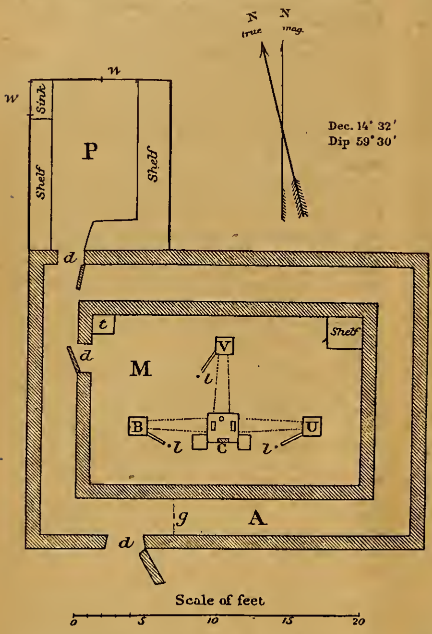
In July, 1882, the instruments, were shipped to Los Angeles, Cal., in the care of Mr. Werner Suess, a skilful mechanician in the coast-survey, and who had attended to the mounting of the instrument in 1878, and to its packing up after the test trial was complete.

At the same time, the writer was assigned to the charge of the observatory, with instructions to mount and adjust the instrument, determine its constants, and proceed to bring out a continuous record of the changes in the elements of the earth's magnetism. Leaving Washington July 26, he arrived in Los Angeles Aug. 7, 1882, where he found Mr. Suess in waiting, and the observatory complete.

After arranging preliminaries, the work of mounting and adjusting the instrument was begun, and pushed forward as rapidly as possible. Observations for the determination of the constants and scale values were made; the compensation of the vertical-force magnet for temperature was made; temperature coefficients were determined; and finally, on Sept. 28, every thing was in readiness, and the first sensitive paper was put upon the cylinders, and the first record made. The first few days were in the nature of a trial. A slight re-adjustment was made on Oct. 13, after which every thing worked satisfactorily. On Oct. 31 the horizontal and vertical force constants were redetermined; and since that date the instrument has continued to work almost perfectly, and to make a complete and continuous record of the changes of all the magnetic elements.

The observatory is situated in latitude 34° 03′ N., longitude 118° 15′ W. from Greenwich, and 317 feet above the level of the sea. It is on a rather steep hillside sloping to the south-west in the grounds of the Branch normal school in the city of Los Angeles, exactly one mile, in a direct line, from the centre of the plaza, or park, in the centre of the old town, or about a mile from the central business part of the town. Street-cars run within two squares of the observatory. It is on adobe soil underlaid by clay, and in the midst of an orange plantation formerly known as Belle Vue Terrace.

The observatory is built of redwood fastened with copper nails, is double walled, with an air-space 2.5 feet between the walls; which walls are fourteen inches thick, and filled with adobe soil. It is twenty-eight feet long by twenty-one feet wide, and painted white. The entrance to the observatory is on the south side. On the north side is the photographic or dark room, P, where the various photographic processes are carried on. This room is twelve feet long by ten feet wide. The accompanying plan will show the arrangement of rooms and instruments. The three magnets are placed, the unifilar or declinometer, U, to the east, the bifilar or horizontal-force magnetometer, B, to the west, and the vertical-force magnetometer, V, to the north, of the central driving-clock, C. A picture of the instrument, showing it as a whole, and also showing details, may be found in Gordon's Electricity and magnetism. For illumination, student-lamps burning kerosene-oil are used, and yield satisfactory results. The record is made on paper sensitized by the bromo-iodide process. The paper is sensitized at the observatory. Each trace contains two days' record; and the record is absolutely complete and continuous, except the time lost in changing papers to begin a new record, and in 'moving spots,' or shifting the luminous dots to get the second day's record on the same sheet. The time required for the first operation is from seven to eight minutes; for the second, from two to three minutes. Thus only about ten minutes are lost in two days, or an average of five minutes per day, —



a quantity too small to be of any importance on any occasion thus far observed.

One minute of time on the traces is represented by $\frac{1}{100}$ of an inch approximately, and a movement through one minute of arc by the unifilar magnet is represented on the trace by $\frac{3}{100}$ of an inch. A motion of the bifilar magnet of one scale division, represented on the trace by 0.027 inch, corresponds to a change of horizontal force of about its $\frac{1}{9000}$ part. The traces can readily be read off within half a scale division, or changes of force of its $\frac{1}{18000}$ part are recorded. This adjustment has not proved too sensitive, as the luminous dot has never left the recording cylinder, except once for a short time during the great magnetic storm of November, 1882.

Visitors are admitted to the observatory, and the traces generally show their presence by a break in the curve.

The instrument records, as is well known, changes of declination, changes of horizontal force, and changes of vertical force. Each of these changes is recorded on a separate sheet, or trace as it is called; and thus, on an average, forty-five traces are produced each month. These traces are six inches by sixteen inches and a half, and are made on plain photographic paper prepared for use at the observatory.

This preparation consists of two processes, salting and silvering. The salting process, as it is called, consists in soaking the paper from ten to fifteen minutes in a bath of iodide and bromide of potassium, with a little tincture of iodine added, after which the paper is hung up to dry. This process is carried on in the daylight.

The silvering or sensitizing process is carried on in a room as dark as can well be made, and then lighted up dimly with a red lantern. Some difficulty has been found in keeping the room dark enough, and on some occasions the silvering has been done at night.

For silvering, four wooden trays are placed in a row: the first containing a bath of nitrate of silver, acetic acid, and water; the second, distilled water; the third, a weak solution of chloride of ammonium; and the fourth, distilled water. A sheet of salted paper is then floated on tray no. 1, special care and some skill being required to prevent (*a*) any of the solution from getting on the *back* of the sheet, and (*b*) any air-bubbles from clinging to the front side of the sheet. The first defect produces stains, and the second, spots. In about nine minutes the paper is transferred to tray no. 2, being floated on as in the case of no. 1, and a new sheet is floated on tray no. 1. In about nine minutes more, the sheets are moved forward, as before; the paper in no. 2 is floated on no. 3; that in no. 1 is transferred, as before, to no. 2, and a new sheet floated on no. 1. This continues till tray 4 is reached; after which the sensitizing is complete, and the paper is then hung up to dry in the dark. Special care is necessary in hanging up the wet paper to avoid stains from the fingers, from the line, or from the pin which holds the paper on the line.

After drying thoroughly, the papers are taken down, packed in a large envelope, and kept in a dark drawer to be used as needed. From this envelope the sheets are transferred to the three recording cylinders prepared to carry them. They remain two days upon the cylinders, and thus receive two days' record. At quarter-past nine A.M. of each alternate day the papers are changed.

Over the central driving-clock is hung a heavy orange-flannel curtain. To change papers, the attendant, with the envelope of sensitive paper, goes behind this flannel curtain, through which sufficient light from the three lamps comes to enable the change to be made without further artificial light. The orange flannel serves to satisfactorily exclude actinic light.

The traces, removed from the cylinders, are then carried in a large envelope to the dark room, and there developed, the developer used being pyrogallic acid. The best developments are those which take place rather quickly, in about ten to fifteen minutes. When the development is slower, the traces are usually found inferior. After the development is complete, the traces are fixed in hyposulphite of soda cleansed in a saturated solution of alum, washed for about two hours in running water, and then hung up to dry. After drying, the date is stamped upon them. The exact instant of beginning and ending of each line on the trace, together with the corresponding scale value, is written on. Time observations, with sextant and artificial horizon, are taken from time to time, usually monthly, to regulate the standard chronometer.

After the traces have been thus completed, they are practically paper negatives, from which any number of copies may be made photographically. Two sets are made by the well-known blue-print process. The traces require no special treatment, such as oiling, waxing, etc., for the successful application of this process.

For tabulating from the traces, it is found most convenient to use a ruler subdivided into hourly divisions for the time scale, and a triangular piece of card-board upon the edge of which is ruled the scale corresponding to the trace to be read. The unifilar and bifilar traces have all been read, tabulated, and the means calculated. The vertical-force traces have not yet been read.

There is also in the magnet-room of the observatory a thermograph, which records the temperature every half-hour. From the records produced by it, the time of maximum temperature in the observatory is found to be about five P.M., and the time of minimum temperature, about half-past eight A.M. At these hours the thermometers under the bell glasses and near the magnets are read; and from these readings it appears that the magnets are subjected to an average daily range of temperature of about 1¾° C.

On the 14th, 15th, and 16th of each month, observations are made to determine the absolute declination, dip, and intensity. These observations are made in the usual manner of taking such observations by field parties in the coast and geodetic survey. Monthly reports and returns of results are made to the superintendent of the survey.

The declinations and dips have all been computed, but the intensities only approximately as yet. The following table contains the declinations and dips resulting from the monthly absolute determinations. Each declination is the mean derived from the elongation on three successive days, and each dip is the mean of six sets with two needles on the same three days.

U. S. magnetic observatory at Los Angeles, lat. 34°03′, long. 118°15′ W. G.

	Declination.	Dip.
1882, Sept. 14, 15, 16	14°35.5′ E.	59°30.1′
Oct. 14, 15, 16	33.7	30.2
Nov. 14, 15, 16	34 6	29.7
Dec. 14, 15, 16	32.7	31.6
1883, Jan. 14, 15, 16	35.1	30.8
Feb. 14, 15, 16	31.5	28.4
March 14, 15, 16	32.4	31.7
April 14, 15, 16	32.1	29.2
May 14, 15, 16	32 5	29.7

The horizontal intensity is approximately 5.97 in British units = 0.275 dyne.

U. S. magnetic observatory,
Los Angeles, Cal., June 1, 1883.

NOTES AND NEWS.

Professor Huxley has been elected president of the Royal society of London, in the place of Mr. Spottiswood.

— The recently issued report of the signal-office for 1881 contains a record of primary and secondary observing stations, established in that year in Alaska, with summaries of observations at some Alaskan stations in preceding years. There is also some account of the fitting-out of the Greely expedition to Lady Franklin Bay and that to Point Barrow. But the most important article for arctic students is the report of Prof. E. W. Nelson on the meteorology of St. Michaels, Norton Sound, where, as is well known, he had been stationed for four years; his leisure being employed in pursuing investigations into the natural history and ethnology of the region with the greatest energy, devotion, and success. The article itself being a summary and an abstract, with somewhat wider limits in regard to the treatment of auroras and the so-called 'polar band' formation of clouds, it will not be attempted to condense it here, but merely to call attention to some of its leading features. According to observations by Danenhower, the position (hitherto somewhat uncertain) of St. Michaels is latitude 63° 28¼′, and longitude 162° 04¾′ west. The mean annual temperature for the period is 25°.5 F. The highest observed temperature was 75°, and the lowest, — 55°. A curious fact was noted with great regularity. In early winter darkness comes on between three and four P.M., and the temperature falls until about six P.M., when a *rise* follows of two or three hours' duration, and sometimes five or six degrees in extent, followed by the usual steady nocturnal fall. It does not result from changes in the wind, but may be due to greater radiation immediately after sunset from the land, resulting in local atmospheric movements, causing warmer air from the adjacent sea to flow in the vicinity of the station.

Alongshore, winds N., N.E., S., S.E., S.W., are most prevalent. Winds off the sea, N.W. and W., are the least frequent, not exceeding together over ten per cent of the whole. Topographical bias is, however, distinctly evident, as at most stations in Alaska.

The measured precipitation averaged twelve inches and a quarter, to which Mr. Nelson estimates a correction of one-half more must be added for unmeasurable drizzle and blown snow. The record and discussion of the aurora is a valuable contribution to the subject, and cannot be summarized. Thunderstorms are almost unknown. Lightning was observed but twice, and no thunder was heard during the whole period. It is referred to as reported common on the upper Yukon in summer; but in 1865–68, by the explorers of the Telegraph expedition on the upper part of the river, thunder and lightning were not observed on a single occasion. There are but two seasons at St. Michaels, — winter (October–May) and summer (the remaining five months). The sea is open until about Oct. 15; and the ice disappears in the spring, usually in early June. The tides are small, but over the shallow sea adjacent the rise in level due to gales is often sufficient to submerge the marshy shores for miles inland. Gardening is not a success, except for turnips, radishes, and lettuce. The earliest birds, chiefly geese, begin to arrive in April; and the migration continues to June, the main body of birds arriving between May 15 and 25. Most of the birds leave for the south in August, and the first sharp frost of September sends away the laggards.

— On the 1st of January, 1883, there were in existence 79 societies of geography, distributed all over the world, with about 38,000 members.

— The American society of mechanical engineers met at Cleveland, O., June 14, President E. D. Leavitt, jun., of Cambridge, Mass., in the chair. Eighty members were present, and fifty-four were elected, raising the total membership to four hundred and sixteen. The papers were generally short, plain, and practical. Mr. J. K. Holloway described a steam starting gear for throwing marine engines 'off the centre.' It consists of a steam-cylinder and a friction-wheel on the main shaft, which can be actuated by the auxiliary steam-cylinder. The device works either way, and may be applied repeatedly if necessary. Mr. Charles N. Comly detailed his experience with lubricating materials, resulting in the substitution of grease for oil. Other members had found grease the cheaper lubricant, but had observed that it had a much higher coefficient of friction than oil. Mr. J. E. Sweet described a new method of casting iron pipe having flanges, making chilled flange-faces and cored bolt-holes. Other papers remain to be reported. During the session, it was announced that an honorary degree had been conferred on President Leavitt by the Stevens institute of technology.

— W. H. Edwards announces that he will not, at present, complete the Synopsis of species commenced in the tenth part of his Butterflies of North America, but substitute for it a mere list of species, which will be issued with the next (concluding) part of the second series.

SCIENCE.

FRIDAY, JULY 20, 1883.

THE U. S. NATIONAL MUSEUM.

I.

The brief pamphlet recently issued by the assistant director of the museum as his special report for 1881 is, perhaps, one of the most important documents which has yet appeared in the history of science in this country. It represents the institution which in the natural course of events should become the leading organization of its kind on this continent, and also furnish the motive and the pattern for the many similar copies which will naturally follow its example in other parts of our extensive possessions. It also presents to foreign nations the ideals, which, they will naturally suppose, represent our existing scientific culture and the tendencies of science in this country. They will hardly imagine that it has not been debated at all by scientific men at large, that it is the work of no representative commission, and that it cannot in any sense be considered as the deliberate result of consultation with the leading men of the United States in all departments.

In this respect, we think that the action of the government — if the plan is, as we understand, already adopted in the museum — is open to the severest criticism, and that it shows a curious want of prudence to definitely settle the future of an institution in which the whole country is more deeply interested than any other of its kind, without allowing the voice and criticisms of scientific men to be heard. It is certainly a wide departure from the wise example of the Smithsonian, and shows, that, at Washington, success has already begun to dull the edge of the wise forethought which led to such successful results in the planning of that institution.

That the museum must be a loser in influence by such a proceeding lies in the nature of things. The science of this country is certainly not responsible for the plan, and, however good it may prove to be, has had no proper opportunities for expressing its opinion about a matter in which its deepest interests are concerned.

In his opening considerations, Mr. Goode divides museums into three classes, — those for record, those for research, and those for education. He considers that all three of these objects are essential to the development of any comprehensive and philosophically organized museum. By record, the author means the preservation of collections which have served as the instruments of past research; and by research, the accumulation of materials of all kinds to provide for new investigations. The author here assumes an historical standard, and thinks that the objects of museum administration determine their classification; whereas, in our opinion, practical considerations really settle the class to which a given museum should be referred. There is, as the author remarks, no separation of the two purposes of record and research; and it would perhaps have been clearer to the inexperienced in this branch of technology if the preservation of records, and accumulation of materials for research, together with adequate provision for the publication of original results, which is not mentioned by him, had been defined as the inseparable trinity of a museum of the first class. Mr. Goode's opinion, that such museums should have exhibition-rooms, and display both their records and the results of research, indicates a broad and well-balanced judgment of the aims of museum administration. The prevalent opinion among young investigators, that no public display of records should be made, arises from obstacles which the expenses of exhibition have heretofore presented to the successful performance of the proper functions of this class of museums in the encouragement of research, and also to their frequent failures as instruments for the education of the public.

Two functions, that of museums of research and that of museums of education, have been confused in their display of specimens; but, while this shows the necessity of a separation and a change of policy in their choice of collections for exhibition, it does not justify the withdrawal of valuable and useful records from public view. Leave to consult original specimens cannot be lightly granted, and the idiosyncrasies of their guardians is a large element of uncertainty in the way of those desiring to see such treasures. There are also classes of persons daily on the increase who should, at any rate, have the privilege of seeing them, though not fit to be trusted with their direct handling; and the wants of this class cannot be justly disregarded. We are therefore most heartily in sympathy with Mr. Goode in his opinion, that the highest value of original records is given to them when they are placed on exhibition; but we probably differ in thinking that this should be done in museums or collections exclusively devoted to research, and meant for the use of the special student rather than the general public.

Mr. Goode's third class of museums, the educational, we should designate as the second class; since these are often separated from the former, and ought always to be conducted with distinct purposes, and governed by a class of men who are familiar with the educational wants of the public, i.e., all those classes of persons who must get their information through the glass, and are not permitted to handle specimens. The needs of this class are but imperfectly understood by the investigator, or, if understood, very apt to be considered by him as of slight importance. It is certainly not his essential function to satisfy these demands, as in the case of the true educator, and as should be the case with the curator of an educational collection.

Mr. Goode's ideal of a great educational museum is accomplished by the union of the natural history and industrial museums; and this has evidently arisen from his experience and study of similar unions occurring more or less accidentally in the different great exhibitions held in civilized countries of late years. He points out, that, while these great industrial exhibitions have shown a tendency to become purely commercial, they have served, wherever they have been held, as the starting-points, in time and materials, of permanent industrial museums. The effect of the world's fair in Philadelphia in 1876, in accordance with this law, demonstrated the educational value of a more permanent industrial museum, and suggested that an immense field of usefulness would be open to an institution which should be based upon similar grounds, but which would endeavor, by a more efficient and scientific arrangement of its specimens, to impart "a consistent and systematic idea of the resources of the world and of human achievement."

This novel and somewhat startling aim is announced as the future guiding-star of the National museum, which is declared to be in the best possible trim for the accomplishment of such a purpose, since it is now starting anew, and is not encumbered by the immense masses of duplicates which have become the most serious obstacles in the path of the older museums. It is, in other words, free to choose the path of its future work; and while this seems to be true, and the author must be acknowledged the best judge of the fact, we do not find any allusion to the accumulations formerly stored in the Smithsonian, nor as to how these and other collections, made upon the old basis for purely scientific research, are to be brought into harmony with the new ideal.[1] It is much to be regretted, that, in this preliminary announcement of so important a national enterprise, the author had not taken more space for such interesting explanations, and also for the fuller consideration of the arrangement of topics according to their relative importance.

This treatise shows, nevertheless, in all its

[1] Though we do find (as quoted in italics immediately below) that these collections, and we presume those which will be continually flowing in from the Geological survey, the Fish-commission, and other sources, are to be arranged on a different plan from all the other collections. It would have greatly enlightened us if we could have known what this plan was, but nothing further is said of it.

parts, that the practical aspects and difficulties of the question have been studied with great thoroughness and ability, and have naturally absorbed the time and thoughts of the author, and taken, therefore, the most prominent place.

What seem to us the most valuable and fundamental of all the considerations are brought in as secondary. Thus we find an intimation only that the museum "attempts to show the evolution of civilization;" we cannot be wrong, it appears to us, in imagining that this is to be the great aim of the National museum; and again, "the collections should form a museum of anthropology, the word 'anthropology' being applied in its most comprehensive sense. It should exhibit the physical characteristics, the history, the manners (past and present) of all peoples (civilized and savage), and should illustrate human culture and industry in all its phases. The earth, its physical structure and its products, is to be exhibited with special reference to its adaptation for use by man and its resources for his future needs. *The so-called natural history collections — that is to say, the collections in pure zoölogy, geology, and botany — should be grouped in separate series, which, though arranged on another plan*, shall illustrate and supplement the collections in industrial and economic natural history." We felt immediately the deepest interest in knowing how so large a part of the National museum could be arranged on another plan without confusing the effect of the whole, but looked for explanations in vain.

The idea of making the National museum a museum of anthropology must, we think, command unqualified respect; and it seems to us to contain so much of future promise, that we feel all the more regret that the details of the scheme had not received the healthy purgation of general and expert criticism. The classification is also highly original, and shows the result of extensive study, and practical knowledge of ways and methods.

The general outlines of the scheme of classification, which is announced as provisional and open to necessary] modification, are as follows: the exhibition of articles is to be divided into eight large divisions, or 'sections,' including sixty-four smaller divisions; which last we shall, for convenience, designate under the name of 'topics,' to distinguish them from the sections into which they are grouped by Mr. Goode. — "Section I., Mankind; II., The earth as man's abode; III., Natural resources; IV., The exploitative industries; V., The elaborative industries; VI., Ultimate products and their utilization; VII., Social relations of mankind; VIII., Intellectual occupations of mankind."

We recognize the enormous difficulties in the way of the author of this scheme; and, while we congratulate him upon the successful handling of the details, — which we have not the space to quote in full, and therefore cannot do him personally full justice, — we must dissent strongly from the main ideas, which, we think, show the want of a broad and masterly comprehension of the philosophical ideas which should govern the classification and purposes of our National museum. The scheme itself, in this respect, is a curious mixture of the old notion, that, in order to understand man, we must necessarily start with the study of mankind, and of the modern idea of evolution. The legitimate process of instruction from this stand-point begins with the simplest forms of life, and follows up their developmental and evolutionary history in organization and in time, until we arrive at the most highly specialized forms. Man is the most highly specialized of all animals, physically and psychologically, and therefore, it is claimed, needs to be viewed in the light of all knowledge, unobscured by the prejudices and misconceptions which are liable to arise from the adoption of the opposite modes of study.

Certainly the former mode is incompatible with the thorough and direct method of studying the principles of evolution, whether these relate to one set of objects or another, and is not accordant with the idea of the 'evolution of civilization' and the evident necessity of expressing, in all the minor industrial collections, "the steps by which man has arrived at the present condition in every direction in which human industry has been exerted, — a graphic history of the development of the human culture and civilization."

These are Mr. Goode's own declarations of what seem to be the vital intentions of his scheme; and it is therefore a serious error, both practically and theoretically, when he places the natural history of man, including his psychology and individual manifestations, at the head of his scheme, in place of making this department the terminal one, to be viewed by visitors only after they had gone through with all the other departments.

The author has arranged the sections and sixty-four topics according to a system which is artificial, and irreconcilable with his intentions and his general objects, and shows this in the place assigned to mankind. Man is essentially the product of the forces which have acted upon this earth. Without going into the question of whether these forces were divine or material, which is of no value in such a technical discussion, it is certainly very illogical to place the conclusion before the beginning, the consequent before the antecedent, man before the earth. This may be very satisfactory to those who need, or think they need, to perpetually swing the censer before the old idol of man's supremacy in the universe; but it is none the less unnatural and illogical to have one mode of arrangement for the parts of a great collection, and another for the whole.

In a future number we shall consider some of the minor features of this elaborate scheme.

THE UNITED STATES FISH-COMMISSION STEAMER ALBATROSS.[1] — II.

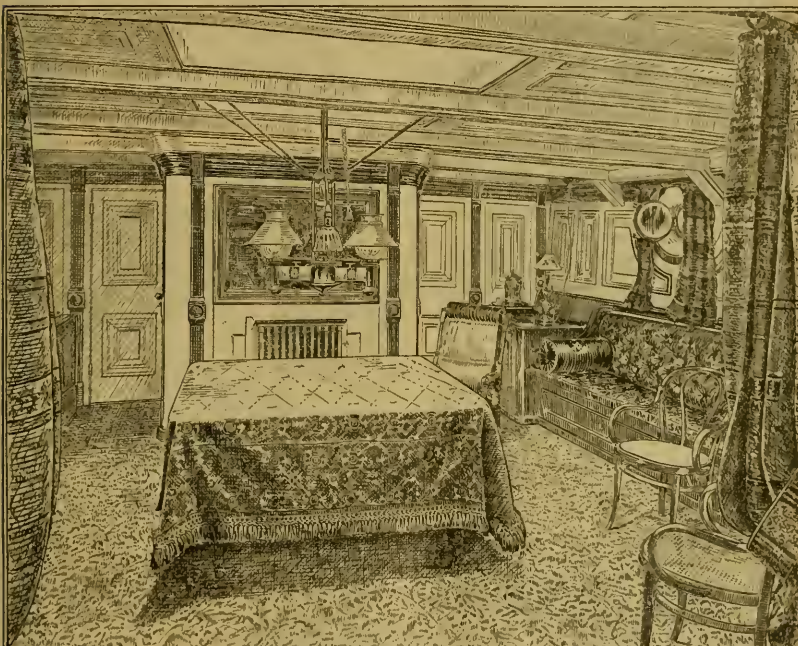
THE fitting-up of a small floating scientific laboratory, which might remain at sea for a month or more at a time, and yet include every necessary convenience, was a somewhat novel problem, and required a considerable amount of planning, based mainly upon past experiences of the fish-commission. The general arrangements are now, for the most part, complete, but they are subject to alteration and improvement.

The main laboratory (see figures, pp. 68, 69) is twenty feet long, twenty-six feet wide, and nearly eight feet high. The forward-end of the room is devoted to storage, and the sides and

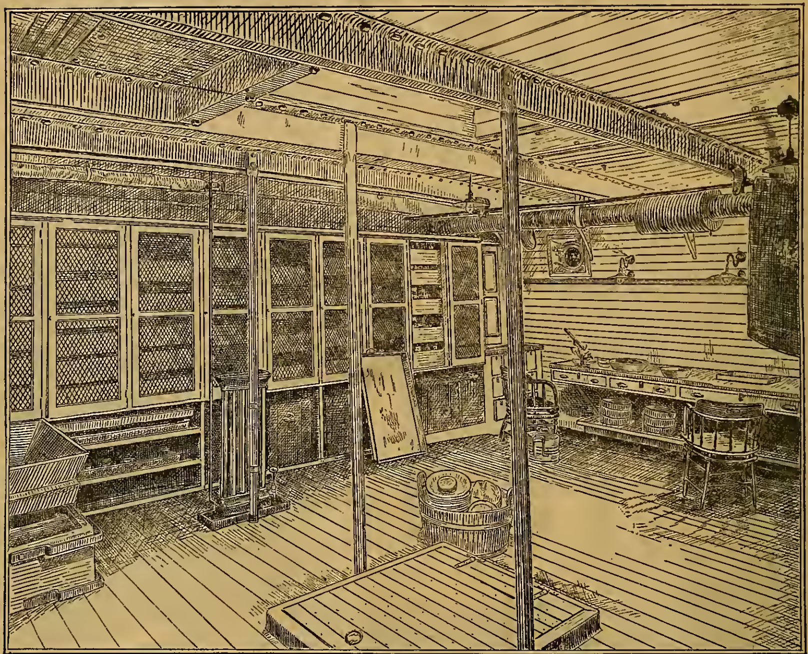
[1] Concluded from No. 22.

after-end to work-tables. The storage-case consists of a series of six double racks, with wire doors in front for holding the trays of bottles and jars, the trays being all of the same size, so as to fit any part of the case. Under the racks are six large bins for the tanks of alcohol in use, the large fish-pans, dishes, and other heavy laboratory utensils, and at either side is a small case for chemicals and preservatives. In one of the after-corners is a photographic dark room, and opposite to it the sink and water-supply. The remainder of the space on each side is occupied by a sorting-table, one being at the proper height to work while standing, the other while sitting. The after-bulkhead contains the arrangements for chemical and physical investigations, consisting of a broad table, with drawers and cupboards underneath, and racks above.

The storeroom is of about the same size as the general laboratory, though of less height, and is entirely fitted up for the storage of jars, bottles, tanks, alcohol, zoölogical specimens, and the lighter kinds of collecting apparatus. A single series of bins on a level with the floor extends around the entire room, excepting in front of the stairway, and serves as compartments for the copper tanks of alcohol, which are contained in uniform-sized boxes. In these bins there is room for fifty tank-boxes, each with a capacity of sixteen gallons, making a total of eight hundred gallons of alcohol which it is possible to carry in this way. Against the fore and after bulkheads, above the bins, are two sets of racks for bottle-trays, similar to those in the general laboratory. They are intended for the storage of the main supply of bottles and jars; and, as rapidly as those in the laboratory become filled with specimens, they are carried below, and their places supplied



CAPTAIN'S CABIN.



MAIN LABORATORY, FORWARD-END.

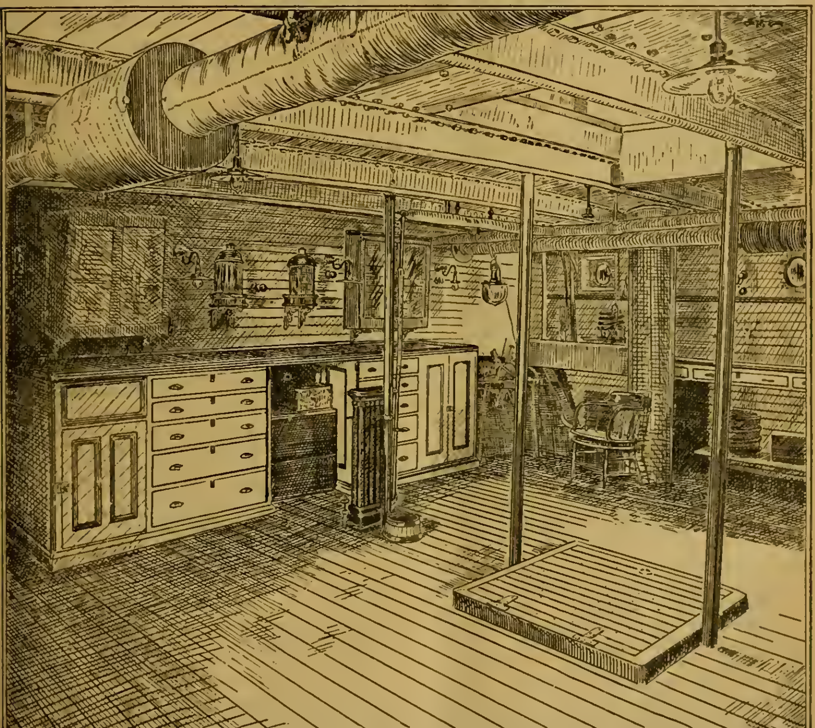
with empty ones, without the necessity of removing any from the trays. On the two sides of the storeroom are large, deep bins for nets and other light appliances, the dredges and trawls being stored elsewhere.

The deck-laboratory, which receives the greatest amount of light, is more especially arranged for study. The after-end is occupied by a bookcase, with a cupboard for the physical apparatus on one side; and the forward-end, by the medical case, and stairway to the lower laboratory. A large square table, with accommodations for four persons, stands in the centre of the room, under the skylight. Under one window is the sink, and beside it two upright cylindrical tanks for sea-water and alcohol, which empty by means of faucets. The other window-spaces are supplied with folding tables, which, when not in use, can be shut down against the wall. Arrangements are yet to be made in this room for small working-aquaria, where the living forms and colors of delicate marine animals can be studied and pictured. They will probably be modelled after the new style of hatching-jars, recently introduced at Washington, for the propagation of shad and salmon.

The Albatross is furnished with two propeller-screws instead of the usual number, one, to enable her to execute more readily the various manoeuvres demanded by the peculiar character of her work. They are right and left handed, — one being placed under each counter, — and measure nine feet in diameter. By their means the steamer can be turned completely around almost within her own length, and placed in position for dredging and sounding without the delays incidental to most exploring steamers. The motive power is furnished by two compound engines, with two cylinders each, — one of high, the other of low pressure, — the stroke of piston being thirty inches. The engines are slightly inclined, the upper ends of the cylinders being drawn inboard over the condenser, which is common to both engines, and forms their framing. The boilers are two in number, of the overhead return-flue pattern, and measure twenty-one feet and a half in length by eight feet and a half in diameter.

The proper ventilation of all parts of the ship was carefully considered during her construction, and the plan adopted has given the greatest satisfaction. It consists simply in withdrawing the foul air from the lower parts of each room through small ventilators, by means of a Sturtevant exhaust-fan with Wise's steam-motor attachment. The influx of air is from above, through open doors or ports; and a constant circulation is maintained, even in the lowest inhabited portions of the ship.

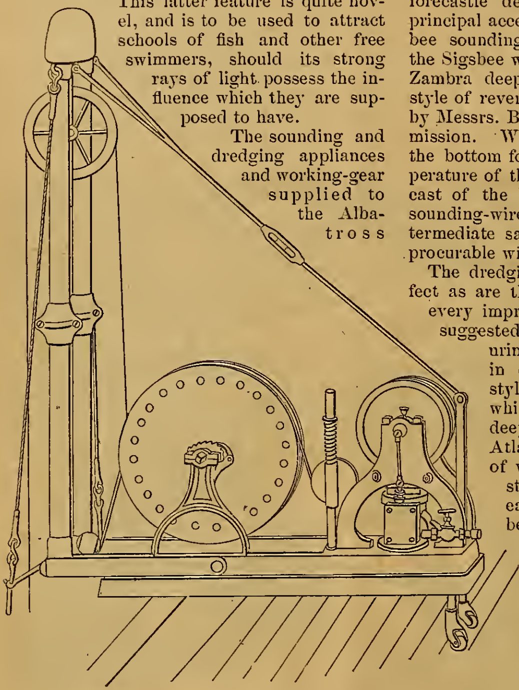
One of the most interesting features of the Albatross is the system of electric lighting, which has already been referred to. Some such method of replacing the dingy lamps common to most ocean vessels was rendered imperative from the fact that this steamer is supposed to continue her observations as regularly through the night as through the day, and the surrounding surface of the sea must also be lighted. To accomplish this, a hundred and twenty eight-candle B lamps of the Edison incandescent system are distributed through the ship; every portion, including the



MAIN LABORATORY, AFTER END.

holds, storerooms, and open decks, having its share. They are controlled by a Z dynamo, driven by an Armington and Sim's high-speed engine. An arc-lamp of great power, designed by Dr. O. A. Moses, and intended for illuminating the surface of the water, works in circuit with the same system; and there is also a powerful submarine lamp which can be lowered to any depth not exceeding a thousand feet. This latter feature is quite novel, and is to be used to attract schools of fish and other free swimmers, should its strong rays of light possess the influence which they are supposed to have.

The sounding and dredging appliances and working-gear supplied to the Albatross are mainly patterned after those which have been successfully introduced by the U. S. coast-survey and fish-commission in recent years. All sounding operations are to be conducted with steel piano-wire of No. 21 American gauge, on the system of Sir William Thomson, for which purpose two styles of sounding-machines are furnished. One of these is the invention of Commander Sigsbee, U.S.N., and the other of Lieut.-Commander Tanner, U.S.N. The Tanner machine, in which the reeling-in is accomplished by hand, is extremely simple in its workings, and is intended for moderate depths of water only. It is attached to the rail on the port side of the main deck, forward of the pilot-house. The Sigsbee machine can be used in all depths of water, down to the deepest parts of the ocean, and is worked by steam. It occupies a prominent position on the port side of the top-gallant forecastle deck (see opposite page). The principal accessories to sounding are the Sigsbee sounding-rod, with detachable weights; the Sigsbee water-cup; and the Negretti and Zambra deep-sea thermometer, with a new style of reversible metal case recently devised by Messrs. Bailie and Tanner of the fish-commission. With these appliances, samples of the bottom formation and water, and the temperature of the latter, can be obtained at each cast of the lead; and, by using a heavier sounding-wire (No. 18 wire gauge), several intermediate samples and temperatures are also procurable without much additional trouble.

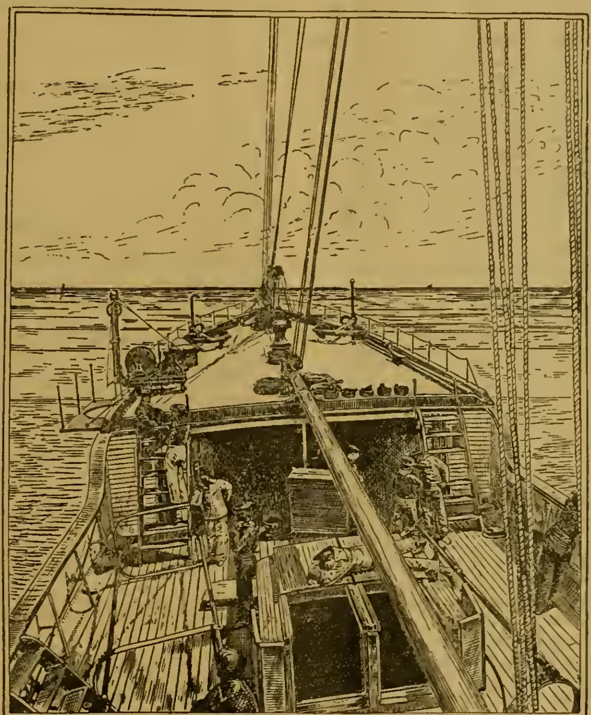


THE SIGSBEE SOUNDING-MACHINE.

The dredging appliances are as nearly perfect as are those for sounding, and comprise every improvement which has been hitherto suggested. Steel-wire dredge-rope measuring only an inch and an eighth in circumference replaces the old style of three-inch hempen rope, which is no longer recognized by deep-sea dredgers on this side of the Atlantic. The principal advantages of wire rope are its compactness, strength, and durability, and the ease and speed with which it can be handled. The working-reel of the Albatross, on which 4,000 fathoms can be stored at a time, occupies so small a space on the ship that its presence is scarcely noticeable.

The dredging machinery consists of a powerful hoisting-engine on the main deck directly in front of the foremast, and a reeling-engine and reel on the berth-deck underneath. A strong dredging-boom, thirty-six feet long, and pivoted to the foremast about seven feet above the deck, carries the dredge-rope clear of the vessel, and can be raised and lowered, or bent aside at any angle, to suit the convenience while dredging or trawling. Sudden strains on the dredge-rope are relieved by a Sigsbee accumulator, consisting of about thirty-five rubber car-buffers arranged for compression on an iron rod. This important accessory hangs suspended from the masthead above the hoisting-machine. The course taken by the dredge-rope while in use is as follows: starting from the reel on which it is contained, it passes through a pulley on the berth-deck to the drum of the hoisting-engine, thence up to and through an iron block at the lower end of the accumulator, and down again through a sheave in the heel of the boom, from which it extends to the outer end of the boom, where there is another large pulley. The free end of the rope is spliced into the eye of a set of safety-hooks, to which the dredge or trawl is fastened, and which are so arranged as to open and release the apparatus, should the strain, by reason of fouling on the bottom, exceed a certain amount. These hooks can be adjusted to detach at any point between three thousand and six thousand pounds, which is less than the tensile strength of the rope they are intended to secure from breakage. The amount of rope out at all times is recorded by a register attached to the sheave in the heel of the boom, the sheave measuring just half a fathom in circumference.

In preparing for work, the dredging-boom is topped up at the requisite angle over the starboard bow, and the loaded dredge or trawl is hoisted above the deck, on which stands the sieve or tubs ready to receive its contents. Two methods of sifting or washing the materials are followed. For the trawls, which generally bring up a heavy load, a large and deep square sieve, standing upon legs at a convenient height for working, is used. As the tail of the trawl is lifted above the deck,



FORWARD DECK.

the sieve is shoved under it, and the contents of the former are released. In case no washing is necessary, the specimens are rapidly transferred to their proper receptacles; but if, as usually happens, the load consists mainly of mud or sand, a stream of water from a hose is turned upon it, and it is thoroughly washed down. A nest of three or four small circular sieves, each having a different mesh, is generally employed for washing the contents of the dredges.

To describe the various appliances of research belonging to the outfit of the Albatross would carry us beyond the proper limits of this article: suffice it to say, that every method of obtaining results known to the fishermen and marine zoölogist will be tried. The scientific apparatus is mainly such as has already been thoroughly tested by American expeditions, and much of it has been described in published reports. There are many additional features, however, which have been lately added. The fisherman's outfit is complete, and comprises all kinds of seines and gill-nets, line-trawls, and hooks and line. The principal appliances for deep-sea research will be the dredges and beam-trawls, both in their original and modified forms; and, in connection with the latter, two large towing-nets will always be used. They are fastened, one at either side of the trawl, in the shape of wings, which name they now bear in the dredger's vocabulary. They were introduced as an experiment two years ago by the fish-commission; and, proving an invaluable adjunct to the trawl, they soon became a permanent fixture. The simple open towing-nets are to skim the surface of the sea at all times, when the speed of the vessel will permit; and occasional trials will be made with the Sigsbee trap for ascertaining the amount of animal life within any prescribed area below the surface.

The chemical department has not yet been completely furnished, but all the more important apparatus for making the principal tests, and glassware for saving water-samples, have been supplied. The photographic section has, however, been placed in perfect running-order, and affords the means of illustrating all sorts of objects, whether large or microscopic. It also contains improved appliances for registering the intensity of light at different depths.

Among the small boats with which the Albatross is liberally provided are two steam launches of the Herreschoff pattern for use in setting and hauling nets, and in spearing porpoises and large fish which cannot be reached from the high deck of the steamer.

From the above brief account, it may be rightly assumed that this new addition to our coast-marine is the most perfect floating workshop and laboratory for scientific purposes ever constructed. Its first cruise, during which it encountered severe winds, gave proof of its superior sailing qualities; and, judging of its outfit from past experiences, we are justified in predicting for it a long life of usefulness to science and the fishing interests. RICHARD RATHBUN.

SUN-SPOT OBSERVATIONS.

THE U. S. signal-service has published month by month since June, 1877, observations of sun-spots, made by Prof. D. P. Todd (now of Amherst college) with a telescope less than three inches aperture.

As a maximum of solar spottedness seems to have passed, it has been thought wise to collate these observations in the accompanying table, and present them for comparison and study.

In this table the Roman figures are the actual observed values, and interpolated values in Italic type are added for the sake of completeness.

The observations for August, 1878, were made by the Signal-service at Fort Whipple, Va. The mean monthly results combine both actual and interpolated values, and show that the last minimum epoch was at 1878.9, and the last maximum was at 1882.4.

Professor Fritz of Zurich gives the following table of maxima and minima of sun-spots for the present century to 1878. These agree in the main with the results of other researches.

Epochs of maximum and minimum sun-spots of the nineteenth century.

Maximum.	Period.	Minimum.	Period.
1804.2	12.2	1810.6	12.7
1816.4	13.5	1823.3	10.6
1829.9	7.3	1833.9	9.6
1837.2	10.9	1843.5	12.5
1848.1	12.0	1856.0	11.2
1860.1	10.5	1867.2	11.7
1870.6	11.8	1878.9	
1882.4			
Mean . . .	11.2	Mean . . .	11.4

Taking the mean of each twelve months, we have mean yearly numbers, in 1878, 2.2; 1879, 2.0; 1880, 14.3; 1881, 26.7; and, in 1882, 28.3. The last two agree with the observations of Tacchini in Rome.

Prof. D. P. Todd's sun-spot observations.

Plotting the monthly numbers, it will be seen that there are plain indications that the maximum has passed, though it is thought by some that it is still to come. H. A. H.

FIFTEENTH ANNUAL CONVENTION OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS. — I.

The members of the society began to assemble in Chicago as early as Thursday, June 14, to visit the exposition of railway appliances, and to take part in the excursions planned for their benefit by the Engineers' club of the north-west.

By Monday morning, June 18, the number of those intending to take the special train for St. Paul, generously tendered by the officers of the Chicago, Milwaukee, and St. Paul railway, had swelled to three hundred. The train of eight cars, well filled, left Chicago at 7.30 A.M., arriving at St. Paul at 10 P.M. But few stops were made on the way, the principal one being at the crossing of the Wisconsin River, for the object of inspecting the railway bridge, and taking a better view of the fine scenery at that point. Quite an accession to the party came on board at Milwaukee.

Upon reaching St. Paul, an engine of the St. Paul, Minneapolis, and Manitoba railroad was attached; and the train was drawn over that line, through Minneapolis, to Lake Minnetonka, — a beautiful sheet of water some thirty miles long, where, at Hotel Lafayette, thirty-three miles from St. Paul, the members of the society and their invited guests were to be quartered during the convention.

The two cities of Minneapolis and St. Paul, only a few miles apart, and each containing over eighty thousand inhabitants, were rivals for the opportunity of entertaining the society; and to prevent any ill-feeling, as well as to avoid crowding any of the city hotels, already taxed to accommodate their own patrons, this summer hotel, just opened for the season, only built one year, newly enlarged and furnished, and capable of providing for the comfort of five hundred or six hundred guests, was chosen for headquarters. With the exception that some valuable time was lost in going to and returning from the place of holding the daily sessions, this selection is to be commended; for the location was extremely pleasant, and the air fresh and cool. Those who did not desire to go to the meetings each day could find rest and enjoyment at this agreeable summer resort. A special train was at the service of the convention each day throughout the entire week. A large accession to the number of members present was made as the week progressed, so that the attendance was larger than at any previous convention.

On Tuesday morning the engineers took the special train for St. Paul, and thence went to the state capitol, where the first meeting was called to order in Representatives' hall. After formal announcements of programme and arrangements, the usual addresses of welcome were made.

The first paper read was by the late Major F. U. Farquhar, U.S. eng., on the building of the dike for the preservation of the Falls of St. Anthony.

The falls, which furnish the water-power for the mills of Minneapolis, were first described. A stratum of upper magnesian limestone, eleven feet thick at the lower edge, is underlaid by an extremely soft sandrock, which is rapidly worn away; and the limestone is thus undermined and broken off. The recession of the falls was rapid; and, as the limestone outcrops with a thin edge twelve hundred feet above the present brink of the falls, their final reduction to rapids would occur, if not prevented. Citizens dug a tunnel for a tail-race in the sandrock, and the river broke in at the upper end. The immediate destruction of the falls was imminent; and attempts to check the rush of water, which rapidly enlarged the tunnel and repeatedly broke through in different places, proved ineffectual. The citizens, after building cofferdams at various weak points, discouraged by failures at times of high water, obtained an appropriation from the U. S. government, on the ground that the wearing-away of the falls would injure navigation above. A plan was finally proposed by Major Farquhar, of excavating a tunnel across the entire river, through the sandrock, from the limestone overhead to the sound rock below, some forty feet, and filling it solidly with concrete. This work was carried out under his direction, and was fully explained in the paper, and illustrated by drawings. The dike is eighteen hundred and seventy-five feet long, and has successfully shut off the water which worked its way through the soft sandstone. The detailed statement and cost can be found in the Report of chief of engineers, U.S.A., for 1879. The action of the water has been injudiciously concentrated upon a limited space of some three hundred feet by the erection of wing-dams by the mill-owners.

In the discussion on this paper at the time of its reading, and in remarks made the next morning by the engineer officer now in charge of the falls, the other works of preservation — the timber apron, the rolling dams above, and the crib which had been placed below, the falls — were described and commented upon.

Dr. C. E. Emery read a short paper, and submitted a table, showing the cost of steam engines and boilers complete, and the cost of operating the same for three hundred and nine days in the year, including repairs and renewals, and giving, upon the data assumed, the total cost per horse-power maintained continuously. He pointed out why small engines were comparatively more expensive to maintain than were large ones. The discussion of this paper was postponed until the next day.

The convention re-assembled at the state capitol on Wednesday morning. The discussion of Messrs. Farquhar and Emery's papers was first in order. The question was asked whether the amount expended in the preservation of St. Anthony's Falls would not have sufficed to establish and maintain an equivalent plant of steam-engines. Dr. Emery thought not.

Prof. T. Eggleston followed with a paper on 'An accident to steam-pipes arising from the use of blast-furnace wool.' He attributed a corrosion and subsequent explosion of steam-pipes at Columbia college to the setting-free of sulphur from the wool by the action of extremely diluted solutions of organic acids and the rapid corrosion of the pipe by the sulphuric acid, sustaining his position by reports of analyses and tests.

He was strongly opposed by Dr. Emery, who claimed that the corrosion was due to leakage and moisture, with alternate wetting and drying of the pipes, and that blast-furnace wool was entirely innocuous.

Mr. John Lawler of Prairie du Chien described the construction of the two pontoon draws in the railway-bridge across the Mississippi at that place. Each pontoon is four hundred and eight feet long, six feet deep, thirty-six feet wide on bottom, and forty-one feet wide on top. The interior details, the regulation of height of track, the means for fastening and for manoeuvring the draws, were described at length; and the cost was stated as one-sixth of the estimated cost of the usual iron swing-bridge. The bridge was built in 1874, and has been in continued use ever since. This bridge was seen from the train on the trip from Chicago.

The last paper at this session, by G. Lindenthal of Pittsburgh, Penn., was upon the rebuilding of the Monongahela bridge at that place, from his design and under his direction. The first portion of his paper entered minutely into details of the new structure, and was illustrated by tracings. The latter portion was occupied with a discussion of the old suspension-bridge, built in 1846 by John A. Roebling, the condition of the same before removal, the tests of the material removed, and the effect of the excessive overloading to which it had been exposed for years by the increasing and heavy traffic over the bridge.

After a brief discussion, the convention then adjourned; a portion of the members repairing at once to Lake Minnetonka, and the remainder going to Minneapolis, where visits were made to the Washburn flouring-mill and to the bridges.

KINETIC CONSIDERATIONS AS TO THE NATURE OF THE ATOMIC MOTIONS WHICH PROBABLY ORIGINATE RADIATIONS.[1] — I.

THE assumption that the mean kinetic energy of translation of the molecules of a gas is the measure of its temperature is one whose beautiful agreement with experiment has led to its acceptance as a necessary part of the kinetic theory of gases, and it has often led to the thoughtless conclusion that this translatory motion is also the mechanical source of the disturbances in the ether which originate radiations. But there are many difficulties in the way of accepting this view. One of the first, and perhaps the least, is the difficulty of conceiving how such a motion of translation, which is essentially longitudinal, can originate a lateral vibration, such as light and radiant heat must be.

A greater difficulty appears to be found in the extremely moderate mean velocity of translation which the molecules of a gas are found to have. Molecular velocities, which are of the same order of magnitude as that of sound or of a rifle-ball, seem hardly fitted to cause the necessary compressions or disturbances in a medium in which the rate of propagation is so immense; or, to state it in another way, if molecules, in describing their paths, originate radiations, then the motion of a rifle-ball ought also to do so, or, indeed, any much more moderate motion, such as that of a vehicle or animal.

A still further difficulty is, that there is another part of the kinetic theory which appears to be so related to this that both cannot

[1] Presented in abstract to the Section of chemistry and physics of the Ohio mechanics' institute, April 26, 1883.

be rigorously true at the same time, as appears from the following considerations. The most probable distribution of the component molecular velocities of a gas in equilibrium is the same as that of errors of observation. This distribution is brought about by fortuitous molecular encounters, and its permanence is insured by reason of them. But in case the progressive motion of a molecule gives rise to radiations, those molecules whose velocities are the greater are the hotter, and consequently radiate more heat to other molecules than they receive from them. They therefore lose part of their progressive energy before the next encounter. The whole effect would be to retard the motion of those molecules whose kinetic energy is greater than the mean, and accelerate those whose kinetic energy is less. This would cause a constant interference with the distribution of velocities according to the law of probabilities; and the interference would, so far as we are at present able to form an estimate of its amount, be sufficient to cause the kinetic energy of each molecule to approach indefinitely near its mean value during the time in which it describes a very small fraction of the mean path between two successive molecular encounters. If this is the case, the kinetic energy of any molecule does not differ for any appreciable time from its mean value, and is in effect the same during the whole path, so that there is no such distribution of velocities as has been assumed. In case the interference with the assumed law is not so complete as this, it must apparently exert an important influence upon the distribution of velocities, especially in the case of rarified gases, in which the encounters are comparatively infrequent.

Again: if the progressive motion of the molecules can originate radiations consisting of transverse vibrations, it would appear highly improbable that their rotary motion should not also do the same. But, as has been shown in a former paper,[1] the kinetic energy of translation differs from that of rotation for imperfect gases; and the temperature cannot be simply proportional to the mean rotary energy, though it might possibly be proportional to the sum of the rotary and translatory energies combined.

But aside from these difficulties, which may serve to show the intrinsic improbability of the supposition that the progressive motion of the molecules originates radiations, we seem to reach pretty decisive evidence against the supposition, when we consider the specific heats of solid bodies, or when we consider the nature of the radiation itself as revealed by the spectroscope.

The experimental law of Dulong and Petit, and the analogous results of Neumann,[1] show that in solid bodies we must consider the temperature to be measured more nearly by the energy of the atom than by that of the molecule. Now, it is hardly supposable that the translatory motion of a gaseous molecule should originate radiations, while that of a solid should not. We shall not, at this stage of the discussion, consider the spectroscopic evidence as to the nature of the motions which originate radiations, further than to notice that the characteristic spectra of gases appear wholly inexplicable, on the supposition that they are originated by translatory motions, with velocities distributed according to the law of probabilities, or with velocities reduced by radiation to an approximate equality, as it has been shown they might be; for even the simplest gases have spectra consisting of at least several lines.

If these reasons compel us to distrust the supposition that radiations originate in the progressive or rotary motions of the molecules, does the supposition that radiations originate in the vibratory motion, with respect to each other, of the atoms in the molecule, afford a better explanation of the facts? Such a motion, analogous to the elastic vibrations of a bell or other sonorous body, might very readily, perhaps, be shown, in case of a complex molecule, to have such a relation to the molecular encounters, and thus to the mean kinetic energy of translation, that its energy would be directly proportional to it for each given gas. In case this were established, such vibrations, considered as the physical cause of radiations, would explain the phenomena of gases as well as the supposition that they are due to the progressive kinetic energy; and they might possibly be shown to explain those of solids also.

But there is at least one difficulty, in the way of accepting this supposition, which seems insuperable in the case of monatomic molecules; for, if radiations could only originate in the vibrations of atoms with respect to each other within the molecule, monatomic molecules could not radiate heat at all, and could not have a temperature. That this should be true is not only inconceivable, but contrary to the known fact that monatomic mercury gas has a perfectly ascertainable temperature: hence

[1] An extension of the theorem of the virial, etc. — (*Sc. proc. Ohio mech. inst.*, March, 1883.) See also SCIENCE, i. 65.

[1] *Ann. phys. chem.*, xxiii. Wüllner's *Experimental-physik*, iii. 506.

the motions which originate radiations are not confined to such vibrations of atoms, even if it be possible that such vibrations do originate radiations. And this consideration leads us to what appears to be the truth of the matter, which is, that the atoms themselves are in a state of internal vibration. As will be seen subsequently, this internal vibration is, no doubt, accomplished under the action of internal forces, which permit extremely small deformations only of the atom by any external forces which can be brought to bear upon it; i.e., the modulus of elasticity of an atom is very large indeed, and very large, no doubt, when compared with that of the molecule. Indeed, if such vibrations exist within the atom itself, it is not difficult to prove that the force which binds the parts of an atom together (and consequently its modulus of elasticity) is much greater than the chemical force binding the atoms together into a single molecule; for it has been shown, in my paper upon the internal molecular energy of atomic vibration, that the amount of energy which can be imparted to a system like this is inversely as the modulus of elasticity. But chemical atoms are bodies which we are now supposing to be in internal vibration, but to which it has been found impossible to communicate energy in amount sufficient to cause them to fly to pieces. Since atoms do not become decomposed, while molecules do under various circumstances, it must be that their modulus of elasticity is much larger than that of molecules.

This view accords with that of Lockyer,[1] who has endeavored to explain the coincidence of lines in the spectra of different elements, and the relation of temperature to spectra, by the supposition that the so-called chemical elements are merely molecules which have never yet been decomposed by chemists. It must be admitted that the experimental evidence he adduces is of a very cogent character; and it seems to me that the demonstration by which I have shown that the mean energy of such a vibration would be extremely small explains how such a vibration can exist without decomposing the more complex atoms even at the highest artificial temperatures, though Lockyer has reason to think that they are decomposed in the hotter stars, where only the spectra of the elements of low atomic weight are to be found.

Were it true that every degree of freedom must have the same kinetic energy, we could not admit the possibility of such a vibration; for not only would such large amounts of energy be required by the degrees of freedom which seem certainly to exist between the atoms of complex molecules as to entirely contradict experimental values of the specific heat, but the supposition of additional degrees of freedom within each atom would require an amount of energy, on the whole, many times the actual specific heat of such bodies. But when the amount of energy required by such degrees of freedom is nearly a vanishing quantity, as I have shown, there is nothing to prevent us from assuming that to be the truth which spectroscopic evidence makes most probable.

We may notice, in passing, that the principle upon which this paper rests, that vibrations of this character can exist without absorbing an appreciable amount of kinetic energy, enables us to explain at the same time the extremely moderate rate at which exchanges of heat take place between bodies by radiation. They become only very slowly of the same temperature, which fact needs explanation in view of the extremely rapid propagation of radiations themselves. Now, according to our supposition, during a molecular encounter the molecules are roughly shaken, and there is a determinate distribution of energy to be found among the atoms, at its conclusion, in the form of internal atomic vibration, which distribution is due to the circumstances of the encounter. Those atoms which by chance have more energy than others radiate more rapidly; and since the velocity of radiation is so great, and the atomic distance so small, we may assume that the several atoms acquire almost instantaneously an energy of internal vibration sensibly equal to the mean, so that in a gas this is their condition during almost the entire free path of a molecule. In case the gas is becoming cooler by radiation to surrounding bodies, the atoms which radiate to these bodies lose more of their vibratory energy than they otherwise would, and thus have less mean energy of internal vibration than they should have under the law of distribution which determines what fraction this energy shall be of the mean kinetic energy of the molecules. At the next encounter, the atoms receive their proper share of the mean kinetic energy, which, being partially lost by radiation, is again supplied; and so on. And because this transformation into internal atomic vibration must take place before it can be radiated, and because at the same time the energy of this vibration is but an unappreciable fraction of

[1] Discussion of the working hypothesis, that the so-called (chemical) elements are compound bodies (*Nature*, Jan. 2 and Jan. 9, 1879). Necessity for a new departure in spectrum analysis (*Nature*, Nov. 6, 1879).

the total kinetic energy, the process of exchange by radiation is, on the whole, slow. Were, however, the translatory motion the direct cause of radiation, the exchanges between diathermous bodies must apparently be nearly instantaneous.

(*To be continued.*)

OYSTER-CULTURE IN HOLLAND.

THE first of a series of papers on the European oyster and oyster industry of the Eastern Schelde[1] has just been published by Mr. P. P. C. Hoek, secretary of the commission of the zoölogical station of the zoölogical society of Holland. It is to be followed by a series of papers gotten up in similar style by eminent specialists: 1°. On the embryology of the European oyster; 2°. On its food, parasites, and commensals; 3°. A review of the fauna of the Eastern Schelde; 4°. A report on the physical conditions presented by the Eastern Schelde; 5°. A report on experiments made to determine the conditions under which the fixation of the larval oyster occurs.

In this report the author devotes a short chapter to a discussion of the classical allusions to the animal, from the Homeric period to the time of Oppian. Then comes a chapter on the references to the oyster found in Conrad Gesner's *Historia animalium*, lib. iv., edition of 1620; followed by an exhaustive bibliography of ninety pages, in which the works of upwards of two hundred and seventy-five authors are mentioned, covering the period from 1685 to 1883, or nearly two hundred years.

Then follows a paper on the organs of generation of the oyster, by Mr. Hoek, accompanied by an excellent series of lithographic plates representing microscopic transverse sections of the European oyster. The text of this is in Dutch and French on alternate pages. A chapter is devoted to a historical *résumé* of our knowledge of the anatomy of the generative organs, and is succeeded by an account of the author's investigations.

A second part is devoted to the physiology of reproduction, and is preceded by an historical sketch of this part of the subject, from the time of Leeuenhoek to the present. The author gives a summary of his results, both anatomical and physiological, as follows: the genital gland is not a compact organ: it lies on the surface of the body of the animal under a thin layer of connective tissue (mantle), below which branched ducts spread out over the reproductive organ, connected on the inner side with the reproductive follicles, which have a generally vertical direction to the surface of the visceral mass, and which anastomose with each other. The generative products develop on the walls of the follicles, the ova and spermatozoa being formed side by side. The author inclines to the belief that the generative products are developed from the ectoderm. The ova are developed from single epithelial cells adherent to the wall of the parent follicle, while the mother-cells of the characteristic masses of spermatozoa are only portions of such cells. The organ of Bojanus does not have a compact structure as in other lamellibranchs, but is composed of a mass of ducts and blind sacs, which forms a thin flat plate of considerable extent. Contrary to what may be noted of the reproductive glands, the organ of Bojanus extends somewhat into the mantle. The ducts and cavities of the organ of Bojanus pour their contents into a longitudinal cavity, — the urinary chamber, — the walls of which are also excretory in function, and open outwardly by way of a short urinary canal. The external orifice of the renal organ opens into the same cleft as the genital duct, a little behind the latter, but they do not actually join. These genito-urinary sinuses lie below the adductor on either side of the ventral process of the body-mass. A reno-pericardiac canal connects the urinary chamber with the pericardiac cavity. It is probable that the auricles of the heart also exercise an excretory function.

An oyster which has fry in the branchiae is the parent of the same. At the moment of emission from the ovaries, not only have the ova been fertilized, but they have also passed through the first stages of segmentation. The sperm necessary for fecundation does not come from the same parent. The water which flows over other oysters in the vicinity charged with sperm, which they have set free, is carried into the mantle-cavity of egg-bearing individuals, and into their genital ducts and their branches. The oysters of the Eastern Schelde are two years old before they have brood; they are most prolific at the age of four or five years. There are more sperm-bearing oysters in the Eastern Schelde than egg-bearing ones. All of the mature eggs are laid at once; the production of sperm is probably continued for a longer time. In every instance that was investigated, the production and emission of ova is followed by a period during which no sperm is produced. A large proportion of the spat found fixed on the banks in the Eastern Schelde was probably not derived from the oysters inhabiting the cultivated beds. Culture appears to act injuriously upon the reproductive powers of the animal. In old oysters the liver is much more developed than in younger ones. This greater development of the liver is dependent upon the less marked development of the reproductive organs. J. A. RYDER.

GALTON'S HUMAN FACULTY.

Inquiries into human faculty and its development. By FRANCIS GALTON, F.R.S. New York, *Macmillan*, 1883. 12 + 380 p., 6 pl. 8°.

MR. GALTON'S researches have for a good while attracted the attention of English and American students of psychology and anthropology. As they are here brought together, the practical purpose of their author is impressed upon us more clearly than ever. Mr. Galton means to introduce to our notice new aspects of the study of human character. He wishes to make this study more exact and scientific by founding it upon detailed investigations of facts previously neglected; and he proposes to offer the results as useful for a future science or art of eugenics, which shall teach the human race how to breed so that its best stock shall be preserved and improved, and its worst stock gradually eliminated. This seemingly utopian end is to be gradually approached by the formation of a public sentiment that shall encourage a new sort of family pride and exclusiveness; namely, when eugenic science has taught us what are the most useful human qualities, what their accompanying marks, what qualities are best transmitted to posterity, and what are the conditions that favor such transmission, then people otherwise not known to fame will be able, by a proper study of their family history, to discover their inherited wealth of valuable qualities, and their resulting eugenic rank; and such persons will be respected by an enlightened public according to their rank. People who rank high in the eugenic scale will be unwilling to contaminate their stock by unions with persons much lower in the scale, and their feelings in this matter will be appreciated. Thus marriages will become less blind, and civilization will progress faster.

That Mr. Galton's researches will be of much immediate use to young people about to marry, no truthful reviewer can promise; but to the psychologist, at least, they are in their present condition both attractive and useful; and, for the rest, it is much for Mr. Galton merely to have suggested, more definitely than Plato was able to do, that there ought to be, and some day may be, a real art of eugenics, which may be of practical importance for mankind. Just yet, neither Mr. Galton nor any one else can hope to do much more than to insist that the best parents may be expected to produce the best children; but there are many ways of insisting. Mr. Galton's most important contribution to this practical aspect of the subject lies in the facts that he has collected to give new importance to the matter by proving the vast predominance in ordinary cases of the influences of nature over those of nurture. Nature means for Mr. Galton the sum of all the inherited qualities of the individual, while nurture stands for the educating influences of the environment. In case of twins, Mr. Galton collects facts to show that in one strongly marked class of such persons the resemblance between the twins is very strong from the outset, and then often extends through life to the smallest possible matters of physical and mental condition, even when the twins live far apart. But in other cases, which form a second equally marked class, the twins, contrasting somewhat strongly from the outset, never are brought nearer to likeness, notwithstanding all the similarity of the circumstances of their nurture and training. Thus, when the physiological conditions of their origin give them like nature, difference of nurture does not prevent very striking similarity throughout life; while, where the conditions of origin favor unlikeness, likeness of nurture goes but a little way to overcome the contrast. A similar result is indicated, according to Mr. Galton, by our experience with races of animals, some of which seem by nature disposed to domestication, while the stubborn nature of others resists the advantages of any nurture, so that they remain wild, however much we may try to tame them. From whatever side, then, the matter is viewed, nature seems superior in its persistence to the forces of nurture that opposed this persistence; and, if we want human stock to grow better through voluntary effort, we must undertake to study and improve pre-natal and ancestral influences yet more than we try to better the influences of education.

This, then, is Mr. Galton's most significant practical result. His researches upon various problems of the science of character, that have not yet been long enough studied to have much immediate practical significance, cannot easily be summed up in one short notice. The psychologist is most interested in his researches on mental imagery and on association of ideas. Mr. Galton is of the opinion that introspection can be made a more exact science than psychologists have previously found it. And so, indeed, it can be, no doubt, at least when it is limited to the lowest orders of mental facts. Here introspection is greatly aided by plain and simple questions. Ask a man to tell you all he can about what now goes on in his mind, and he will answer as wildly as you could wish; but ask him to call up in mind the picture of his hat or of his house, or to tell you whether in some concrete instance he can vividly remember musical harmony as distinct from melody, and most honest men can then answer intelligibly and usefully. It is Mr. Galton's service to have shown how much can be done by thus systematizing and simplifying the method of introspection, so that people who are not psychologists may be able to furnish to the psychologist important and trustworthy data.

We do not remember that our author is quite plain in defining one of the safeguards needed to make this method useful. He says, in describing his researches into mental imagery (p. 87), "The conformity of replies from so many different sources, which was clear from the first, the fact of their apparent trustworthiness being on the whole much increased by cross-examination, and the evident effort made to give accurate answers, have convinced me that it is a much easier matter than I had anticipated, to obtain trustworthy replies to psychological questions. Many persons, especially women and intelligent children, take pleasure in introspection, and strive their very best to explain their mental processes. I think that a delight in self-dissection must be a very strong ingredient in the pleasure that many are said to take in confessing themselves to parish priests." But there is an obvious moral from all this. The method, with its questions and cross-questions, with its interested subjects and their pleasure in confessing themselves, is indeed fruitful; but the outcome must be controlled by the maxim that the subject's statements, when he is not himself an expert, must be trusted implicitly only when they are out of relation to any preconceived theory of his own about his mind, and equally out of relation to any popular prejudice or superstition that could influence him. Generally Mr. Galton seems to follow this maxim without explicitly recognizing it. The simplicity of his questions is itself a security. If you ask about one's mental picture of his breakfast-table or of his hat, you can be tolerably sure that he has no prejudices or superstitions that will affect his answer. But it is another thing, in case one is inquiring about the 'visions of sane persons,' and mentions some great man, say Napoleon, who is declared by some one to have had visions of his 'star,' and to have boasted thereof. Here such evidence as can be got would be worthless, even if the great man in question were not a notorious liar. For superstition, once for all, attributes stars to great men; and, when a story exactly corresponds to a known and wide-spread superstition, we may usually disregard the story save for the purposes of folk-lore. Yet, on p. 176, Mr. Galton makes a story of this sort the basis of reflections that of course may possibly be true; so that his caution is not quite perfect.

In fact, we should be disposed to apply the maxim just stated yet more carefully; namely, if the subject shows an uncommon visualizing power, he is both instructive and dangerous, and ought to be treated very tenderly. He can furnish many facts, but his replies are by so much the more apt to be influenced by some theory of his own. Accustomed all his life to his vivid imagery; very possibly a member of a family several of whom are uncommonly gifted in this respect; accustomed, therefore, to notice and talk about his power, and perhaps to boast of it, — he may have formed already some vain-glorious idea of what he can do or ought to do; and, when you set him at the task of talking about himself, you must be careful how you accept all that it may occur to him to say. A brief experience with one such subject as we have just described has convinced us that serious danger would arise from applying Mr. Galton's method to him without great care. And if we intended to publish any of his experiences, we should confine him strictly to commonplaces, should not publish his stories of what he used to see when a child, and should not introduce any thing that he connected with 'elevated spiritual experiences,' or with any other artistic excellence of which he seemed to feel proud. We fear that some of Mr. Galton's subjects needed more such watching. In fine, though Mr. Galton's researches on mental imagery, since their first publication in the form of memoirs, have greatly helped introspective psychology, no one, doubtless, would fear or deplore more than himself any misuse of them that should tend once again towards the mythological. Our suggestion is intended to help to ward off such a sad result, which, for the followers whom Mr. Galton is certain to have, might not be very far off. What might not our author have to mourn over, if 'psychological associations' were to become fashionable in country towns, and were to produce acres of manuscript or printed proceedings containing elevated spiritual visualizing experiences by old maids and semi-spiritualistic reformers? Yet, in these days of popular science and associations, who knows what Mr. Galton's pleasing way of speech might not produce, if he does not add to every new chapter of facts a note strenuously insisting that the exact and cautious methods that are commonplaces for him should be studied and followed by every ambitious one that would do likewise, however simple the subject-matter investigated may seem to be?

Mr. Galton can claim especial credit for his investigations into visualized number-forms. Here the nature of the facts is the best guaranty of their general accuracy. They have generally been unknown, save to the subjects; they are not things of which people are apt to boast; their psychological significance is far greater than their popular interest; they have nothing of the elevated or of the spiritual about them; the research is quite new. All this secures the substantial correctness of the results, though, plainly, further accurate research will become harder when Mr. Galton's facts become more popularly known.

One general result that Mr. Galton seems to have established is, that growth in the power of abstract thought is opposed to the free development of the visualizing faculty. Scientific men have, as a rule, less vivid imagery than persons of less abstract habits of mind. Adults visualize less clearly than children. But this loss of visualizing power does not signify, he tells us, loss of clear memory of details. "Men who declare themselves entirely deficient in the power of seeing mental pictures can, nevertheless, give lifelike descriptions of what they have seen." Again: "it is a mistake to suppose that sharp sight is accompanied by clear visual memory." Yet more: "the visualizing and the identifying powers are by no means necessarily combined." Thus our author tells us that one distinguished subject is good at recognizing faces, but cannot visualize them at all. All these facts, and many others, seem to us to point to a result that Mr. Galton sometimes approaches, but does not distinctly formulate. On the contrary, in one place he says something directly opposed to it. "A visual image," he says (p. 113), "is the most perfect form of mental representation, wherever the shape, position, and relations of objects in space are concerned." And he thinks that mere laziness is responsible for the common starvation of this faculty; but, if this were so, it is hard to see how a healthy mental organism should, in the course of its normal development, generally tend to outgrow the visualizing faculty. 'The most perfect form of mental representation' for any purpose will not be the one that we should, as evolutionists, expect to find growing naturally less as the mind devotes itself more to that purpose; yet who are more concerned with the exact relations of things in space than workers in the details of descriptive natural science? And they, we are told, are apt to lack the faculty in question. The statement just quoted seems, then, to lack probability, and to be against the main result to which, as we have said, all these researches seem to lead.

This result, we think, is that the clearest memory, in the long-run, tends to be the memory of acts, and not of the content of a sensation apart from its immediate relation to an action. This seems reasonable from the point of view of evolution. The life of an animal consists in doing what seems best under the circumstances; and the seeming is determined by instinct or individual experience, coupled with immediate sensation. All, then, that sensations mean for the animal, is summed up in saying that the sensation is useful as the sign of the need of a certain kind of action. The association of a given kind of sensation with a given kind of action results from individual or ancestral experience; but, in forming this association, not the whole of an experience need be remembered, but only so much as shall serve as a sign of a given sort of action. The mouse, even if it fled from the cat, not by instinct, but voluntarily, would still not need to visualize cats, but only to remember so much of the sensations aroused by a cat's presence as should suffice to arouse the right action.

On the other hand, if a given action is to be not automatic, but voluntary, the action must be conceivable clearly and in detail. If this is so, it will follow that the memory for ideas connected with muscular sensations, and so for actions, both bodily and intellectual, would not merely be capable of substitution for visualized images, but would normally tend to be so substituted. In fact, if a visualized image were the 'most perfect form of mental representation' for space relations, then geometrical reflection and definition would be a useless amusement in all cases of small objects. The other facts noted above, such as the relative power to identify without being able to visualize, seem to us capable of explanation in a similar fashion, by the relative preponderance of the memory for actions, and consequently of relations (which we know by virtue of our own bodily and mental actions), over the memory of the contents of bare sensation.

But we have said nothing of Mr. Galton's composite photographs, of his researches on association, or of the many other topics that render his book not only very amusing, but especially instructive, as showing how what in the hands of another man would be mere dilettanteism becomes in the hands of the master a very valuable series of contributions to science. And with these suggestions we must leave a very pleasant topic.

STOWELL'S MICROSCOPICAL DIAGNOSIS.

Microscopical diagnosis. By CHARLES H. STOWELL, M D., and LOUISA REED STOWELL, M.S. Detroit, *G. S. Davis*, 1883. 8+93+118+35 p., 10 pl. 8°.

THE title of this book led us to expect a work specially referring to the applications of the microscope in medical practice, and we felt that a good book of that scope would be welcome and valuable. As in the opening sentence of the preface Professor Stowell says it has been his good fortune to be so situated, during the past few years, that his entire time has been devoted to the study of histology and microscopy, with special reference to the microscope in its relation to the practice of medicine, our anticipations seemed confirmed, and the expectation added, of finding much new and original matter. An examination of the body of the book was disappointing, because it gave us acquaintance with contents so miscellaneous and varied that we were reminded of those so-called 'happy families' where discordant associates live in compulsory peace, — something quite unlike a natural and well-proportioned assemblage.

The first eighty-two pages alone deal with clinical microscopy, and we think not satisfactorily; for the treatment is hurried and incomplete, though certainly accurate, what there is. The best part is the few pages on urinary deposits, with the accompanying admirable plates by Mrs. Stowell. The portion on parasites and tumors is extremely inadequate. The three specimens of Demodex figured, must have encountered some frightful disaster before they were drawn. We regret, that, instead of all this, the author did not prepare a translation of Bizzozero's *Manuale di microscopia clinica*.

The bulk of the book is made up of botanical articles, by Mrs. Stowell, on starch, wheat, and various medicinal plants. These are pleasantly written, and the illustrations display the authoress's skill in drawing; but we miss in these, as in the other parts of the volume, any definite purpose, either of text-book writing or original research. In this connection, we are impressed by the absence of references to scientific literature.

Part iii., by Mr. Walmsley, describes the methods employed by him in the commercial manufacture of microscope slides. It is extremely elementary, and the methods most employed in scientific biology are in large part unmentioned. The same subject of methods has been far better treated by numerous previous writers.

In short, we are quite at a loss to discover the *raison d'être* of this pleasantly and clearly written, as well as beautifully illustrated work. The new and original matter which we looked for, after reading the preface, we have not found; yet the facts and figures seem all to rest upon personal observation.

To the amateur microscopist, the book may well serve as a guide to certain things not elsewhere so well described.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Classification of surfaces. — In a memoir contained in the Abhandl. kön. akad. wiss. zu Berlin for 1868, M. Christoffel treated of the classification of surfaces by formulating the changes which took place in a geodetic triangle on the surface when it was displaced or moved along on the surface. M. Christoffel was thus led to a classification of surfaces which divided them into four groups. The first group contained all surfaces upon which no displacement of a geodetic triangle could take place without altering the triangle; the second group contained surfaces upon which a geodetic triangle might be displaced without alteration, provided its angles moved upon certain determinate curves; the third group contained surfaces upon which the geodetic triangle might be displaced without alteration in a singly infinite number of ways; and the fourth group contained surfaces upon which the triangle could be displaced in any manner without alteration. In the present paper, M. v. Mangoldt revises this classification, and shows that the surfaces contained in the third and fourth groups are identical, and that they include all surfaces with a constant measure of curvature, and only these. Also he shows that the second group contains all surfaces which are developable upon surfaces of rotation which have not a constant measure of curvature, and only these. The author further revises a paper of Weingarten's, correcting an error which appeared there. — (*Journ. reine ang. math.*, xciv. i.) T. C. [74

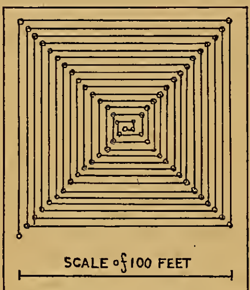
PHYSICS.

Electricity.

Aurora borealis. — Professor Lemström has now given a somewhat detailed account of his apparatus and experiments in Lapland. He and others had years ago in that country observed a pecular luminosity, which he calls 'phosphorescent,' in the form of 'tiny flames' playing about the tops of small mountains.

As long ago as 1871 an attempt was made to assist the production of the aurora upon these hilltops; but the results obtained were not, to scientific men in general, entirely satisfactory. Accordingly, in 1882, Prof. Lemström prepared to repeat his experiments upon a more extended scale.

Upon the top of Oratunturi Mountain (lat., 67° 21′; long., 27° 17′.3 east of Greenwich), about 540 meters above sea-level, he laid out, upon insulators raised about 2½ m. above the ground, a bare copper wire in the form shown in the illustration, the wires being about 1.5 m. apart. The area covered in this way was about 900 square metres. The single wire which made up this spiral was provided with numerous points soldered on; and the inner end was connected by an insulated line with the observing-station at the foot of the mountain, where the circuit ran through a galvanometer and into the earth.



ARRANGEMENT OF WIRES.

From the day the apparatus was finished, viz., Dec. 5, "there appeared almost every night a yellowish-white luminosity around the summit of the mountain, while no such luminosity was seen around any one of the others! The flames were variable in intensity, and in constant oscillation as those of a liquid fire. Three times it was tested, 2½ miles off in south-east, by a Wrede spectroscope (small size with two prisms), and it returned a faintly continuous spectrum from *D* to *F*, in which the auroral line $\lambda = 5569$ with soft variable intensity was observed." The galvanometer, meanwhile, showed an extremely variable positive current from the wire at the top of the mountain to the earth.

An attempt was made to determine approximately the electromotive force of this current by occasionally introducing into the circuit a Leclanché element, and observing the change thus produced. As the insulation of the line leading up the mountain was not good, however, we must accept with caution, as Prof. Lemström admits, the results thus obtained. The current from the mountain top was apparently sometimes less, and sometimes considerably greater, than the Leclanché element produced.

Similar results were obtained at Pietarintunturi Mountain (950 metres above the sea, in lat., 68° 32′.5; long., 27° 17′.3 east of Greenwich), where a smaller spread of wire was used.

There seems to be very little doubt that Prof. Lemström has succeeded in producing the aurora at will, or rather in assisting nature to produce it. Some of the conclusions which he draws from his experiments, however, will, no doubt, be received with caution, not because they set forth any thing in itself improbable, but because the experiments described seem too few and rough to decide the matter beyond a doubt. Thus he believes that "the *electricity* which descends into the auroral belt [the circumpolar belt of maximum auroral activity] is the *primary* cause of the greatest part of the terrestrial current, and, through this, of the variations of the magnetic elements." Moreover, finding that in several cases observers in different stations were near mistaking different auroral arcs for the same one, he concludes that "*all* measurements of the height of the aurora, calculated on those with a long base north and south, are always erroneous, as the two observers *never* see the same aurora. And even those calculations which are based on the measurements of the height and length of an arc from one point, and the hypothesis that the arc extends around the magnetic pole, must be considered very unreliable, as no satisfactory answer can be given as to what results would have been obtained a little farther north or south. This is also the case with aurorae with long bases east and west," etc. He says, therefore, "That the height of the aurora borealis is very variable I fully admit, but in my opinion it has been greatly over-estimated."

It seems probable that a great many people incline to a similar opinion,[1] and will merely regret that Prof. Lemström has not given them some better foundation for their disbelief. For many years, however, the doctrine has been current that auroras frequently exist at a height of a hundred miles or more; and the substance of Prof. Lemström's present arguments against such a belief must have been old for a long time.[2]

On several occasions it was observed by Prof. Lemström's party that the peculiar spectroscopic auroral line "was returned from every quarter of the horizontal plane, (and) even from the zenith, *without any aurora being visible.*"

Another phenomenon of much interest is a "peculiar phosphorescent 'shine,' or diffused luminosity, which possesses several phases, but the general character of which is a luminosity of a yellow-white color, which renders the night as light as the moon with a thick hazy air." On one occasion "every object around stood out clearly in a yellow-white hazy phosphorescent luminosity of quickly-shifting intensity." Apparently no spectroscope was at hand at this time; but on another night, when a similar 'shine,' less bright, but still sufficient to nearly obscure the stars upon the horizon, was seen, an attempt to discover the auroral line was unsuccessful. It is true that the spectroscope used was not well

[1] *Proc. roy. soc.*, 1879–80, xxx. 332.
[2] *Amer. journ. sc.*, xxxix. 286.

adapted for the purpose; and Prof. Lemström attributes the phenomenon to the same origin as the aurora.

Prof. Lemström refers to Groneman's meteoric theory of the aurora, and no doubt considers it to be disposed of by the experiments above described. It happens, however, that the same number of *Nature* contains an article from Dr. Groneman, in which he says, "I believe I have proved by this research that there existed with the aurora of Nov. 17, 1882, cosmic dust, passing through the upper strata of our atmosphere with great velocity, and giving, according to the most interesting observation of Mr. Rand Capron, 'the usual green line' of the aurora spectrum;" and, further, "It is very remarkable that this experiment comes at the same time as the interesting experiment of Prof. Lemström, showing that electric currents are able to give a development of light in our atmosphere, possessing the same number of undulations in a second as the auroral light. Now our meteoroid being part of an aurora, it gives a stronger proof of the origin of that phenomenon than Prof. Lemström's experiment, the greatest attraction of which is that we are able to repeat it arbitrarily and with our own means. Further, I have always maintained that electricity, excited easily by friction, must be one of the causes of the auroral light . . . and it seems to me very plausible that cosmic matter, approaching the earth, induces electric currents through the air. Therefore I think that the results of Prof. Lemström are in full harmony with the idea of a cosmic origin of aurorae." — (*Nature*, May 17, 31, June 7.) E. H. H. [75

CHEMISTRY.

(Organic.)

A new acid occurring in the juice of the beet. — E. O. Lippmann claims to have discovered a new acid in the incrustations which form in the evaporating-pans from the juice of unripe or partially decomposed beet-roots. Analyses gave results corresponding to oxycitric acid

$$\left(COOH-CH_2-C\frac{OH}{COOH}C{}^{H_2}_{COOH}\right),$$

obtained by Pawolleck by boiling chlorcitric acid. — (*Berichte deutsch. chem. gesellsch.*, xvi. 1078.) C. F. M. [76

Cinnoline-derivatives. — V. v. Richter found, that, by warming an aqueous solution of the diazo-chloride of orthophenylpropiolic acid, a carboxylic acid of *cinnoline* was formed, a substance which he regards as an analogue of chinoline.

Chinoline.

Cinnoline.

— (*Berichte deutsch. chem. gesellsch.*, xvi. 677) C. F. M. [77

Compounds of the ketones with hydrazine. — The action of phenylhydrazine upon ketones seems to be analogous to that of hydroxylamine. With acetone, H. Reisenegger obtained the compound $C_6H_5N_2HC(CH_3)_2$, which was decomposed, by warming with dilute acids, into acetone and phenylhydrazine. Acetophenonphenylhydrazine resulted from the action of phenylhydrazine upon acetophenon. Oenanthol gave the substance $C_6H_5N_2HC_7H_{14}$. With dimethylhydrazine, acetophenon formed chiefly $(CH_3)_2N_2C{}^{C_6H_5}_{CH_3}$. — (*Berichte deutsch. chem. gesellsch.*, xvi. 661.) C. F. M. [78

METALLURGY.

Sulphuric acid from pyrites. — There are very evident advantages in using pyrites instead of brimstone for the manufacture of sulphuric acid, provided the right kind of pyrites is at hand. The qualities necessary are a high per cent of sulphur and iron, in order that the cost of handling may be a minimum. Lead, zinc, calcium, and magnesium can only be present in very small quantity, as they will roast to sulphates, and so cause a loss of sulphur; moreover, they lessen the value of the iron as a by-product. Copper to the amount of two or three per cent is found in some of the best pyrites for this purpose, and is extracted as a by-product. But the especial element to be avoided is arsenic, both on account of the rapid corrosion of the chambers, and the rendering of the acid unfit for many uses. The cost of a ton of oil of vitriol made from brimstone is estimated at \$13.58; made from pyrites, at \$8.22. A number of localities in America furnish pyrites of good quality. The only alterations in the plant are the addition of a Glover tower, and the substitution of suitable kilns, of which illustrations are given, as well as of the Schaffner shelf-burners. — (*Eng. min. journ.*, May 5.) R. H. R. [79

The Henderson gas-furnace. — This furnace attempts to attain to the highest heats required in the shortest possible time, and with a complete utilization of the fuel. These objects are reached by the use of separate engines, one for the supply of air for the generation of the gas, and the other for its combustion. The details of a trial and illustrations of the furnace are given. The consumption of fuel, three hundredweight per hour for the two-ton furnace, is low. — (*Eng. min. journ.*, May 19.) R. H. R. [80

GEOLOGY.

The mines of Cuba. — Salterain gives a brief account of the mines now worked, or that have been worked in the past, at least so far as known by the general inspection of mines. The 'minas de asfalto y de aceites (oils) bituminosos' are divided into mines of asphalt, of petroleum, and of naphtha, and number seventeen in all. The prospects are considered favorable, about eleven or thirteen hundred tons being produced annually. They are situated mostly in the provinces of Pinar del Rio, Matanzas, Santa Clara, Pto. Principe, and Habana. The copper-mines are thirty in number, almost all situated in the province of Santiago de Cuba, and a few in Santa Clara. The mineral consists of veins of sulphate of copper, oxide of copper, native copper, carbonate of copper, and indications of copper pyrites, all of which, at a certain depth, are supposed to unite in one vein of sulphate of copper. The iron-mines, seventeen in number, are all situated in the province of Santiago de Cuba. The iron consists of large superficial masses of oligist and magnetic iron ore. Manganese is very abundant in the province of Santiago de Cuba, but only two mines have been registered on account of its small commercial value. There are five gold-mines situated in the provinces of Santiago de Cuba and Santa Clara, whose prospects are considered good, but which are not worked at present. Guano is worked in the islets south of Cuba, and 104 workmen were employed on this work last year. — (*Breve reseña miner. Isla de Cuba.*) J. B. M. [81

The Prescott (Arizona) mining region. — A map of this region, with some account of the rocks and veins, has been published by John T. Blandy. The rocks appear to be mainly granites, argillites, and schists. The majority of the veins trend approximately north and south. In the stratified rocks many veins occur having the strike and dip of the enclosing rock, but they are of limited extent. In the Peck district the veins are of quartz, carrying silver in the form of chlorides, sulphides, and in galena. The argillite has been eroded away so that some of these veins stand as much as fifty feet high, while they are not more than six feet thick at the base. In the granite ridge next north, the veins are quartz and barite, carrying silver, while in the gneissoid rocks they are part silver and part gold bearing. The veins in the Mount Union granite are principally gold bearing, the gold being free on the surface, but in pyrite in depth. The chief portion of the remaining veins in the region are mixed gold and silver bearing, some being as much as thirty feet in thickness. Some veins of copper pyrites also occur. — (*Trans. Amer. inst. min. eng., Boston meeting.*) M. E. W. [82

GEOGRAPHY.

Russian cartography. — M. Michel Venukoff presents frequent brief reports of Russian explorations and topographic work to the French geographical society, and has recently described the annual exhibition of astronomical and geographical works held last April in the Winter palace at St. Petersburg. The number of exhibits exceeded one hundred and forty, among which the more notable were a route-map of Russia in Europe (1 : 1,050,000), in twenty-five sheets, of which seventeen are finished; the latest sheets of the special maps of the same country (1 : 420,000), published under the direction of Gen. Strelbeitsky; the general map of Russia in Asia (1 : 4,200,000), in eight sheets, extending to lat. 30° N; maps of the provinces of Finland and Bessarabia; of the peninsula of Kamtchatka, prepared at Irkutsk; of the territory of Semipalatinsk, lithographed at Omsk; the Chinese and Persian frontiers (1 : 840,000); and many others of regions concerning which our chief knowledge comes from Russian surveys. — W. M. D. [83

(Arctic.)

Notes. — Professor J. E. Nourse of Washington announces that he has in preparation a work relating to American polar expeditions. —— The Russian imperial geographical society of St. Petersburg suggests that the observations of the international polar stations be prolonged over another year, on the ground that a single year's observations cover too short a time to afford really satisfactory comparative results; and, moreover, it will be necessary for some of the more advanced parties to make an end of their observations before the full year is out in order to be sure of returning during the present autumn. —— Reports from Bering Sea indicate that the winter there has been a severe one. Early in the spring there was an abundance of ice as far south as St. Paul Island. Very few whales had been taken up to latest advices. —— The report of the court of inquiry into the circumstances of the loss of the Jeannette and the death of members of the expedition is just printed. It does not contain the private journals of De Long and Collins, nor the papers of the latter which were before the court. The text of the report has been mostly summarized by the daily press, and contains nothing new of importance. It is presumed that the log-books, and records of observations, etc., are reserved for a report on the results of the voyage, to be hereafter issued. The most valuable thing in the whole document, which contains a number of maps and diagrams, is the map of the Lena delta constructed by Nindemann, which contains additions to and corrections of the maps in present use. — W. H. D. [84

(Asia.)

Notes. — The Revue géographique presents its subscribers with a new chart of Asia on a scale 1 : 34,000,000. Although containing some new matter, it is not up to date, and is of very imperfect mechanical execution. —— The Russian explorer Konchin telegraphs from Krasnovodsk, that, in crossing the steppe between Charzhui and Uzboi, he has discovered that Kalitin was mistaken in supposing it to be traversed by an ancient channel of the Oxus. What the latter explorer, three years ago, took for the dry bed of the Charzhui-Daria, is really only a plain bounded on the north by a series of elevations, and appearing to have no definite limits toward the south. —— Potanin and Skassi are about to explore the Chinese province of Gan-su and the adjacent parts of Mongolia. Sukhacheff, a young proprietor of Siberian gold-mines, has contributed 20,000 rubles toward the expenses of the exploration. —— The topographic and geodesic work in northern Khorassan and southern Turkestan being finished, the boundary-line between Russia and Persia from the Caspian to the Heri Rud River of Afghanistan will be established immediately. —— The definite establishment of the boundary between the Russian province of Semipalatinsk and the Chinese district of Tsungari will also be concluded this summer. By recent conventions a considerable part of the basin of the upper Irtish River is annexed to Russia. Topographers are busily engaged in determining its limits, while others continue the work of demarcation of the districts of Kuldja and Tarbagatai, which is already well advanced. Still others are developing the official limits between the basins of the Syr Daria and the Tarim rivers. — W. H. D. [85

Oxus and Caspian. — A recent report on the levellings undertaken by the Russian engineers to determine if the Oxus (Amu-daria) could be turned from its present channel, which leads to the sea of Aral into the Usboi channel, leading to the Caspian Sea, decides that it is impossible without extended artificial works. A canal would have to be constructed for a length of over two hundred versts, at a cost of at least fifteen to twenty million rubles, before it would be possible to divert the Oxus from its present course. — (*Peterm. geogr. mitth.*, 1883, 231.) W. M. D. [86

(*Africa.*)

Notes. — Joseph Thompson's party has been heard from, having been obliged to retreat to Mombasa, on account of hostilities excited by a caravan in advance of them. All well, and would make another start with a different caravan. —— Schweinfurth has made a scientific journey from Cairo to Mirsa Tobruk in Cyrenaica. —— News has been received from the delayed Italian expedition to Abyssinia and the coast of the Red Sea, according to which the principal official party are detained at Debra Tabor by King John, while the explorer Antonellé has succeeded in getting away from Assab and in travelling through the Aussa country, previously closed to Europeans, to Schoa. —— Dr. Pogge has returned to Mukenge, according to a letter forwarded by Portuguese traders from Malange, and will shortly depart for Europe. —— The German traveller Flegel has returned to the coast from his journey in Adamaur. —— The British government has annexed the territory lying south-east of the former limits of Sierra Leone as far as the Liberian boundary, between that and the Sherbro Islands. —— Several French trading-stations have recently been established on the Futa Diallon coast, northward from Sierra Leone, in the hope of opening a lucrative traffic with the rich interior districts. —— The French naval surgeon Colin has been intrusted with a mission to the old gold-country of Buré on the upper Senegal. —— The Morocco authorities have permitted Spain to undertake a topographical investigation of the country around Santa Cruz de Mar Pequena, on the coast opposite the Canary Islands. —— The khedive has appointed the minister of the interior and former governor of the Soudan, Eyoub Pacha, to the presidency of the Société de géographie de Cairo. The general secretary Is Dr. Bonola. —— The credits granted for the Algerian administration, by the commission to revise the estimates, amount to about twenty-eight and a half million francs, of which about three million francs are for purposes of colonization. The imports into the colony from all sources in 1880 were about eighty millions, and the exports about fifty-six millions. The customs receipts from all sources were about ten million francs. —— Lieut. Angelo Cardozo of the Portuguese navy has just returned from Mosambique, where he has been eight months engaged in explorations in Sofala-land. He ascended last September from Inhambane toward Mulamula and Pachano, along the mountains to Maringua, and across the Sabia River to Goanha; thence, descending the Gorongoza to Sofala, he returned to Inhambane by the seacoast. —— Herr Beine has just been sent by the International African association to relieve Becker and replace M. Maluin, whose state of health requires an immediate return to Europe. —— M. J. Lapeyre, second in command of the Giraud expedition, whose health had given way, was obliged to return from Aden to France on that account. — W. H. D. [87

BOTANY.

Systematic histology. — By this term, Vesque designates the systematic classification of plants on the basis of histology. The variations of histological elements, as regards size, shape, and distribution, even in a single genus or species, are very wide, and, with limited exceptions, have not hitherto been regarded as very useful characters in classification. Vesque endeavors to show by an examination of the orders Capparidaceae, Cruciferae, and Frankeniaceae, that some histological characters are so nearly constant as to justify their employment in systematic botany. Such, for instance, are the stomata and hairs, the mucilage-cells, the palisade-cells, the shape and composition of the fibro-vascular bundles, etc. But, as was to be expected, the cases in which the histological characters are uncertain are so numerous as to be discouraging. That the species in many genera can be arranged in natural groups on the basis of their minute structure appears to be pretty clearly made out by Vesque's contributions. — (*Ann. sc. nat.*, Oct., vi. xv. 2.) G. L. G. [88

Flowers of Aesculus glabra. — One of Prof. Coulter's students finds that the perfect flowers of the buckeye are protogynous, while others, which at first sight appear protandrous, really have imperfectly formed pistils. They are thus polygamous, with, it is thought, a tendency to monoicism. Bees, especially Apis, visit them, but go only to unopened buds, from which they obtain nectar by crowding their tongues between the petals. "The open flowers were avoided, and could only have been fertilized by the chance of being near the buds; for the bees had evidently learned that the latter contained the nectar. . . . It is a case of an insect attracted by a flower which it does not visit, but may accidentally fertilize, and obtaining nectar from a flower which it can neither fertilize nor obtain pollen from." The species is worthy of further study. — (*Bot. gazette*, June.) W. T. [89

ZOÖLOGY.

(*General anatomy and physiology.*)

Olfactory lobes of insects and vertebrates. — G. Bellonci, in continuation of his two previous articles (*Mem. accad. sc. Bologna*, 1880, and *Atti accad. reale lincei*, 1880–81) on the olfactory lobes of arthropods, now reports his further observations, which he has also extended to vertebrates. The same fundamental plan determines the structure and relations of the olfactory lobes in both the higher arthropods and the vertebrates. The olfactory and commissural fibres of the lobes are resolved into a fine reticulum, which, grouped in certain spots, forms what Bellonci calls the olfactory glomeruli. The lobes of arthropods have an outer portion with a diffuse reticulum, and an inner portion with glomeruli. In vertebrates the ganglion-cells lie within the region of the glomeruli. In vertebrates and crustaceans there are numerous small, and fewer large, cells. In insects the elements are of small or medium size. In both arthropods and vertebrates the fibres establish both a direct and a cross (chiasma) communication between the olfactory and optic lobes; likewise between the olfactory lobes and the higher centres (reniform bodies of Squilla, fungiform of insects, and hemispheres of vertebrates). These resemblances the author attributes to an analogy of function, and not to a morphological homology between vertebrates and arthropods. The observations were made on Squilla, Gryllotalpa, the eel and frog. — (*Arch. ital. biol.*, iii. 191. A wrong title is given at the head of the pages.) C. S. M. [90

Protozoa.

Action of tannin on Paramecium. — H. J. Waddington states, that, by bringing a drop of a solution of one part tannin in four parts glycerine in contact with a drop containing a Paramecium, the motion of the animal is stopped, and the cilia become beautifully distinct. They appear quite straight and surprisingly long, equal to the short diameter of the body. Previous ideas as to the size and number of the cilia have been very incorrect. To kill infusoria he recommends a saturated alcoholic solution of sulphurous acid; for, if a small quantity be added to water, the gas is set free, and the animals in the water poisoned. He also reports an ingenious device to catch infusoria: crumbs of very hard baked biscuit are put in the water, where they will be held up by confervae; fungoid growths spring from each crumb, the infusoria collect between the filaments as in a favorite resort, and the whole colony may be captured by pulling out the crumb. — (*Journ. roy. micr. soc. Lond.*, iii. 185.) C. S. M. [91

Descriptions of rotifers. — To the eight species previously described of the genus Floscularia, C. T. Hudson now adds three, and gives also some notes on F. regalis Hudson. These four last-mentioned species are described and figured, and a synoptic table of all the species is added. In an appended note, the author comments on Leidy's Acyclus and Dictyophora (cf. SCIENCE, i. 37). He thinks Acyclus is related to the floscules. "Its 'oral cup' with the 'incurved beak' may be fairly said to be the buccal funnel of a floscule reduced to the possession of one lobe, viz., the dorsal one." The remainder is concerned with details, and with the degradation of certain rotifers, considered in connection with the absence of the trochal disk. — (*Journ. roy. micr. soc. Lond.*, iii. 161.) C. S. M. [92

Worms.

Anatomy of Gephyreans. — Dr. C. Ph. Sluiter gives a preliminary notice of his observations on the anatomy of various species. An abstract will be given of his definite memoir when published. — (*Zool. anz.*, vi. 222.) C. S. M. [93

Annelid messmates with a coral. — J. W. Fewkes finds annelid tubes formed on the rim of young Mycedium fragile. As the coral grows, it spreads round the worm-tube; but the latter grows usually equally with coral. The presence of these tubes affects the regular growth of the coral. The species of worm does not appear to have been determined. — (*Amer. nat.*, xvii. 595.) C. S. M. [94

Spermatogenesis of Nemertines. — In an article in the *Revue sc. nat.*, 1882, 165, Sabatier describes the development of the spermatozoa in nemertean worms. The parent cells separate into two parts, the central blastophore and peripheral bodies, which become independent, and attach themselves to the wall of the spermisac. From these bodies the spermatozoa arise by differentiation of the peripheral part into spherules, which elongate and become spermatozoa. In his theoretical conclusion, the author adopts the theory first advanced by Minot (*Biol. centralbl.*, 1882), that the ordinary cells are neuter, or combine both sexual elements, and that when a separation takes place the sexual products are generated. He makes an addition, however, to the theory, by the hypothesis that the central portion is female, the peripheral male. (There are many facts which appear at present irreconcilable with this view of the sexual relations within the cell.) — (*Journ. roy. micr. soc. Lond.*, April, 1883.) C. S. M. [95

VERTEBRATES.

Action of alcohols on the heart. — The relative effects of different alcohols of the marsh-gas series of hydrocarbons upon the ventricle of the frog's heart have been compared experimentally by Ringer and Sainsbury. The method of experimenting was to place the heart in a Roy's tonometer, and feed it with the extract of dried bullock's blood until it was beating normally; the alcohol used was then added to the circulating liquid in such quantities, determined by previous experiments, as to completely arrest the contractions of the heart within an hour. The toxic action of the alcohols used was measured by the dose sufficient to arrest the activity of the heart. The following results were obtained. Normal methyl, ethyl, and propyl alcohol, — all three stop the heart in diastole, the ventricle losing its power to beat spontaneously, and refusing to respond to external stimulation. The excitability of the heart to electrical stimulation is diminished. The 'period of diminished excitability' is shortened. The primary effect of the alcohols on the heart is not, as might be supposed from their therapeutical use as cardiac stimulants, to increase the force or frequency of the ventricular contractions. The height of the curve given by the tonometer diminished steadily from the first application of the alcohol, and the frequency of the beats remained unaffected, except in the later stages, when the power of the heart to beat spontaneously was lost. With regard to the toxic action of the different alcohols, the following numbers are given (the figures represent the number of minims of absolute alcohol in a hundred cubic centimetres of the circulating liquid, necessary to cause complete arrest of the heart): methyl, 205.5; ethyl, 114; propyl (primary), 59.3; isobutyl, 17; isoamyl (amyl alcohol of fermentation), 6.6. The activity of the higher members of the series increases rapidly; and as the propyl, butyl, and amyl alcohols are constituents of fusel oil, we have evidence of the directly injurious effect of this impurity of ordinary alcoholic drinks. — (*Practitioner*, xxx. v. 339.) W. H. H. [96

Pulmonary epithelium. — Bozzoli and Graziadei publish a note chiefly to claim priority for certain of their observations on the lungs. We have only to notice that they have not seen any hyaline plates without nuclei in the epithelium, such as Feurstack has described. They also again insist upon the presence and pathological importance of groups of little cells, not yet differentiated into the special pulmonary epithelial cells (plates). — (*Arch. ital. biol.*, iii. 222.) C. S. M. [97

Birds.

Molecular layer of the retina. — According to Bellonci, the formation of the inner molecular layer of the retina begins in the chick on the eighth day of incubation. At that time there is a special row of clear cells just outside the layer. The cells in the situation of the layer disappear on the ninth day: the clear cells undergo fatty degeneration of the nucleus, and disappear by the twelfth day. They form the molecular layer, which, however, continues to enlarge. Both the inner and outer molecular layer are penetrated by optic nerve-fibres. Thus is produced a structural relation with the molecular layers of the brain. — (*Arch. ital. biol.*, iii. 196.) C. S. M. [98

The birds of Tonkak. — In this paper Herr Müller has given us an elaborate review of the birds of this island, based on a collection of sixteen hundred skins of one hundred and fifty-five species. The paper contains many systematic notes of interest. The author has prepared an extended set of tables from which he concludes that the Tonkak birds belong rather to the Indo-Chinese sub-region than to the Indo-Malayan as given by Wallace. — (*Journ. f. ornith.*, xxx. iv.) J. A. J. [99

Mammals.

Development of the liver and lungs. — In connection with his researches on the development of the body-cavity Uskow made some observations on the liver and lungs of embryos. From the sinus venosus there grow out irregular cavities into the septum transversum, which extend into papillary growths, projecting into the pericardial cavity. The papillae are, of course, covered by a continuation of the epithelium of the pericardial cavity. They afterwards unite into a spongy mesh of tissue, into which the liver extends as it grows. The further history was not followed, but it is probable that the hollow outgrowths from the sinus venosus become hepatic vessels.

Concerning the lungs, from a study of a rabbit embryo of a little less than ten days, Uskow draws the following conclusions. At the time of the closure of the 'vorderdarm,' the separation of oesophagus and trachea is already indicated. The lung is an unpaired evagination of the ventral wall of the 'vorderdarm.' The trachea and the lung arise at the same time, and independently; but the separation of the lung from the 'vorderdarm' precedes the separation of the trachea. The lung arises immediately in front of the liver; at the same time the cells of the mesoderm around the lung proliferate; and Uskow believes that the pleural (i.e., coelom) epithelium forms not only the pleural epithelium, but also the deeper-lying mesodermic elements (muscles, etc.) of the lung. — (*Arch. mikr. anat.*, xxii. 219.) C. S. M. [100

A hybrid between the gayal and zebu. — Dr. Julius Kühn announces the birth, at the agricultural institute of the Halle university, of a hybrid between the gayal of eastern India and the long-horned race of zebus known as sangas, which was held in domestication by the ancient Egyptians, and is now abundant in Soudan and Abyssinia. The hybrid in question is a female; it weighed, at birth, 21.5 kilograms, or about one-twentieth the weight of the sanga mother. The latter is of a mottled red and white color, while the calf is of a clear red brown, only the belly and inner sides of the legs and the fetlocks being white. The hump on the withers, so characteristic of the zebu, is only slightly developed. "In the birth of this animal it is shown that animals of the most primitive forms, which for thousands of years have had unchanged surroundings, by suitable treatment, may remain unimpaired in fertility, even when placed in relations which are in the greatest degree different from those of their native home." — (*Zool. garten*, xxiv. 1883, 126.) F. W. T. [101

ANTHROPOLOGY.

Origin of the Magyars. — Mr. Herman Vambery published a work in Leipzig last year, in which he takes the ground that the Hungarians are of Turkish and not of Finno-Ugrian origin, as is believed by most ethnologists, and especially by M. Hunfalvy. A census of the Turco-Tatar stock is given, which may be of service to some of our readers.

Turco-Siberians	141,992
Eastern Turkestan	1,040,000
Kirghiz	2,299,366
Kara-Kirghiz	350,000
Turcomans	1,000,000
Kara-Kalpaks	70,000
Usbegs	2,500,000
Kipchaks	70,000
Kuramans	77,301
Sarts	900,000
Bushirs	500,000
Tatars	638,710
Nogajs	200,000
Kuvaks [?]	600,000
Kalmuks	71,000
Transcaucasic Turks	900,000
Iranic Turks	200,000
Osmanli	10,000,000
	21,558,369

— (*Archiv. per l'anthrop.*, xii. 297.) J. W. P. [102

Macrobiotia. — The narrative of Genesis about the long lives of the patriarchs has very frequently led to the collation of the ages of persons who have lived to a very great age. Lord Malahide is inclined to give credit to the great number of cases of recorded longevity occurring among the inscriptions recovered from old Roman graves in Algeria and Tunisia. Mr. Renier has published a collection of these, and a still more complete series is by Mr. Willman, under the auspices of the Royal academy of Berlin. Upwards of ten thousand inscriptions are thus calendared.

The following is a list from Numidia: —

101	14 persons.	110	5 persons.
101	10 "	115	4 "
102	2 "	120	3 "
103	1 person.	125	2 "
105	7 persons.	126	1 person.
106	1 person.	127	1 "
107	1 "	131	1 "
108	1 "	132	1 "

At Mastar, a small town, the cemetery yields the following: —

Anna R.	101	Marcela	120
Coecilius	100	Januarius	101
Gargilius	103	Martialis	105
Granius	110	Another	115
Ninava	115	Jussata	105
Petreia	115		

Lord Malahide, in order to show the credibility of these figures, speaks at length upon the duties of the Roman censors. — (*Journ. anthrop. inst.*, xii. 441.) J. W. P. [103

The Pawnees. — Mr. John B. Dunbar of Bloomfield, N.Y., has brought together in a quarto pamphlet his researches into the Pâni family of North American Indians. The tribes embraced in this group are the Pawnees, Arikaras, Caddos, Huecos or Wacos, Keechies, Tawaconies, and Pawnee Picts or Wichitas. The last five are the southern or Red River branches. A brief account of each of these is given in the first few pages of the pamphlet. The third paragraph is devoted to the Arikaras, and the remainder of the monograph to the Pâni, or Pawnees. A very extensive bibliography of the stock has been collected, commencing with the expedition of Lewis and Clarke, and including the publications of Pike, Long, J. T. Irving, Murray, Hayden, and the reports of the several commissioners of Indian affairs. Earlier notices are found in la Harpe, du Pratz, and Charlevoix.

The name 'Pawnee' is probably derived from *Pá-rik-ĭ* (a horn), referring to their peculiar scalp-lock. The original hunting-ground extended from the Niobrara, south to the Arkansas, but no definite boundaries can be fixed.

Mr. Dunbar has collected from various sources the traditions of their origin and migrations (§ 8), their conflicts (§ 9), their census (§ 10), and their later history since the beginning of our century. Considerable space is given to their tribal organization, physical characteristics, social usages, dress, names, lodges, arts, trade, feasts, hunting, war, medicine, mourning, religion, calendar, present condition and prospects. Brief chapters are devoted to the celebrated chiefs, Pitale-sharu, Lone Chief, and Medicine Bull. — J. W. P. [104

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

STATE INSTITUTIONS.

State university of Kansas, Lawrence.

Weather report for June. — The chief meteorological features of this month were the low mean temperature and the abundant rainfall. During the fifteen preceding years, three Junes have been cooler than this, and only one (1876) has had a larger rainfall.

Mean temperature, 71.38°, which is 2.87° below the June average. The highest temperature was 94°, on the 22d and 30th. The mercury reached or exceeded 90° on only six days. The lowest temperature was 48.5°, giving a range of 45.5° for the month. Mean temperature at 7 A.M., 66.22°; at 2 P.M., 80.3°; at 9 P.M., 69.5°.

Rainfall, 7.73 inches, which is 2.80 inches above the June average. There were seven thunder-showers, one of which, on the night of the 11th, continued for six hours, and brought 2.92 inches of rain. The entire rainfall for the six months of 1883 now completed has been 21.80 inches, which is 5.05 inches above the average for the first half-year of the past fifteen years.

Mean cloudiness, 38.56% of the sky, the month being 3.64% clearer than the average. Number of clear days (less than one-third cloudy), 14; half clear (from one to two thirds cloudy), 12; cloudy (more than two-thirds), 4. There were four entirely clear days, and only one entirely cloudy day. Mean at 7 A.M., 42.67%; at 2 P.M., 39.33%; at 9 P.M., 33.67%.

Wind: S.W., 24 times; S.E., 24 times; N.W., 17 times; N.E., 14 times; N., 4 times; S., 4 times; E., 3 times. The entire distance travelled by the wind was 10,737 miles, which is just two miles above the June average. This gives a mean daily velocity of 357.90 miles, and a mean hourly velocity of 14.91 miles. The highest velocity was 45 miles an hour, on the 22d and 23d. The thunder-storm of the 11th was ushered in at 11.30 P.M. by a very strong 'straight' wind, which unroofed a portion of the Central school building at Lawrence, but was in no sense a tornado.

Mean height of barometer, 29.028 inches; at 7 A.M., 29.050 inches; at 2 P.M., 29.013 inches; at 9 P.M., 29.020 inches; maximum, 29.217 inches, on 14th; minimum, 28.671 inches; monthly range, only 0.546 inch.

Relative humidity: mean for month, 74.3; at 7 A.M., 83.1; at 2 P.M., 57.7; at 9 P.M., 82.1; greatest, 97, on 23d and 24th; least, 37, on 14th.

PUBLIC AND PRIVATE INSTITUTIONS.

Ohio Wesleyan university, Delaware, O.

Additions to the museum. — The increase to the collections for the year amounts to 9,202 specimens. The aim of the curator is not to build up a great museum, but one of great educational value, which shall in time contain every specimen needed to explain the facts of natural history as presented in the text-books of the department. All purchases and solicited exchanges are for this end, and even the volunteer exchanges are turned in this direction as far as practicable. W. F. Falconer has given an extensive collection made at the phosphate beds of Charleston, S.C. An elephant's tooth in this collection measures ten by fourteen inches, and weighs twenty-nine pounds.

Prof. R. E. Call of Nebraska, a most enthusiastic naturalist, spent the summer of 1882 on a collecting trip through Georgia. The museum joined with other institutions in defraying his expenses, and sharing the results. Although all the material has not been distributed, over five thousand specimens have been received, and a large number of new and valuable species.

The U. S. fish-commission has presented a collection illustrating the marine fauna of the New England coast. It contains nearly one hundred species, many of which were obtained by dredging at depths as great as two hundred fathoms.

Collections of importance have also been received from the late Mr. C. R. McClellan, a former assistant, and from Revs. J. M. Barker of Mexico, and H. Mansell of India, and the Brothers Willis, recently returned from a tour of the world.

The shelves in all the cases are overcrowded; and at least twenty-five thousand specimens are packed away in boxes and drawers, awaiting study, and room in which to display them. The erection of one or more new cases is required.

NOTES AND NEWS.

The summer courses of instruction in chemistry, offered to teachers by Harvard university, opened July 6, in the chemical laboratories of Boylston hall, and will continue six weeks. The course in general and descriptive chemistry is taken by twelve persons, the course in qualitative analysis by ten, and quantitative analysis by five. There are also eight persons who are engaged on advanced quantitative analysis, organic chemistry, and original research. Lectures are given twice a week on general chemistry, dailv on qualitative analysis, and twice a week on quantitative analysis. The laboratories are open daily from 8 A.M. to 6 P.M. The following states are represented: Maine, Massachusetts, New York, New Jersey, Ohio, Illinois, Michigan, Minnesota, Nebraska, and Georgia. Of the thirty-five persons mentioned above, five are women, and eight are continuing their work from former courses. As in previous years, these courses are under the direction of Dr. C. F. Mabery.

— Upon the death of Charles Darwin, last year, the advocates of evolution in the Paris anthropological society organized a *Conférence annuelle transformiste*, in which one of their number who is a specialist shall set forth the manner in which the doctrine of transformism has affected his department of research, and also the arguments which his studies have furnished for the substantiation of the doctrine. The opening lecture of the course was delivered by M. Mathias Duval, upon the mutual relations of evolution and the embryology of the eye, and is published in the *Revue scientifique* for May 12. The first part of the discussion is an attack upon the doctrine of special creation and final causes. It does not seem to have come to the notice of our French colleagues, that the doctrine of special creation, like all other doctrines (evolution, for instance), has modified itself from time to time by the increase of knowledge. "These admirable appropriations of an organ to an end," says M. Duval, "are explained by the gradual perfecting of a mechanism, which, setting forth from simple and elementary adjustments, develops, by heredity and selection, the forms that are more and more advantageous to the individual. Upon the question whether embryology confirms this theory, it is proposed to examine the successive forms which the eye presents in the animal series, and the successive stages of its development in man or the higher vertebrates. In other words, the phylogeny will first be questioned, and afterward the ontogeny, of the *globe oculaire*, to see whether these two series of facts are a repetition the one of the other." Briefly passing over the unicellular forms, and those in which the eye is undifferentiated, the author commences his more special investigation with the tunicates and amphioxus, from which point the argument is conducted with great precision, and is well illustrated.

— The French academy of sciences proposed as a subject for one of its 1882 prizes the following: "To find the origin of the electricity of the atmosphere, and the causes of the great development of electrical phenomena in storm-clouds." Several memoirs were received by the academy; but no one of them was adjudged worthy of the prize, although a reward and encouragement of a thousand francs was granted to one of the competitors. The academy, therefore, continues the above as one of the prize subjects for 1885. Memoirs will be received up to June 1, 1885. Each must be accompanied by a sealed envelope containing the name and address of the author. The envelope will not be opened unless the memoir is successful. The value of the prize is three thousand francs.

— The sixth annual convention of American librarians will be held in Buffalo, Aug. 14 to 17. The opening address will be delivered by the president, Justin Winsor. Excursions will be made down the Niagara River, and, at the close of the session, to Niagara Falls. Further details may be obtained from Mr. John N. Larned, Young men's library, Buffalo.

— The Smithsonian institution will soon publish

Professor Bolton's Catalogue of scientific and technical periodicals. Proof-sheets have been sent to the leading libraries of the country, with the request that it should be noted what journals might be on their shelves; so that we shall have a complete list of available scientific periodicals.

— The Johns Hopkins university circular for June is given up to a statement of the work of the past year, and a programme of the courses offered for the year 1883-84.

— According to *Nature*, the emperor of Austria, on June 5, inaugurated the new Vienna observatory on the Turken Schanze, in the northern outskirts of the town. The new building has taken nine years to construct; and during that time the present director has travelled all over Europe and America in order to study the construction and equipment of the best observatories. The result is, that the Vienna observatory is probably one of the most complete in existence.

— Dr. Ph. Paulitschke's work on the '*Geographische erforschung des afrikanischen continents*' (Vienna, 1880), in which he gave a brief statement of the work of all explorers from ancient times down to the date of publication, is now supplemented by his '*Afrika-literatur in der zeit von 1500 bis 1750 n. Chr.*' (Vienna, 1882), — a work of 122 pages, with 1,212 titles. Valuable cartographic aid to study in the same direction is given in H. Kiepert's maps of the progress of African exploration from 1750 to 1873, and of the expeditions of this century, colored according to their nationality; these being published in the journal of the Berlin geographical society in 1873 and 1874, and again in the ten larger scale charts of inner Africa by Petermann and Hassenstein, issued as a supplement to the *Mittheilungen* in 1863.

— Mr. W. G. Black is preparing the index for his Folk-medicine, already in print, and to be issued immediately by the Folk-lore society. The work treats of the origin and communication of disease, and the influence in folk-medicine of charms, saints, and heavenly bodies.

The same society hopes soon to obtain for publication a collection of Zulu nursery literature, which has been in the hands of Bishop Callaway for ten years. This will be an addition to folk-lore of very great interest and value.

SCIENCE.

FRIDAY, JULY 27, 1883.

THE ADVANTAGES OF STUDY AT THE NAPLES ZOÖLOGICAL STATION.

THE opening of the marine laboratory in Naples in 1874 marks an important epoch in the progress of biological studies, as seen, not only in the prodigious and ever-increasing amount of work which it produces, but also in the general interest which its success has inspired in other quarters. As in America sea-side schools and laboratories may be traced to the example set at Penikese, so in Europe most of the marine laboratories owe their origin to influences emanating from Naples. But the beneficial influence of the Naples station is by no means confined to Europe. Already we hear of marine stations in Algiers, in Sydney, and in Java. In Japan too, as we are informed, a laboratory has been established by Professor Mitsukuri in a Buddhist temple, — an example the moral of which is easily drawn. Thus the prediction made by the founder of the Naples station, Professor Anton Dohrn, some ten years ago, — that marine zoölogy was destined to become paramount, and that the earth would soon be encircled by a net-work of zoölogical stations, — seems to be rapidly approaching its fulfilment.

Every one can now see that the Naples laboratory was a gigantic enterprise, magnificent alike in conception and in achievement, although few are aware of the magnitude and varied nature of the difficulties which opposed its progress. It is a matter for rejoicing, that this institution was planned on such broad and liberal views, and with such wise prevision of the course its development should take in order to secure a long and prosperous existence. With the addition of a physiological department now determined upon, it becomes a biological station in the broader sense of the word, — an organization on a grand scale for the study of marine life in all its aspects. Its brilliant career during the first nine years of its existence not only insures its permanency, but also gives pledge of future growth commensurate with the ever-expanding needs of biological research.

The station is no less liberal in its management than comprehensive in its aims; for it opens its doors to naturalists from all quarters of the globe on like conditions. It is the international character of the station, combined with the natural advantages of situation, which has made it, in so short time, the Mecca of biologists, and a seat of unprecedented prolific activity. The mild and equable climate of Naples, the unsurpassed richness of the fauna and flora of its bay, and the best equipped laboratory in the world, conspire to give the Naples station pre-eminence among institutions of its kind, and to render it probable that it will remain what it is now acknowledged to be, — the world's great biological station.

The detailed account given in Miss Nunn's valuable article (Science, Nos. 17 and 18) makes it unnecessary to enter here into a description of the laboratory; and Mr. Cunningham's excellent review of the work which it has already accomplished (*Nature*, March 15) is doubtless accessible to most of the readers of Science.

Let us rather consider the practical question of our own interest, as Americans, in this institution. Except in a single and noteworthy case of very recent date, we have thus far taken no active interest in this matter. The distance between us and Naples has seemed to foster the idea that we have no immediate and common concern with European nations in opportunities that lie so much nearer their doors than ours. But recent events have demonstrated that there *is* a demand on the part of American naturalists for just such opportunities as are now offered at Naples, and nowhere else; and with them political isolation is not likely to be mistaken for scientific isolation. That this demand does not arise from whimsical reasons will certainly be conceded by all who understand its meaning. Still there may be some who will ask if the field for investigation is not sufficiently broad at home, and the facilities for work sufficiently ample, to satisfy the requirements of American naturalists. With all due respect to such queries, we would suggest that they do not contain the gist of the matter: for even on the preposterous supposition that our facilities for biological research are fully as great as those at Naples, no one could claim that they are identical; so that it would still be pertinent to ask, Can we not profitably *add* the advantages in Naples to those enjoyed at home? The real question comes to this: Are there advantages at Naples which are not offered here, and are they worth the time and money required to obtain them? Now, it is no disparagement to home talent and resources, to say that the advantages of study at the Naples station are incomparably greater, and certainly more numerous, than those at our command. More than this, there is not a single laboratory in Europe where the student of natural history can pursue his studies under so favorable circumstances as at Naples. This is doubtless much to say, when we remember that the laboratories of Huxley, Lankester, Lacaze-Duthiers, Van Beneden, Leuckart, Haeckel, Gegenbaur, Claus, Semper, Kölliker, Barrois, and Giard are of world-wide repute; but it is not merely our private opinion, it is an acknowledged fact. Of course, we are not now speaking of the comparative merits of this institution for students just beginning their studies, but for those who are already more or less prepared for independent work.

The Naples station makes no pretension to fulfilling the functions of a school or a college: its aim is to advance biological research; and to this end it consecrates all its energies. It is a laboratory organized and equipped, not for training the inexperienced, but for aiding the investigator. It represents, in many respects, the excellences of all the best laboratories of Europe combined, and surpasses them all in the inexhaustible wealth of its resources, and in the many exceptional advantages that naturally spring from its international character.

Although no lectures or courses of instruction are provided for, an able staff of assistants are constantly employed, whose aid and counsel in all matters pertaining to methods of work leave nothing to be desired. It is one of the great advantages of work at the station, that it gives one opportunities for the acquisition of methods. An institution which pushes research with such energy and success will naturally be prolific in the discovery of ways and means. The station brings together a body of zealous workers from the best laboratories of Europe, and thus, besides giving a rare opportunity for the formation of valuable acquaintances, direct interchange of thought, and discussion of problems, opens another way for the accumulation and refinement of methods. It is in this way that it becomes a sort of international depot for the reception of discoveries and improvements made elsewhere. The heterogeneous material thus obtained is sifted, systematized, tested, further elaborated and refined, and redistributed. The methods of microscopical research published by Paul Mayer, and the well-known discoveries of Giesbrecht, show that the station is doing no less important work as an originator than as an accumulator and a distributer of methods.

Now, whoever knows the value of methods — and we need not argue with those who do not — will admit, that, in this particular, the Naples station is unrivalled, and that, from the nature of things, it will probably remain so indefinitely. However successful we may become in the development and application of methods, we are not likely to see the time when it will not be desirable to see, and to know by experience, how work is done at Naples. This one but all-important matter, to say nothing of the many other advantages that must accrue to an occupant of a table at the station, — such as social intercourse, direct knowledge of a very important fauna, and opportunities of acquiring a knowledge of the four languages with which every naturalist must now be familiar, — makes it very desirable, particularly for our younger naturalists, to spend some time at Naples.

One of the indispensable requisites to successful work in natural history is an extensive library; and this is precisely one of the needs most felt in seaside laboratories. As a rule, naturalists are compelled to select a few of the books which they conjecture will be useful to them, and transport them to the place of study. This method is, of course, very unsatisfactory, for reasons too obvious to be mentioned. The Naples station has met this difficulty by establishing a permanent library in an apartment adjoining its laboratory. Already this library has become one of the most complete biological libraries in Europe, and forms one of the chief attractions of the station. Its management, we are happy to say, is the least conspicuous thing about it. Those accustomed to depend upon public libraries, open only at stated hours, approached only through officials, and encumbered with rules, blanks, fines, etc., have a pleasing sense of relief on finding the doors of this rich library thrown open to them, with the liberty of helping themselves at any time to whatever books are desired, with no further requirement than to place a card bearing their name in the place of each book taken. This simple device enables others who chance to want the same books to know precisely where to find them.

The supply of material furnishes another topic well worth consideration in this connection. It is the method of supply, rather than its richness, which merits attention. An organized body of men is constantly employed for this purpose; and they make it their business not only to know what material can be obtained, but also when and where. These men now work with all the advantages of long experience and systematic training. The occupant of a table has only to announce what object he wishes to study, and it is delivered alive at his table. In this way the investigator is able to accomplish the largest amount of work in a given time, and with the least possible annoyance.

The furnishing of the table also deserves attention. Within twenty-four hours after notice is given, one finds his table ready for use, supplied with drawing-material, a large variety of reagents, staining-fluids, and all the appurtenances required for the most difficult kinds of research. It is not the raw material that one finds on his table, but every thing actually prepared and ready for immediate use. Further needs are promptly supplied on request. Thus every thing is arranged to save the time of the investigator, and render his work as effective as possible. Compare these facilities for study with those offered anywhere else, and the contrast is at once apparent.

The conservator's department, under the direction of Salvatore Lo Bianco, has become one of unusual interest and importance; and the work it is doing deserves to be generally known in this country. The work of this department is the preservation of all the material brought to the station, except what is required to supply the tables and the public aquarium. The success with which this most difficult business of preserving marine animals in lifelike appearance is accomplished, is certainly marvellous, and richly deserves the highest tribute of praise. This department is producing results of immense value to science, and its usefulness is now widely recognized. Its beautiful preparations adorn the shelves of nearly every museum in Europe; and it is constantly sending out supplies to laboratories for teaching purposes. Many naturalists who find it inconvenient to work at Naples are supplied by this department with material in such perfect state of preservation for anatomical and histological study, that they are enabled to carry out their investigations without once visiting the station. There are undoubtedly museums and laboratories in this country that would do well to avail themselves of this opportunity. This department has been created for the special purpose of serving science in the above-named ways, and not for increasing the funds of the station; and hence the preparations are made for a sum that scarcely more than covers the expense of the alcohol and other reagents used in their preservation.

There is still another way in which this department of the station might be of importance to this country. Doubtless some arrangements might be made between our naval authorities and the director of the station, such as have been made in the case of Germany and Italy, which would enable us to send an officer from time to time to the station, with a view to gaining a practical knowledge of the methods of preserving animals. In this way each of our war-ships might be supplied with one officer prepared to take advantage of the rare opportunities for advancing our knowledge of marine life which arise in the course of their distant cruises.

In view of the considerable number of American students in the biological laboratories of Europe, and the many applications on their part for permission to work at Naples, there has naturally been some surprise at the fact that America has hitherto declined to contribute any thing towards the support of the station. The honor of taking the first step towards rectifying our mistake in this matter belongs to Williams college. It is to be hoped that the example set by President Carter and the trustees of this college will not long remain the only evidence of our appreciation of the Naples station. Three or four tables will at least be required to meet the demands of our zoölogists alone, judging from the number now at work there. It is not right that American students should go to Naples as beggars, to be received out of courtesy, or indirectly through the liberality of English or German universities. Of the twenty-six tables now taken at the station, Germany controls twelve; Italy, four; England, two; Russia, two; Belgium, two; Holland, one; Hungary, one; Switzerland, one; and Williams college, one. There are four tables not yet disposed of, two of which, at least, should be secured at once by America. Will not some one or more of our universities take this matter in hand?

The establishment of a biological station at Wood's Holl, which, in the hands of Professor Baird, will doubtless be pushed to a speedy completion, will create facilities for the study of marine life on a much larger scale than we have hitherto seen in this country; and the successful issue of this enterprise, we venture to predict, will increase rather than diminish the number of American naturalists at Naples. Whatever improves our facilities for study will tend to increase the general interest in biology, and to augment the number of naturalists who will seek the best that the world affords in the way of methods. The time will never come when direct interchange of thought, and comparison of methods of research, will cease to be of the highest importance to the biologist. On the contrary, these things will become more and more a necessary part of the experience of every one who aims to be a useful and successful student of life. The progress of biological studies will soon create a demand for more than one international laboratory, and we certainly hope that the new station at Wood's Holl will take this character. The establishment of several great stations at different points, selected according to the relative richness and importance of the fauna and flora, each offering facilities for study similar to those enjoyed at Naples, and open to naturalists of every country, would prepare the way for a concentration and organization of forces, and inevitably raise the standard of work, and check the accumulation of driftwood. It is obvious that the usefulness of one station would not be impaired by the existence of others, since the work of each would be supplementary to that of the others.

The character and importance of the publications of the station have been so well stated by Mr. Cunningham in the article before referred to, that little remains to be said on this topic. In looking over the list of subscribers to the *Fauna and flora*, we are again forced to acknowledge the slender interest which America has taken in the Naples station. Here is a colossal series of magnificent monographs, designed to give an exhaustive treatment of the plants and animals found in the Gulf of Naples, and published at a price that ought to insure them a place in the private library of every zoölogist and botanist in the country; and yet the list of subscribers, according to the last circular, numbers only eight. Even such countries as Holland and Switzerland outdo us. Austria and Russia have each twice this number of subscribers; Italy has nearly four times, England about five times, and Germany ten times, as many.

As our poor representation cannot be attributed wholly to indifference, it is safe to conclude that these monographs are not so generally known as they deserve to be. Thirty of the series have already been announced, six of which have been completed. From two to four are published each year in quarto form, and illustrated with numerous expensive plates, at an annual subscription-price of only twelve dollars and a half. The number of subscribers is now two hundred and seventy, and the three hundred and fifty copies of Dr. Chun's *Monographie der Ctenophorae* — the first in the series — have been already nearly exhausted. The monographs are written either in English, German, French, or Italian, according to the preference of the authors. Such brilliant achievements in the line of exhaustive research as are embodied in these monographs certainly command our homage, and assuredly deserve a more generous recognition than they have yet received in this country.

C. O. WHITMAN.

THE NATIONAL RAILWAY EXPOSITION.[1] — III.

IN England and Europe generally, signals of every conceivable variety have been used; but experience has shown that the semaphore is the best signal, and its universal adoption in Great Britain and on the busiest railways on the continent of Europe is a good example of the doctrine of the survival of the fittest. The exposition, we regret to observe, contains many forms of signals that are neither distinct in appearance nor positive in meaning. It is hard to say whether some of them mean safety or danger. A mere change

[1] Continued from No. 23.

of color from red to white, without any change of form, conveys no information whatever in certain states of the weather and with certain backgrounds. Other signals are alike, back and front. Facing the train, they signify danger; standing edgewise, they mean safety: but unfortunately it is difficult to know whether they refer to an east-bound train or a west-bound train; and, though they may be placed on the right hand of the engineer to whom they refer, this arrangement is not always free from ambiguity.

The semaphore signals, as shown at the exposition, consist of vertical posts which have one or more arms pivoted at their upper ends; and these arms are capable of moving through a right angle in a vertical plane. An arm raised to a horizontal position signifies danger; inclined at an angle of about 45°, it signifies safety. A powerful lamp is fixed near the top of the post; and, when the arm stands horizontally, a disk of red glass stands in front of the lens of the lantern, which then, of course, shows a red light, indicating danger. When the arm drops to an angle of 45°, the red disk moves, and leaves the lantern unobscured, showing a white light, and indicating safety.

The semaphore arms are weighted, so that their normal position is horizontal, indicating danger; and the signalman has to overcome this weight in pulling them to safety. The object of this arrangement is, that the breakage of the connection between the lever in the signalman's cabin and the semaphore will release the signal, and let it fly to danger.

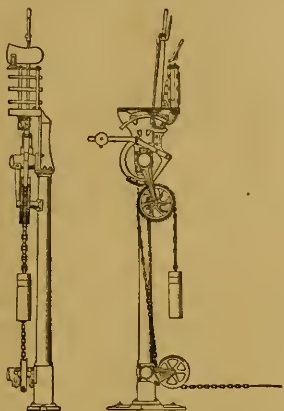
It is usual to place one signal at or as near as possible to both the signalman's cabin and the spot where the engine of an advancing train should stop if the signal is against the train. This signal is called the 'home' or 'main' signal. Another signal is placed some distance off in the direction from which the train comes: this is termed the 'distant' signal. The object of this arrangement is, that, on catching sight of the distant signal, the engineer is warned, and has some time and distance in which to stop his train before he reaches the home signal, beyond which the danger lies.

As the levers work switches and signals at a considerable distance, the connections between them have to be carefully made and protected from accidental injury and the effects of the weather, while the difference in length due to difference in temperature has to be compensated for; so that the signal is moved with certainty, though the wire or pipe connecting it to the lever vary in length several inches in the twenty-four hours, owing to the difference in temperature between the day and night. The Pennsylvania steel company exhibits an especially neat device for keeping the wire or connection to a distant signal always tight. The wire is kept stretched by an ingenious application of the pull of a weight, which acts only when the signal is in its normal position of danger to which it is weighted. When the signal is

SEMAPHORE.

pulled to safety, it is directly controlled by the signalman.

Connections to switches are generally made by means of rods or pipes jointed together,



DEVICE FOR KEEPING SIGNAL-WIRE TIGHT.

and running on rollers. A 'trunking' or wooden covering is then placed over them to protect them from snow and the feet of any-one walking about the yard.

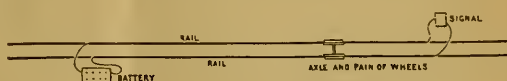
As it is very important that the movement of switches should be absolute and exact under all conditions, — that is to say, that the switch be always either tightly closed or wide open, and never stand partly open, — a compensating arrangement is introduced half way between the switch and the signal, so that, whatever the variation of length of connection from temperature, the switch is unaffected, and its movements can always be under exact control.

COMPENSATING JOINT FOR EXPANSION OF RODS.

The full lines show the position in cold weather; the dotted lines, in hot. It is evident, however much the rod expand, the distance between switch and signalman is unaltered, and therefore the movements of the switch and lever are unaffected.

In working railroads, some difficulty has always been experienced in keeping trains running in the same direction, on the same line of rails, from running into one another, as naturally, on a crowded line, an accidental stoppage to even a fast train may enable a slow train to overtake it and cause a rear collision. The Pennsylvania railroad adopted, some years ago, what is known as the block system, by which a definite interval of space (the distance between two adjoining signal-cabins) can always be maintained between two following trains. The system is too well known to need description here; but Mr. George Westinghouse has invented a system in which the same results are obtained, not by men signalling from one cabin to another, but by the trains themselves operating signals through the medium of electricity. The principle of the invention is easily understood, although the details are complicated and the results marvellous. A battery is connected to each signal by means of the rails, the current flowing to the signal by one rail, and returning by the other. The presence of an axle and pair of wheels on the track enables the current to flow through them, instead of through the signal apparatus. Directly the current is thus short circuited, the signal flies to danger.

This simple principle is so ingeniously worked out in detail, that a train approaching a road-crossing rings a bell fixed on a post at the crossing until the crossing is reached, when the bell stops ringing; and this is done by trains travelling in either direction. In working on an ordinary piece of road, two signals behind the train are always kept at danger; and, on a single line, two signals in advance of the train are always kept at danger against a train advancing in the opposite direction. In a few words, the trains warn one another of their proximity.



AUTOMATIC ELECTRIC BLOCK SYSTEM.

We have dwelt on the subject of signals at considerable length, as the question is novel, and of great and growing importance; and we have no doubt that those who take an interest in railroads have found much to be gained by visiting the exposition, and studying this question on the spot. The two exhibits we have mentioned represent the best results attained in England after forty years' patient and careful study of signals, under such trying conditions that the very existence of railways there depends upon the handling of enormously concentrated traffic with safety, certainty, and rapidity; and the results of these labors are probably not far from a perfect solution of the problem, and deserve our most careful study.

(To be continued.)

FIFTEENTH ANNUAL CONVENTION OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS.[1] — II.

ON Thursday the convention again assembled at St. Paul, at 11 A.M., and listened to a paper by J. P. Frizzell of St. Louis, upon the water-power at St. Anthony's Falls. The height of fall, watershed, rainfall, and horse-power utilized were given. He criticised the means taken for preserving the falls, the building of storage-dams at the head waters of the Mississippi, and the method of using the water at Minneapolis. He condemned the waste of power occasioned by a gross disregard of the laws of hydraulics, and pointed out the remedy. He stated that three things should be done, — the U. S. government must be induced to withdraw wholly, leaving the work of preservation of the falls to the owners of water-power; the two companies controlling the power must be united under one management; the natural width of channels at the falls must be restored.

Capt. O. E. Michaelis, U.S.A., followed with a short paper on metrological investigations, which he said were brought about by the attempt to determine how much a certain bullet was 'out of true.' He constructed, and exhibited an instrument closely allied to the spherometer, to which he gave the name of 'tripod caliper.' He read results of measurements with this instrument, and applied it further to testing the accuracy of one turn of a screw-thread.

Mr. D. J. Whittemore, chief engineer of the Chicago, Milwaukee, and St. Paul railway, read a brief paper on the use of the Nasmyth steam-hammer for driving piles, and gave instances of the hindrance which a very slight 'brooming' of the pile-head offered to the effective action of the hammer. He also submitted a section from the top of a green Norway pine pile, where the friction of the fibres, under the rapid blows of the hammer, had generated sufficient heat to burn the heart of the head of the pile quite across.

Papers by Benjamin Reece, of Toledo, O., upon railway-track repairs, and by J. W. Putnam, upon cause of decay in timber, were read by title, and ordered printed in the proceedings.

[1] Concluded from No. 24.

In another room, before the persons most directly interested, a paper was read by F. P. Stearns of Boston, upon the current meter, giving a theory for the maximum velocity of water, flowing in an open channel, being found below the surface.

The society then held a business-meeting, in which a committee for nominating officers of the society was elected. Committees on uniform tests of cement and on the preservation of timber were granted further time. The committee appointed to procure aid from Congress to carry on the tests of iron and steel reported progress, and was continued.

The special committee on standard time made a report through Dr. Eggleston to the effect that they had obtained a general expression of opinion from men prominent as engineers, railway managers and operators, and others in all parts of the United States and Canada, and found that exceptional unanimity prevailed with respect to the fundamental principle which should govern in the adoption of a system of standard time for the whole country. The benefits of a change from the present lack of system were illustrated, and it was claimed that the time had arrived for action in the matter. The report was accepted, and the committee continued.

The convention at St. Paul then adjourned. The U. S. engineer officers on duty in this vicinity had an exhibit, in another room, of plans showing the various works of improvement under their charge.

On Friday, June 22, the convention met in Minneapolis. The party was carried from Hotel Lafayette across Lake Minnetonka by steamer, and thence by a narrow-gauge railway, in open cars, to the city. The meeting took place in the opera-house. A welcome was given by ex-Mayor Rand in behalf of the city; a reply and the annual address, in the absence of President Charles Paine, was read by Director William Metcalf, who took for his subject 'Engineering improvements in the Mississippi valley.'

Mr. William P. Shinn then read a paper upon the subject, 'How can railways be made more efficient in the transportation of freight?' which is a sequel to his paper of similar title read at the annual meeting in 1882, and aims to sum up the discussion, and more particularly to reply to the criticisms of Mr. O. Chanute thereon. He claims that facts and figures, which he adduces, prove that the present mileage basis for the adjustment of car accounts between different railroad companies is unjust to the companies furnishing the cars; that it is costly and discouraging to prompt shippers; that it leads to slow movement of loaded cars and to non-movement of empty cars; that it is not practised in other countries, nor does any like practice obtain in any other business in this country. The *per-diem* basis, on the contrary, is perfectly practicable, as proved by two years' trial on the Union Pacific, and Chicago, Burlington, and Quincy railroads, and its use in a modified form in two European countries.

At noon the convention adjourned. The rest of the day, and Saturday, were given up to the very pleasant excursions and entertainments furnished by the people of the vicinity.

If one-half as much is done to render the coming meeting of the American association pleasant, those who attend will find themselves well entertained.

SOME GEYSER COMPARISONS.

HAYDEN'S twelfth annual report, published by the U. S. interior department, has been in the printer's hands for some time, and will doubtless be shortly issued from the government printing-office. Part ii. of this report relates to the Yellowstone national park, and in it the hot-springs are fully described, and the geology and topography of the park treated of in detail.

It is proposed here to point out briefly some of the differences in relation to geysers between the results of the work in the park and those reached by Bunsen in his study of the Iceland field. It is not necessary to present Bunsen's conclusions in detail, nor to describe his theory, with which doubtless the majority of the readers of SCIENCE are familiar.

Bunsen's conclusions, as presented here, are mainly the same as stated by LeConte in his Elements of geology, although not considered in the same order.

1. Bunsen found in Iceland two kinds of springs, viz., *acid springs* and *alkaline carbonate springs;* and he says that only *alkaline carbonate springs* become siliceous, and that only silicated springs form geysers.

2. The silica in solution does not deposit on cooling, but only by drying.

Our observations in the Yellowstone national park in the main verify this last conclusion, and it is inserted, because LeConte takes exception to it as follows: "This, however, is not true; for the Yellowstone geyser-waters, which[1] deposit abundantly by *cooling*, evidently because they contain much more silica than those of Iceland."

[1] This is evidently a grammatical error.

The following table gives the results of the observations in the park as far as they have been made in regard to the points just enumerated.

Name.	Character of spring.	Grains of silica to imperial gallon.	Reaction of water.	Condition of water after three years, when bottles were opened.
Jug . .	Quiet spr'g,	14.56	Alkaline,	Perfectly clear, no deposit.
Echinus .	Geyser . .	10 60	Acid . .	Perfectly clear, no deposit.
Pearl . .	Geyser . .	7.84	Alkaline,	Clear, with small deposit of gelatinous silica.
Opal . .	Quiet spr'g,	53.76	Alkaline,	Opaline as when bottled, no deposit in bottle.

Here, then, we have an alkaline spring and an acid spring, both of which are geysers. We see, also, that the mere fact of cooling has little to do with the throwing down of the silica, nor does the precipitation appear to be due to the amount of silica held in the water. Ordinarily the formation of siliceous sinter or geyserite must be explained by the evaporation or drying of the water as it flows from the springs, or falls from the geysers.

The chimney-like form is very noticeable in the craters of the Yellowstone geysers; and LeConte attributes it to the greater abundance of silica in solution in the waters of the Yellowstone geysers.[1]

As a fact, however, the analyses already made of geyser-waters from the park show usually a smaller percentage of silica than do those of Iceland. Opal spring (see table above) is an exception, and it is a spring without the least appearance of a crater or chimney. The real explanation is probably in the greater age of our geyser region.

3. Bunsen's conclusions as to temperature are as follows: —

a. The temperature increases with the depth of the tube.

b. At no point in the tube does the water have the temperature of ebullition which it should have under the pressure to which it is subjected.

c. The temperature depends on the time that has elapsed since the last eruption; and, as a great eruption approaches, the nearer it comes to the boiling-point.

d. At a depth of forty-five feet in the Great geyser, the difference between the observed temperature and the calculated boiling-point of the water for that depth and pressure was the least.

[1] Elements of geology, p. 104.

In the Yellowstone national park, wherever deep temperatures were taken in active springs and geysers, they were found to increase with the depth; but temperatures of ebullition were found at the surface of many springs, and in some the temperatures exceeded the boiling-point. As the time for an eruption in a geyser approached, the temperature increased, which fact agrees with Bunsen's observations.

In 1865 a Mr. Bryson of Edinburgh found that the tube of the Great geyser of Iceland has a ledge about forty-five feet below the top of the tube, and that, from beneath this ledge, steam-bubbles rose while the tube was filling. A thermometer sunk to this point was violently dashed about and broken, but, when sunk below it, was quiet and undisturbed. The conclusion is, that here is an opening by which steam and superheated water have access to the main geyser-tube from the side. Similar side-openings are known to exist in Strokhr; but the Great geyser is so full of water that its structure cannot be so readily studied as in the case of the smaller Strokhr. In Bunsen's theory this point forty-five feet below the surface plays an important part. He allowed his thermometer to remain at the bottom of the geyser-tube during a great eruption, and it was undisturbed. Mr. Bryson's discovery explains its safety. It was below the active side-vent of the geyser.

Bunsen's conclusion would therefore probably have to be modified so far as relates to the temperature of ebullition not being reached; for, could he have obtained temperatures in the side-conduit, there is but little doubt that the boiling-point would soon have been reached, even for the pressure of that depth. The mass of water in the main tubes prevents that condition at the surface; and, when it is attained opposite the aperture, an eruption occurs.

Bunsen's theory of the formation of geyser-tubes also requires some modification. Contrary to his opinion, the deposit of silica is not necessary for geyseric action. In the Gibbon geyser basin in the national park are several geysers conspicuous from the small amount of siliceous deposit surrounding them; and one in 1878 was entirely without a deposit, having just broken out as a steam-vent. By the following year it had settled down to regular geyser action.

As already mentioned, there are, in the park, geysers the water of which is acid in reaction; and therefore the theory that before developing into a geyser the spring must pass through a preliminary tranquil or non-eruptive stage (in which it is an acid spring) is not warranted by the facts observed in the Yellowstone region. It is probable that all geysers are originally due to a violent outbreak of steam and water, and that the first stage is that of a huge steam-vent. Under such conditions, irregular cavities and passages are more likely to be formed than regular tubes. The lining of the passages and tubes takes place afterwards, and is a slow process. Whether the subterranean passages in which the water is heated are narrow channels, enlargements of tubes, or caverns and tubes, is probably of little consequence, except as the periods or intervals of the geyser are influenced. If water in a glass tube be heated rapidly from the bottom, it will be violently expelled from the tube, or, if boiled in a kettle that has a lid and a spout, either the lid will be blown off, or the water will be forced out of the spout. In the first case we have an explanation, in part at least, of Bunsen's theory; and the second exemplifies the theories which presuppose the existence of subterranean cavities and connected tubes. The simpler the form of the geyser-tube, the less is the impediment to the circulation of the superheated water; and in this fact lies the explanation of the difference between constantly boiling springs and geysers. The variations and modifications of the subterranean water-passages, however, must be important factors entering into any complete explanation of geyseric action.

Bunsen's theory, somewhat modified, is probably the best yet proposed, especially that part of it which explains the effect of the rise of water nearly at the boiling-point to an upper portion of the channel where its temperature is in excess of that necessary to cause ebullition. The excess of heat is violently and instantaneously applied to the production of steam. McKenzie, in 1810, also recognized the fact that the sudden evolution of steam was the proximate cause of the eruptions; but he could not account for their periodical production.

The water of geysers and hot-springs has been boiled and reboiled for an inconceivable period, and is freed from air as no other water is. Its cohesion is therefore immensely increased; and this fact, together with the obstruction to the free escape of steam caused by irregularities in the channels, offers a complete explanation of the superheating of the water; and it is well known, that, when water so heated does boil, the production of vapor is instantaneous.

A. C. Peale.

THE AFFINITIES OF RICHTHOFENIA.

Dr. W. Waagen considers the results of his recent study of the new genus Richthofenia Kays. (Anomia Lawrenciana Koninck) so remarkable as to deserve a preliminary notice (*Rec. geol. surv. India*, xvi. 1). Mr. Barrande and Professors Valérin and Möller were of opinion that this fossil was more nearly related to the corals than to any other class of animals, while Professors Zittel and Lindström seemed to be in favor of the view that it was a brachiopod. In favor of the latter view, the microscopic structure of the shell is the most important point. Its silky lustre is identical with that of Productus, though this seems to be effected by different means. In the shell of Productus it is caused by obliquely ascending prisms, whilst in Richthofenia it depends apparently on the fine lamination of the shell, as in Placuna or similar genera. Of great importance is the prismatic structure of the single laminae of which the shell of Richthofenia is composed. Such a prismatic structure is chiefly characteristic of mollusks and molluscoids. Dr. Waagen has never yet observed this structure in corals. In Calceola sandalina, which seems the most kindred form among corals, a microscopic section through the larger valve showed well its radial septa ; but all these septa exhibited a granular, not a prismatic structure. The punctation of the shell is very similar to that of Productus, and so are the hollow root-like tubes which penetrate the shell-substance of the larger valve, and adhere to other bodies. The smaller valve can also be very well compared to the same valve of Productus, although it is doubtful whether the thick parallel ridges on the hinge-line of this valve of Richthofenia can at all be compared to a cardinal process, and whether the impressions on the valve can be taken as muscular impressions. Reniform bodies are most certainly absent. Nevertheless, among the brachiopods, the Productides are the only ones to which the genus Richthofenia might stand in any relation.

Richthofenia possesses certain points of resemblance with rugose corals, — the irregular partitions in the lower part of the larger valve ; the columella-like portion, which is divided off by three vertical septa ; these septa themselves, which can well be compared to the primary and the two lateral septa of a rugose coral ; the cellular structure of the shell ; the septa-like ridges on the outer wall of the animal chambers, which are in connection with the hollow canals which pierce the substance of the shell ; and the tortuous tubes themselves, into which the canals are prolonged on the outer side of the larger valve. There can be no doubt, that on first inspection, ignoring the silky lustre of the shell, one would be far more likely to regard this fossil as a coral than as a brachiopod.

The points of similarity between Richthofenia and the Rudista, chiefly Hippurites, are not very numerous. If we make a section of Richthofenia from the hinge-line to the opposite wall, so as just to touch the median vertical septum, we obtain a figure very similar to what a Hippurites shows when cut so as to touch the first columellar fold. Another point of similarity consists in the direction of the prisms, of which the substance of the shell is composed. The Rudista differ from all the other groups of Pelecypoda in having the prisms of the outer shell arranged vertically ; i.e., longitudinally to the whole extension of the shell. The same is the case in the median shell-layer of Richthofenia. A third point of great importance exists in the pallial impression which is common to Richthofenia and the Rudista ; and, finally, it is not quite certain that the sinuations of the large valve of Richthofenia on both sides of the hinge-line, which stand in so close a connection to the lateral vertical septa, may not be regarded as the beginning of the infoldings of the shell, so characteristic of the Rudista. The distance in time between Richthofenia, which comes probably from the limits between the carboniferous and Permian formations, and the Rudista, which are for the most part upper cretaceous, is so enormous, and the absence of every connecting-link so complete, that a close affinity between the paleozoic and the cretaceous forms should not be expected. It will therefore only be possible to prove the connection between the present fossil and the Rudista, when further members of such a developmental series are discovered.

As the case now stands, it will be most prudent, in accordance with the microscopic structure of the shell, to consider the fossil as something like a brachiopod. As far as Dr. Waagen's opinion goes, he is convinced that Richthofenia is a member of a series, which, branching off somewhere from the rugose corals, has reached in Richthofenia a brachiopod-like stage, and is going to terminate its career as a Pelecypod, as one of the Rudista. But opinion is nothing in science, and proofs are every thing. As yet, it cannot be positively denied that Richthofenia may be a predecessor of the Rudista.

J. B. Marcou.

THE GREENWICH OBSERVATORY.

Among the leading points referred to in the report of the astronomer royal, W. H. M. Christie, F.R.S., to the board of visitors of the Royal observatory, Greenwich, read at the annual visitation on June 2, are the following: —

Besides the regular subjects of observation with the transit-circle, — the sun, moon, planets, and fundamental stars, — a new working-list of 2,600 stars, comprising all those down to the sixth magnitude inclusive, and not observed since 1860, has been prepared, and was brought into use at the beginning of March. The entire number of transits observed with this instrument during the year was 4,188; determinations of collimation-error, 354; determinations of level-error, 323; number of circle-observations, 4,485; determinations of nadir-point, 298; reflection-observations of stars, 484. Comet *a* 1882 was observed seven times on the meridian, and comet *b* 1882, three. The routine reductions of all the observations with this instrument are reported in an extraordinary state of forwardness. From the beginning of this year, a correction of $-0''.39$ has been applied to the results of the nadir-observations to make them agree in the mean with the results of the reflection-observations of stars. This discordance was insignificant in 1878, and is on the increase: its source has not yet been traced. Three determinations of flexure have been made during the year. The correction for $R-D$, the error of assumed co-latitude, and the position of the ecliptic, have been investigated for 1882. The value for the co-latitude, from the observations of 1882, is 38° 31′ 21″.93. The correction to the tabular obliquity of the ecliptic is + 0″.44. The mean error of the tabular right ascension of the moon, from observations with the transit-circle, is + 0ˢ.82.

The observations of the moon with the altazimuth have been restricted to the semi-lunation between last quarter and first quarter; and some limitations have been adopted in the computations which render the reduction of observations with this instrument comparatively light. The moon's diameter has been measured thirty-three times, counting measures in both co-ordinates with the transit-circle and the altazimuth.

A very valuable addition has been made to the instruments of the Royal observatory by the gift of the Lassell two-feet reflecting equatorial, generously presented by the Misses Lassell. This is the instrument with which the Saturnian satellite Hyperion was discovered in 1848. It was removed from Maidenhead early in March, and has been suitably mounted in the grounds of the Royal observatory. The telescope has two large mirrors available for use; and the astronomer royal contemplates attaching one of them to the tube of the 'south-east equatorial,' which has a firm mounting and a perfect clock-work, and employing it for spectroscopic and photographic work. The Lassell telescope itself is well suited for the observation of faint satellites and comets which are beyond the present instrumental means of the observatory.

The observations of the solar eclipse of 1882, May 17, with the south-east equatorial, have been completely reduced, and the final equations solved.

Spectroscopic observations during twelve months have been somewhat restricted through the pressure of photographic reductions at the time of a maximum of sun-spot frequency. The solar prominences were observed on eight days, and four sun-spots were examined on eight days with reference to broadening of lines in their spectra. The spectrum of the great spot of 1882, Nov. 12–25, showed some remarkable reversals of the lines of hydrogen and sodium, and extraordinary displacement of the F line.

As regards determinations of motion of stars in the line of sight, a hundred and forty-two measures have been made of the displacement of the F line in the spectra of twenty-three stars, and twenty-six measures of the line b_1 in nine stars. The observations of Sirius during the past winter tend, on the whole, to confirm the impression that the rate of recession of this star had diminished progressively since 1877, and that its motion is now on the point of being converted into one of approach.

The spectrum of comet *a* 1882 was examined on three nights; that of the great comet *b* 1882, also on three nights; and that of comet *a* 1883, on one night. The spectrum of the first-named object showed the yellow sodium-lines with great brilliancy just before perihelion passage. The spectrum of the aurora was also examined in 1882, Nov. 17. The spectroscopic observations of all kinds are completely reduced to 1883, May 20.

During the year ending at this time, photographs of the sun were taken on two hundred days, and three hundred and thirty-nine plates have been selected for preservation. The sun's disk was free from spots on seven days; and, since the extraordinary outburst of last November, the sun has been comparatively quiescent. The astronomer royal proposes soon to employ a modified photoheliograph for this work, so as to obtain photographs of the sun eight inches in diameter instead of four. The measurement of a large number of Indian and other photographs of the sun, required to fill gaps in the Greenwich series, has been completed, these photographs having been received from the Solar physics committee.

The course of the magnetic observations has remained the same as in former years. Improvements have been made in the methods of photographic registration. There has been considerable magnetic activity during the year. The disturbances of November last are to be detailed graphically in the 'Greenwich magnetic results for 1882.' Particulars of magnetic disturbances are regularly communicated to the *Colliery guardian* newspaper, for the information of mining surveyors.

The mean temperature of 1882 was 49°.6, or 0°.1 lower than the average. The highest air-temperature was 81°.0, on Aug. 6; and the lowest, 22°.2, on Dec. 11. The mean monthly temperature was above the average from January to May, then below until September, and differed little from the average during the remainder of the year. The mean daily motion of the air was 306 miles, 27 miles greater than the average. The greatest daily motion was 758 miles, on Nov. 4; and the least, 30 miles, on Dec. 11. The greatest hourly velocity was 64 miles, Oct. 24. The number of hours of bright sunshine, as recorded by Campbell's sunshine instrument, was 1,245; that is, 40 hours above the average of the five preceding years. The rainfall of 1882 was 25.2 inches, slightly above the average.

In conclusion, the restriction in the observations of the moon with the altazimuth enables more attention to be given to observations with the equatorials. Two observers are now available for spectroscopic observations during the coming year. Mr. Christie characterizes the past year as, in some slight degree, one of transition, and preparation for future work. Some administrative changes have been made; but the regular course of observation and reduction has not been disturbed, and the standard meridian observations have been maintained in full vigor.

LETTERS TO THE EDITOR.

Impregnation in the turkey.

WHEN I was a boy, my father used to send me to some of the neighbors with our turkey-hen, and we left her there with the cock a day or so. Either this, or we would borrow a cock for a day or so, and turn him with our hen. This was not only for one year, but our custom; as we never wintered a turkey-cock, and we did raise turkeys by this process. There was no possibility of the turkey-cock getting with our hen after the contact mentioned above. I did not know that this fact was still unknown to people. What is still a question that I should like settled by experiment is, whether the spermatozoids are retained somewhere in the oviduct until the eggs reach a certain stage of development, or whether they at once impregnate the eggs. W. MANN.

Potsdam, N.Y., July 5.

[We give place to the foregoing extract from Mr. Mann's letter, referring to Mr. Shepard's communication in No. 20, p. 576, on the same subject. There are probably many species of birds in which one connection with the male suffices to impregnate a whole batch of eggs. That the turkey, like the common hen, is one of these, is a fact which hardly requires further confirmation. There can be little question that the spermatozoids are retained in the oviduct, as in other animals, and the eggs impregnated as they successively mature.]

Macloskie's Elementary botany.

The review with which you favor my Elementary botany catechises me as to whether I am sure that the seeds of Lepidium emit mucilaginous threads. Permit me to answer that I am sure, having made the experiment a dozen times. Violets, besides the orders cited by the reviewer, prove that the statement as to cymose flowers being actinomorphic requires modification. I sympathize with the objection to the terms 'exotest' and 'endotest;' but the terms 'primine' and 'secundine' are bewildering to authors as well as students, and give priority to the part which is in most cases a result of secondary differentiation; 'tegmen' is obsolete, and the whole subject of the development and structure of the seed-wall requires revision: hence the provisional use of terms which, though hybrid, are easily understood, and not likely to mislead the young. G. MACLOSKIE.

July 10, 1883.

[We conjecture that Professor Macloskie had mixed in his mind, or at least in his statement, two different cases, — one, that in which the wall of the surface-cells of the seed-coat, changed into a substance which swells into mucilage upon wetting, contains a spiral thread, as in Collomia; the other, in which there is no contained thread. According to our observations, the seeds of Lepidium belong to the latter: hence the 'catechism,' which was intended to call attention to a possible oversight. We have to-day verified our observation upon seeds of Lepidium ruderale. Perhaps Professor Macloskie will kindly indicate the species in which he found the threads. — REVIEWER.]

Primitive streak of vertebrates.

Dr. Strahl of Marburg has had the kindness to write to me concerning the abstract of his researches (SCIENCE, i. 521). A part of his letter contains an explanation which I shall be glad to have published in justice to Dr. Strahl. Translated, the passage is as follows: —

"As regards the esteemed remark at the close of the abstract, — that I have declared erroneous Balfour's comparison between the primitive streak and neurenteric canal on one side, and the blastopore of Amphia and fishes on the other, — the remark may be due to a misunderstanding. So far as known to me from his descriptions, Balfour placed the neurenteric canal at the anterior end of the primitve streak. But, as I have shown in my paper, the neurenteric canal originally lies in the middle of the primitive streak. The object of my demonstration is to show that the premises from which Balfour starts do not agree with the observations: this, I believe, was accomplished. This would also decide the second point made by you, — that my argumentation against Balfour was defective."

I am much indebted to Dr. Strahl for his letter, and I think others will value his short statement of his position. CHARLES SEDGWICK MINOT.

In an Indian grave.

In an Indian grave in Santa Barbara county, Cal., the writer found a beautiful specimen of doubly terminated limpid quartz, with a cavity half an inch long containing water or some other fluid. It was about four feet below the surface, and had been carefully deposited with many other stone implements, and was doubtless highly prized by its aboriginal owner. STEPHEN BOWERS.

WARD'S DYNAMIC SOCIOLOGY.

II.

IT is proposed to show the relation of Mr. Ward's publication to current thought.

The law is composed of the rules of conduct which organized society endeavors to enforce. The law, therefore, represents the quantity and quality of regulation, or, in other words, of government, which the people of the state in their corporate capacity deem necessary for their welfare. With respect to the amount and kind of government (i.e., of regulation, i.e., of law) which the best interests of society require, there is a very wide divergence of opinion between the chief publicists of civilized nations and the people themselves as they are represented by law-making bodies. The publicists tell us we are governed too much; but the people are demanding more government, and, in obedience to this demand, law-making bodies are rapidly extending the scope of law. The careful observer of the progress of government, who is at the same time a careful reader of opinion presented in the larger body of works on state craft, in the more carefully prepared dissertations on this subject appearing in the great reviews, and in many of the best editorials of the daily press, is astonished at the extreme conflict between opinion and practice.

There are two classes of law-making bodies, — courts and legislatures. The growth of law through the courts is almost unrecognized by the people at large; yet its development by this agency is perhaps more rapid than by legislation. The legal principles enunciated in the decisions of a system of courts such as we have under the general government and in the several states are rapidly developing to meet the demands of the vigorous growth of civilization. Some months ago the public prints announced a decision of the supreme court of California which well illustrates this statement. In more than two-fifths of the area of the United States all agriculture is dependent upon artificial irrigation. In 1866 the Congress of the United States, in order to promote mining industries in this region, and incidentally to promote agriculture, enacted a statute giving to individuals and corporations the right to take the water of the running streams of that country from the natural channels in which they run, and use the same for mining and agricultural purposes. Now, the nature of this use is such that the water itself cannot be returned to the natural channels to be used again; and by this law the antecedent common law relating to riparian rights was repealed. As the agricultural interests of the country were developed, it was soon discovered that all agricultural operations were under the control of water companies; for these companies claimed ownership to the water, and the right to use it themselves or to sell it to whom they pleased. But the decision mentioned above was to the effect that these companies possess only the water-ways, the canals and hydraulic appliances connected therewith; that they are common carriers of water, and are themselves subject to the law relating to common carriers. By reflection it will be perceived that this decision will affect vast interests, and deeply influence the daily life of thousands, and eventually of millions, of people. This serves to illustrate the nature of the court-made law, which is so rapidly growing, and affecting in a multitude of ways the relations of men, and restricting the rights of the few for the benefit of the many, which is in the very nature of law. In the above statement it will be observed that the initial change in the law was the statute of 1866. So the national and state legislatures are constantly engaged in making new laws for the government of the people; and this, in the main, ever in obedience to popular demand.

Such is the practice. The legislature stimulates the court, and legal decisions incite new legislation; and thus it is that the public men of this country and of other civilized nations devote their energies to the development of government by devising new laws for the regulation of conduct, and creating new offices for the administration of law.

Again: in every community there is a body of good and earnest people demanding reform, or devising methods for the improvement of mankind in diverse ways, — for the relief of the unfortunate, for the education of the masses, to diminish suffering, crime, and ignorance; and the energies of these people, exerted everywhere, in season and out of season, create a sentiment that law-making bodies cannot ignore.

Yet, in opposition to all this, the publicists ask for less government, and say, 'Let society alone.' This theoretic opposition to the course of progress, manifest in the development of institutions, arises from the standpoint, or phase of the philosophy of evolution, at which our thinkers have arrived. The laws of biologic evolution are applied to sociology. The philosophy of science, which is but inchoate, is adjudged to be complete, and principles that require restriction are held to be universal.

In biologic evolution the cause of progress is recognized as the survival of the fittest in the struggle for existence; and this has been widely accepted as the cause of sociologic progress, and Herbert Spencer is the prophet of this philosophy. As set forth by him and his large following, progress is secured by an inexorable law of nature, which brooks no interference; and the efforts of mankind to improve the condition of mankind do but retard the natural process; and the proper sphere of government is the direct suppression and punishment of crime, and that only. It is from this postulate that the theorists are antagonizing the practice of all the legislatures and courts of civilization. Though Mr. Ward does not state the problem as above, yet his book is written to controvert the Spencerian and generally accepted theory, to present a new philosophy of society which shall be sufficient warrant for the course pursued by practical statesmen and jurists, and to support the earnest people of the world in their efforts to benefit the race. His postulate, though stated in other terms, is essentially this: that social progress is due to the struggle for happiness, and the adoption of that conduct which secures happiness; and that the process, instead of being natural and genetic, is artificial and teleologic; that men devise methods for securing happiness, and gradually attain their ends.

Mr. Spencer looks upon society as an organism, and in this he is followed by Mr.

Ward; but the former author makes it the central point of his sociology, around which all other facts are gathered, and he elaborates a system of analogies with biologic organization, as if, in fact, they were homologies. It will perhaps be nearer the truth to speak of a state, rather than society at large, as an organism.

The organization of mankind is twofold, — activital and regulative. By the activital organization, which is usually discussed in works on political economy under the title 'division of labor,' the industries and other occupations of mankind are parcelled out to individuals and corporations; so that a man, in working for himself, works for many others, and an interdependence of parts in the social organism is thus established. For the successful operation of the activital organization, the regulative organization is established, which results in government, with its three co-ordinate departments, — executive, legislative, and judicial. Without division of labor and governmental regulation, the individuals of the human race would be entirely discrete; with them, mankind is organized into societies which we call 'states.' In so far as the people of one state are related to the people of another through their industries, there is an inchoate organization of state with state, which can only be completed by the consolidation of such states. Though Mr. Spencer devotes an inordinate space to the demonstration of the organization of society, he fails to discover, that, in so far as organization is accomplished, the method of biologic progress by the survival of the fittest is repealed. In the struggle for existence, state comes into competition with state; and to this extent the biologic law of the survival of the fittest applies. But in the relations of the interdependent parts of states, i.e., the different classes of people existing in a tribe or nation, the law of the survival of the fittest in the struggle for existence no longer applies; the unfit do not succumb; the welfare of each class (i.e., each organ, interdependent part) depends upon the welfare of each other part, — of the whole. There may be a competition for leadership, or for eminence in other respects, but not for existence.

Those who adopt the Spencerian theory believe that they find confirmation of their doctrine in the history of legislation. In modern times, since the differentiation of executive, legislative, and judicial organs and functions in government, legislation has often been unwise, and laws have failed to secure the purposes for which they were enacted. In this branch of human endeavor it would be strange if it were everywhere and at all times characterized by wisdom, when man has so frequently failed in other effort.

But beside the general failure for lack of wisdom, there has been failure for certain special reasons. Early law was common law; later law is in part statutory. In the change from the former to the latter, many great mistakes have been made. The body of law existing in a state, be it tribal or national, is the chief body of the ethics of the people of such state. But among such people there are ethical rules not found in the law, but held by individuals in a greater or less number. These non-legalized ethics are of two kinds, — first, those which have passed from the law, and are yet held in veneration by a part of the people; second, those which the more advanced minds are endeavoring to establish. The first are obsolete; the second, inchoate. Much of the law which Spencerian philosophers have used to illustrate the folly of legislation has been in instances where an attempt has been made to revive obsolete common-law principles by effective statutory law. Mr. Spencer's illustrations are chiefly of this class; and he has been followed by many a writer. This source of disaster can be avoided, not by refusing to legislate, but by a proper knowledge of the course of progress in social evolution. This course of evolution has not been, as Mr. Spencer postulates and elaborately discusses, from more regulation to less, from militancy to industrialism, but from less to more law, and from non-essential to essential regulation. When diseases were believed to be the work of evil spirits, or to result from the practice of sorcery, the relations of men to supposed spiritual beings were regulated, and witchcraft was punished; but, when diseases are discovered to be due to unwholesome conditions of environment, sanitary laws are enacted. And in like manner in every department of government the change is going on. Laws are sociologic inventions, analogous to the technologic inventions of the industries. Along with much failure there is much success. As the progress of industries would cease were no new methods devised, so the progress of society would end if new law were not enacted.

Dynamic sociology, as presented by the author, is the philosophy of human endeavor, and the justification of man in his effort to to improve his condition. Those persons, and they are many, who are actively engaged in the promotion of institutions and regulations for the benefit of mankind, will find in it philosophic hope; while those who are opposed to the course of practical events appearing in public affairs cannot afford to ignore their strongest opponent.

The evolution which is discovered everywhere in nature, to be properly demonstrated, must have its explanation set forth in three parts. First, it must be explained why there is change, for without change there can be no development; second, it must be shown by what agency change results in progress, for change to inferior or co-ordinate conditions is not evolution; and, third, what is the course of progress, for, if there is progress, it must be in some direction that can be determined, and thus science becomes prophetic.

Of the three departments of sociology, — namely, the causes of social change, the causes of social progress, and the course of social progress, — the work under consideration, as its name indicates, is devoted to but one, — the cause of social progress; though it incidentally discusses many of the subjects of evolution in other branches of science, and the author ultimately reaches the conclusion that education is the chief means to secure social progress, and thus secure human happiness.

SIEMENS' SOLAR ENERGY.

On the conservation of solar energy: a collection of papers and discussions. By C. WILLIAMS SIEMENS, F.R.S., D.C.L. London, *Macmillan & Co.*, 1883. 20+111 p. 8°.

THIS is a collection of the original paper read before the Royal society by Siemens, and the criticisms from Fitzgerald, Faye, Hirn, Archibald, and others, together with the replies of Siemens.

The theory, well summed up on p. 22, supposes that space is filled with aqueous vapor and carbon compounds; that these, at low pressures, are dissociated by the radiant energy of the sun; that the dissociated elements are drawn into the sun at its poles, unite, and generate heat sufficient to give a temperature of about 2,800° C.; and that the aqueous vapor and carbon compounds formed are again thrown off by centrifugal force at the sun's equator.

As evidence of the presence of carbon vapors in space, Siemens refers to the analyses of meteors, which in some cases have proved that hydrocarbons were a component of the meteoric mass, and again to the work of Abney and Langley on the absorption of the radiant energy of the sun.

The dissociation of vapors at low tensions is a point which seems to be well established. One of the earliest proofs is given in Prof. J. Willard Gibbs's paper on the equilibrium of heterogeneous substances.[1] He shows, that in a mixture of gases, as of oxygen, hydrogen, and vapor of water, in which the vapor is formed with a decrease in volume from that of the components, it is possible to assign a value to the tension such that the mixture may be in a state of dissipated energy; i.e., in such a condition that the energy of the system is a minimum for its entropy; and that any change in energy can be brought about only by work done by some outside system and in proportion to that outside work. In such a state, nothing of the nature of an explosion could be caused by an electric spark: the elements would cease to show the phenomenon of chemical affinity. Willard Gibbs writes, "It may, indeed, be true, that at ordinary temperatures, except when the quantity either of hydrogen or of oxygen is very small compared with the quantity of water, the state of dissipated energy is one of such extreme rarefaction as to lie entirely beyond our power of experimental verification." In the formula from which these results are deduced, the ratio occurs of the amounts of the components to that of the compound, these amounts being raised to small powers. This explains the qualification as to the amount of components which may exist in a free state.

This last condition may have an important bearing on the possibility of the truth of Siemens' theory; for, although Gibbs has shown that dissociation may occur in rarefied vapors, still the amount of the dissociation is limited unless the rarefaction be very great.

Some two or three years ago Professor Ogden Rood succeeded in getting experimental evidence of dissociation in rarefied gases at ordinary temperatures, but has never published his results.

Dr. Siemens gives, on p. 13, what evidence he early obtained of dissociation of gases in vacuum tubes under the influence of sunlight. What he has done since may be found from an account of his recent lecture at the Royal institution (*Nature*, May 3). Objections to the theory are well put by Fitzgerald when he asks (p. 41) "how the interplanetary gases near the sun acquire a sufficient radial velocity to prevent their becoming a dense atmosphere round him; why enormous atmospheres have not long ago become attached to the planets, notably to the moon; why the earth has not long ago been deluged when a constant stream of aqueous

[1] Proc. Conn. acad. sc., iii.

vapor, that would produce a rain of more than thirty inches per annum all over the earth, must annually pass out past the earth in order to supply fuel to be dissociated by the heat that annually passes the earth; and why we can see the stars, although most of the solar radiations are absorbed within some reasonable distance of the sun."

It can be hardly looked on as a strong answer to the first question, that "the gases, being for the most part hydrogen and hydrogen compounds, have a low specific gravity as compared with the denser gases forming the permanent solar atmosphere. On flashing into flame in the photosphere, their specific gravity would be vastly diminished, thus giving rise to a certain rebound action, which, coupled with their acquired onward motion and with the centrifugal impulse they receive by frictional contact with the lower atmosphere, constitutes them a surface-stream flowing from the polar to the equatorial regions, and thence into space." It is certainly hard to understand why the atmosphere of any member of the solar system should not be made up of the gases of interplanetary space in the same proportions in which they may exist in such space, if there is the free circulation called for by Siemens' theory.

Faye objects that the presence of such a resisting medium in space as the vapors is not to be accepted, with our present knowledge, and that the centrifugal force at the sun's equator is far too small for the action required.

Hirn, starting with the supposition that the sun's temperature is 20,000° C., writes, that, although the dissociated gases might unite in the chromosphere, they would, on passing down through the sun's atmosphere, be again dissociated, and absorb as much heat as they had given out on combining. To this, Siemens might have answered that the gases would again combine on passing off at the equator.

The discussion of the theory at the time of its first statement was most earnest; but, in spite of the ingenuity displayed in its elaboration, it as yet cannot be accepted as probable.

INSPIRED SCIENCE.

Eureka; or, The golden door ajar, the mysteries of the world mysteriously revealed. By ASA T. GREEN. Cincinnati, *Collins*, 1883. 141 p., portr., cuts. 16°.

THE publisher acts as editor of this book, interspersing his own chapters among the author's in an odd fashion. The florid periods of the one form a curious setting for the rough, ungrammatical language of the other.

The author has 'revelations' of a 'wonderful knowledge' which he obtained, partly in the woods, and partly in Oil City, and desires to impart them to scientific men. We will offer them a bit.

"If we would lay a telegraph-wire down down (*sic*) from every point of the earth, and of water, and all points telegraph at one time to a given point, the result would be to find that the atmosphere was going as fast as the earth, and the earth as fast as the atmosphere. *Thus you see* it is the atmosphere that carries the earth around. . . .

"Third reason why the earth is round; namely, because the mountains are up. If the earth was flat, the mountains would be just as liable to be down as up, but as the curvature of the earth is up, hence the mountains are up. . . .

"If sound travels by vibration, as science teaches, and science teaches that vibration creates heat, that if a cricket should stand on one end of a solid slabstone and rub his wings together, why is it that the vibration with the particles of stone does not completely melt the stone in ten minutes? I deny the hypothesis."

'Wonderful knowledge,' indeed!

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Points of inflection. — Let $U = x^{\alpha}y^{\beta}z^{\gamma} + ku^{\delta} = 0$ be an equation in homogeneous co-ordinates; x, y, z, are the sides of the triangle of reference, and $u = ax + by + cz$; $\alpha, \beta, \gamma, \delta$, are integers such that $\alpha + \beta + \gamma = \delta$; a, b, c, are given quantities, and k a variable parameter. For $\alpha = \beta = \gamma = 1$, this equation gives a system of cubics having, as is well known, their points of inflection distributed by threes upon three right lines; viz., the three real points of inflection upon u, and the remaining six points, in threes, upon two imaginary lines.

The author, M. A. Legoux, proposes to consider the general case of curves of the order δ. The three sides of the triangle of reference are tangents to all the curves of the system in the points where these sides meet the line u. The order of contact is $\delta - 1$: if δ is even, the curve in the neighborhood of the point of contact lies on one side of the tangent; if δ is odd, the curve here cuts the tangent, giving a point of inflection of a higher order. M. Legoux shows that the proposed curves have imaginary points of inflection, which are distributed upon two conjugate imaginary right lines which are independent of the value of k. If δ is even, there are no other inflections; but, if δ is odd, there exist three real points of inflection upon the line u, so that in the last case there exists, as in the case of cubics, an inflectional triangle. — (*Nouv. ann. math.*, Feb.) T. C. [105

ENGINEERING.

Electric-lighting machines on shipboard. — More than a dozen of the steamers plying between New York and Liverpool are fitted up with electric-lighting machinery. Probably three times as many are so fitted out on the various other lines of ocean-going steamships. The British steamers are largely supplied with the Siemens and Swan apparatus, but the other systems are well represented. The electric-light apparatus of the Arizona consists of two Siemens compound dynamos, each sufficient to supply current to three hundred high-resistance Swan lamps. They are driven by a pair of 'Caledonian' engines of nine and a half inch cylinders and fourteen inches stroke of piston. The two machines are mounted upon a common foundation, and are set in such manner that the driving-pulleys do not interfere with each other. The belts are tightened by moving the machines away from each other; they are formed of one continuous rope carried around each pulley ten times. Both cabins, and the steerage as well, are lighted by these machines. — (*Engineering*, May.) R. H. T. [106

New engine for electric-lighting. — Mr. E. D. Farcot has designed a new form of compound engine for electric-lighting machinery. It consists of two cylinders, the larger set above the smaller. The space between the two pistons is undivided, and is in communication with the interior of the engine-frame, and is never put in connection with the steam-supply pipe. The steam first enters the small cylinder, and is thence exhausted into the large cylinder, thus driving the pistons, which are both on a single rod, in opposite directions by a system of intermitted expansion. The engine is thus seen to be of the 'Wolff system.' The space between the two pistons is made to communicate with the larger space in the frame, merely to secure a reduced variation of uncounterbalanced pressure. No stuffing-box is needed in this engine in any inaccessible part of the machine. The valve-gear is of the plainest possible description, and the whole engine is built with a view to simplicity and small cost in construction and operation. It is intended to be driven up to four hundred revolutions per minute. — (*Publication industrielle*, May.) R. H. T. [107

Steam-jackets for steam-engines. — Herr Heim reports to the German society of engineers the results of experiments to determine the economy to be derived by the addition of steam-jackets to various forms of steam-engine. He finds that a six-horse power portable engine, unjacketed, demanded an excess of thirty-five per cent over the theoretical quantity of steam that should have been required to do the work; an eighteen inch Wheelock engine required the same excess over the calculated quantity. Both were non-condensing. Condensing-engines experience a still greater loss due to internal 'cylinder condensation.' Engines expanding ten times demand seventy-four per cent excess; when cutting off at one-fifth, sixty-two per cent; and expanding three times, fifty-five per cent more than the calculated amount when they are unjacketed. By adding a jacket, he concludes that the loss can be reduced to sixty-four, fifty-four, and forty-eight per cent. The effect of increase of piston speed is similar to that of adding a jacket. An engine at three feet, and at seven feet piston speed per second, gave a record of loss amounting to ninety-six and seventy per cent. The addition of the condenser causes increase of this loss. A twenty-inch non-condensing engine, working at five atmospheres pressure, was provided with a condenser, and, while the power was increased one hundred and forty per cent, the waste was increased from forty-two to sixty-two per cent. A hoisting-engine, working intermittently, exhibited a loss of a hundred and forty-two per cent of the weight of steam utilized. — (*Mechanics*, June.) R. H. T. [108

AGRICULTURE.

The gases evolved during the conversion of grass into hay. — In a series of experiments on this subject, conducted by Dr. P. F. Frankland and Mr. F. Jordan, freshly-cut grass in quantities of five grams each was allowed to stand in a glass tube over mercury. The glass tube was filled with air, inert gases, and experiments were also performed *in vacuo*. In air all the oxygen was absorbed at the end of three days, and 46% of carbonic dioxide was evolved. At the end of thirty days the percentage of carbonic dioxide reached 85.33, requiring a corresponding amount of oxygen, which must have come from the substance of the grass itself. Nearly pure carbonic dioxide was evolved in an atmosphere of the same gas, and a higher percentage seemed to be given off in darkness than in sunlight, although the authors were somewhat in doubt on this point. In an atmosphere of pure oxygen, the latter was absorbed completely in seven days, and the evolution of nitrogen ceased when the oxygen disappeared. When the experiment was conducted in an atmosphere of hydrogen, 21.11% of this gas was replaced by carbonic dioxide at the end of three days. It thus appears that certain constituents of the grass undergo a rapid process of oxidation, and that nitrogen is evolved as long as the atmosphere contains free oxygen. The decomposition-products of grass, when allowed to stand under water, were also examined. The grass was first soaked in distilled water, and the dissolved air removed with a Sprengel pump. Carbonic dioxide formed about 90 %, and hydrogen about 9 %, of the gases collected at the end of thirty days. No gas was evolved when the formation of bacteria was prevented by the addition to the water of phenol or mercuric chloride. As the other products of the fermentation, acetic and lactic acids, and probably propionic acid, were identified. — (*Journ. chem. soc.*, June, 1883.) C. F. M. [109

Absorption of moisture by soils. — Fisher finds that, contrary to Knop's statement, the amount of hygroscopic moisture retained by a soil varies greatly with the amount of moisture present in the air, as well as with the temperature. At temperatures ranging approximately from 20° to 30° C., about half as much water was retained in a half-saturated as in a saturated atmosphere. As the temperature was raised, more water was absorbed from the saturated atmosphere, but less from the half-saturated one. — (*Rep. Cal. college agr.*, 1882, 52.) H. P. A. [110

Influence of organic manures on temperature of soil. — In experiments on this subject, F. Wagner finds that organic manures raise the temperature of the soil to an extent increasing with the quantity of the manure, the temperature of the soil, and its moisture, so long as the latter is not in such excess as to hinder access of oxygen to the organic matter, or to cool the soil too much by its evaporation. Porosity and ready decomposability on the part of the manure favor the action. The increase of temperature is greatest at first, may continue from four to twelve or more weeks, but under practical conditions is too small to be of much significance. — (*Forsch. agr. phys.*, v. 373.) H. P. A. [111

Moisture of the soil. — In pot-experiments with peat, Heinrich obtained the largest crop when the peat contained sixty per cent of the total quantity of water which it was capable of containing. Earlier experiment by Hellriegel on sandy soil gave nearly the same results. When the moisture of the peat fell below twenty per cent of its water-capacity, no crop was obtained, while in case of sand a small crop was obtained when the moisture was only ten per cent of the total water-capacity. — (*Bied. centr.-blatt.*, xii. 109.) H. P. A. [112

GEOLOGY.

Lithology.

Cleopatra's Needle. — In a paper by Dr. P. Frazer is given a description of some thin sections of the New-York obelisk, made by Prof. A. Stelzner of Freiberg, accompanied by four lithographic plates. The rock is composed of fresh microcline, showing in polarized light its characteristic grating; oligoclase, somewhat decomposed, and showing fine twinning striation; quartz in grains and granular aggregates, containing fluid cavities, trichites, and hematite plates; light green hornblende with irregular outlines; biotite in large brown, translucent scales; titanite in numerous small yellowish-red grains; water-clear acicular apatite crystals; magnetite in opaque irregular grains and in octahedrons; minute zircon crystals; yellowish-green needles of epidote and viridite. A granite from Germantown was regarded as similar to the Syene granite. The former is composed of microcline, plagioclase, quartz, hornblende, biotite, muscovite, titanite, etc. Frazer gives the literature of the subject. — (*Trans. Amer. inst. min. eng.*, *Boston meeting.*) M. E. W. [113

Journalistic lithology. — A weekly journal was established last year in England on the peculiar plan of publishing descriptions of microscopic slides, with figures of the same, while duplicates of the described preparations were to be sent to every subscriber. This method, if under the direction of competent specialists, would serve as a valuable means of home training for those who are unable to place themselves under the direct instruction of competent teachers. It promised twenty-six histological, eighteen botanical, and eight lithological sections a year.

The lithological descriptions, so far, have embraced the following rocks: pikrite, dolerite, diabase, red and white syenite, and serpentine, with some bibliographical lists. While the journal contains some matter of interest to lithologists, it is, on the whole, a disappointing and unsafe guide for a student. In some cases the style of the lowest grade of 'popular scientific lecturers' has been adopted; and the phrase 'plugs of exosmotic transference,' used for veins, is too good to be lost. — (*Studies in microscopical science, London*, 1882–83.) M. E. W. [114

METEOROLOGY.

Sun-spots. — At the university observatory at Rome on 269 days in 1881, and 290 in 1882, Tacchini has made observations of sun-spots. He shows that in 1882 there was an increase in spots over 1881. The mean daily number by months was, in 1881, 19.55, and, in 1882, 22.57. There were peculiar maxima in the number in April and November, 1882. Taking each period of constant activity in the daily observations in 1882, a second maximum and minimum period appears at the half sun's rotation. For the faculae we also find that the increase is less with the growth of the spots; the yearly mean in 1881 being 88.36, and, in 1882, 81.55. It is believed from the character of the sun's activity at the last maximum period, as compared with the present, that the maximum spottedness will occur in 1883. — (*Naturforscher*, May 12.) H. A. H. [115

PHYSICAL GEOGRAPHY.

Artesian wells in Algeria. — In the south of the province of Constantine, Algeria, the boring of artesian wells, begun in 1856, was continued with renewed activity, after the interruption occasioned by the Franco-Prussian war, under the direction of M. Jus. At the end of 1879 the long line of wells following the Wady Rir, between Biskra and Tugurt, included 434 sunk by the Arabs, and yielding 64,000 litres a minute, and 68 bored by the French, yielding 113,000 litres. In the same decade, the number of palm-trees in the oases had increased from 359,000 to 517,000; of fruit-trees, from 40,000 to 90,000; of inhabitants, from 6,672 to 12,827. During the first half of 1880, twelve new wells were bored, yielding 22,000 litres, and, at the end of 1881, the total supply of water from these underground sources was 209,000 litres a minute. — (J. J. Clamageran, *Rev. géogr. internat.*, 1883, 43.) [116

Currents of the Pacific Ocean. — Antisell discusses the general motion of the warm currents of the western and northern Pacific, brings together a number of data not before correlated, illustrates them by maps and diagrams, and comes to the conclusion that, 1°, the warming influence of the North Pacific is the Kurosiwo, the motor power of which is the south-west monsoon, blowing from April to October; and, 2°, that the North Pacific Ocean has practically no northern outlet, Bering Strait affording no real access for ocean-currents into the Arctic Ocean. — (*Bull. Amer. geogr. soc.*, ii. 1883.) W. H. D. [117

The Connecticut River in the glacial period. — Professor J. D. Dana continues his studies on the former lines of flow of the flooded Connecticut at the end of the ice time, and finds evidence, from the height and coarseness of the terraces, that some of the river's waters found their way southward along the Farmington valley (where the Farmington River now runs northward), down the upper course of the Quinnipiac, and thence directly southward along the present Mill River channel, to the Sound at New Haven, and not all the way along the Quinnipiac, as was formerly supposed. — (*Amer. journ. sc.*, xxv. 1883, 440.) W. M. D. [118

GEOGRAPHY.

(Asia.)

New Guinea. — A ten-days' trip inland from Port Moresby, made by W. G. Lawes and two others, with a party of natives, led them over the Veriata Mountain, about two thousand feet high, and up the valley of the Laloke River. From the mountain-summit, they had a fine view of sea and coast, hill and valley, intersected by many winding streams. In the valley, they visited the Rouna Falls, — about two hundred and fifty feet in height, and a hundred and fifty feet wide. The travellers saw many of the natives of the Koiari tribes, and found them all friendly and honest. They are smaller, darker, and more hairy than the coast tribes, and it was not uncommon to find a man with beard and mustache. They have a superstitious belief, that, when a man dies, he has been bewitched by a spirit belonging to a neighboring tribe, who then must pay for the loss: fighting, therefore, always follows the death of a man of any consequence. Fruit is very plentiful and in great variety. Salt is highly prized, and makes a very acceptable present. The native method of getting fire is peculiar: a piece of dry, pithy wood is split a little way, and held open with a stone; some tinder is put in the cleft, and a strip of rattan or bamboo is passed through it, and then pulled rapidly one way and the other till smoke and fire appear. In the 'Sogere' district, the villages consist of only eight or ten houses, and two or three 'tree-houses' which serve as forts. The occupants prepare for an attack by carrying up a supply of stones into the tree-houses; and as they are sometimes over one hundred feet high, and command the whole village, they are not easily taken. Travelling was not easy, as there were numerous streams to cross, and leeches were very plentiful in the wet grass. — (*Proc. roy. geogr. soc.*, v. 1883, 355.) W. M. D. [119

Indian surveys. — A general report on surveys in India during 1881–82, by Gen. J. T. Walker, announces the completion of the triangulation of all India on the lines long ago marked out by Col. Everest and sanctioned by the East India company. The latest part of this Great trigonometrical survey was the eastern frontier series of triangles extending from Assam to Tenasserim, where it was brought to a close on a base line of verification at Mergui. The topographical survey has continued its work in various parts of the peninsula, turning out maps on several scales embracing nearly twenty-five thousand square miles, besides forest and town surveys on large scales. A new survey of the Hoogly is begun, as the existing maps are out of date and on too small a scale for utility in so densely populated and valuable a region.

The chief geographic interest in the volume is found in the reports on trans-Himalayan explorations by trained native travellers, and in the reports of various executive officers of the survey on their districts. — (*Proc. roy. geogr. soc.*, v. 1883, 368.) W. M. D. [120

BOTANY.

Cryptogams.

New Ustilagineae. — Cornu gives an account of the anatomy and germination of the spores in several curious Ustilagineae. Ustilago axicola, Berk. and Curt., is made the type of a new genus, Cintractia, characterized by the formation of the spores in successive concentric circles. The curious Testicularia Cyperi from the United States is figured, and a second species of Leersia is described. The new genus Doassansia, in which the spore masses are surrounded by a peculiar envelope, has one representative from North America which is figured by Cornu. — (*Ann. sc. nat.*, xv. 269.) W. G. F. [121

Zygospores of Mucors. — Bainier has studied the conditions which favor the production of zygospores in Mucors, and finds that the conditions vary in the different species. The absence of free oxygen or of light is not a necessary condition, nor is a deficient supply of nourishment always required for the production of zygospores. Bainier cites a considerable number of cases where he has cultivated different species, and gives the manipulations required in each case for securing sporangia and zygospores; and he adds some observations on the chemical action of certain species. It appears that Phycomyces nitens, which usually grows on fatty substances, which it decomposes, can also be cultivated on cochineal, causing it to assume a deeper color, and rendering it more valuable commercially. Mucor racemosus, and a new species, M. tenuis, are described and illustrated in full. — (*Ann. sc. nat.*, xv. 342.) W. G. F. [122

Phenogams.

Lignification of epidermal membranes. — Besides cutinization, the change which characterizes epidermal cell-walls in general, the exposed wall may undergo two others: it may be converted into mucilage, thereby becoming weakened, or it may be rendered firm by the deposition or infiltration of mineral matters. To these well-known transformations of epidermal cells, Lemaire now adds *lignification*, hitherto supposed to be confined to internal tissues. For the detection of lignine, he uses the useful reagent suggested by Wiesner, phloroglucine. A section of epidermis is transferred from an alcoholic solution of the agent to hydrochloric acid, when the lignified membranes assume a rose color, the other parts remaining unchanged. For purposes of control, similar sections are first treated with either nitric acid or a solution of bleaching-powder, by which reagents, preferably the latter, the lignine is removed. Lemaire has detected lignine in the epidermal walls of Cycads, many Coniferae, and in the petiole of certain ferns. The stomata of gymnospermous plants have been found by him to always have the membranes somewhat lignified. — (*Ann. sc. nat.*, xv. 302.) G. L. G. [123

Mentzelia laevicaulis as a fly-catcher. — Marcus A. Jones of Salt Lake City, acting upon Dr. Gray's suggestion, examined this plant with the following interesting results: "the leaves are thickly beset with coarse hairs, which are furnished with several pairs of barbs pointing downward along them, while the top has an anchor-shaped summit twice as large as the other barbs. These hairs stand so close together that the barbs almost touch. Thickly studding the leaf, were many dead and dying mosquitoes, species of aphis, and other small insects. Some of these were caught by the head; but most of them were held by the proboscis, as their heads were too large to slip between the barbs. All were more or less mutilated, probably by other insects. A sweet fluid was secreted by the leaf, and this attracted the insects. There was no evidence of any digestion going on, as none of the victims could get close enough to the surface of the leaf to be touched by the fluid." — (*Bull. Torrey club*, June.) G. L. G. [124

Elongation of pedicels in Didymoplexis. — Hemsley calls attention to the elongation of the pedicels in these Asiatic orchids after fertilization, by which the ripening capsules are carried up above the decaying vegetable matter in which the plants grow. It is thus quite different from the elongation of the flower-stalks of Arachis and other plants which bury their ripening fruit. What its exact bearing on dissemination may be is not quite clear. — (*Journ. Linn. soc. bot.*, June 6.) W. T. [125

ZOÖLOGY.

Mollusks.

Mediterranean Mollusca. — Dr. J. Gwyn Jeffreys publishes a useful annotated list of species obtained near Crete by Admiral Spratt in seventy to a hundred and twenty fathoms. They are mostly quite minute. Ten new species are described and well figured. One, an extremely minute shell, which might well prove the fry of something larger, is globosely conical, imperforate, and with the pillar angulated and spread out at its base. It is referred to a new genus, Brugnonia, and placed in the Solaridae. A list of Ostracoda and Foraminifera, collected with the shells, is added by Mr. David Robertson. — (*Ann. mag. nat. hist.*, May.) W. H. D. [126

Structure of the shell in brachiopods and chitons. — Van Bemmelen has prepared an English abstract of that part of his Dutch paper which relates to the brachiopods. The principal points of the dissertation are also to be found in the *Jenaische zeitschrift*, ix. h. 1–2, 1883. That part relating to the chitons, which is the more interesting because in a fresher field, has not been made available for students who do not read Dutch. The paper is decidedly sophomorical, containing much that is important but not new, and a little that is new but not important, if we except the opinions of the author. The statement that there is any difference, except in degree, between the structure of the peduncle in Lingulidae and in other brachiopods, will require much more demonstration before it can hope to be accepted; and the principles upon which he includes the greater in the less by placing brachiopods among the chaetopods, would, if carried to their logical conclusion, include man among the Ascidians. — (*Ann. mag. nat. hist.*, May.) W. H. D. [127

Economic mollusks at the Fisheries exhibition. — The catalogue of the economic mollusks exhibited by the U. S. fish-commission at London, prepared by Lieut. Winslow, U.S.N., has just appeared, and forms a pamphlet of 85 pages, containing much information. — W. H. D. [128

VERTEBRATES.

Homologues of the parts of the temporal bones. — M. Lavocat, at the close of his revision of this subject, offers the following conclusions: —

1. That the relations of the squamosal and the zygomatic process in mammals show how ill applied to the oviparous vertebrates are the terms 'tympanic bone' (*os tympanique*), generally applied to the squamosal, and 'squamous portion of the temporal' (*écaille temporale*), given to the zygomatic process. In the oviparous vertebrates the tympanic bone does not exist. 2. That the zygomatic process, always included between the squamosal and the jugal, should never be confounded with the squamosal. 3. That there is a vulgar error relative to the temporal of serpents, in which the superior part of the squamosal has been considered to be the mastoid; while, in reality, the mastoid is invariably situated above or behind the auditory cavity, and is never movable. 4. That in birds the squamosal cannot be represented by the posterior frontal, because the latter is orbital in its relations, while the former is temporal; also that the zygomatic process should not be confounded with the jugal, the one having relations with the squamosal, the other with the maxillary.

The author also states concisely that that bone must be considered the squamosal which, though fixed or movable, is situated in front of the auditory canal, and articulates with the pterygoid and the mandible. In the oviparous vertebrates, the squamosal has commonly been wrongly designated 'the tympanic.' The zygomatic process, whether fixed or free, is always included between the squamosal and the malar. The parts of the temporal are also clearly distinguishable by their teleological relations.

The author furnishes the data for the table (see p. 114) of the synonymy of the temporal bone in the fishes and lower vertebrates. — (*Mem. acad. sc. Toulouse*, iv. 1882, 71.) F. W. T. [129

Nomenclature of the squamosal bone (temporal écailleux) of the Vertebrata pisciformes.

ANTHROPOLOGY.

Domestication of the horse. — M. Cornevin, discussing the earliest evidence of taming the horse, very pertinently sets out with the question, "What is a domestic animal?" and replies, "One that participates in the *domus*, submits itself to the domination of a master, to whom it renders its products or its services, reproduces in captivity, and gives birth to young, which become more and more submissive to control." The idea of domestication comports with that of property in some form. M. Cornevin, for reasons mentioned in his communication, places the time of the event in the bronze age contemporaneous with the bronze bit. The fact seems incontestable that the use of bronze was imported into Europe and Africa from the orient. M. Pietrement, in his work on the origin of the domestic horse, and, before him, M. Pictet, in his *Origines indo-européennes*, have proved that the Aryans, of the central Asiatic plateau, utilized the horse at a time when Europe was in the stone age. In the discussion which followed M. Cornevin's paper, M. Faure remarked, that, while the bronze bit was good proof of the domestication of the horse, the latter may have been tamed long before bronze was known. Indeed, the Gauchos catch the wild horses with a simple lasso. Could not prehistoric man, after catching a horse by means of a lasso, like the Gauchos, have made a simple bridle of raw hide, and have managed the animal thereby? — (*Bull. soc. anthrop. Lyon*, i. 116.) J. W. P. [130

The troglodytes. — M. Alex. Bertrand, conservator of the museum of national antiquities of St. Germaine-en-Laye, delivered an address in December last on the cave-dwellers, now published with copious illustrations in the first part, vol. ii., of the *Revue d'ethnographie* (Jan.–Feb., 1883). The address is in popular language, and gives many valuable particulars, deduced from their remains, of the environment, habits, utensils, and art of the prehistoric inhabitants of Europe. Perhaps the most interesting points are the evidences presented of their domestication of the reindeer, and the parallel drawn between their supposed mode of life and that of the modern hyperboreans. — J. W. P. [131

The Serers of Joal and Portudal. — Dr. A. Corre of the French marine service gives an interesting and illustrated ethnographic sketch of the remarkable people on the west coast of Africa, chiefly near Cape Verd, and mentioned by Brue, towards the end of the seventeenth century, as being strongly distinguished from the surrounding negroes. In many particulars, these people show characteristics similar to those of tribes separated from them by half the circumference of the globe. A short sentence may be literally translated in illustration: "They call the uncle, father; the aunt, mother; the cousins, male and female, brothers and sisters." The writer of the sketch did not appear to understand, or at least to follow up, this evidence of the system of consanguinity and affinity so frequently found in the stage of savagery. — (*Rev. d'ethnographie*, Jan.–Feb., 1883.) J. W. P. [132

Roumanian ethnology. — Trajan conquered Dacia in A.D. 106, colonizing it with subjects drawn from various parts of the empire. When this same country became known to the inhabitants of western Europe, they found there a people speaking a language derived from the Latin, and evidently descended from Roman provincials. With their imperfect knowledge of the intervening centuries, it was but natural, says A. J. Patterson, that they should connect these facts together, and assume that the Wallachs of their own times were the direct descendants of Trajan's colonists, and that they had dwelt uninterruptedly on Dacian soil. As soon, however, as the Rouman language and Rouman institutions were examined in detail, more and more points were discovered which could with difficulty be brought into harmony with that *prima facie* view. Inquirers who were not subject to the disturbing influence of Rouman patriotism came to the conclusion that the present Romance-speaking population of Roumania and Transylvania have migrated thither from the lands south of the Danube since the beginning of the twelfth century. In addition to the ordinary ethnologic evidence, the philological argument has been effectually urged by Paul Hunfalvy. Both in the middle ages and at the present time, a people is found in various parts of the Balkan peninsula whose speech so closely resembles that of the northern Roumans as to prove that they are dialects of one language, and must have been diffused from a common centre. — (*Academy*, May 19.) J. W. P. [133

NOTES AND NEWS.

It was known some months since how Mr. Henri Harrisse had made, as he claimed, a discovery that the Portuguese had as early as 1502 mapped out the eastern seaboard of the present United States from Florida to the neighborhood of 40° north latitude. A few weeks ago Mr. Harrisse laid a copy of the discovered map before the French institute with documentary proof of its date (1502). A more particular statement has reached us in a letter from the Rev. Edward E. Hale, written in Paris, where he had inspected Mr. Harrisse's copy of the map and document which were found in the archives of the Este family in Modena. We must await conclusive particulars, to be published by Mr. Harrisse, before determining if this last be one of the important contributions to the study of early American cartography, which this whilom New-York lawyer has made. Meanwhile it is not at all clear whether the new map is going to contribute any thing further than what we have already known from the old Portuguese chart, which Lelewel gives in his *Géographie du moyen âge*, pl. 43, with a conjectural date between 1501 and 1504. This gives a rude representation of Florida, with its easterly coast trending northerly, and coming abruptly to an end. Lying to the north-east, and in mid-ocean, is a bit of continental shore, indicating the Cortereal discoveries in its latinized name, 'Regalis domus,' with a large island adjacent called 'Terra laboratorum,' or Labrador. The earliest printed map of this region bears a strong resemblance to the Portuguese chart, and would seem to have been based on the same or similar information; and this is the famous Stobnicza map, which was published at Cracow not far from 1512. The 1511 Ptolemy has the Cortereal region, but omits Florida. From two maps in the 1513 Ptolemy a delineation very like the Portuguese chart can be made up; and after this its contours became for some years an established type frequently met with. Another Portuguese chart is well known to students in this field; and that is the one which has been reproduced by Stevens, Kunstmann, Kohl, and others, and is usually placed between 1514 and 1520. If it embodied current knowledge in Portugal, it was certainly not generally known there that the eastern coast united with the Cortereal region; for the ocean is represented as washing uninterruptedly between.

From what Mr. Hale writes. the newly found map would seem to be much the same in character as the 1513 printed Ptolemy maps, thus carrying back their delineation ten or eleven years earlier; and this, we have seen, takes us to the supposed date (1501–1504) of the Lelewel Portuguese chart, which is essentially like the 1513 maps, and seemingly like the Este map: but a sight of Harrisse's discovered chart, in due time to reach us, will give us something more than conjecture on which to base an estimate of its importance.

There is one discovery, however, which we are waiting for, and in time it may come; that is, the evidence, cartographical we hope, rather than documentary, that the Biscayan fisherman knew the Grand Banks and the adjacent coasts long before Columbus. It seems harder not to believe that this was the case than to believe it. The hardy fishermen of the Bay of Biscay had stretched their courses farther and farther to the north in pursuit of the stock-fish or cod, which was the staple food of Catholic Europe for more than a hundred days in the year. They had gone to Iceland, and, by easy gradation, to the Greenland seas; and we must remember that on this very Portuguese chart of 1501–1504, and in the Ptolemy, preceding the time of Columbus, Greenland was but a prolongation of north-western Europe. Accordingly, following their game, the fishermen could easily have cruised still farther along the Labrador coast, and to the neighborhood of Newfoundland, without in the least supposing they had found a new world, but rather a hitherto unvisited region of the old world. So, on their return, their sailor's yarns would raise no suspicion of a new quarter of the globe, such as Europe was startled at when Columbus returned from his purposed quest. It was not the fishermen's report, accordingly, that could have incited Cabot; but, when news reached England of the discovery of the Spaniards, it can easily be conceived how these sailor's yarns may have been interpreted in the belief that the land found by Columbus must, by the analogy of continents, have stretched to the north, and could be found by sailing west from England. Further, so far as Columbus' views were shared, that he had reached the coast of Asia, the reports of Marco Polo and the rest showed that the Asian coast must lie also in that very direction. Now, when Cabot reached the land, and found the natives calling the stock-fish or cod, *baccalaos*, where did they get the very term which Biscayan fishermen had applied to the same fish for centuries? This has always been a puzzle. It seems to us that it will yet be discovered that Cabot had only reached by a southern passage the region which the Biscayans had long been sailing to by the northern. The archives of Europe, we are confident, will yet reveal the proof. Only last summer the Rev. Mr. Hale, searching the archives at Madrid, found a sketch by Cortes of the Gulf of California, made six years before the earliest that had previously been known; and it disclosed the extent of Cortes' own examination of the Pacific coast in advance of his captains. The archives of the old world have by no means yet yielded all that they may.

— The funeral of the late Mr. William Spottiswoode took place at noon July 5 in Westminster Abbey, and was attended by many distinguished men from the various scientific and other societies with which the deceased was connected. There was also a large attendance of the general public. The pall-bearers were Marquis of Salisbury, Oxford university; Lord Granville, London university; Sir W. Siemens, British association; Sir F. Leighton, Royal academy; Sir J. Lubbock, Linnaean society; Sir Bartle Frere, Royal Asiatic society; Sir W. Armstrong, Institute of civil engineers; Dr. Evans, Royal society; Chancellor of the exchequer, H. M. government; Duke of Northumberland, Royal institution; Master of the stationers' company, the company; Lord Aberdare, Royal geographical society; G. Busk, Esq., Royal astronomical society; Professor Flower, Zoölogical society; Mr. Shinn, Mr. Carey, Mr. Hunt, Mr. Millwood, Mr. White, Mr. Wilson, representing departments in the Queen's printing-office.

The *Athenaeum* says of Mr. Spottiswoode: "Mr. W. Spottiswoode's illness had from the first caused serious alarm; still it was hoped that he would triumph over typhoid-fever, though complicated by congestion of the lungs. His strength had, however, been shaken by the severe accident he met with some months ago, and there is little doubt that his indefatigable attention to duties of various sorts had overtasked even his vigorous constitution. He combined with the studies of a physicist and a mathematician the supervision of a great mercantile concern. To accomplish all this; to make elaborate and delicate experiments, contribute a succession of papers to the *Transactions* of the Royal society and *The Philosophical magazine;* to mix frequently in general society; to preside over the chief of our scientific bodies, and manage a large business, — was possible only to a man who would map out the work of every day, and never waste a minute of his time. And this was the case with Mr. Spottiswoode. His was eminently an organizing brain, gifted with great clearness, complete mastery of detail, unfailing punctuality, and power at once to seize the essence of any matter brought under his notice. Personally he was most kind and generous, eminently tolerant of differences of opinion, and courteous to all with whom he came in contact."

— On Thursday night, July 12, 1883, the newer of the buildings of the Indiana university was struck by lightning and thoroughly destroyed. The building was a four-story brick of Gothic design. Upon the first floor were the collections of geology, mineralogy, and archeology, and the chemical laboratory; on the second floor were the libraries and the physical laboratory; while the third contained the valuable zoölogical collections of the university, and the museum of comparative anatomy. The loss as reported is as follows: museum, $75,000; library, $36,000; laboratory, $10,000; building, $45,000; total, $166,000; upon which there was a total insurance of $27,454.54.

The entire Owen collection of 85,000 specimens of geology and mineralogy was destroyed. This collection contained many types of species described by David Dale Owen and others. The geological collection also contained many noted specimens from Europe and America, among the more celebrated of which were the large Würtemberg Ichthyosaurus, and a Megalonyx from Henderson, Ky. The latter has fortunately been described and figured by Professor Cope for the forthcoming report of the Indiana geological survey. A fine set of Ward's casts was also destroyed, but can readily be replaced.

Professor Van Nuys' chemical laboratory, containing a number of fine imported pieces of chemical apparatus; Professor Wylie's physical laboratory, including a number of the owner's ingenious mechanisms, and the entire ichthyological collections of Professors Jordan and Gilbert, — representing years of patient work, and probably the finest private collection of fishes in the United States, — were also destroyed, together with valuable collections belonging to the U. S. national museum, Yale college, Cornell university, and other institutions.

The Brookville society of natural history, of Brookville, Ind., has been the first to offer aid to the institution: they have placed their entire collection of duplicates at the service of the trustees, from which several thousand specimens will be received as soon as arrangements can be made to accommodate them. It is understood that the trustees will proceed at once to replace the building which was destroyed; and they should erect a substantial fire-proof building in which to keep what valuable material they may hereafter acquire.

— The circular of the local committee of the American association announces reduced rates on very many railways and at the hotels of Minneapolis. The latter, however, are crowded at this season; and members are recommended to resort to the suburban hotels on Lake Minnetonka and Lake Calhoun, about twelve miles from the city, to and from many of which the railways will carry members free, the time being about half an hour. Many members will be entertained by the citizens of Minneapolis; and a sub-committee will endeavor to find entertainment for all who will notify its chairman, Hon. A. C. Rand, early, of their intention to be present.

The usual favors will be granted by the telegraph companies. Badges, a daily lunch, and low-priced carriages will be furnished, together with a descriptive and illustrated guide to the city of Minneapolis, now in preparation. Express packages containing apparatus, specimens, maps, books, drawings, or other articles designed for use in the meetings, will be forwarded by the American express company, and delivered free of charge at the University of Minnesota. Such parcels should be addressed in care of Prof. J. A. Dodge, to whom, also, all correspondence relating to the same should be sent. After Aug. 12, letters may be addressed to members at Minneapolis, in care of the association, and they will be delivered from the office of the local committee at the university.

An excursion will be made to Minnetonka, and return, on Saturday afternoon, when a lawn picnic will be served at the Lake Park Hotel. If a party of a hundred and fifty or more desire to make an excursion to Winnipeg, and return, at one-half of regular fare, the St. Paul, Minneapolis, and Manitoba railway will send a special train for their accommodation. No definite arrangements have yet been made for other excursions.

The retiring address of President J. W. Dawson will be given at the Westminster church, on Nicollet avenue, on Wednesday evening. After the address a reception will be held by the local committee at the Nicollet House.

The meeting will probably be one of special interest to glacial geologists, numerous papers concerning the terminal moraine and other glacial phenomena being expected.

— The annual meeting of the Society for the promotion of agricultural science will be held in Minneapolis on Aug. 13 and 14, in the Agricultural college building, of the State university.

— A special public meeting of the Cambridge entomological club will be held in Minneapolis, at the chapel of the university, at two P.M. on Tuesday, Aug. 14, to which all persons interested in entomology are invited.

— The annual meeting of the American forestry congress will be held at St. Paul, Minn., commencing on Wednesday, Aug. 8, 1883. The local committee has in charge the arrangement of railroad facilities, etc., announcement of which will be sent to all members in due time, and to all those who express their desire to attend the meeting. Papers to be read at the meeting, or abstracts of the same, should be sent in to the corresponding secretary two weeks before meeting, according to the by-laws of the congress.

— A geographical and ethnological exhibition will be held in Nancy from Aug. 20 to Sept. 20.

— The French association for the advancement of sciences meet at Rouen, Aug. 16–23.

— The sixth congress of the French geographical societies will meet under the presidency of M. de Lesseps at Douai on the 26th of August, and remain five days in session. A geographical exposition will form a feature of the meeting. The seventh congress will meet at Rouen in 1884, and the eighth at Oran in 1885.

— The seventh congress of the Russian scientific association will be held in Odessa from Aug. 30 to Sept. 9.

— The sixth annual meeting of the American society of microscopists will be held in Chicago, beginning Tuesday, Aug. 7, 1883, and continuing four days. Ample preparations are making by the committee of the State microscopical society of Illinois, and the Chicago academy of sciences; and the attendance of members is expected to be larger than ever before. First-class hotel accommodations at reduced special rates have been secured, and choice arrangements made for the comfort and convenience of the meeting. Titles of papers may be sent to the secretary, Prof. D. S. Kellicott, Ph.D., 119 14th St., Buffalo, N.Y. Full provision will be made for illustration, by projection apparatus, of any article when the authors may so desire. A special hour will be allotted each day to the exhibition of objects and apparatus referred to or described in communications read before the society; an evening will also be set apart for the presentation of methods of work, including staining, section-cutting, mounting, microphotography, etc. A general microscopical *soirée* will be held on another evening, and members are requested to bring instruments and slides with them. The exhibition of instruments and accessories by makers and dealers promises to be unusually fine.

The officers of the society are Albert McCalla of Fairfield, Io., president; E. H. Griffith of Fairport, N.Y., and George C. Taylor of Thibodeaux, La., vice-presidents; D. S. Kellicott of Buffalo, N.Y., secretary; and George E. Fell of Buffalo, N.Y., treasurer.

— The Société académique of Brest held an exhibition of matters relating to geography, June 3–17. An especial object was to bring to notice the rich ethnological material which has accumulated in this city during many years. The halls devoted to Japan, China, Cochin-China, and West Africa, presented much of interest.

— In the *Philosophical transactions* for 1817 (p. 325), Sir William Herschel says, that, "beside the 683 star-gauges published in the *Philosophical transactions* for 1785 (p. 221), above 400 more have been taken in various parts of the heavens."

These four hundred unpublished gauges have lately been extracted from the original observing-books preserved at the Herschel family residence at Collingwood, through the kindness of Sir William Herschel, the present baronet, and of his brother, Major John Herschel; and the manuscript has been presented to Professor Holden, director of the Washburn observatory.

The original records are in the handwriting of Miss Caroline Herschel, and by her faithful care every detail necessary to their accurate deduction is preserved. It will be observed that only two-thirds of the star-gauges of Herschel have heretofore been known. The new acquisition will be welcomed by those interested in this class of observations. They are a new gift from an inexhaustible mine.

— The bureau of education has just published a circular of information, containing the results of an inquiry into the effects of co-educating the sexes in three hundred and forty cities and large towns of the Union. Of these, three hundred and twenty-one practise co-education throughout the public-school course, seventeen co-educate for part of the course, and two separate the sexes entirely. A careful analysis of the reasons adduced for co-education enables the editor to formulate them as follows: co-education of the sexes is preferred where practised, because it is, 1°, *natural*, following the usual structure of the family and of society; 2°, *customary*, or in harmony with the habits and sentiments of every-day life and law; 3°, *impartial*, affording to both sexes equal opportunities for culture; 4°, *economical*, using school-funds to the best advantage; 5°, *convenient* both to superintendent and teachers in assigning, grading, instruction, and discipline; and, 6°, *beneficial* to the minds, morals, habits, and development of the pupils. The pamphlet concludes by observing that "both the general instruction of girls, and the common employment of women as public-school teachers, depend, to a very great degree, on the prevalence of co-education, and that a general discontinuance of it would entail either much increased expense for additional buildings and teachers, or a withdrawal of educational privileges from the future women and mothers of the nation."

— Mr. Charles B. Dyer, a well-known collector of Cincinnati fossils, died at his home on Wednesday, July 11, after a painful illness of over three months' duration. He was for many years engaged in amassing one of the finest collections of local paleontology in the country, which now reposes in the Agassiz museum in Cambridge. His rarest fossils were collected by himself, and his industry in the pursuit of new and fine specimens was untiring. In connection with Mr. S. A. Miller, Mr. Dyer issued a few years ago, at his own expense, a pamphlet with two plates, containing descriptions of new forms from his collection, entitled 'Contributions to paleontology.' Thirty years ago Mr. Dyer retired from business with a moderate fortune, and devoted all his time to collecting. He was an eccentric man, with strong feelings, but a fast friend and a pleasant companion. He was in the seventy-eighth year of his age, and had lived in Cincinnati for over fifty-five years. His name is attached to one of the commonest crinoids of the Cincinnati rocks, Glyptocrinus Dyeri, and to several very rare and beautiful forms discovered by him.

— The Imperial geographical society of St. Petersburg has awarded its great gold medal to H. W. Abich for his researches into the geology of the Caucasus. The Lütké medal was received by W. K. Döllen of the Pulkova observatory for improvements in astronomical instruments; Vitkoffski, Barsoff, and Krasnoperoff have received medals for ethnographic and statistical works; Oshanin, for travels in Turkestan, etc. Silver medals were awarded to Brunoff for meteorological researches, and to Lessar, Schultz, Gladisheff, Kiseleff, Rodionoff, and Slovtsoff for surveys and journeys, chiefly on the Asiatic frontier of Russia.

— The observatory at Moscow was among the establishments of the northern hemisphere which co-operated with Mr. David Gill, Her majesty's astronomer at Cape Town, in securing observations of the small planet Victoria, at its late opposition, for a new determination of the solar parallax. The ninth volume (livraison i.) of the *Annales* of this institution contains the results of these observations, together with several papers by its director, Dr. Bredichin, relating to comets and allied subjects.

RECENT BOOKS AND PAMPHLETS.

**** Continuations and brief papers extracted from serial literature without repagination are not included in this list. Exceptions are made for annual reports of American institutions, newly established periodicals, and memoirs of considerable extent.*

SCIENCE.

FRIDAY, AUGUST 3, 1883.

THE U. S. NATIONAL MUSEUM.

II.

In a former number we reviewed some of the important principles of general classification suggested by Mr. Goode's plan of the National museum. We resume the topic to discuss some of the salient points in the minor groupings of the same scheme.

Section iii., 'natural resources,' i.e., 'force and matter,' appears to be out of place. Certainly these are primary subjects; and we cannot, as a merely practical matter, understand why the study of physics and chemistry is placed after that of the earth, which is to be treated of earlier under the separate heads of 'cosmology,' 'geology,' 'physiography,' etc., in section ii. Imagine a person trying to learn something of the relations of force and matter to the history of the development of the earth and its topography as it now appears, and having in view the applications of these studies to the explanation of some of man's migrations or racial differences, or to any other anthropological problem which might reach back to primary connections. Is it supposable that his inquiries would be facilitated by placing the collection in such relations to each other as completely to cover up and invert their natural relations and logical order? Or is it probable that the mind of the visitor would be more enlightened by getting his information about the relations of the elements after he had passed through celestial and terrestrial physics and chemistry, and all the applications of these to the history of the development of the earth?

We can readily picture to ourselves the confusion which might be generated in his mind, and the discovery he might make of the necessity of reviewing all he had passed over before; but we fail in attempts to imagine the advantages of this inversion. We cannot, therefore, understand the considerations which induced Mr. Goode to adopt this method of arranging the sections, nor why he did not place natural resources first, and man last, in his natural history division; for that is what the first three sections really constitute when taken together. They would then have stood in approximately natural, and certainly respectably logical, relations to each other.

We should then have had in section i., physics, chemistry, and all the mineralogical, botanical, and zoölogical collections as introductions to the study of section ii., where the principles of science learned in passing them in review would be found of essential assistance in understanding the earth, with all the topics of cosmology, geology, etc., whether presented, as Mr. Goode proposes, solely as man's abode, or in its more natural relation to the universe as a planetary body. The last seems to us the preferable because more natural mode of presentation; and the author shows this by bringing in cosmology. This, if at all effective, must show that the earth is a planet primarily uninhabitable by man, and evolved without reference to his existence, conducted in its career by cosmic forces uninfluenced by his presence, and, in all likelihood, destined to become unfit, in course of time, for his existence.

After the earth as man's abode had been passed through by the visitor, we could readily conceive of his being all the better prepared for the understanding of section iii., 'the natural history of man and his adjuncts of all kinds.'

Passing over section iv. ('the exploitative industries') and section v. ('the elaborative industries'), which together constitute what appears to be a second grand division of the museum representing the purely industrial side, we come to section vi. In this section are included foods, and drinks in their final stages of preparation for the use of man, narcotics, dress, buildings, furniture, heating and illumination, medicine, hygiene, transportation. All of these are supposed to have a more direct relation to the physical condition of mankind, either from their nature, or in the peculiar stages of their manufacture which makes them admissible to the cases of this section.

Section vii., 'social relations of mankind (sociology and its accessories),' is to be an exposition of the appliances and methods made use of by man in his social relations, communication of ideas and their record, trade and commerce, societies and federations, government and law, war, ceremonies.

Section viii., 'intellectual occupations of mankind (art, science, and philosophy),' is to show the existing intellectual and moral condition of man, and the most perfect results of human achievement in every direction of activity. Its topics are to be games and amusements, music, the drama, the arts, literature, folk-lore, science, philosophy, education, and climaxes of human achievement.

The sixth to the eighth sections contain the special topics which can be used to illustrate the results of the intellectual progress of man more completely and directly, perhaps, than the industries, in sections iv. and v.; and these are accordingly placed in a succession leading naturally to their culmination in the topic which terminates section viii., and is at the same time the sixty-fourth and last of all of the topics. This terminal topic is to be an exposition of the most remarkable achievements of man. The separation of this from the final topic of section i. ('man in his individual manifestations, representative men, biography') shows, that, though Mr. Goode has kept in view the key-note of man's progress in civilization, the development of the individual, he has nevertheless either failed in seeing, or considered of subordinate importance, the racial peculiarities and advantages of which the representative man is necessarily only the concentrated or focalized expression.

In fact, this want of what we might call psychological insight is apparent everywhere; and throughout the scheme the race is subordinated to the notion that man should be presented and considered as a whole, whether in the development of the topics separately, or the purely comparative arrangement of the sixty-four topics themselves as assembled in the different sections of the museum. In section i. man is treated of 'psychologically as a unit;' and it is only in the second topic of this section, where the natural relations of men force the treatment to stand upon a racial basis, that we find this policy even apparently abandoned. We say apparently; because, as we understand it, the effort here will be not to show the historical or physical development of the races, so much as to contrast them side by side and exhibit the characteristics of each race.

In all its parts, the arrangement is based in each topic upon a comparison of the work of different races; and the objects used for these purposes must be withdrawn from their natural associations in other collections, and their significance in the history, physical and psychological, of any particular race, be sacrificed.

This is the method of comparative anatomy, and has certain obvious advantages for the study of anatomy if it is confined in application within the well-defined limits of any one type of plants or animals; but it is liable to lead to serious errors when carried beyond these limits. The dismembered organs or parts, though similar, are, when found in distinct types, unquestionably often distinct in origin. The comparative method necessarily cuts across the natural order of things in their relations to time and to the successive stages of their development: and this is an obvious defect, which, when applied to anthropological collections, is destructive of all natural conceptions as to the way in which modifications and changes really arise or flow out of pre-existing localized or racial conditions.

Anthropology as a science is essentially concerned in tracing the history of different races of men: it clings to the race as the safest basis of classification at present existing, and it is the test by which all general conclusions with regard to the nature of man and the evolution of civilization are judged. A museum of anthropology departs widely from this basis and true scientific conservatism when it assumes the task of harmonizing the psychology of all the races of men, especially in the present almost unexplored condition of this field in savage races, and when it declares that it can present a true picture of the existing condition of man by the method of general comparison of things whose connections, as they stand side by side, are obviously unnatural.

The presentation of the results of achievement in all directions, as attained by each race or natural association of races, could not have been open to such serious objections, would have been far more effectual, and more in accordance with the principles of modern classification and the practice of museums of anthropology. It would, at any rate, have retained the collections in what are known to be their natural relations; such a presentation could not have failed, therefore, to meet the wants of the future and the demands of the present in a more effectual way than by any artificial classification, whatever its convenience.

We do not think that the industrial side would have suffered from this policy, but, on the contrary, we think its subjects would have greatly gained in interest from being shown as developed by the different races; nor do we believe that such a plan would have demanded more room than the present plan, required any more duplicate collections for its proper illustration, or yet have greatly increased the difficulties of the classification of topics which Mr. Goode has so ably handled in his scheme.

The comparative method could then, if deemed necessary, have been resorted to as a crowning effort to show, side by side in a single collection, the ultimate achievements and results attained by each race, how far it had been able to advance in civilization, and what influence, if any, its finest work had had upon the existing conditions of that civilization. Such a summary certainly could be so limited by judicious selection as to be brought within the mental grasp of the intelligent and diligent student; whereas a definite conception of Mr. Goode's sixty-four topics presupposes mental powers of a titanic order. In fact, the graphic picture of civilization which they will present will, from their number and mode of arrangement, be necessarily heterogeneous, — an improvement, no doubt, on general notions in being composed of objects instead of individualized mental conceptions, but certainly not capable of giving the harmonious effect which the author aims at producing.

The National museum is, however, to be not only the representative educational museum of this country, but is also to be combined with departments of research. We have, therefore, to consider the probable influence of the museum of education and its collections upon the departments of research, bequeathed to its care by the Smithsonian, as well as those likely to come under its influence in the future. These last collections might, perhaps, be safely left to themselves; but it must be remembered, that, though at present secure, they will eventually obey the law of attraction, and their curators must begin immediately to take an active interest in the collections which are to represent their achievements before the country at large, and the relations of these departments to the prospects of investigators.

At present the departments of research and those of education are not only under one head, but the subordinate offices are also united in the same persons. Under these circumstances, we view with apprehension certain tendencies, which are evident in the pamphlet before us, and especially the prominence given to the industrial sections. Their present mode of arrangement and ideals do not definitively shut out all possibility of co-operation with business; on the contrary, if we understand certain passages in Mr. Goode's pamphlet, this co-operation is invited, and some firms are already providing the cases with collections of industrial products. We know that science is not the weakest now in the National museum, and our fears will probably highly amuse the officers of the industrial sections; but nevertheless, we cannot see what is to prevent enterprising firms from presently finding out the value of these departments as advertising mediums, and being aggressively if not successfully generous in supplying their wants with expensive gifts, accompanied by their business-cards. The fertility of the imagination in the construction of wedges may certainly be counted upon as quite equal to the opening of any cracks which may present themselves; and we think it would have been far more prudent to recognize and provide for these dangers, however remote they might be considered.

We are, of course, conscious that the joining of hands between science and the industries is the general drift of the tendencies of the day, especially in this country. That this will elevate the industries, we have no doubt; but that it will also elevate the ideals of science, we do not believe. How will the future director, however scientific, avoid the necessity of becoming, before the government and the country, the representative of great commercial and industrial questions and interests, and be in danger of having his interests and his thoughts drawn into the vortex of such affairs, to the exclusion and neglect of the purely scientific aims and objects of the museum? We do not claim that this will be sure to be the case, but simply that we do not see how he can avoid the natural results of his position at the head of the great industrial museum of the country.

Mr. Goode's pamphlet also contains other matters, which, when viewed in the light given by the past history of other museums, show the neglect of essential precautions. There is, for example, no provision for limiting the accumulations of specimens. On the contrary, overpowered by the wants of his world-embracing scheme, he appeals to public-spirited citizens to come forward and deposit their valuable and extensive private collections; and it is especially recommended that the officers, by a wise forethought, should encourage this propensity to the utmost.

Private collections have been made for the most heterogeneous purposes; and it is well known that their possessors usually demand, in return for their generosity in giving them, that they shall be kept together, or have a goodly proportion of exhibition space allotted to them. Such unqualified appeals, and the neglect of all other precautions [1] against the unlimited acquisition of materials, are entirely at variance with the selective policy previously announced, and a complete surrender of the principles which should govern a museum starting with a new ideal, and bent upon avoiding the errors of policy and the unnecessary burdens which had been previously and truthfully described by Mr. Goode as the greatest obstacles in the path of the older museums.

It does not require a prophetic eye to see in the near future, that assisted by the Fish-commission, the Geological survey, and other departments of the government, the business energy and liberality of the American citizen, the pride, energy, and influence of the present staff of museum, uncontrolled by any prudential considerations, and stimulated by the universal field they are required to cover, will heap up materials not only faster than they can be handled, but in such masses that they will become, as in older museums, serious obstacles to the progress of the museum of education itself, and be still more serious in their effects upon the museum of research. The resources of the National museum, however great they may be, will inevitably find themselves, sooner or later, blocked by these accumulations; and their care will occupy the time of the officers in an increasing ratio. Luckily for science, men in such positions have frequently found themselves unable to resist the suggestive seductions of research, and allowed collections to suffer while they studied; but many, too conscientious to do this, have been sacrificed to the mere preservation of materials, whose labors would have repaid the daily wages of many more lower-class laborers to any civilized government. Large accumulations, however, not only directly discourage the investigator by

[1] That we are not misrepresenting the spirit of the museum by this remark may be learned in Mr. Goode's own words: "The classification proposed should provide a place for every object in existence which it is possible to describe, or which may be designated by a name. When the object itself cannot be obtained, its place should be supplied by a model, picture, or diagram."

wasting his time, but their necessary preservation strikes at a still more vital point in using up funds which could otherwise be employed for the publication of the results of researches. They also equally interfere with the purchase of delicate instruments, the employment of labor to directly assist in carrying out the purposes of research, prevent the purchase of such specimens or collections as may be essential, and cut off opportunities for travel and study in other museums or parts of the world.

We think, therefore, that, while the National museum may open some paths to the investigator, it will neither directly do the very best work in this direction, nor give us any grounds for believing that it will introduce a new era of prosperity for abstract investigation. It will add one more to the useful scientific institutions of its kind, it will undoubtedly contribute to the progress of science by increasing the opportunities for employment and by the example of its officers; but it will not do much for them or for us in the way of an exalted ideal.

If the museum of education had been limited by a wise policy of selection in its accumulations of materials, and placed under a distinct staff, we could have made no such objections; then the practical objects of its existence would not have suffered, as they now surely will, from the psychological tendencies of the investigating curators; nor, on the other hand, would the investigators themselves have been distracted by having a double purpose in all that they were doing, and frequently obliged to sacrifice one or the other. We do not wish to imply that the museums should not be under one general head, and have all the benefits of mutual association, but simply insist that the ideals are quite distinct, and the officers should realize this by being under different regulations, and under a different government, in each of the two museums. The investigator cannot avoid placing on exhibition the record of his own and others' work; and he will find a thousand good reasons for crowding the cases with fine collections, because they are fine, and because they are important in research, or unique, or remarkable; and the educational idea will be subordinate or completely lost in such parts of the museum, so far as the average student is concerned.

The cost of the museum will be enormous; but if its lessons can be easily mastered by the average student, and in this case the student is the average congressman, he will not begrudge the funds which are necessary for its support. It must be remembered that these are keen men, quick to see the advantages of such lessons as the museum can teach them; especially if, like the library, it can make itself really useful to them, and keep up with the times by illustrating the new results of discovery and research in all departments of learning in an explanatory and popular way. We imagine that they will not be slow in calling upon the officers of the museum whenever they have need of their services, and that they will be rather disgusted if any of the requirements of research interfere with their desire for information.

While we wish the greatest success to the National museum and its energetic and deservedly popular director, and have the highest respect and friendliest feeling towards their undertaking, and a faith that they will finally work out a better result than is promised, we think that neither this faith nor their great scientific achievements, of which we are justly proud, nor the liberality of the government, can entirely make up for the absence of the public recognition of a more purely scientific ideal in *our* National museum.

KINETIC CONSIDERATIONS AS TO THE NATURE OF THE ATOMIC MOTIONS WHICH PROBABLY ORIGINATE RADIATIONS.[1] — II.

Having now sufficiently cleared the field of inquiry by this preliminary discussion, let us consider the proposed hypothesis somewhat more closely, both as to what it is precisely, and as to how far it is in accordance with the phenomena. The whole outcome of Lockyer's investigations, to which we have referred, leads to the conclusion that atoms of the chemical elements are complex bodies, all of which

[1] Concluded from No. 24. See also *Proc. Ohio mech. inst.*, II. 89.

are formed of ultimate atoms of the same kind; so that, on this hypothesis, there is but one kind of substance from which all others are compounded. Chemical atoms might be compared to a chime of bells all cast from the same material, but each having its own special series of harmonic vibrations.

A necessary result flowing from this hypothesis would be, that the atomic weights should all be exact multiples of some fraction of the atomic weight of hydrogen, which would include Prout's hypothesis as a particular case. The experimental data are, perhaps, not yet sufficiently precise to enable us to obtain a trustworthy result as to the probability of the truth of Prout's hypothesis; yet Clarke's[1] results as to the atomic weights seem to show that the hypothesis has a high degree of probability.

If the chemical atoms of all bodies are assumed to be formed of ultimate atoms, which are in all respects equal and alike, this hypothesis furnishes a basis for investigation at once definite and simple, some of whose consequences we shall now endeavor to show to be in accordance with experimental facts.

We wish, in the first place, to show that this hypothesis will make the temperature of a gas proportional to its mean kinetic energy. A chemical atom may be assumed to be a perfectly elastic body, as its deformation is assumed to be extremely small. But according to the mathematical theory of elastic impact,[2] "when two such bodies come into collision, sometimes with greater and sometimes with less mutual velocity, but with other circumstances similar, the velocities of all particles of either body at corresponding times of the impacts will always be in the same proportion;" from which it is clear, that in a mixture of two kinds of gas, as hydrogen and oxygen for example, when the mean velocity of the molecules is so increased that the vibration of the ultimate atoms of the hydrogen is increased a certain per cent, then that of the ultimate atoms of the oxygen is increased by the same per cent. But the circumstances of the encounters and the forces acting between the ulitmate molecules determine what fraction the mean kinetic energy of vibration of the ultimate atoms shall be of that of the molecules whose encounters cause these vibrations. Since the circumstances attending the encounters are dependent simply upon the forces acting between the ultimate atoms assumed to be in all respects equal, the energy of their vibration will be the same in an atom of hydrogen as it is in an atom of oxygen; for each degree of freedom of every ultimate atom of either element is similarly circumstanced, both as regards forces between itself and other ultimate atoms of the same chemical atom, and also as regards the impacts of other molecules. The proposition of the kinetic theory which makes the energy of each degree of freedom the same, which has been erroneously applied to the degrees of freedom of molecules, can therefore be correctly applied to the ultimate atoms.

But it might not, at first glance, be apparent whether these vibrations are caused by, and are proportional to, the mean progressive energy of the molecules, or to their rotary energy combined with it. But it is not difficult to show that the vibrations of the chemical atoms with respect to each other are proportional to the mean progressive energy alone, and then to show the same for the ultimate atoms. Although, in the paper upon the vibratory motions of atoms within the molecule, we have for mathematical purposes considered the centrifugal force as causing vibrations of atoms with respect to each other, yet in fact the vibrations so caused are vanishing quantities, compared with those caused by the component of the impulsive force acting during an encounter along the line joining the atoms of a molecule. The magnitude of such a vibration, other things being equal, depends upon the suddenness of the impulse; and the suddenness of the force called into play during a change of rotary velocity, by deviation from motion in a tangent to motion in a circle, can bear no comparison to the suddenness of a direct impulse along the radius of the circle. Hence the direct impulse due to the progressive motion need alone be considered.

It thus appears that the energy of vibration of chemical atoms with respect to each other in a simple gas is proportional to its mean progressive energy. The same is true of the vibrations, with respect to each other, of the ultimate atoms which form a chemical atom, and for the same reasons; for the forces which act upon the ultimate atoms are the impulses due to the encounters of other molecules, and those due to the remaining chemical atoms of the same molecule. The energy of the latter of these motions is proportional to the former, as has just been shown; hence their sum is so also: therefore the energy exerted to deform a chemical molecule, and set it in vibration, is proportional to the mean progressive energy.

[1] Constants of nature, part v. A recalculation of the atomic weights. Washington, 1882.
[2] Thomson and Tait's Natural philosophy, 1867, art. 302.

But it is to be noticed that the impulses due to the vibrations of the chemical atoms within a molecule are vastly more frequent than the molecular impulses; and it appears probable that the vibrations of the chemical atoms set up during an encounter will rapidly decay, even in case they do not themselves directly originate radiations. The vibratory energy of this kind may then be changed almost instantly into that of vibration of the ultimate atoms.

According to the hypothesis which we are now considering, the temperature of the body and the intensity of the radiation depend solely on the vibratory energy of the ultimate atoms; but, since these ultimate atoms are assumed to be in all respects equal, they vibrate under the action of the same forces, and have the same degrees of freedom and constraint within the chemical atoms of one element as they do within those of a different element. Hence it appears, that if the ultimate atoms of two different gases have the same vibratory energy (i.e., cause vibrations of the same intensity), so that the flow of radiant energy is the same from all the ultimate atoms of each gas, then there will be no disturbance of this equilibrium when these gases are mixed; in which case the distribution of energy is effected by molecular encounters, which distribute equal mean amounts of energy to each molecule, instead of by radiations, which distribute equal mean amounts of energy to each ultimate atom.

In attempting to account for the high specific heat of liquids, I have elsewhere given reasons for supposing that it is due to a certain per cent of dissociation, which increases with the temperature. It appears probable, that, although some small amount of dissociation may exist in gases also, there is not so large a per cent as in the liquid state, nor does the per cent necessarily increase with the temperature; for by reason of the free progressive motion in a gas, which does not exist in a liquid, any dissociated atoms have a much better opportunity to recombine; and, as the velocities (especially those of free atoms) increase with the temperature, these opportunities increase, as well as the number of dissociations occurring in a unit of time; so that, at a high temperature, an atom of gas may not stay dissociated so long as at a lower temperature, while in a liquid this interval will not be sensibly affected by the temperature.

It is thought that the law of Dulong and Petit receives reasonable explanation on the hypothesis that the ultimate atoms have each the same kinetic energy at the same temperature, as will be shown in a subsequent paper: but perhaps the strongest direct evidence in favor of the proposed hypothesis is found in the fact that even the simplest elements, such as hydrogen or mercury, have spectra of several lines at least, showing that the source of the light must be sufficiently complex to be able to vibrate in a number of different ways, such as may well be possible for an atom formed of a number of ultimate atoms, but such as is inconceivable in a molecule consisting of one or two perfectly hard atoms. H. T. Eddy.

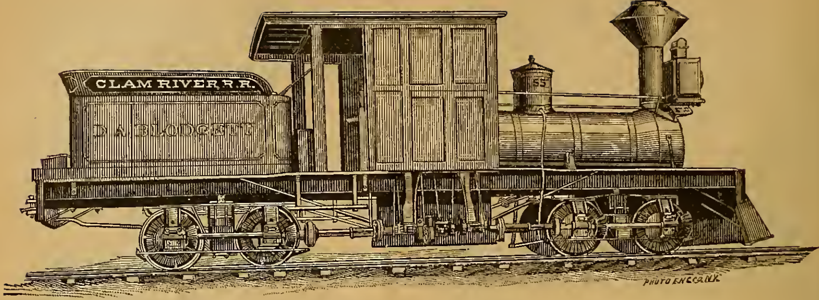
THE NATIONAL RAILWAY EXPOSITION.[1] — IV.

The exhibit of locomotives was remarkably complete, and comprised engines differing widely in size and power, and adapted for every variety of work; but a certain uniformity of the design of the main features would seem to indicate that locomotive practice has settled down into a certain groove, and that the methods of construction now adopted are so satisfactory that few exhibiters propose to greatly improve upon them by any radical alterations, though one or two of these new departures, such as the Wootten firebox and the Stevens valve-gear, seem likely to come into extensive use.

The main tendency of locomotive design seems to run rather in the direction of larger bearing surfaces and stronger working parts than in any novel methods of construction; while sound and accurate workmanship, and plenty of good material judiciously distributed, are relied on to make a locomotive durable, hard-working, and trustworthy under trying conditions.

Mr. E. Shay of Haring, Mich., exhibits a model of an engine of peculiar construction for 'logging' purposes. These small railways are exceedingly light in construction, and the rails and ties are generally laid directly on the surface of the ground, without any great attention being paid to preliminary grading or alignment; and therefore a suitable locomotive must unite considerable tractive power with great flexibility of wheel-base, and a small weight, on any one pair of wheels. Mr. Shay accomplishes this by using a Forney type of locomotive, having a pair of drivers under the barrel of the boiler, and a four-wheel truck, carrying the tank and fuel, behind the firebox. All the wheels being made of the same diameter, a pair of vertical engines are secured to one side of the firebox, working a longitudinal shaft which

[1] Continued from No. 25.



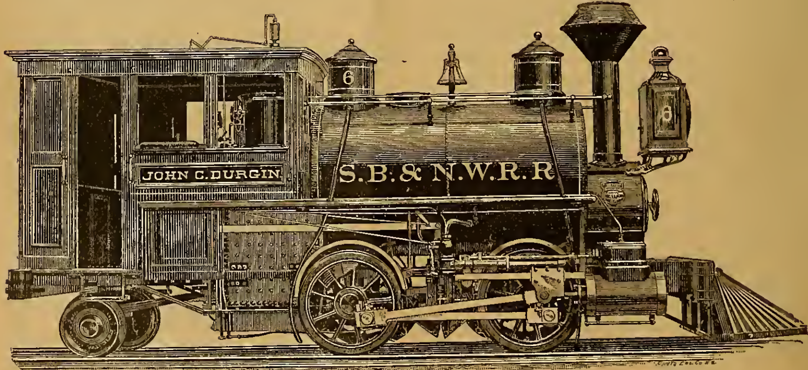
Logging locomotive with geared driving-wheels.

runs beside the wheels. Bevel pinions on this shaft engage bevel wheels on the hubs of the wheels, and, as the shaft is provided with universal and telescopic joints, the whole of the wheels can be driven simultaneously, no matter how sharp the curve over which the engine may be running; and, owing to the interposition of gearing, comparatively small-sized cylinders are sufficient to enable the engine to haul very heavy loads, and yet run sufficiently fast for the nature of the work.

Mr. Shay informs us that nearly a hundred of these engines are at work, some on wooden rails, and that they are giving great satisfaction. The mode of driving appears to be novel, and, despite some complexity, is free from many of the disadvantages of the Fairlie system, which also utilizes the adhesion of radiating axles.

Messrs. H. K. Porter & Co. of Pittsburgh, Penn., also exhibit an engine specially adapted for logging railways. Ordinary methods of construction are, however, followed; and the consequent greater simplicity is of great advantage where the work for a few months in the year is very severe, and no repair-shops are situated within convenient distance. The engine exhibited is of the following dimensions, and is calculated to work safely on a rail weighing only thirty pounds per yard: —

Cylinders, diameter and stroke	10 in. × 16 in.
Driving-wheels, diameter	36 in.
Truck-wheels, diameter	22 in.
Rigid wheel, base	5 ft. 3 in.



Logging locomotive exhibited by H. K. Porter & Co.

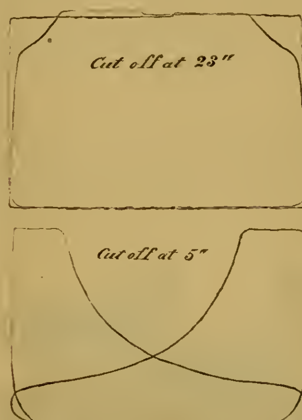
Total wheel base	13 ft. 4 in.
Weight in working order	31,000 lbs.
Weight on drivers	26,000 lbs.
Water-capacity of tank	500 gallons.

Messrs. Porter state that a similar engine, working day and night on a road 11 miles in length, with grades of 53 feet per mile, has handled 350,000 feet of logs in 24 hours, running about 180 miles in that time.

The engine exhibited is well designed, and the workmanship is fully equal to that on a first-class main-line engine.

The Cooke locomotive works of Paterson, N.J., exhibit an engine for the Southern Pacific railroad which is believed to be the largest locomotive in the world, the cylinders being 20 inches diameter by no less than 30 inches stroke. The designer of this engine, Mr. N. I. Stevens, general master mechanic of the Central Pacific railroad, is, however, building a still larger engine at the company's shops at Sacramento, Cal., the cylinders of which measure 21 inches by 36 inches. This latest development will exert a tractive force of 278 pounds for every pound per square inch average pressure on the pistons; that is to say, with an average pressure on the pistons of 100 pounds per square inch throughout the stroke, this engine would exert a tractive force or pull of 27,800 pounds, less the internal friction of the working-parts of the engine. Whether the average drawbar of the average freight-car is capable of safely standing such a strain is a question which experience will probably solve in a direction unfavorable to weak draw-gear. Apart from their immense size, these engines are interesting as being fitted with a novel form of valve-motion. The engine exhibited has four slide-valves to each cylinder, two main valves, and two riding cut-off valves. An excellent diagram is obtained, the cut-off being sharp, and the compression very slight; and the gear seems well adapted to a slow-running freight-engine. In the later and larger engine, but two valves are employed, and but one eccentric; motion being taken from the engine crosshead. The results of this simpler gear promise to be equally good, and the trial-trip of this engine will be looked forward to with great interest.

The Grant locomotive works are the makers of the only engine which departs from the sober suit of black in which its competitors are arrayed; and further examination shows that its peculiarities are not confined to the outside appearance, but extend to the fuel to be used, which is entirely novel in character. The inventor, Dr. Holland, proposes to raise steam by means of the combustion of decomposed water. The heat evolved by burning naphtha is used to separate the oxygen and hydrogen in superheated steam; and, the carbon of the naphtha kindly uniting with the oxygen thus set free, the hydrogen is burnt by means of oxygen obtained from atmospheric air. The inventor states that the only products of this combustion are carbonic acid and water, the nitrogen disappearing in some mysterious manner not yet fully understood. The old fallacy that water can be decomposed and then reunited, with a positive advantage as regards heat, is here again illustrated; while the strong smell of burning naphtha during the trial of the engine in the exposition indicated that this convenient auxiliary was used to a considerable and probably wasteful extent.



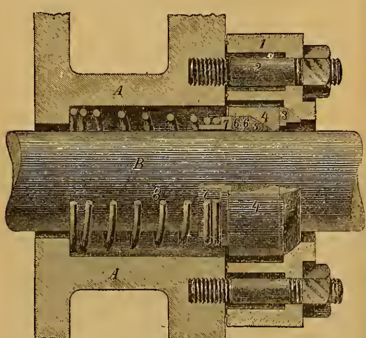
Indicator diagrams obtained on locomotive built at the Cooke locomotive works.

The Philadelphia and Reading railroad exhibit a fast passenger-engine fitted with Wootens' patent firebox, which is adapted to burn any waste or inferior quality of fuel. Reversing the usual practice on locomotives, the combustion on this engine is slow, owing to the enormous area of the grate (72 square feet), instead of a small one (16 or 17 square feet), while the blast is not severe, and the fire is one-third the usual thickness (4 inches instead of 10 or 12 inches); the result being a less vivid combustion, the interior of the fire-box being dull red in place of the white heat usual when a locomotive is at work. Trials at Chicago seemed to indicate that the engine was capable of maintaining steam with almost any kind of fuel, and that the lignite and inferior coal of the new north-west, which often contains only thirty-five per cent of carbon, can therefore be utilized under locomotives.

The slow combustion does not produce a heat intense enough to fuse the slag, and therefore the firebars keep clean and free from clinker; and it need hardly be pointed out that this is an important practical consideration in dealing with fuel which contains over fifty per cent of ash.

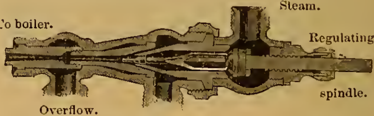
The large grate area is obtained by placing the fire and grate bars completely over the driving-wheels, where plenty of width is obtainable; and the firebox is accordingly made no less then 8 feet wide inside, instead of the usual 33 inches. It might be anticipated that the increased height of the centre of gravity would tend to make the engine unsteady at a high speed; but a precisely opposite result is obtained, as the engine rides with remarkable steadiness and smoothness, even at the highest speeds.

The Shaw engine has been so often described, and been so prominently before the public, that it is only necessary to say here, that, though exhibited at the Chicago exposition, want of time prevented any proper scientific tests being made to ascertain the real value of the invention.



METALLIC PACKING FOR PISTON-RODS.

Various forms of metallic packing for piston-rods are now being extensively used with ex-excellent results, the wear of both rod and packing being very slight, while the use of anti-friction metal obviates the frequent renewals necessary with hemp, rubber, and other packings which are destroyed by heat rather than by wear. In the packing which we illustrate, provision is made for any inaccuracy in fitting by allowing the piston-rod some play in the stuffing-box; the vibrating cup, 4, sliding on the ball and socket ring, 3. As the packing rings are pressed to their work by a spring, it is impossible for a careless engineer to screw his packing too tight, or to make it bear on one side only of the rod.



MACK'S IMPROVED LIFTING INJECTOR.

The National tube-works of Boston, Mass., exhibited an injector at work, which possessed some points of novelty, and appeared to be well adapted for use on locomotives working with bad water. The very fact that a simple arrangement of hollow cones can enable steam to lift and force water into a boiler working at the same pressure is in itself a remarkable paradox; but Mack's injector, as shown at work in the exposition, forced a small quantity of water into a boiler working at two hundred pounds per square inch when the injector itself was only supplied with steam of half that pressure. The apparatus was so arranged that the quantity of water forced against different boiler-pressures by the same pressure of steam could be readily gauged; and the results were interesting as showing what a large range of work can be performed by an apparatus which has no moving parts. The injector is made in several pieces, so that it can be readily taken apart, and cleaned of scale deposited by hard or lime water. When the injector is started, the water is lifted by means of a jet of steam, which rushes through a very fine hole running longitudinally through the centre spindle; the injector becomes full of water, which escapes at the overflow; the regulating spindle is then screwed back, and the large volume of steam thus admitted is condensed by the water already in the injector, mingles with it, and the momentum of the steam due to its great velocity (some five thousand feet per minute) drives the combined steam and water into the boiler.

THE INTERNATIONAL FISHERIES EXHIBITION.— THIRD PAPER.

IN eight weeks over seven hundred thousand persons have visited the exhibition; and there are no signs of any decrease in the daily attendance, which averages from twelve thousand to eighteen thousand, except on Wednesdays, when, the price of admission being half a crown instead of one shilling, the number is only about half as great. Wherever one travels by public conveyance, some of his neighbors in the car or the omnibus are always laden with the ponderous blue catalogue of the exhibition. London is thoroughly permeated by the interest in fish and fisheries. On Sunday I felt a desire for a change of topic, and sought refuge under the dome of St. Paul's; but the canon of Worcester, who officiated at the service, preached a sermon on the miraculous draught of fishes.

Since the middle of July the galleries have been lighted by electricity until ten o'clock. The result has been very satisfactory, the illumination in many cases being more effective than that by sunlight. The annoyance of heavy shadows is avoided by the use of a large number of lamps. All the principal systems being represented, there is an excellent opportunity for comparison. The following is the official distribution of the electric lighting of the exhibition: —

1. Siemens Brothers and company (limited)	Conservatory	4 arc-lights, 6,000-candle power.
	Main gallery, Great Britain	1,200 incandescent lamps (Swan).
2. Swan united company (limited)	Royal pavilion	280 incandescent lamps (Swan).
3. Gülcher electric-light company (limited)	China, New South Wales, etc.	600 incandescent lamps (Crookes).
	Canada and United States, Norway and Sweden	30 arc-lights, 1,000-candle power.
4. Electric-light supply company (limited)	Fish-market	7 arc-lights (Volta), 50 incandescent lamps.
5. Ferranti, Thompson, and Ince	Aquarium and west corridor	1,000 incandescent lights
	Machinery in motion, Electric-light machine-shed, Greece, Italy, Great Britain	25 arc-lights (Ferranti), 5,000-candle power each.
6. H. Edmunds	Promenade	50 arc-lights.
	Upper terrace	6 large arc-lights on mast.
	Eastern corridor and fine arts vestibule,	500 incandescent lamps.
7. Charles Lever	Council-room, Lecture-hall, Dining-rooms, Kitchens	28 arc-lamps (Lever).
8. Jablochkoff electric-light company (limited)	Netherlands, Belgium, Part of the United States, etc., Part of Sweden, etc	60 lamps (Jablochkoff).
9. Mackie	Life-saving apparatus shed	15 arc-lamps (Lea).
	Board of trade shed	6 arc-lamps (Werdemann).
10. Brockie	North corridors, for exhibition of stuffed fish	20 arc-lamps (Brockie).
11. Gérard	Spain and Russia	36 arc lamps (Gerard).
12. Sun-lamp electric-light company	Entrance vestibule	24 lamps (Soleile).
13. Goulard and Gibbs	Sixteen stations in different parts of the building	Arc and incandescent lamps of various characters.

I have been particularly interested in studying the adaptability of the various lights to museum purposes, and am thoroughly satisfied that a few large arc-lamps are preferable to a great number of small ones. The light seems softer, more powerful, and more evenly diffused, in a room like the main gallery assigned to the United States, where there are six lamps in a room fifty by a hundred and forty feet, at a distance of perhaps fifteen feet from the floor, than by a system like that in the British sea-fishery gallery, where the twelve hundred Swan incandescent lamps are used 'to demonstrate the possibility of lighting large areas by incandescence,' as the official catalogue states. Thirty lights of the Gülcher or Edmunds patterns would give a much better effect in this great shed, eight hundred and forty by fifty feet in dimension. The effect of a large number of incandescent lamps disposed along the roof of a room in every direction is very bewildering: they detract the attention, and give one the feeling that a long stay will be sure to result in a headache. In the Chinese court the Crookes incandescent lamps are used, each suspended under a shade of brightly-colored glass: the general effect is rather pretty, but the collections are scarcely discernible.

My observations at the exhibition have been confirmed by what I saw at the Royal college of surgeons at the conversazione recently given by the president and Lady Wells. The museum was perfectly lighted by about six arc-lamps in each of its spacious halls. The arc-lights, too, are used in the art museum at South Kensington with very excellent effect; six of them accomplishing what is done, no more effectively though perhaps more agreeably, in a hall of the same size by about two hundred gas-jets. The expense of lighting some twenty halls by gas in this generous manner must be far greater than by electricity.

On the 18th of June the International fishery conference began its sessions in the conservatory of the Royal horticultural society, adjoining the exhibition galleries. Meetings have since been held every day except Wednesdays and Saturdays. The inaugural address was delivered by Professor Huxley, and was an admirable introduction to the papers which were to follow. First referring to the antiquity of fisheries and their influence upon the history of man, he spoke at some length of the fisheries of the Phoenicians, the Romans, and the early Britons. Insisting upon the importance of fish as food, he next took up the question, 'Are the fisheries exhaustible?' and, after tacitly admitting that certain fisheries may be destroyed, went on to describe the enormous abundance of cod, mackerel, herrings, and sardines, and to express his firm belief that their numbers cannot be effected by human agency. He concluded with a very strong condemnation of unnecessary legislation.

Upon this occasion the Prince of Wales presided, and there was an impressive assemblage of diplomats and state officials. On the following day the prince again was present, and read a paper an hour and a half in length, written by his brother the Duke of Edinburgh, who is absent in Russia attending the coronation of the czar. This paper, entitled 'Notes on the sea-fisheries and fishing population of the United Kingdom,' is in many respects the most remarkable which has been presented to the conference. It is by far the most exhaustive and scholarly essay on the fisheries of Great Britain which has ever been published, and contains a great store of valuable facts gathered by the Duke of Edinburgh during the three years in which he served as admiral in command of the naval reserve, together with extensive statistics obtained at his instance by the men of the coast-guard. On the 21st Sir James Gibson Maitland, the proprietor of the most extensive fish-cultural establishment in Europe, located at Howieton, near Stirling, read a paper on the 'Culture of Salmonidae and the acclimatization of fish,' and the following day Professor Leone Levi of University college, London, on the 'Economic condition of fishermen,' — an important contribution to social economy. On Monday, the 25th, the American commissioner read a paper on the 'Fisheries of the United States and the work of the U. S. fish-commission.' Mr. James Russell Lowell occupied the chair, and made one of his wise and witty little speeches which are so thoroughly enjoyed by the English people.

On the 28th Mr. R. W. Duff, M.P., spoke on the 'Herring fisheries;' on the 29th Prof. A. A. W. Hubrecht of Utrecht university, on 'Oyster-culture and the oyster-fisheries in Holland,' and Mr. R. B. Marston, on 'Coarse fish-culture,' — 'coarse fish' in England signifying fresh-water fish other than the Salmonidae. On July 1 Mr. L. Z. Joneas read a paper on the 'Fisheries of the Dominion (of Canada);' and, on the 3d, Professor Huxley spoke most instructively upon the 'Diseases of fishes,' confining his remarks to the history of the salmon-infesting Saprolegnia ferax. On the 5th several of the commissioners from continental European nations spoke of the fisheries of their respective countries, and on the 6th Capt. Temple gave an account of the antarctic seal-fisheries.

The discussions have been in some instances important, though the usual disposition to ramble has been difficult to check. In fact, the ponderous British system of closing each session with four formal speeches, in connection with the votes of thanks to the chairman and the speaker, has rather tended to encourage the utterances of generalities. The 'practical men,' as they style themselves, who take the very unnecessary precaution of informing their hearers that they make no claim to being 'scientific,' have been rampant at these meetings. Professor Huxley's inaugural address has caused great unhappiness to those who believe in legislative protection without limit or reason. Close seasons for river-fisheries are needful and useful; but what is to be done with economists who claim that legislation will relieve the salmon from its pestilential parasite, the Saprolegnia ferax?

The juries began their sessions about the middle of the month; and the galleries are still daily invaded by enterprising little groups of men with note-books. Their task is not a light one; for the number of exhibiters must be at least three thousand, and the heat is greater than London has known since 1860. Science is well represented among the jurymen: Professor Flower, Professor Allman, Mr. John W. Clark of the Cambridge museum, Mr. Henry Woodward of the British museum, Professor Moseley of Oxford, Mr. John Murray of the Challenger, Lord Russell, Dr. Murie (secretary of the Linnaean society), Dr. Francis Day, Professor Huxley, Mr. R. H.

Scott, Professor Ray Lankester of University college (London) and Professor Jeffrey Bell of Kings college, Dr. Spencer Cobbold, Mr. Romyn Hitchcock of New York, Mr. R. E. Earll of Washington, Dr. Hubrecht of Utrecht, Professor Smitt, Professor Torell and Dr. Trybom of Sweden, Dr. W. A. Buch of Norway, Professor Giglioli of Florence, Dr. Steindachner of Vienna, and Mr. E. P. Ramsay of the Sydney museum (New South Wales), — are all here in the work. Just before the opening of the exhibition, *Nature*, in an editorial, after stating that the management of affairs had been trusted almost entirely to 'practical' men, to the exclusion of English men of science, expressed some doubt as to whether this policy would effect as satisfactory results as that of the Berlin exhibition. It would be interesting to know how far this hint has influenced the action of the executive committee. The committee has shown itself singularly sensitive to the voices of well-meaning advisers, and changes are constantly being made for the better in the management of affairs. For instance: the conference chamber has been removed from the conservatory, where it was torture either to speak or to listen, to one of the picture-galleries near the main entrance; and the experimental fish-market in connection with the exhibition has been thrown open to the public without admission-fees, and a separate entrance cut through from Exhibition road.

The papers read at the conferences are being printed in full, together with the discussions which follow them, and will form a valuable little library, when supplemented by the shilling handbooks to the exhibition, which are being rapidly printed. Fifteen of these handbooks are announced, in addition to the eighteen or more 'papers of the conferences.' The literature of the exhibition is reserved for future discussion. It is much to be hoped that the authorities will crown the series with an illustrated report, prepared by scientific committees, similar to the valuable 'Amtliche berichte über die Internationale fischereiausstellung zu Berlin.'

The closing address at the conference by Professor Ray Lankester will be upon 'The scientific results of the exhibition.' It would not be surprising if Professor Lankester were to choose to act the part of the prophet rather than that of the recorder, and to point out in his discourse what the exhibition ought to do for science. A number of prominent educators and investigators have already addressed to the executive committee a memorial advocating the establishment of a national marine zoölogical station with a part of the surplus funds, which, from present appearances, are likely to remain over at the end of the exhibition. In another letter I hope to review briefly the most important features of the exhibits of the several countries. G. Brown Goode.

Richmond Hill, July 10.

THE PARIS OBSERVATORY.

We abstract from *Nature* the items of chief interest in the report of Admiral Mouchez, the director of the Paris observatory, on the state of that institution during the past year. Its service has been considerably deranged by the preparations for the transit of Venus. The various members of the expedition attended the observatory to be trained either in photography or in the use of the artificial transit, and no less than five of the *personnel* of the observatory themselves took part in the work. The grounds of the observatory have been extended, the equatorial *coudé* has been installed, and several underground chambers have been constructed for the purpose of studying magnetism and terrestrial physics generally. A revision of Lalande's catalogue of stars, numbering forty thousand, has been going on for the past four years. The general catalogue, which will form eight volumes in quarto, is well in hand; and four volumes will be published during the next three years. Meridian observations, numbering a hundred and ten thousand, have already been made, to assist in the construction of the catalogue.

The common inconveniences attending the use of equatorials of the usual form of construction have led M. Loewy to conceive the idea of adapting to the equatorial the system of '*lunette brisée*,' employed first in England, and afterward to a greater extent in Germany, especially in small transit instruments. The new *coudé* equatorial may be thus described: the polar axis of the instrument is supported at its extremities on two pillars, like a meridian instrument; round this axis the telescope turns, forming a right angle at the lower support; by means of a mirror placed at the summit of this angle, the light is reflected along the pierced axis, at the end of which the eye-piece, or micrometer, is placed. Under these conditions, with the telescope at rest, objects on the celestial equator pass across the observer's field of view. In order to secure the observation of objects not on the equator, a mirror free to rotate is placed before the object-glass, and connected with the declination-circle. The inclination of this mirror may be changed so as to throw into the tube the light coming from a star of any declination. The observer may thus explore every part of the heavens without quitting his position at one end of the polar axis. The telescope may practically, by a rotation of this axis, be directed toward any part of the celestial equator, whilst a star of any declination may be made to throw its light down the broken telescope by means of the external mirror. Preliminary experiments have shown that this double reflection does not occasion a great loss of light; and the figure and polish of the silver on glass mirrors are very satisfactory. The observatory possesses this new instrument through the liberality of the well-known patron of French astronomy, M. Bischoffsheim.

In regard to physical observations, M. Egoroff, professor of physics at Warsaw, was occupied at Paris during the months of July and August, as in preceding years, with the spectroscopic study of atmospheric absorption, working with a beam of electric light sent from Mont Valérien to the observatory. In consequence of the decision of Admiral Mouchez to separate special meteorological investigations from the astronomical work of the observatory, meteorological observations of a much higher value are now being made, with the special object of determining the different corrections, of the nature of refraction, to be applied to the astronomical observations. A series of observations is to be made from a captive balloon of such size, that, with ordinary gas, it can, in calm weather, take self-registering barometers, thermometers, and hygrometers up to a height of five hundred, and with pure hydrogen to a height of eight hundred metres. The balloon cannot be well managed if the velocity of the wind exceeds four or five metres per second; but this is not regarded as inconvenient, because it is during complete calm that the greatest abnormal perturbations of astronomical refraction manifest themselves. Simultaneous observations will be made on the meridian of the Paris observatory, north at the observatory of Montmartre, and south at the observatory of Montsouris.

The construction of the great refractor of 16 m. focus, together with its dome 20 m. in diameter, is steadily progressing. The object-glass figured by M. Martin is already complete. The dome is to be of the same dimensions as the Pantheon, and the largest ever attempted. The arrangement for insuring its turning with ease, and which has been adopted for its construction, is that proposed by M. Eiffel. In order to reduce to a minimum the friction of circular rollers, he proposes to float the dome by means of an annular *caisson* plunged in a receptacle of the same form, and filled with a liquid which will not freeze, such as an aqueous solution of chloride of magnesium. At the Paris observatory it is quite necessary that some such arrangement as this should be adopted; for the observatory is situate over the catacombs, one result of which has been, that for many years the pillars of the meridian-circle erected in the gardens have gradually inclined toward the east in consequence of the displacement of the soil. With mechanism of this form for rotating the dome, any probable change of level would not prevent the dome from turning.

The magnetic observatory now being completed will be one of the first order. Six subterranean chambers of constant temperature have been built under the best possible conditions of isolation and stability. An outer wall of nearly 2 m. thickness encloses a rectangular space 40 m. in length and 14 m. wide, completely impervious to moisture. The vaulted roof, 1 m. thick, is covered by earth to the thickness of 2 m., and grass and planks protect the soil from the direct rays of the sun and from frost. The observing chambers can be lighted either by gas, or by reflection from without.

Advantage has been taken of the existence of these chambers by placing in them the clocks from which the time is distributed throughout Paris; but, in spite of all precautions, the chambers are found to be not altogether free from minor trepidations resulting from the traffic of the streets. Apparatus has been constructed, and is now ready for use in investigating the vertical and slow movements of the soil. This will be placed in a gallery in the catacombs 27 m. below the surface.

The erection of an astronomical observatory on the Pic du Midi, at a height of 2,859 m., is engaging the attention of the director. At this elevation, it is said to be easy to read at night by starlight alone, and fifteen stars are visible to the naked eye in the cluster of the Pleiades. It is intended that any astronomer who wishes to make any special researches may take advantage of the observatory on the Pic du Midi.

LETTERS TO THE EDITOR.

The right whale of the North Atlantic.

I HAVE noticed in a late number of your journal a criticism on the last Bulletin of the American museum of natural history. Being away from town, I have not access to works referring to the subject of cetology; but with the aid of notes that I have with me, as well as drawings of the subjects involved, I hope to show conclusively that other views than those taken by the critic are the correct ones.

I shall not attempt to justify the carelessness that permits the presence of typographical errors; but, when an *errata* list accompanies a work, it should have due credit for its intentions.

The writer says, "There are errors of statement of so grave a character as to require notice," and continues, "It would seem, for instance, that only the merest novice in cetology could have been misled," etc. — referring to the identity of the St. Lawrence whales.

Lesson wrote, "What an impenetrable veil covers our knowledge of the Cetacea! Groping in the dark, we advance in a field strewn with thorns." I believe that some in later days, not quite novices, admit a degree of unfamiliarity with the great beasts of the sea. In that view, let us see if 'errors of statement of grave character' have really been made.

The president of the Quebec historical society, Dr. Anderson, with Dr. DeKay's Report on mammalia before him, says, speaking of a large whale that had foundered in the St. Lawrence River, "It turned out to be an aged male, apparently the species Balaena mysticetus. . . . The back was black; the belly, furrowed, presenting the appearance of a clinker-built boat. . . . I concluded, after a careful examination, it answered fully the description given by Dr. DeKay for the mysticetus. . . . As the whale lay upon the beach, he was sixty-five feet long; the fluke of his tail was twelve feet; his jaw, fifteen feet."

This whale was noticed primarily by us for the purpose of directing attention to the fact, that such a great form had really pushed into the fresh-water stream as far as Quebec, and to show that possibly Professor Flower had misapprehended when he was told of stranded whales in the St. Lawrence; he, in absence of description, naturally regarding them as white Belugas.

Besides this, several alternatives were presented in the absence of the mention of *most distinctive* characters; but no definite statement was hazarded, nor was one intended.

The first paragraph touching on this notice of the St. Lawrence whale, and which is included by the critic as among the 'grave errors of statement,' is as follows: "It is pretty certain that if the creature was really a Balaena, and not a Balaenopter, it was an example of unusual size." As we had no intention of arguing any case, this cannot be regarded as more than courtesy to Dr. Anderson, who had stated his unqualified opinion as above.

The next passage in our text is, "The furrows on the belly naturally suggest the Balaenopters; but it is inferred that there was no dorsal fin." The dorsal adipose fin being an essential feature in the latter, absence of any notice of it naturally seemed strange.

As there was no description of the head, save as related to its length, the baleen not being measured, the only character that suggested strongly the fin-back was the clinker-built aspect of the belly. In this view the statement of Scoresby might well lead to misapprehension, even by some not wholly novices.

Scoresby says (in his description of the B. mysticetus), "The skin of the body is slightly furrowed, like the water-lines in coarse-laid paper."

The fluke of the tail is described as twelve feet in length. Here, regarding the possible fact of there being *two* flukes to the tail, the total width of the caudal extremity would be twenty-four feet, the actual measurement of a large example of a right whale. That the writer in the bulletin did so regard it is true; but, in the light of after-knowledge, we have no doubt that Dr. Anderson meant to include the whole width as twelve feet.

In the absence of definite features in Dr. Anderson's description, and in view of the absence of any attempt in the bulletin to argue in favor of any one genus or species, we regard it as a subject that hardly calls for criticism. In short, taking the evidence recorded, to our mind it seems to be quite as easy to prove the creature of one genus as the other; and by that we mean that Dr. Anderson's positive statements should not go for nothing. We are not, however, ready to hazard an opinion that the whale was not a fin-back, as we certainly did not in the bulletin.

The next point refers to Scoresby and his drawings. That Scoresby did not portray his subject correctly, so far as relates to the Greenland whale, is, we feel sure, susceptible of demonstration, even if we should omit the opinions of three of the most able cetologists. The critic claims, "That it was the best figure [Scoresby's], if not quite correct in all points, of the species down to 1874, when Scammon's admirable illustration was published, has, I think, hitherto been unquestioned." When we are told that our opinion that Scoresby 'furnished to science an incorrect figure' is 'an error of statement of so grave a character as to require notice,' we answer by quoting from Professors Eschricht and Reinhardt, in their article on Greenland whale, in Ray society's publ., p. 29. It is well known that these distinguished authors are leading cetologists, whose work is edited in English by Professor Flower. The latter, therefore, is supposed to acquiesce in their opinions. These authors say, "We must confess, that as to proportions we confide more in these drawings [referring to Marten's and Zorgdrager's] than Scoresby's, which certainly represents the Greenland whale (B. mysticetus) more slender than it really is."

Besides this, we claim to be able to demonstrate the correctness of our statement by reference to the figures. We have before us those of Scammon, Scoresby, Zorgdrager, and Lacépède, representing the Greenland whale. We also have the Bachstrom figure of nordcaper, published in Lacépède's work. With Capt. Scammon's figure before us, the one admitted by our critic to be an 'admirable illustration,' compare now Zorgdrager's; and we find, that, though rude in finish, it is nearly an exact counterpart of the Scammon figure. We see that the form is bulky, and has a very short 'small,' or caudal region; that its head is of the proportion of one-third the total length of body; its pectoral limbs are situated very closely behind the eye and angle of the mouth, not a quarter of the total length of the 'flipper' distant therefrom, — all of which features are recognized as correct.

Let Scoresby's figure be compared with Zorgdrager's, which we have seen is essentially the same as Scammon's. We see that the form is not only not bulky, with a very short 'small,' or caudal region, but has the body very slender, with an elongated 'small;' the latter being so slender that it is represented whipping the air like the tail of a saurian. Its head is one-fourth of the total length of body, instead of one-third, as in nature, and in the Zorgdrager and Scammon figures. Its pectoral limbs are situated at a distance from the eye and angle of mouth represented by the *total* length of the limbs. It is therefore seen, that, in accordance with all evidence, Scoresby's figure was not correct. Hence it *is* "deplorable that nearly every book published to this day has an illustration copied from Scoresby."

"'Tis true 'tis pity, and pity 'tis 'tis true."

Our critic next attributes unfamiliarity with Scoresby's cetological writings, from the fact that we credit Godman with 'an amount of anatomical knowledge quite unusual.'

The truth is, the edition of Scoresby in our possession does not contain the portion relating to interior anatomy and physiology, and the plates representing the spiracles. It is 'An account of the arctic regions, Edinburgh, 1820.' The work is not before us, but a reference to this edition will verify our statement. Since the matter was prepared for the bulletin, we find that the several pages relating to this portion of Scoresby's description were probably never printed therein. We have, however, found the whole in Sir William Jardine's Naturalists' library, volume on whales, by Col. Hamilton.

In view of this fact, one may venture to claim a degree of immunity from severe criticism, though evidently he may be open to the accusation that 'he is none too familiar with Scoresby's cetological writings,' or at least his various editions.

Not having met with this matter relating to the anatomy and physiology in Scoresby's book, it was but natural to attribute to Godman 'an amount . . . quite unusual.'

A point succeeds this, concerning which we must take issue with the critic. He says, "The fact being that Godman's account is an unaccredited compilation from Scoresby's work, whole pages being taken entire," etc. We find in our edition of Godman's Natural history, instead of 'an unaccredited compilation,' the following: "Having never personally enjoyed opportunities of studying the whale in his native floods, and having derived all we know in relation thereto from Scoresby, we should deem it injustice to the reader to give this account in any other language than that of the original. We do this without reluctance, as our object is to convey the most accurate knowledge, rather than produce a work exclusively of our own composition. All that follows in relation to the whale is selected from the different works of the accurate and philosophical Scoresby." If the critic's edition of Godman has played false with him, as our edition of Scoresby has with us, perhaps he may think it wise to 'cry quits,' and join with us in throwing out of the case the two slippery points.

It may be proper to add here, that we are familiar with Scoresby's second figure of mysticetus, which is so far improved as to have the 'small' shortened; but unfortunately the first figure, with all its imperfections, is the one that has been brought down to us through every book on natural history.

The reference to Bachstrom's figure of nordcaper is obscure.

It matters not what that figure *is:* it was regarded as one of nordcaper by Cuvier; and he, in comparison with the old figures of mysticetus, which we claim were nearer true than Scoresby's in general proportion, wisely admitted two species.

They were both, as we have said, about equally incorrect; yet they both had certain features that agreed with the descriptions of the two forms. The nordcaper had been described in nearly the same terms by various authors, great stress being laid on its slenderness and mobility. Scoresby now presents his figure, which, instead of being bulky, with a very short 'small,' or caudal region, and a head one-third the total, had quite nearly the proportions of the figure of Bachstrom, received by Cuvier as that of nordcaper, and with no other specific feature to distinguish them.

The mention of inaccuracies, seen near the close of the criticism, is not wholly free from error; for example: the citation touching Col. Hamilton and the Naturalists' library is exactly correct, yet it is noticed as one of the errors that render the historical *résumé* 'seriously defective and misleading.' We are now willing to rest this showing, trusting to the facts herein referred to for our vindication in the face of this grave charge. J. B. HOLDER.

Fortunately for Dr. Holder, he did not state directly and unequivocally that the St. Lawrence whale was a Balaena; but he occupies several pages in trying to explain away the obvious discrepancies in the way of such an identification and in offsetting them with the *possibilities* in its favor, leaving the reader with the conviction that the specimen is cited as, in Dr. Holder's opinion, an instance of the occurrence of a Balaena in the St. Lawrence near Quebec. Indeed, he goes so far as to say, "and the second example [the one here in question] . . . shows that the largest of the right whales [Balaena] have really found their way as far up a fresh-water stream as Quebec and Montreal" (p. 116). Again he says, "This example is valuable for record, 1°, as a specimen of unusual size; 2°, as one of great age; 3°, as one out of its usual habitat in so far as to be quite within fresh water" (p. 115). From the context, the point in doubt seems to be, not whether the species is a Balaena, but whether it is B. cisarctica or B. mysticetus; and the whole tenor of the argument (for such it really is) is fairly open to only this construction, whatever may have been intended. In evidence that my criticism on this point is not groundless, or due to perversity on my part, I may cite Mr. F. W. True's notice (*Scient. lit. gossip*, i. 72) of Dr. Holder's memoir, where the same criticism is made.

As to other points, I will take space to say merely that I regret to notice that Dr. Holder forgets to tell us where Scoresby got his drawings, which, he (Dr. Holder) informs us, 'were evidently ill-considered and taken at second hand,' and to ask for proof that Col. Hamilton wrote the 'Cetacea' of Jardine's 'Naturalists' library.' The copies of the work I have seen are anonymous, but the work is accredited by Gray and other cetologists to Jardine; and some time since, I took pains to satisfy myself that Jardine was the author. As to Godman, I confess to having done him injustice in overlooking his credit to Scoresby, which my friend Dr. Holder appears to have unfortunately only recently discovered; otherwise, doubtless my stricture on this point would not have been called out. J. A. ALLEN.

The Ainos of Japan.

On p. 307 of SCIENCE, D. P. Penhallow objects to my statement of the number of Ainos. It is rather surprising how little he heeds what I said. The numbers he gives are official; i.e., he gives the number of Ainos known to the Japanese government. Therefore he reaches the surprising result, that, with the exception of the Ainos brought over from Saghalien (now about 800), there are but 200 in all the province of Ischicari. That province is about as large as Hitaka (according to Penhallow, with 5,000 to 6,000).

Penhallow gives the Aino population in Kitami, Kushiro, Tokachi, and Teshiwo as ranging from 350 to 1,500 in each, when it is well known that they are full of Ainos, as any one travelling there will see, their villages being thickly scattered along the coast and the banks of all the larger rivers. I should estimate from those seen at such points that there must be more than 50,000 Ainos in all. Taking Penhallow's figures for Iburi and Hitaka as correct, and assuming that the four provinces named above must have as many Ainos as Hitaka, we should have about 26,000 in these five. Granting that Ischicari, Shiribeshi, and Nemuro have also been taken as much too thickly populated, still we must give them 4,000 more than Penhallow allows; i.e., about 6,000.

Now add to them Penhallow's number for Iburi, nearly 4,000, and the small remnant of Oshima, (Penhallow, 250), and lastly for Chishima (not Chisuma) or the Kuriles a minimum of 750, we get 33,000 as the minimum for Yezo. Saghalien having 10,000 to 12,000, and South Kamtchatka 5,000 to 6,000 (perhaps less), there cannot be fewer than 50,000 Ainos altogether. D. BRAUNS.

The Iroquois.

A close study of the Mohawks of Quebec province, Canada, after the plan and in the service of the Bureau of ethnology, reveals several facts hitherto unnoticed in the various histories of the Iroquois.

Isolated by the early Jesuit fathers from their former Pagan friends and surroundings, every trace of their old folk-lore and of their Pagan customs has disappeared. The division and nomenclature of their gentes differ materially from those of any of the other tribes, and present an interesting field of inquiry. The Mohawk gentes, as given by Morgan, are the wolf, bear, and turtle. Among the Mohawks at Oka, we find, in addition to those, the lark and the eel, while at Caughnawaga they are the bear, wolf, calumet, rock, lark, turtle, and dove.

Among the wampum belts of this tribe is a very fine one, upon which the calumet is figured in white wampum beads, the remainder of the belt being in dark purple. This probably belonged to the gens bearing the name of the calumet, and whose office it was to prepare and present the grand calumet in all the solemn assemblies.

The effect of the isolation of this tribe upon its language is also an interesting and important study. Through the courtesy of Superior Antoine and Père Burtin, I have obtained access to an invaluable collection by the French missionary Marcoux, which will furnish Mohawk synonymes for a dictionary of the six Iroquois dialects, for which thirty thousand words have already been gathered. Erminnie Smith.

203 Pacific Ave., Jersey City.

Many snakes killed.

The number of snakes killed near this city during the late overflow of the Nemaha River is almost beyond belief. They were driven by the water from the bottom-lands to the higher grounds, and especially to the embankments thrown up across the bottom for the Burlington and Missouri and the Missouri Pacific railways. It is estimated that more than three thousand snakes were killed within a mile of this town. They were chiefly garter snakes; but water moccasons, blue racers, and rattlesnakes were also killed. A horse was confined in a pasture surrounded by a wire fence in the overflowed district, and, when released, it was found that several snakes had taken refuge in the long hair of his mane. Since my residence here, I have travelled nearly all over this county, a portion of the time engaged in geological explorations; yet, up to the time of the present June overflow, I had failed to see half a dozen snakes all told. The overflowed district along the Nemaha would not average over a mile in width; and it is astonishing where so many snakes found hiding-places. Undoubtedly, nearly all the snakes in this county are confined to the creek and river bottoms.

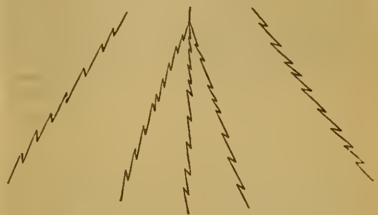
Falls City, Neb., July 10, 1883.

Swallows in Boston.

Has any one seen a swallow in Boston this summer? The old proverb says, 'One swallow does not make a summer.' Have we a summer and not one swallow? Carl Reddots.

Singular lightning.

On the evening of July 4, 1883, I noticed some lightning which differed from any that I have previously seen. About sunset a mass of very threatening clouds, accompanied by heavy rain and lightning of the usual character, rose in the north-west, and, following an easterly course, passed a little to the northward, giving us a few drops of rain from its ragged southern edge. It was quickly succeeded by a comparatively thin cloud-stratum, — apparently the after-birth of the main storm, — the course of which was directly overhead. During the passage of this cloud, rain fell briskly but not heavily for perhaps half an hour, and rather frequent flashes of lightning preceded and followed the first sprinkle. Owing to my position on the eastern side of a large building, I could not see the earlier flashes; but their light, thrown on the walls of neighboring houses, was noticeably rose-colored. At length, however, one came that could be accurately noted. It passed directly overhead, forking into five fine, thread-like lines of vivid yellow light. Each line was distinctly zig-zagged with sharp though not prominent angles. The divergence of the lines was nearly regular, but the outer pair branched at a greater angle than the inner three. The relative divergence was similar to that of the outstretched fingers of a human hand; but a still more accurate idea may be given by the following sketch.



The flash above described was followed, in a few minutes, by a second one, apparently similar, but less satisfactorily noted. After this the rapid passage of the storm carried the lightning beyond my limited space of observation.

I may add that none of the lightning from this cloud seemed to come to the earth, its course being on an apparently horizontal plane. The accompanying thunder was unusually deep and grand.

Cambridge, Mass.

Deflective effect of the earth's rotation.

In Science for March 2 (No. 4), Mr. W. M. Davis says, "A correct knowledge of the deflective effect of the earth's rotation is generally accounted the result of studies made within the last twenty-five years."

This correct knowledge, he says, is still disputed by some authors.

By transferring the axis of rotation to the tangent plane on which the body is supposed to move, and resolving the earth's rotary motion into two motions, — one around the meridian of the tangent plane, and the other around a vertical to that plane, — it is easily seen, without recourse to the equations of motion, that the angular motion of the tangent plane with respect to a fixed plane will depend upon the angular rotation of the earth and the sine of the latitude of the tangent plane; from which it follows that the deflective force is the same, in whatever direction the body is supposed to move on any given tangent plane.

But in resolving the actual motion into two motions, respectively around the vertical to the tangent plane and around the meridian of that plane, we have neglected the effect resulting from the latter, — a consideration of which would have introduced another term, containing a function of, and therefore varying with, the cosine of the angle contained between the meridian and the line of projection of the moving body; we have also neglected the effect of the centrifugal force resulting from the motion of the body, which is a minimum when the motion is in the meridian, and a maximum when at right angles to the meridian, and therefore also variés with the cosine of the angle contained between the meridian and the line of projection of the moving body. When the velocity is considerable, both these terms become sensible; and therefore the deflective force is least when the body moves in the meridian, and greatest when the motion is at right angles with the meridian.

This conclusion is in conflict with the 'correct knowledge' above alluded to; viz., that the deflection of the moving body depends 'not at all on the direction of its motion.' But I may remark, that Routh (see Rigid dynamics, p. 192) has also given the subject a rigorous investigation by means of the equations of motion, and finds for the deviation to the right, in north latitude, two terms, — the one agreeing with the above, as found from the component about the vertical; and the other, a function of the cosine of the angle contained between the meridian and the line of projection of the moving body.

Des Moioes, Io., July 16, 1883.

ALNWICK CASTLE ANTIQUITIES.

A descriptive catalogue of antiquities, chiefly British, at Alnwick Castle. Printed for private distribution. Newcastle-upon-Tyne, 1880. 11+210 p., 43 pl. 4°.

By the generosity of the Duke of Northumberland, the Boston public library has recently been made the recipient of a copy of this truly magnificent work, and of the companion volume descriptive of the important collection of Egyptian antiquities, also preserved at Alnwick. In no more satisfactory manner could the liberality and public spirit of the noble proprietor have been manifested than in thus sharing his treasures with the antiquaries and art-lovers of other countries. Such sumptuous volumes as these constitute a monument *aere perennius*, like those which illustrate the literary and artistic treasures of Earl Spencer at Althorp, or the magnificent publications in which the Archduke Ludwig of Austria has recorded his travels.

In its artistic and mechanical execution, this catalogue is beyond praise: never have we seen more beautiful or more faithful delineations of the various kinds of antiquities. If we cannot speak in quite such high terms of commendation of the accompanying letterpress, the fault should not be laid to the charge of Dr. Collingwood Bruce, upon whom devolved the task of preparing the work for the press. His competency as an antiquary has been sufficiently manifested by his able and thorough study of 'The Roman wall,' whose 'stations' have yielded to the explorer many of the objects described in the volume. It is to the untimely death of Mr. Albert Way, by whose assistance and advice much of the collection was gathered, who knew its contents thoroughly, and to whom the preparation of the catalogue had been originally intrusted, that any shortcoming must be attributed. Although several distinguished English antiquaries have lent their aid to the editor in their respective departments of knowledge, we miss the influence of one guiding mind, familiar with the results of recent archeological research in all its various branches, and capable of 'speaking the latest word' upon the many interesting and important topics suggested. Still the reader cannot fail to receive instruction from the accounts given of numerous relics of various periods in the ages long since past, while the beauty of many of the objects delineated goes far to justify the claim that, —

> "Not rough nor barren are the winding ways
> Of hoar antiquity, but strewn with flowers."

The expression 'chiefly British' in the title must be understood to mean that the greater part of the antiquities described have been found in Great Britain. Those first represented belong to the prehistoric periods of stone, of bronze, and of iron, and consist mainly of weapons and implements, such as axes and celts of stone, and swords and celts of bronze, or of a great variety of those rude, hand-made, sepulchral vases found in grave-mounds, in which was stored a supply of food for the dead. To the same remote ages are to be ascribed those singular markings found upon stones, known to archeologists by the name of 'cup-cuttings,' of which two remarkable examples occurring in Northumberland are represented. They are found in countries widely separated, and everywhere they closely resemble one another, and they have greatly exercised the minds of antiquaries as to their origin and significance. They consist of a series of shallow pits or cups, incised upon ledges, or, more frequently, upon bowlders. Of these, a central one is often found surrounded by one or more concentric circles; and a characteristic feature of such groups is a longitudinal groove extending from the central cup to beyond the outermost of the circles that surround it. That they are religious emblems is generally conceded, as the same kind of markings is found upon the slabs of stone of which ancient graves have been constructed. It is highly probable that they are a conventional representation of a primitive system of nature-worship that prevailed among our Aryan ancestors, symbolizing the mysterious origin of life. The whole subject has recently been treated in the most able and exhaustive manner by the learned archeologist of the Smithsonian institution, Mr. Charles Rau, in the fifth volume of Major Powell's 'Contributions to American ethnology.' We cannot help feeling surprised that the editor, while quoting largely from Sir James Simpson's 'Archaic sculptures,' makes no reference whatever to the late Professor Edouard Desor of Neuchâtel, whose various writings upon *Les pierres à écuelles* have shed much light upon this obscure subject.

Another strange problem bearing upon this vexed question of early religious symbols is but just touched upon in this volume. We refer to the use from a very remote period, either for emblematic or decorative purposes, of a peculiar form of cross, resembling the Greek letter gamma four times repeated.

This has been called by various names, — the 'digammated cross,' or 'gammadion;' in the middle ages the 'fylfot;' and recently, by Sanscrit scholars, the 'swastica.' M. Burnouf believes that this, also, is a primitive religious symbol of the Aryan races, and that it represents the two pieces of wood which in early times were laid crosswise before the sacrificial altar in order to produce the holy fire, having their ends bent at right angles and fastened in such a way as not to be moved. Where the pieces crossed there was a small hole, in which a third piece of wood was rotated by means of a cord until fire was generated by friction. This sign occurs upon two Roman altars figured in the volume, which have been transferred to the museum at Alnwick from neighboring stations upon the Roman wall, where they had been disinterred. Several references are given to authors who have treated of this emblem, — among them, to Dr. Schliemann, who found it at Hissarlik upon 'whorls' of baked clay; and the statement is made, that it eventually came to have a Christian signification, and is found in the catacombs at Rome in conjunction with the usual Christian symbols. The elaborate study, however, by De Mortillet, entitled *Le signe de la croix avant le christianisme*, is entirely overlooked, in which its occurrence is traced down from the 'terremares' of the age of bronze, in Emilia, in upper Italy.

A unique object represented is an example of the so-called 'chrisma,' the monogram formed by uniting the first two Greek characters of the name Christ, X and P.

This combination had long been in use as an abbreviation of different words, and it is found upon the coinage of various eastern nations. Constantine placed it upon the 'Labarum' as a Christian emblem; and it is often met with upon his coins and those of his immediate successors, and upon terra-cotta lamps found in the catacombs at Rome and elsewhere. Three, at least, of such ancient Christian lamps, have been discovered in England; but the rarity of the present example consists in the fact that it is embossed upon the outside of a little drinking-cup made of red clay. This is of the very uncommon kind of pottery occasionally brought to light in England, which was manufactured by the Romanized Britons at Caistor, in Northamptonshire, the Durobrivae of the Romans. It is used as an ornament in association with a very well executed representation of the coursing of a hare, and it is probably to be referred to about the middle of the fourth century.

Several fine specimens of ancient Roman fictile ware from Pompeii are delineated, as well as those found in Great Britain, among them handsome lamps and facsimiles of the potter's stamps, which are often found impressed upon their under side. Such stamps were also usually placed upon the bottom of the finest kind of table-ware that was manufactured by the Romans, — that called 'Samian ware' from the place of its origin, but of which the best quality was fabricated at Arezzo, and spread by commerce over the whole Roman world. It is of a lustrous coral color, and often has embossed upon the outside, figures of different deities, or of men and animals, especially of those gladiatorial scenes of which the Romans were so fond. These figures were fashioned in moulds, many of which have come down to our own times, and are of a high grade of artistic merit. Frequently, however, the ornamentation consists only of harmonious conventional patterns, or of a scroll-work of leaves and vines of much grace and beauty of design. The potter's stamp sometimes contains the whole name, sometimes only initials, and occasionally it consists merely of some symbol. One figured in the volume is a representation of 'a tiny human foot,' which the editor thinks is "probably a rebus upon the name of the potter, which may have been CRASSIPES." This is rather an unfortunate conjecture, as it was a special whim of some of the potters of Arezzo to have their stamps made in the shape of a human foot. They are found in this form containing a variety of names, as well as no name at all. The writer has in his possession at least twenty different inscriptions of this sort.

It is certainly remarkable that only in England have there been found, it would appear, any specimens of the actual shoes or sandals worn by the Roman soldiers. One such is represented from the ruins of one of the camps that mark the line of the Roman wall. Similar discoveries upon such sites are recorded, and a few of these objects have been found in the bed of the Thames at London. The writer saw several that came to light in London in 1873, in excavating the foundation for a large building in the heart of the 'city.' On that occasion the ditch that surrounded the fortified Roman town was laid bare, formed out of the natural bed of a little brook, and in it these and many other curious relics were found. These ancient Roman shoes are singularly like modern ones in pattern and mode of fabrication; and, in consideration of their wonderful state of preservation, they would seem to justify the cobbler's proverb, 'There's nothing like leather.'

Among the 'medieval remains,' we find figured and described 'a bronze eagle with uplifted head and open mouth.' The bird, however, strongly resembles one represented in *Archaeologia*, vol. 46, pl. 17, that was discovered in the recent excavations at Silchester in 1870. This, the late John Richard Green, in his Making of England, calls "a legionary eagle, hidden away, as it would seem, in some secret recess, and there buried for ages to tell the pathetic tale of the fall of Silchester." In Horsley's Britannia romana, there is also figured a similar bronze eagle discovered in England. It is true, that the Roman eagles that are delineated upon Trajan's Column and upon the Arch of Constantine are represented with expanded wings, and that Montfauçon and recent writers upon classical antiquity, copying him, have stated that they were *invariably* made in this manner. All three of these birds, however, have their wings folded, from which we may infer that the other fashion of representing them may have arisen in part from the exigencies of pictorial art.

We have an example given of one of those singular seals, in the shape of a monkey perched upon a cube, made of a peculiar kind of porcelain, and bearing an inscription in ancient Chinese characters, such as are occasionally found in the bogs in various parts of Ireland. At first they were believed to be of remote antiquity; and it was even supposed that they had been brought into the country by the Phoenicians, since it was asserted that they are not to be found in China at the present time. But this is not the case, as they can now occasionally be procured of the dealers in curiosities in that country. The inscriptions are engraved in an antique character, now only employed for seals, and known as the 'seal character.' Frequently they consist of some poetic quotation like the one given: 'When the water falls, the rocks appear.' Their presence is undoubtedly due to modern commerce, though not of a very recent period. In this particular they resemble the little Chinese bottles used for holding snuff, which are found in ancient Egyptian tombs, one of which is preserved in the museum at Alnwick. They are about two inches in height, and have on one side a flower, and on the other an inscription, which on several specimens reads, 'The flower opens; lo! another year!' This is known to be a quotation from a poet who lived in the eighth century P.C., and the object evidently was intended for a New-Year's gift. Instead of proving, as Rosellini supposed, the existence of a commerce between the two countries in Pharaonic, or at all events in Ptolemaic times, it is now known that they were brought to Egypt in the middle ages by caravans from western China. They are not of exceeding rarity, as Sir Gardner Wilkinson states that he has seen more than twenty of them, found in the tombs at Thebes and other places, and the writer has half a dozen obtained in Cairo.

Unquestionably the most pleasing object delineated in the volume, and one of the glories of the collection, is the well-known 'Rudge cup.' This is a little bronze vessel, about four inches in diameter and three in height, of a simple bowl shape, and adorned in the most tasteful manner with different colored enamels, in the style called *champlevé*. In this, the metallic field is cut away so as to produce cavities, in which is inserted the paste that becomes vitrified upon being subjected to heat. The ornamentation consists of a series of panels made up of four squares of various colors, alternating with compartments containing four crescents of different hues, set back to back. The colors are turquoise and dark blue, beautifully contrasted with a narrow border of pale red, which outlines and separates the several compartments. Around the top runs an inscription which is supposed to contain the names of several localities lying along the line of the Roman wall, but which has thus far proved a puzzle to the interpreters. It was found in the year 1725, at a place called Rudge Coppice, near Froxfield, in Wiltshire, in a well near the site of some Roman ruins. The well was filled with rubbish; and in it were also found four or five human skeletons, some animal bones, and several coins of the lower empire. It is described as merely 'a remarkable relic of the Roman times;' but this would appear to be a very unmeaning designation, when we call to mind the fact that 'relics' of this description are never discovered in Italy. It may be worth the while to give a brief account of the more important specimens of ancient *champlevé* enamelling that have come to light in Europe, and to state what is known or surmised in regard to their probable origin and place of fabrication.

For purposes of comparison, the editor has given an engraving of an enamelled bronze cup, of similar shape and method of manufacture, which was found at Harwood, in Northumberland, and is now in the British museum. He also describes a facsimile cast of a beautiful vessel, known as the 'Bartlow vase,' the original of which was nearly ruined in a fire which took place in the mansion of Lord Maynard, by whom it was discovered in 1832, during excavations made in a series of remarkable flat-topped tumuli situated at Bartlow, in Essex. A plate showing it in all its pristine beauty may be found in *Archaeologia*, vol. 26, pl. 35. It is now in the British museum, where can also be seen a similar vase, discovered at Ambleteuse, near Boulogne. Still another of the same character, found in the western part of France, is preserved at Angoulême. Finally in the *Mémoires de la société des antiquaires du nord*, n.s., 1868, there is represented an exceedingly beautiful specimen of an enamelled bronze cup of the same pattern, discovered in 1867 in a peat-moss at Maltboeck, in the southern part of the peninsula of Jutland, in Denmark.

Beside these vases, enamelled fibulae and horse-trappings have frequently been found in ancient graves, especially in England. Professor Boyd Dawkins, in his Cave-hunting, also gives a plate representing several brooches of this kind, which were discovered during the explorations of the Victoria cave, in Settle, Yorkshire. This was so named on account of its discovery upon the coronation day of Queen Victoria, in 1839; and it is especially interesting as having been a place of refuge of the miserable British fugitives who fled before the sword of the 'conquering Engle.'

The art of enamelling was known to the ancient Egyptians, the Etruscans, and the Greeks; but the last had ceased to make use of it at least two hundred years B.C. By the Romans it was never practised at all; and it is not alluded to by Pliny in his encyclopedic 'Natural history.' The only reference to it to be found in any ancient author occurs in the *Imagines* of Philostratus the elder (lib. i., im. 27). In a description of a picture of a boar-hunt, after enumerating the different colors of the horses ridden by the youthful huntsmen, and saying that the bits were of silver and the housings enriched with gold and various colors, he adds, "They say that the barbarians, who dwell near the ocean, pour these colors upon heated brass, and that they adhere, and become like stone, and preserve the designs made by them." Now, Philostratus was a Greek rhetorician, called from Athens, in the beginning of the third century, to the court of Julia Domna, wife of the emperor Septimius Severus. As this emperor passed considerable time in Britain, where he built, or at any rate repaired, the wall that goes by his name, and died at York, it is by no means improbable that Philostratus gained his knowledge of the processes of enamelling from accounts brought to the court from that region. To the English antiquaries it seems to be established, by the number and the beauty of such objects that have been discovered in their own country, that this was the principal seat of its manufacture; and Mr. John R. Green does not hesitate to call the 'party-colored enamel the peculiar workmanship of Celtic Britain.' But from the fact that the late Abbé Cochet has found precisely similar enamelled objects in his explorations of ancient cemeteries in Normandy, and from the discovery of cups of the same kind upon the soil of France, the antiquaries of that nation maintain that their own countrymen were 'the barbarians that dwelt near the ocean.' *Non nostrum tantas componere lites;* but certainly objects of this character ought never to be styled 'Roman.'

We wish that we had more space at our disposal to direct attention to the many other beautiful objects of antiquity to be found in this fine collection. Henry W. Haynes.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Linear differential equations. — M. G. Floquet, in a paper entitled "*Sur les équations différentielles linéaires à coefficients périodique*," has made an interesting and seemingly important addition to the literature of periodic functions. He considers a homogeneous linear differential equation of the form

$$P(y), = \frac{d^m y}{dx^m} + p_1 \frac{d^{m-1} y}{dx^{m-1}} + p_2 \frac{d^{m-2} y}{dx^{m-2}} + \ldots + p_m y = 0,$$

the coefficients being uniform functions having all the same period, ω, and the general integral being supposed uniform. If the variable be changed by the substitution

$$e^{\frac{2\pi i x}{\omega}} = \xi,$$

the result is a linear transformation of P, in which the coefficients are uniform functions of ξ. From the known expression for its integrals in the region of a singular point, we may, by giving ξ the above value, vary the form of the solutions of $P(y) = 0$. The author prefers, however, to treat the question directly, inasmuch as he is thus enabled to employ many of the results arrived at by M. Fuchs, and as he can use processes identical with those employed by Fuchs in his study of the integrals around a singular point. M. Floquet obtains thus a fundamental system, S, of solutions connected with a certain algebraic equation, $\Delta = 0$, which he calls *the fundamental equation relative to the period* ω; the first member of $\Delta = 0$ is a determinant of degree m with respect to the unknown ε. The elements of the system S constitute as many *groups* as the equation $\Delta = 0$ has distinct roots; and, by applying a process due to M. Hamburger, these groups are divided into *sub-groups* which are mutually independent. The particular conclusions arrived at are as follows. I. Let $\varepsilon_1, \varepsilon_2 \ldots \varepsilon_n$ denote the distinct roots of $\Delta = 0$; let λ_i denote the order parting from which the minors of Δ cease being all zero for $\varepsilon = \varepsilon_i$. 1°. $P = 0$ admits as distinct integrals $\lambda_1 + \lambda_2 + \ldots + \lambda_n$ periodic functions of the second kind, and no more. 2°. There exists a fundamental system of solutions, including, first, $\lambda_1 + \lambda_2 + \ldots + \lambda_n$ periodic functions of the second kind; second, $m - (\lambda_1 + \lambda_2 \ldots + \lambda_n)$ expressions, each having the form of an integral polynomial in x, and having for coefficients periodic functions of the second kind possessing the same multiplier. 3°. The multipliers of the periodic functions which appear in the fundamental system, either as elements or as coefficients in the elements, are equal to the different roots $\varepsilon_1, \varepsilon_2 \ldots \varepsilon_n$ of the fundamental equation. II. In order that $P = 0$ may have m periodic functions of the second kind as distinct integrals, it is necessary and sufficient that each of the roots of $\Delta = 0$ shall annul all the minors of Δ up to those of an order equal to the degree of the multiplicity of each root. In the above, a periodic function of the second kind, with a period ω, means a function defined by relation $F(x + \omega) = \varepsilon F(x)$; ε is the multiplier; and, if $\varepsilon = 1$, the function is said to be periodic of the first kind. — (*Ann. l'école norm. sup.*, Feb.) T. C. [134

PHYSICS.

(Photography.)

The effect of pressure on the gelatine film. — Capt. Abney has shown, that, if pressure is applied to the sensitive surface of the gelatine plates, the same result is obtained as if the plate had been exposed to the light. The editor of the *British journal of photography*, experimenting further, finds that abrasion, such as may be produced by the motion of a glass rod drawn out to a fine rounded point, is necessary to the action, and that mere pressure, such as would be obtained by a carpenter's vise, produces no effect whatever. A stripped film was next placed upon the other one, and the markings made with the rod upon it, with very heavy pressure. On development with pyro, no effect was at first produced; but, by prolonged action, a green fog was created in the adjacent regions of the film, leaving the figures clear on a dark ground. — (*Brit. journ. phot.*, June 15.) W. H. P. [135

Electricity.

Unipolar conductivity. — Hugo Meyer confirms the result previously obtained by him, that the mineral psilomelan possesses the curious property of unipolar conductivity for electricity. He finds, also, that the resistance to a constant current is independent of the duration of the current, and that different specimens of the mineral are radically different in electrical properties: hence the inconsistent results of different observers are admissible. — (*Ann. phys. chem.*, xix. 70.) J. T. [136

A cheap bolometer. — C. Baur describes a thermoscope which consists of thin gold leaves blackened with platinum chloride, and cut so as to combine large surface with low resistance. These are attached to opposite ends of a cylinder which is hollow and open at the ends, and solid in the middle. These leaves are made the arms of a Wheatstone bridge, and prove to be a much more delicate test for radiant heat than the thermopile. The author terms the instrument a radiometer. — (*Ann. phys. chem.*, xix. 12.) J. T. [137

Measurement of the ohm. — J. Fröhlich describes a 'dynamometric' method of measuring the ohm: the secondary coil is balanced on a rigid horizontal arm, suspended bifilarly so that the plane of winding is perpendicular to the meridian; opposite is placed the inducing coil, in which, by an ingenious arrangement of keys, the current is made, shunted, and broken without a spark. The consequent attractions and repulsions are measured by the swinging of the suspended apparatus. From a preliminary experiment, the author is encouraged to consider the method a practical one. — (*Ann. phys. chem.*, xix. 106.) [138

ENGINEERING.

Engines of lake steamers. — One of the steamers of the Western transportation line has engines of the 'compound' type, two low and two high pressure cylinders, of 20 and of 40 inches diameter and of 40 inches stroke. The steam is cut off at 8 inches in the high-pressure cylinder, and the consumption of steam amounts to but 19 pounds per hour and per horse-power. The boat is 256 feet long, 38 feet beam, and 16 feet draught. The engines and boilers weigh about 100 tons. The latter have 100 square feet of grate-surface, and 3,366 square feet of heating-surface. Another vessel, the E. B. Hale, has simple engines, carries 1,600 tons of freight at 14 feet draught, makes about 10 knots an hour on 1,400 pounds of coal. The engines are 36 by 36, and are supplied with steam by one boiler 12 feet in diameter by 18 feet long. — (*Mechanics*, June 23.) R. H. T. [139

Heating by superheated exhaust-steam. — Mr. Levi Hussey has devised a method of heating buildings in winter by the exhaust-steam from engines by first passing it through a superheater in the flue, and there taking up heat which would otherwise be sent up the chimney and wasted. The steam is thus deprived of all moisture, and then heated to so high a temperature that it will heat more thoroughly, and with less obstruction by back-pressure, than saturated and wet steam. Heat is thus obtained without cost, and rendered effective for useful application to a greater extent than has hitherto been possible. — (*Amer. mach.*, July 7.) R. H. T. [140

CHEMISTRY.

(Analytical.)

Electrolysis of bismuth solutions. — Messrs. N. W. Thomas and E. F. Smith find that bismuth may be accurately determined in solution either as sulphate or as citrate by electrolysis. By three bichromate cells all the bismuth was deposited in a compact form in three hours. It was washed, first with water, then with alcohol, dried, and weighed. The reduction goes on equally well in a solution containing an excess of citric acid. — (*Amer. chem. journ.*, v. 114.) C. F. M. [141

Estimation of hardness in water without soap solution. — Instead of the usual method for estimating the hardness of water, O. Hehner prefers titration with standard sulphuric acid and sodic carbonate solutions. He claims that the results obtained with the soap solution are very variable and wholly unreliable. — (*Analyst*, May, 1883.) C. F. M. [142

The presence of copper in cereals. — In an article on this subject, Mr. E. F. Willoughby reviews the instances in which copper has been found in cereals, and he quotes the following results obtained by Dr. V. Galippe: —

		Copper in a kilogram.
Wheat from	Central France	0. 0100 grm.
" "	La Châtre (Indre)	0. 0080 "
" "	Grand Villiers (Oise)	0. 0052 "
" "	Michigan	0. 0070 "
" "	America (Redwinter)	0. 0085 "
" "	California	0. 0050 "
" "	Native Bric	0. 0054 "
" "	America, soft	0. 0108 "
" "	Russia, hard (Taganrog)	0. 0088 "
" "	Algiers, hard	0. 0062 "
Rye		0. 0050 "
Oats		0. 0084 "
Barley		0. 0108 "
Rice		0. 0016 "

— (*Analyst*, May, 1883.) C. F. M. [143

AGRICULTURE.

Preserved milk. — Loew found that a sample of milk which had been sealed up and heated to 101°, and then preserved for eight years, had undergone decided change. The color was brownish, and the taste intensely bitter. The milk-sugar was changed into dextrose and levulose; the caseine and albumen, into peptone. A sediment yielded crystals of tyrosin after boiling with potash. Milk preserved for a year by Scherff's process was found by Vieth considerably altered in taste, but samples kept in a cool cellar for several months appeared unaltered. — (*Bied. centr.-blatt.*, xii. 57.) H. P. A. [144

Calculation of feeding-rations. — In two feeding-experiments with steers, Caldwell and Roberts found that a ration calculated to correspond to that recommended by Wolff for maintenance caused a very decided and steady gain in weight, while a richer ration gave much greater gains than have been obtained by other experimenters from rations calculated to furnish the same amounts of digestible matters. They conclude that "We have not yet sufficient data, from actual feeding-experiments, upon which to base a reliable calculation of the maintenance-ration, or of a ration for the production of a certain effect." — (*Rep. Cornell univ. exp. stat.*, 1882–83, 18.) H. P. A. [145

Determination of proteine. — Trials of Stutzer's method of separating true proteine from other nitrogenous matters failed to give Newbury concordant results in the case of several concentrated fodders, and numerous difficulties in manipulation were experienced. With coarse fodders the results were concordant. — (*Rep. Cornell univ. exp. stat.*, 1882–83, 34.) H. P. A. [146

Determination of phosphoric acid. — Pemberton's method for the volumetric determination of phosphoric acid in fertilizers by titration with a standard solution of ammonium molybdate gave results closely agreeing with gravimetric determinations. Two improvements in the process are described. — (*Rep. Cornell univ. exp. stat.*, 1882–83, 29.) H. P. A. [147

MINERALOGY.

Peculiar crystals of fluorite. — On a hand specimen of fluorite, probably from Zinnwald, Bohemia, F. J. P. Van Calker noticed that there were on all of the small crystals, which were combinations of cube, hexoctahedron, and octahedron, well-defined markings on each cubic face, making a perfect rectangle whose sides were parallel to the intersection of the cube and octahedron. To account for these peculiar markings, which were present on all of the crystals, the author suggested that each crystal might originally have been of a simpler form, around which a subsequent shell of fluorite had been deposited; and a section from a single crystal, cut near and parallel to a cubic face, showed, when examined by transmitted light, a colorless centre, with the rectangular marking appearing as a dotted line, and outside of this another colorless portion completing the crystal. This fully confirmed the author's suggestion of an enclosure of fluorite in fluorite, showing that the crystals were originally of simple form, combinations of cube and octahedron, which had become coated with some pigment, and subsequently another deposit of fluorite had taken place, building up the hexoctahedron planes on all of the solid angles. — (*Zeitschr. krysl.*, vii. 447.) S. L. P. [148

GEOLOGY.

Lithology.

The eruptive rocks of Tryberg, Schwarzwald. — George H. Williams has published for the doctorate degree a valuable petrographical paper on the Tryberg region, the country rocks of which are gneiss, granitite, and granite, cut by dikes of granite, quartz-porphyry, mica-syenite-porphyry, mica-diorite and nepheline-basalt, while porphyrytuff occupies a portion of the Kesselberg area. The granitite is a crystalline granular mixture of felspar, quartz, and biotite, and is regarded as a typical rock of its kind. The quartz-porphyry has a compact, red groundmass porphyritically enclosing quartz and felspar, also biotite, apatite, and magnetite. The mica-syenite-porphyry has a compact, deep reddish-brown groundmass, holding biotite and felspar, as well as some quartz, apatite, and zircon.

The nepheline-basalt shows a compact, greenish-black groundmass, holding crystals and grains of a fresh, nearly colorless olivine. The groundmass is composed of a mixture of augite, little olivine crystals, and magnetite grains cemented by a colorless mass of nephelite and glass. Some reddish-brown biotite was observed, while apatite in little needles occurs abundantly. The paper is accompanied by a plate and map, while the classification followed is that of Prof. Rosenbusch of Heidelberg, with whom Dr. Williams studied. This classification of eruptive rocks is now the prevailing one in Germany, and, on account of the number of Rosenbusch's students connected with the U.S. geological survey and with other institutions, will be soon generally used in America. — (*Neues jahrb. min., beil.*, 1883, ii.) M. E. W. [149

GEOGRAPHY.

(Arctic.)

Danish expeditions in Greenland in 1883. — Dr. Rink, who is now resident in Kristiania, gives some details as to the proposed work for this season. Lieut. G. Holm, assisted by Lieut. Garde, geologist Knutsen, botanist Eberlin (who also acts as surgeon), and a number of Greenlanders, will undertake the exploration of the eastern coast of Greenland in umiaks, in the narrow strip of water between the great stream of drift-ice and the shore, where these boats may be able to accomplish much not practicable for a vessel. They will endeavor to pass the northern extreme reached by Graah, 1828–30, and to penetrate to the interior by some of the deep fiords, thus obtaining some idea of the region between them and the western coast. The other expedition will endeavor to map the unexplored portion of the western coast between 67° and 70° N. lat., and will be commanded by Lieut. Hammer, assisted by Sylow as geologist, and naval Lieut. Larsen. Notice has already been taken of the arrival of these parties in Greenland. — (*Naturen*, Mai, 1883.) W. H. D. [150

(South America.)

The death of Crevaux. — The details of the destruction of this gallant explorer and his party have been obtained from a native interpreter, who was made captive at the time, but finally escaped across the desert to Ankaroinga. The party had arrived at a spot on the right bank of the Pilcomayo, five leagues above the Rio Tigre, where there is a village of Toba Indians called Cuvarocai. After having been assured of a peaceful welcome, the doctor began to distribute presents to the natives, who, at the advice of their chief, rendered covetous by the sight of the valuables in the hands of the party, fell suddenly upon the explorers, and killed those on the shore. Those still in the boats attempted to escape by swimming, and were pursued, and several of them killed in the water. Only two, Haurat and Blanco, being good swimmers, succeeded in reaching the opposite shore, and hiding themselves in the forest. Nothing has been heard of them since. The interpreter was carried off as a prisoner. The bodies were thrown into the water or left where they fell, except that of Dr. Crevaux, which was carried to a neighboring village, where for thirty-six hours the Tobas sang and performed incantations around it, after which it was conveyed to a spot near to and visible from the huts. The Argentine government has sent Col. Sol with two hundred men up the Pilcomayo to punish the assassins, while the geographical society of Buenos Ayres has sent one of its number to search for the two survivors, and report on the whole subject. — W. H. D. [151

Crevaux's voyages in Guiana. — Henri Froidevaux summarizes previous investigations of the rivers of Guiana, and narrates the advances due to Crevaux. He notes that the indigenous population of Guiana is visibly decreasing, and states that Crevaux believed, that, judging by the abundance of village sites and relics on the river-banks now absolutely depopulated, there was formerly an abundant population. — (*Rev. géogr.*, May, 1883.) W. H. D. 152

Notes. — Dr. Güssfeldt has made interesting trigonometrical surveys in the Cordillera, together with observations on glaciers. He will soon take up the region about Aconcagua. —— The English brothers Haspold, with the warmest approbation of the government of the republic, have undertaken a very exact geological, mineralogical, and natural history survey of the different Argentine states. — (*Mitt. geogr. ges. Wien*, xxvi. no. v.) W. H. D. [153

(Africa.)

Number of Jews in Africa. — According to the estimate of Brunialti, the Jews in Africa number 450,000. Gerhard Rohlfs criticises this as much too high, and, by reviewing the estimates of population in all parts of the continent, concludes that 220,000 is much nearer the truth. — (*Peterm. geogr. mitth.*, 1883, 211.) W. M. D. [154

The coast-line of Tunis. — In his description of the Mediterranean lands, Th. Fischer has included Tunis in the area of rising coasts about Sicily, Sardinia, and south-eastern France. The correctness of this is questioned by Dr. J. Partsch of Breslau, who presents a considerable mass of evidence to show that the Tunisian shores have not changed their altitude in the historic period, although their outline has varied distinctly at certain points by delta growth. The river Medjerda (the ancient Bagradas) has shifted its mouth several miles to the north, and built out its delta into the Gulf of Tunis; and this in combination with the wind-action, by which sand has been blown inland from the shore, has added nearly one hundred square miles of lowland outside of the coast-line of the third century before Christ. Former lines of river-flow are distinctly visible at several points. But all this, and other facts of a similar nature, must not be explained by an elevation of the land; for the ruins of Carthage, on a promontory a few miles to the south, are still close to the sea, and the remains of some of its harbor-works are yet at the water's edge. A variety of ancient and modern descriptions of this region are referred to. — (*Peterm. geogr. mitth.*, 1883, 201, map.) W. M. D. [155

ZOÖLOGY.

Protozoa.

New sporozoon. — A. Schneider has discovered in the Malpighian vessels of Blaps an amoeboid parasite. Multiplication takes place principally by means of cysts. Encystment occurs only between individuals with a single nucleus and of spherical form. The two conjugated organisms secrete around themselves several envelopes, each marked with an equatorial line of dehiscence. Each of the two nuclei divide into three. Of the six nuclei thus formed, four, together with a part of the granular mass, remain unused, while the other two become the spores. The species is named Ophryocystis Bütschlii. — (*Comptes rendus*, 1883, 1378; *Ann. mag. nat. hist.*, xi. 459.) C. S. M. [156

Insects.

Observations on Hymenoptera. — In part x. of his Observations, Lubbock answers some of Dr. Müller's objections to his methods in studying the color-preferences of the hive-bee, believing that his conclusions are not invalidated by them. To test the sense of hearing in bees, telephonic communication was established between two sets of bees, one of which was then excited, but with no effect on the other. Others were accustomed to visit honey placed near a music-box, the position of which was several times changed. The bees did not, however, appear to hear the music, though they seem to have connected the presence of the instrument with that of the honey, and were guided by it, even if it were not playing, so long as they could see it; but if they could not see it, even if it were playing, it did not assist them. It is, however, uncertain but that high over-tones, beyond our range of hearing, may be audible to bees.

Further experiments seem to show that the industry of wasps has been underrated. One individual visited some honey no less than a hundred and sixteen times in a day, loading herself each time, and carrying away more than sixty-four grains of honey. Her working-hours extended from 4.13 A.M. to 7.47 P.M., while a bee, working on honey the same day, made but twenty-nine visits, between 5.45 A.M. and 7.15 P.M.

A curious demonstration of the recognition of the queen by worker-ants was made in the following way: "I was starting a new nest of Lasius flavus in which were two queens. We allowed the ants to take one of them into their new glass house; the other we kept with a small retinue in a separate bottle. If this bottle is placed near the nest, some of the retinue leave it, go into the nest, and soon the ants come out in large numbers to see, I had almost said to pay their respects to, their queen."

The dislike of ants for the ultra-violet rays of the spectrum, indicated by earlier experiments, was further shown by the use of two screens, — one consisting of a solution of iodine in carbon bisulphide; the other of indigo, carmine, and roseine, mixed so as to produce the same tint, but not, like the bisulphide solution, intercepting the ultra-violet rays. The ants collected, in most instances, under the iodine screen.

The record of the occurrence of Ponera contracta in England, and the description of a new Australian honey-ant, Melophorus Bagoti, are of interest to the systematist. — (*Journ. Linn. soc., zoöl.*, xvii.) W. T. [157

(Economic entomology.)

Insects affecting the strawberry. — Professor S. A. Forbes summarizes what has been published respecting the insects that infest the strawberry in the United States, and adds original observations respecting several of them. These observations refer chiefly to the crown-borer, the root-worm, and the crown-miner. A very useful calendar is given, indicating in a concise form the periods of each of the species discussed and the particular place in which each insect occurs in each of its stages. — (*Trans. Miss. Valley hort. soc.*, 1883.) J. H. C. [158

The hop-vine borer. — Although this pest has been very destructive for many years, the life-history of the species has not been known till now. Prof. Comstock gives an account, with figures, of the insect in each of its stages. — (*Amer. agric.*, June, 1883.) [159

VERTEBRATES.

Are the lungs air-tight? — That the lungs are normally air-tight under the ordinary condition of life has been accepted in physiology as an almost necessary consequence of the function which they perform. Ewald and Kobert have lately reported some experiments which appear to show that this belief is not strictly correct. If the intra-pulmonic pressure is raised above a certain limit, not higher than may occur normally during life, there is an escape of air from the lungs into the pleural cavity or into the blood-vessels of the pulmonary circulation. When a curarized dog was exposed to artificial respiration at a proportionally high pressure for about an hour, the dog killed, and the chest opened under water, both the pleural cavity and the heart were found to contain air. Experiments made upon excised lungs, expanded under water by positive pressure, showed, that, at a certain pressure, air escaped, while, if the pressure was again lowered, the lungs again became air-tight. The authors satisfied themselves in all cases that there was no actual gross rupture of the lung-tissue or blood-vessels. The maximal expiratory pressure which a dog can produce was found to vary between 50 mms. and 90 mms. of mercury; while, to get an escape of air into the pleural cavity or heart, it was only necessary to keep the intra-pulmonic pressure at about 35 mms. of mercury. A similar result was obtained with rabbits. The escape of air may take place not only through the walls of the alveoli, but also through the trachea, with the production of emphyaema of the subcutaneous cellular tissue of the neck, which in time may spread as far as the extremities of the body. The peculiar pains in the chest which sometimes follow upon violent expiratory efforts may be owing, they think, to a small escape of air into the pleural cavity. So many hitherto inexplicable cases in which, after sudden death, air has been found in the heart or pleural cavity, although there was no evidence of any rupture, may be explained in this way by the escape of air through the lung-tissue. — (*Pflüger's archiv*, xxxi. 160.) W. H. H. [160

Structureless basal substance. — The structureless substance which forms the basis of the 'jelly' in medusae, Emery thinks, is still represented in the higher animals, preceding in certain places the true connective tissue. Emery employs the name given by Hensen, 'tissue of secretion,' it being supposed to be secreted by the surrounding epithelia. In vertebrates an anhistic layer in the cornea precedes the true connective tissue (Kessler, Emery). In the embryos of teleosts, particularly those that leave the egg early, the ectoderm is separated by a thick layer of homogeneous, unorganized matter from the inner tissues. This hyaline mass also fills out the embryonic median fins. It is probably changed later into connective tissue by the immigration of cells. The clear membranes separating two adjacent epithelia, or an epithelium from connective tissue, the vitreous humor, and the substance filling the segmentation cavity of the ovum, are also, perhaps, to be enumerated here as preservations of a very ancient primitive formation, — the tissue of secretion of the most distant ancestors of vertebrates. Its excessive development in teleost larvae is probably an acquired embryonic characteristic. This interesting little paper especially deserves attention from those studying the embryology of fishes. — (*Arch. ital. biol.*, iii. 37.) C. S. M. [161

Fish.

Motor-nerve endings. — Ciaccio has investigated the motor-nerve plates in the depressor muscle of the jaw of Torpedo marmorata by treatment with double chloride of gold and cadmium. From the anterior third of the muscles, strips one millimetre thick were cut with scissors; the strips were then left for five minutes in fresh filtered lemon-juice, washed in distilled water, and placed for half an hour in a one-per-cent solution of gold and cadmium, being kept dark; washed again in one-per-cent aqueous solution of formic acid, in which they were left twelve hours in the dark, then twelve in the light; finally, kept in the dark in stronger formic acid for one day, and preserved in glycerine. Such strips may be easily dissociated into fibres.

Two forms of nerve-endings are observed. One, the rarer, represents probably the initial form: it consists of bunches of grains, suspended by peduncles arising by repeated division of the pale fibres towards their termination. The second form has been previously described (*Mem. accad. sc. istit. Bologna*, 1877), but the following new points deserve mention: the end-plate appears to be more closely united to the sarcolemma than to the muscular substance; between the ramifications of the fibres appear certain corpuscles, probably connective tissue, but whether they lie within or without the sarcolemma was not determined; a secondary sheath extends over the primary and secondary, but stops at the tertiary branches; the ultimate terminations are bunches of pedunculated grains, the grains being colored dark, their stalks light; finally, the presence of a granular embedding substance around the nervous branches. — (*Arch. ital. biol.*, iii. 75.) C. S. M. [162

Fishes of the Batstoe River, New Jersey. — Professor E. D. Cope stated that eleven species collected in the confined waters of a broken dam on the Batstoe River, New Jersey, represented the fish fauna of the Carolinian district of the nearctic realm, only three extending into the Alleghanian district. A species of Amiurus new to science was at first supposed to be an unusually dark-colored example of the common Amiurus nebulosus. A critical examination soon showed that it differs in the important characters of the considerably more anterior position of the dorsal fin, four to seven more anal radii, and more rounded outline of the caudal fin. Its characters ally it to the western A. natalis, from which it differs by its more slender form and more rounded caudal fin. The name A. prosthistius was proposed for it. — (*Acad. nat. sc. Philad.; meeting* June 26.) [163

Mammals.

Color-markings of mammals. — Professor Eimer has continued his studies in regard to the color-markings of vertebrates.

As the result of his observations, he has drawn out certain general principles, which he applies to the different groups, notably to the mammals.

The following general statements are elaborated: 1. That the color-markings of mammals may be reduced to longitudinal stripes, spots, and transverse stripes; 2. That the longitudinal stripes are the oldest form, and that the other two follow in course; 3. That the primitive mammalian fauna was a longitudinally striped one; 4. That the males have been first to take on the new forms of markings, while the females hold longer to the older form; 5. That the effects of the law by which the development of the markings takes place from the posterior part of the body toward the anterior part are not so easily traced in mammals as in the case of other groups, such as the saurians; 6. That in mammals the development of markings follows a regular course, that is, the longitudinal markings are followed by spots, which, in turn, run together, and finally form the transverse or tiger stripes; 7. That the position of the smallest spot on a mammal is not accidental, but due to the action of genetic and philogenetic laws, from which it follows that markings are an available means for the determination of species; 8. That the regularity of the development of markings shows that they arise from constitutional causes.

The author takes the Viverridae as the original types of the carnivores, and believes that in the hyena, cats, dogs, bears, and weasels, he can trace the form and position of markings possessed by the former. He acknowledges several difficulties, however, in the case of the leopard, jaguar, and other peculiarly spotted cats. He believes that the ungulates follow the same law in regard to markings as the carnivores. — (*Jahresb. verein vaterl. naturk. Württ.*, xxxix. 1883. 56.) F. W. T. [164

(*Man.*)

Function of the crico-thyroid muscle. — Martel brings forward some experiments to show that the crico-thyroid, and not the thyro-arytenoid muscle is par excellence the muscle used in the production of different tones in singing and speaking. The most interesting point of the paper, perhaps, is, that he shows, by registering with simple levers the movements of the thyroid and cricoid cartilages respectively, that, when the different chest-notes (from do^2 to do^4) are sounded, the thyroid cartilage remains immovable, while the cricoid is brought closer and closer to it as the pitch of the note is raised. In the contraction of the crico-thyroid muscle, or, as he prefers to call it, the thyro-cricoid muscle, the thyroid cartilage is therefore to be considered as the fixed point. The action of the thyro-arytenoid muscle, according to him, is preparatory to that of the crico-thyroid, in that it gives the vocal cords their proper position, and acts as an antagonist to the latter muscle. The length and tension of the vocal cords, however, are governed by the crico-thyroid. This view of the function of the crico-thyroid is supported by the results obtained when the muscle, or the nerve going to it, is divided in the dog, and, among men, by the pathological cases in which there is paralysis of this muscle. The general result in such cases is a pronounced hoarseness, and an inability to sound any but the lowest tones. — (*Arch. de physiol.*, 1883, 582.) W. H. H. [165

Summation of stimuli in the sensory nerves of man. — From numerous experiments made upon himself with electrical stimuli, de Watteville comes to the conclusion that the action of stimuli applied to a sensory nerve increases, within certain limits, with their frequency. Stimuli which are subminimal, as long as they follow at slow intervals, will call forth a sensation when made to follow each other with greater rapidity. This summation takes place more readily when the stimulated nerve is exposed to the action of the kathode; and the author is of the opinion that it is local, as in motor nerves, and not central. The summation may be explained as the after action of electrical stimulation; the induction shocks following with such rapidity that the excitation in each case falls within the period of heightened irritability. — (*Neurol. centralbl*, no. 7, 1883.) W. H. H. [166

ANTHROPOLOGY.

Tribute to American scholarship. — An interesting tribute to American scholarship is paid in the fact that M. Barbier, on the authority of Mr. Stephens and later writers, was setting up Del Rio's 'images of men in bas-relief' in front of the model of the Temple of the Sun, as he had done in the Trocadero. Dr. Rau of the Smithsonian institution drew his attention to Del Rio's description of the Temple of the Cross, as well as to the statements of Dupaix and Galindo; and the bas-reliefs at Washington will stand in their proper place in front of the shrine containing the group of the Cross. Again, Prof. Cyrus Thomas has discovered that the cast on the left slab of the Tablet of the Cross proves conclusively the correctness of the statement previously made in SCIENCE, that Waldeck's figure of this slab, as published by the French scientific commission, 1860–66, was copied from Catherwood's drawing. This is proved by the fact that Catherwood's errors, of which M. Charnay's cast brings to view quite a number, are all faithfully reproduced in Waldeck. — O. T. M. [167

Prehistoric trepanning. — The object of recalling attention to this much described subject is to speak of the novel experiments of L. Capitan. Many years ago Dr. Charles Rau, wishing to know how long it would take a savage to bore a hole through a hard rock with a wooden spindle, using sand and water, actually made the experiment, and has put on record his experience. M. Capitan has proceeded in the same way respecting prehistoric trephining, testing the various methods of boring and of removing a rondelle or fragment of bone. The experiments on the skulls of the dead were to study the methods, the difficulties in the way of the operation, and the time required. It is the trephining of the living among savages, and the fatality of the result, that most interest the student: therefore M. Capitan continued his researches upon living canine subjects. The first experiment was upon a small spaniel. The skin of the head and temporal muscle were removed, and the trephining was practised upon the antero-superior portion of the right parietal. The operation was not very painful, and in twenty minutes a rondelle of bone was removed. There was little hemorrhage and the meninges were not wounded. After a few days the spaniel was as lively as ever. Two other dogs were subsequently treated, with like success. Just what the method and amount of cicatrization might be, after such primitive operations, will be known when the autopsy of the subjects takes place in the future. — (*Bull. soc. anthrop. Paris*, v. 535.) J. W. P. [168

Catlinite. — The beautiful red stone pipes in collections of Indian culture-objects are made of a stone called catlinite. Mr. E. A. Barber tells us that for many generations the aborigines have procured this material from the Great red pipestone quarry, situated on the dividing-ridge between the Minnesota and Missouri rivers, at a place called by the French *Couteau des prairies*. Catlin, the celebrated traveller, was the first white man permitted by the Indians to visit the place; and therefore Dr. C. T. Jackson, to whom specimens were sent, named the mineral catlinite. The myths relating to the quarry, as well as surface indications, show that the place has been worked for a very long time. In 1673 Marquette smoked in peace a catlinite pipe with the Indians of the upper Mississippi. Father Hennepin applies the term 'calumet' to these ceremonial pipes. There is no doubt that an extensive traffic was carried on in this material for a considerable length of time by the aboriginal tribes, extending from the Atlantic coast to the Rocky Mountain system and from New York and Minnesota on the north to the Gulf of Mexico. The fact that objects of catlinite have been taken from Indian graves in the state of New York, and that others were found on the ancient site of an abandoned village in Georgia, at opposite points twelve hundred miles distant from the pipestone quarry of Minnesota, reveals the great extent of intercommunication which formerly existed among the North American peoples. When we consider that many pipes of catlinite have been taken from the bottom of mounds from four to seven feet deep, where they were found in connection with cloth-wrapped copper axes and many other objects of high antiquity, and that some of them are of the typical form of the oldest mound-pipes, we are forced to ascribe to some of them a high antiquity. — (*Amer. nat.*, July.) J. W. P. [169

The Charnay collection. — Visitors to the National museum at Washington are surprised to find the great hall adjoining the last doorway on the south side shut off by screens. Looking behind this barricade, the visitor may imagine himself transported to Central America, and in the presence of some of her grandest aboriginal remains. Here M. Barbier, from the Trocadero museum at Paris, is setting up casts of the most celebrated relics of Mexican and Central American ruins secured by M. Charnay. The readers of SCIENCE will recall that Mr. Pierre Lorillard of New York, conjointly with the French government, equipped an expedition in 1880, and maintained it for two years, for a systematic investigation of the so-called 'ruined cities' and other remains of ancient civilization in Central America and Mxeico. The expedition was placed under the charge of M. Désiré Charnay, and thoroughly furnished with the means of making photographs and casts by the process of M. Lotin de Laval. Copies of these casts were first to be presented to the Smithsonian institution and to the French government, the latter set to be placed in the Trocadero museum at Paris. The story of M. Charnay's travels and successes has been told in the *North American review*, commencing with August, 1880; the editor, Mr. Thorndike Rice, favoring and encouraging the expedition from the first. M. Charnay's moulds having been transported to Paris, he proceeded to make his reproductions. With reference to the Smithsonian series, now being set up in the National museum, Mr. Rice writes, "These casts are duplicates of those now on permanent exhibition at the Trocadero, Paris. The casts have been made in order to afford to students of American antiquities the fullest opportunity for studying these products of indigenous art and the hitherto indecipherable inscriptions." The collection includes a bas-relief from Ocosingo, the stone of Tizoc, fragment from Tezcuco, thirty-eight pieces from Palenque, including the most celebrated sculptures and inscriptions, and thirty-four pieces from Chichen-Itza. M. Hamy will shortly send a detailed account of each piece, and the readers of SCIENCE will receive the benefit of his information. Professor Baird will have the bas-reliefs of the Temple of the Sun and those of the Temple of the Cross mounted in wooden frames, the exact reproduction of the rooms which they occupied in Palenque. — J. W. P. [170

EARLY INSTITUTIONS.

The Nottingham records. — The records of the borough of Nottingham have been published by Quaritch in London. They cover the period from 1155 to 1399, and contain much interesting matter bearing upon the history of town customs and government in England. Mr. G. L. Gomme, the author of Primitive folk-moots, reviews the volume, and gives us some extracts from it. Assuming that the municipal corporation of the thirteenth century is the primitive village community in a late stage of development, he discovers various customs which he describes as belonging to the primitive village. The history of the primitive village is in this way extended and enlarged. Some very interesting passages, illustrative of the right of pre-emption which kinsmen enjoyed, are given. It appears, that, "if a person sold his land [in Nottingham], his nearest heirs might lawfully enter into such lands and tenements if they offered to the purchaser, in the gild hall of the town, the money which he had given for the property." Some passages bearing upon the history of the open-field system are also cited. Mr. Gomme regards the open-field system as 'the best evidence of the old primitive tenure of land.' The custom of borough English — or 'junior-right,' as Mr. Elton calls it — obtained at Nottingham. — (*The antiquary*, April, 1883.) D. W. R. [171

NOTES AND NEWS.

It is hoped that the new section for mechanics of the American association for the advancement of science will receive the earnest co-operation of all interested, who may find it convenient to attend. The approaching meeting at Minneapolis will be the second held by the section. Those having matters of interest to present are requested to notify the secretary of section D (A. A. A. S.) at Minneapolis as early as possible. Circulars relating to the meeting may be obtained of the permanent secretary of the association, F. W. Putnam, at Minneapolis.

— During the coming year, experiments will be made at the physical laboratory of Johns Hopkins university with a view to aid in establishing an international unit of electrical resistance. The experiments will be carried on, under the direction of Professor Rowland, with an appropriation from the government of the United States. The results will be communicated to the International commission of electricians, meeting in Paris.

— We alluded a few weeks ago to the award of the first Walker prize of the Boston society of natural history to Mr. Howard Ayres of Fort Smith, Ark., for his memoir on the development of Oecanthus. This memoir is now printing by the society. The award of the second prize has now been made. Several papers of unquestionable merit were before the committee, and the subjects were so diverse as to make it difficult to decide between them. Expert aid was sought; and it has been at last concluded to divide it equally between William Patten of Watertown, Mass., who offered an essay on the development of Phryganidae, and H. W. Conn of Johns Hopkins university, who presented an essay on the life-history of Thalassema millita.

— Recognizing the demand for thoroughly trained engineers conversant with electrical science, at the beginning of the next academic year (Sept. 18, 1883) the trustees of Cornell university will receive students who desire to fit themselves to enter this new and constantly extending field. While the general studies are mainly those of the departments of civil and mechanical engineering, the special studies of the course embrace the theory of electricity, the construction and testing of telegraph lines, cables, and instruments, and of dynamo machines, and the methods of electrical measurement, electrical lighting, and the electrical transmission of power.

— During the past year original investigations, the results of which either have been or soon will be published, have been made in the biological laboratory of Johns Hopkins university, in the following subjects: the direct action upon the heart of ethyl alcohol, the influence of digitaline upon the heart and blood-vessels, the influence of quinine upon the blood-vessels, the influence of variations in arterial pressure upon the time occupied by the systole of the heart, the minute structure of the kidney, the life-history of Penicillium, viscous fermentation, the influence of various illuminations on the growth of yeast, the structure of Porpita, the structure of the gasteropod gill, the development of the mammary gland, the structure and properties of the cavernous tissue beneath the olfactory mucous membrane.

— The U. S. geological survey has appointed Prof. H. S. Williams of Cornell university upon its staff. Under its auspices he will carry out more fully the studies he has long undertaken upon the upper Devonian fossils of the rich localities of his neighborhood in New York, and extend the work beyond the limits of the state, as well as into the immediately underlying and overlying strata, for better comparison of the upper Devonian species, and study of their faunal relations. Professor Williams has been endeavoring to build up a thorough school of comparative paleontology at Cornell with good success; and the assistance he will gain from his connection with the U.S. survey will offer a special attraction to those wishing to pursue paleontological studies under him. Mr. C. S. Prosser, a recent graduate of Cornell, assists him this summer in his geological work in connection with the U. S. survey.

— A very interesting sketch of the life of Count Rumford, by Professor Tyndall, is printed in the *Contemporary review* for July. An account of his scientific labors is promised in a future issue.

— W. H. M. Christie, F.R.S., astronomer royal, has withdrawn from the editorship of *The observatory*, a monthly review of astronomy. This periodical will now be edited by E. W. Maunder, F.R.A.S.; and all communications should be addressed to him at the Royal observatory, Greenwich, as formerly.

— Dr. M. Braun in Dorpat proposes a zoölogical investigation of the Gulf of Finland. The Russian government will furnish a steamer, and the explorations are to be made on behalf of the Naturalists' society of Dorpat.

— The *American apiculturist* is the ninth periodical in the United States devoted to bees and apiculture. Several of these papers have a circulation numbering thousands, and one is a weekly. It would seem rash to start another bee paper under these circumstances. Silas M. Locke, editor of this new journal, seems, however, to have counted the cost, and means to act on the principle that there is always room up higher. He is an experienced bee-keeper, and expert in all the manipulations of the apiary. He has paid special attention to the qualities of the several races of bees, and is alive to the importance of great care in breeding bees, if the apiarist would secure the highest success. It is evident that he intends to give special attention to matters of scientific interest connected with bees and bee-culture.

Mr. Locke has also secured the assistance of the ablest writers on the apiary in the country, — not men who are simply given to fine writing, but practical men, who have won eminent success in the art which they practise. The paper is published at Salem, Mass., and, in typography and general style, has no superior among our apiarian periodicals.

— According to *Nature*, the report of the sanitary commissioner with the government of Bombay shows, that, among other causes of death in that presidency in the year 1881, 1,209 persons died from snake-bite. A comparison of the deaths in 1881 with the mean of those of five preceding years shows, that, in 1881 at least, the number had increased. These figures prove that one person in 13,610 of the whole population of the twenty-four presidency districts died from snake-bite. Adding to this the destruction of human life effected by other venomous and carnivorous animals, we see how important a matter to the residents of those regions is the destruction of this unfavorable environment.

— All the readers of SCIENCE have been familiar with the word 'wampum' from their childhood. Roger Williams wrote in his Key, "The New-England Indians are ignorant of Europe's coyne. Their owne is of two sorts, — one white, which they make of the stem or stock of the periwincle, which they call meteauhok when all the shell is broken off. This they call *wampam* (white). The second is black, inclining to blue, which is made of the shell of a fish which some English call hens (poquahock)." This money was called suckauhock (*sucki*, black). Various shells were used in different parts of the country under names adopted from the languages of the tribes who coined the money. But in the history of the early colonies the name 'wampum' has gained a footing for all shell-money as well as for its imitations. Mr. Earnest Ingersoll has brought together a large amount of information on the subject in the May *Naturalist*.

— The death is announced of E. Mohler, secretary of the Danube commission, and of Hermann Alexander von Berlepsch of Zurich, the latter in his seventy-first year.

— The death is also announced of Dr. J. S. Bailey of Albany, a young entomologist who had published a few papers of some importance on Lepidoptera.

— In the June number of the *Journal of science* is given the following account of a bird-eating frog. "A lady living in the George district (Cape Colony) supplies the *G. R. herald* with the following particulars of the remarkable habits of this creature: 'I have much pleasure in furnishing all the information we have, regarding the large frogs which have proved so destructive to our young chickens. A water-sluit runs round our terrace, and passes through the ground over which the poultry range, and in this the frogs harbor. The first time our attention was drawn to their bird-eating propensity was by the cries of a small bird in a fuchsia near the stream. Thinking it had been seized by a snake, several hastened to the spot, and saw a beautiful red and green sugar-bird in the mouth of a large greenish frog. Only the bird's head was visible; and, its cries becoming fainter, the frog was killed, and the bird released. Its feathers were all wet and slimy, and for some days after we could distinguish it in the garden by its ruffled plumage. Since then the same species of frog has on several occasions been killed with young chickens, half-swallowed; and once a duckling was rescued from the same fate. Whether the noise is natural to these frogs, or assumed to decoy the chickens within their reach, we know not; but they constantly make a chuckling sound so exactly like a hen calling her chickens for food that we have seen whole broods deceived, and rushing towards the sluit, where they supposed the hen to be. The frogs are very wary, and it is difficult to find them unless by the screams of their victims. We have lost large numbers of small chickens in an unaccountable manner, and feel sure now that these frogs must be answerable for very many of them, as there are no rats here, and the chickens are carefully housed at night. If I can give you any further details, I shall be glad to do so.'"

— The distinguished spectroscopist, M. Thollon, is now working at the observatory at Paris, as has been his custom during previous summers. The proposed observatory on the top of the Pic du Midi — where the brothers Henry saw the planet Venus with the naked eye in full daylight, when only three or four degrees from the sun, and two days after the transit — is said to be making great progress toward completion. It is expected that Admiral Mouchez, M. Thollon, and other astronomers will visit it toward the end of August.

— The *Vierteljahrsschrift der astronomischen gesellschaft* (18 jahrgang, erstes heft) is frontispieced with a solar print of Dr. Carl Christian Bruhns, the late director of the observatory at Leipzig. In the *nekrologe* are brief notices of Bruhns and C. Baeker, and a more extended one of E. Plantamour, by Dr. Rudolph Wolf of Zurich. Among the *literarische anzeigen* are the following: Backlund, Zur theorie des Encke'schen cometen, by Paul Harzer; Callandrean, Détermination des perturbations d'une petite planète par les méthodes de M. Gyldén, by O. Backlund; Ginzel, Astronomische untersuchungen über finsternisse, by Th. von Oppolzer; and Fischer, Der einfluss der lateralrefraction auf das messen von horizontal-winkeln, by Wilhelm Schur. Among the newly elected members of the *gesellschaft* are P. Harzer of Leipzig, J. Holetschek of Vienna, J. Scheiner of Bonn, and C. Wagner of Kremsmünster. The next meeting of the *gesellschaft* will be held at Vienna, commencing on Friday, Sept. 14, and lasting four days.

— The geological commission of Spain has prepared a pamphlet of twenty pages for the mineral exhibition, now open at Madrid, giving a brief account of the different geological formations occurring in Spain, their geographical distribution, general characters, and the minerals of economic interest occurring in each. It also gives a short orographical account of the country, which has a higher average elevation than any country in Europe excepting Switzerland. The highest peak is that of Mulahacen, in the Sierra Nevada, 3,554 metres above the sea-level. The formation which has the greatest extent in Spain is the tertiary, which covers 34 per cent of the surface; next comes the primary, covering 27 per cent; the secondary, 18½ per cent; the hipogenica, 10 per cent; the quaternary, 10 per cent; and the azoic, ½ per cent. Given in numerical order, the miocene and oligocene cover together 137,877 □ kilom.; the Cambrian and Silurian, 114,382; the hipogenica, 49,665; the quaternary, 49,477; the cretaceous, 47,002; the eocene, 23,564; the Jurassic, 22,697; the triassic, 22,443; the carboniferous, 11,301; the pliocene, 9,064; the Devonian, 5,780; and the crystalline strata, 1,694, — a total of 494,946 □ kilom. The term '*rocas hipogenicas*' is applied to what are generally called plutonic and volcanic rocks, both old and recent eruptive rocks.

— Père Vidal, French missionary at Tutuila, Navigator's Islands, announces the discovery, made last year, of the place of burial of Commandant Fleuriot de Langle, of the unfortunate expedition of la Perouse. De Langle and his companions were killed by the natives at a point named Massacre Bay, in December, 1787; but up to this recent date their remains and place of burial had not been discovered. The pious missionary intends to erect an expiatory chapel for the converted natives on the spot where their barbarous ancestors' victims were buried.

— Mr. Henry H. Howorth, who is our standard authority on the Mongols, reviews with favor the work of the Rev. James Gilmour, who has lived as a missionary among them. We have space only for a brief abstract upon the hospitality of these least sophisticated tribes of men: "Any traveller is at perfect liberty to alight at any village he may wish, and demand admittance; and any Mongol who refuses admittance, or gives a cold welcome even, is at once stigmatized as not a man, but a dog. Any host who did not offer tea without money and without price would soon earn the same reputation; the reason being, I suppose, that Mongolia has no inns, and all travellers are dependent on private houses for shelter and refreshment. At first sight it seems rather exacting to leap off your horse at the door of a perfect stranger, and expect to find tea prepared and offered to you free; but probably the master of the tent where you refresh yourself is at the same time sitting likewise, refreshing himself in some other man's tent some hundred miles away; and thus the thing balances itself. The hospitality received by Mongols in travelling compensates for the hospitality shown to travellers."

— Two noteworthy ornithological papers appear in the August magazines. The habits and mental traits of the cat-bird in confinement have found an excellent student in Olive Miller, who gives us in the *Atlantic* a vivid picture of its curiosity, and its tyranny over weaker birds, with proofs of how it can learn by experience, and its capacity for jealousy. The article is well worth reading.

The friends of Prof. A. M. Meyer of Hoboken, who are aware of his zeal as a sportsman, will be less surprised than those who know him only by his professional studies, at his interesting paper on the quail, or 'Bob White' as it is familiarly known, which appears as the leading paper in the midsummer *Century*. Eight or nine exquisite woodcuts by Beard illustrate the different species of this class of game-birds in Europe and America, and far surpass in finish, and in excellence of delineation, any previous pictures we have seen.

— An increased interest in economic entomology is being shown in England. The Council of education (My lords of the privy council) have formed a committee of advice and reference regarding the entomological collections which have existed for some time in connection with South Kensington museum. This committee is under Professor Huxley as chairman; and among the members are Professor Westwood, Mr. Dyer (sub-director at Kew gardens), and Miss Ormerod. It is planned to form a collection of cases that shall show the insects commonly injurious to a serious extent to the crops, fruit and timber trees, of the British Isles. Each case is to be accompanied by short life-histories of the species in it, and descriptions of the most serviceable methods of preventing their ravages. It is the purpose of the committee to make the collection thoroughly plain to be understood, so that farmers and gardeners may be able to consult it serviceably. As far as possible, the insects will be shown in all stages, together with specimens of the injured plant. In those cases where specimens are too small or too perishable to be used, drawings or models will be substituted. The carrying-out of this plan in a thoroughly scientific manner has been assured by placing the preparation of the cases in the hands of Professor Westwood and Miss Ormerod.

— In order to bring together the greatest amount of solid information respecting the natural history of man, students have published manuals of anthropology from time to time, formulating the questions they desire to have answered. In 1800 Degeraudo, a member of the Institut de France, published a quarto of fifty-seven pages, entitled 'Considérations sur les diverses méthodes à suivre dans l'observation des peuples sauvage.' The Société ethnologique de Paris, in 1839, published its first memoir, which was preceded by general instructions addressed to travellers, among which were three chapters on the individual, family, social, and religious life of peoples. Mr. Gallatin, in our own country, while preparing his comparative Indian linguistics, issued circulars to all army officers, Indian agents, and travellers. Mr. Schoolcraft prepared a very elaborate scheme. George Gibbs published through the Smithsonian institution a linguistic circular, and the same institution has issued a number of others on anthropological subjects. The most elaborate published in our country are Major Powell's manual for collectors of linguistics, and Professor Mason's directions to collectors for the Centennial exhibition, and his pamphlet on the study of North American antiquities. In 1875 the Geographical society of Paris published 'Instructions aux voyageurs.' The British association have printed three sets of questions, in 1851, 1854, and in 1874. The last named bears the title 'Notes and queries on anthropology for the use of travellers and residents in uncivilized lands.' The Austrian expedition in the frigate Novara was furnished with a very elaborate volume of questions upon anthropology. In addition to these, we have 'Instructions anthropologiques' and 'Instructions craniologiques' by the Paris society, and manuals by Roberts and Kaltbrunner. Finally, the last-named society has been discussing with much learning and a slight loss of temper a 'Questionnaire de sociologie et d'ethnographie.'

— The following investigations have been completed by advanced students at the chemical laboratory of Johns Hopkins university during the past year: on the conduct of moist phosphorus and air towards carbon monoxide; white phosphorus; oxidation of a compound containing the sulphamine and propyl groups in the ortho-position with reference to each other, showing protection of the propyl; oxidation of paradipropylbenzine-sulphamide, showing protection of the propyl; on the nature of sinapic acid; the influence of light on fermentation; chemical examination of minerals from the neighborhood of Jones's Falls.

— Regarding the early telescopic observations of the ring of Saturn, Dr. H. G. van de Sande Bakhuyzen, the director of the observatory at Leiden, writes to the editor of *The observatory:* It is clear that Bell is not the discoverer of the division of Saturn's ring: but that Cassini ought to be accounted the discoverer is not quite so certain. In a volume of MS. observations by Huygens, in the library of the university of Leiden, there is a drawing of Saturn, made 1675, Dec. 8 (and which has been copied, and published by Kaiser in 1855), wherein the division in the ring, and the difference of brightness of the two parts, are clearly indicated. Above and on the side of the drawing, Huygens wrote, among other things, ". . . Saturnus cum comite observatus tubo 36 pedum Campani;

aderat de Cassinius. . . . [A description of the ball and the ring as seen by the observer here follows, and succeeding the words] quod a Josepho Campano jam olim observatum, ut figura ab ipso edita comprobat. . . ." When Huygens made this observation, Cassini was with him; but, from the notice in the *Philosophical transactions*, it is probable that Cassini saw the division of the ring in August or September, 1675; so that there is no sufficient ground to think that it was Huygens who showed the division to Cassini. But with regard to the allusion of Huygens to the observation of the two parts of the ring, made by Campani, and the figure of the same which he had published, Dr. Bakhuyzen searched in vain in different books for the figure until he found, between a number of letters addressed to Huygens from Leopold, Prince of Etruria (the same to whom Huygens dedicated his 'Systema Saturnium'), a sheet of paper with two printed drawings of Saturn and Jupiter. The details in the belts of the latter planet show that Campani's telescope was a very good one. The shadow of the ring is to be seen on the disk of Saturn; and the outer part of the ring, for somewhat less than half the total breadth, is dotted, whilst the inner part is bright. There is no line between the two parts, but they are distinctly separated from one another by the difference in brightness. One can also see traces of the inner dark ring. It is highly probable that the above words of Huygens refer to this figure of Saturn; and Dr. Bakhuyzen therefore concludes that Joseph Campani was the first astronomer who, by means of a very good telescope made by himself, saw distinctly the darker and the brighter part of the ring in 1664. It is, however, possible that Cassini was the first who saw the line of separation. The drawings of Saturn and Jupiter made by Campani are printed in 'Stanislai Lubiensecii de Lubienietz Theatrum Cometicum,' Pars prior, page 574. Lubienietz received the drawings from Athanasius Kircher in Rome.

— The proprietors of the *Melbourne age* have sent an exploring expedition to New Guinea.

— In the *Proceedings of the American philosophical society* (xx. no. 113) Professor Pliny Earle Chase has a long paper, thirty-three pages, on 'photodynamics,' in which, starting with 'combined cometary harmonics,' he comes out at 'lines of force and of motion;' and Professor George F. Barker gives an account of his very simple form of constant battery.

— The aeronautical exhibition was held in Paris, at the Palais du Trocadéro, from June 5 to 24, — one week longer than was the intention. There were a number of plans for flying-machines shown, but a strange lack of successful results.

RECENT BOOKS AND PAMPHLETS.

SCIENCE.

FRIDAY, AUGUST 10, 1883.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Next week will see the annual meeting of the American association for the advancement of science. Although the pendulum-like swing of its migration takes it this year to the westernmost point of its meetings, — to a flourishing city that was founded since the association began its good work, — there is a promise of a larger and more successful meeting than has been its lot to have for several years. Though its roots go down slowly, there is good reason to believe that this society is at last taking firm hold in our hard and stubborn American society, which long seemed to deny it a fair chance of growth. It was, in fact, a much more serious task than it at first seemed, to create in America an association on the basis of that which grew so rapidly and so well in the British mother-country. The success of the British association was due in the main to the fact that the distances the members had to travel were small, so that a large part of the working members could be relied on to attend from year to year in a regular way; thus giving a continuity to its intellectual life that has been denied to our association. Then in Britain, and the sister kingdom of Ireland, there are a score or more places where there exists a strong local life, a pride in the reputation of locality, and a mass of inherited wealth liberalized by long tradition that could easily be brought to the support of such meetings. Still more effective was the support which a centralized government could give, and the money that came easily at the call of the scientific leaders who made themselves responsible for the work the association undertook. All these advantages were denied to the American association in its earlier years. In the most of its meeting-places there was little to uphold its work; it toiled as a missionary enterprise — patiently, but with scanty reward. Its recent gain in public esteem has been in part the result of its own good and devoted work, but in larger measure it is the result of the exceedingly rapid change in the condition of American city life. The frontier spirit in our American towns, the greed for immediate ends, is passing away. Few towns of twenty thousand people but have their leisured class, or are without some well-shaped ambition for a good name among men of learning. Although the association was, in its earlier years, somewhat before its time, our life is fast growing up to be a support for such work as it seeks to do. Every friend of learning will welcome the assurance of strong life that these changes give to the association, and will look forward to its future with confidence in its work.

Experience that we may gain from the results of the association and of its kindred societies in the mother-country and on the continent shows us clearly what this work should be. First of all is the good-fellowship, the solidarity that is bred by bringing together in one assembly people who have no other chance to get the light from each others' eyes or the spirit from their fellow-workers' tongues. However we may value the material gain of fact, there can be no doubt that this is the precious thing which the association can give to American science. Our workers are necessarily scattered by the geographical immensities of their land; the teaching that the nature about their homes gives them is, from the conformity of conditions in almost all neighborhoods, limited and incomplete. More than any other men of science, they need a season of contact with those trained amidst other conditions. Some things grow well in a corner, but natural science is not of them. Whoever has brought to a meeting of the American association memories of similar gatherings in

Europe must have felt that this social element in our society left much to be desired. The writer recalls the time when he attended the Swiss association at Rheinfelden in one year, and the American the next, in a rather gloomy manufacturing town. At the Swiss meeting all the members dined together in a garden on the banks of the Rhine, after the morning session had been gone through with all due solemnity. There was, be it confessed, much wine, but so much wit and wisdom, withal, that the very prophets of teetotalism would have been moved to sympathy. In the social fire that only a table can provoke, in ordinary mortals at least, these diverse folk, separated by race and tongue, were fused into unity and brotherhood.

Making all due allowance for our inherited need of taking diversions a little sadly, it does seem that we might heighten the social element in our meetings. Even the most august British societies descend to tea after the meetings, and find their profit in it from the closer and more familiar life that it gives. Although we use it little, our American folk have an unequalled capacity for after-dinner talking; half our folk have the *toast-master* in them: so we need not fear that such gatherings would be dull.

Coming to the apparently more scientific aspects of its labors, maintaining the while that the science of good-fellowship is the prince of all learning, let us consider some other parts of the association's work. The experience of the British association seems to show that they succeed in avoiding the extreme haphazard nature of the discussions which mark our own association. This is in part due to the continuity of attendance of its leading members, but it seems as if a part of its gain in this direction had been due to the fashion of having special committees charged with the study of large questions of public interest. Coming to the association with their minds full of the results of especially designated inquiries, the committee-men have been able to give an element of direction to its discussions that have often made them admirably deliberative, and exceedingly profitable to all who heard them. If our association would take care to provide committees with important inquiries, and could furnish them with the money necessary for the securing of information when such aid was required, we might have each year a solid body of matter which would insure a profit to all who might attend. Giving these reports and their discussion the precedence in the meetings, the vagarists, the lost tribes of circle-squarers, law-finders, and others who wander in the wilderness, would not be able to render the sessions unprofitable to students, as they not unfrequently do, even in these latter days of the association.

There is yet another chance of bettering the association-work. One of its highest aims is to foster the spirit of philosophical inquiry among the people with whom its lot is cast from year to year. Something, but not much, may be accomplished by the mere presence of notable men, and their wise words. Yet the odor of the sanctuary is but fleeting: it is not in the least a monumental thing. The ordinary citizens or the school-children mark the fact that for a week some hall puts on a beehive look; the papers have reports, mostly incomprehensible; and then the matter is forgotten. There seem to be several ways of increasing the local effects of these meetings. First, there should be a careful preliminary study of the scientific problems that the neighborhood affords, a sufficient presentation of those that are understood, and a suggestion of inquiries thereafter to be made. This should be printed, and would serve for a local guide for the use of the association, and as an incentive to local workers. Then, if it seems well, the association should offer some small prize to those students on the ground who would carry farther the inquiries that this report has shown to be desirable. If the conditions permit, the association would do well to see that some local society, such as the field-clubs that were recently advocated in these columns, should be created, to remain as a successor to its objects and a fosterer of its work. In the inspiration that these meetings generally arouse, such a society might even secure a small fund for its maintenance.

Last, and if such a work be possible, best of all, the association might, through a proper committee, do much to promote science-teaching in the schools of the cities where it each year bides. Every meeting of the association has among its attendants those who have the much-needed skill in the matter of teaching science. There is hardly a public school in the land where there is not a crying need of such help as could best be given at such times. There should be a committee, or even perhaps a section of the association, devoted to the promotion of sound teaching in natural science; for the gravest danger before this branch of learning is to be found in the radical imperfection of the methods of science-teaching in use in our schools. These suggestions may seem to lay heavy burdens of advice on the association, but none of them seem beyond the promise of its strength.

RECENT EXPLORATIONS IN THE REGION OF THE GULF-STREAM OFF THE EASTERN COAST OF THE UNITED STATES BY THE U. S FISH-COMMISSION.[1]

4. Nature and origin of the deposits.

Along part of the Gulf-Stream slope examined by us, the bottom, in 65 to 150 fathoms, 80 to 110 miles from the shore, is composed mainly of very fine siliceous sand, mixed with a little clay, and containing always a considerable percentage of the shells of Foraminifera and other calcareous organisms, and frequently spherical, rod-like, and stellate sand-covered rhizopods, sometimes in large quantities. Among the Foraminifera, Globigerina is abundant; but many other forms occur, some of them of large size and elegant in form. Grains of green sand (glauconite) were frequently met with, but were not abundant. Large quantities of the tubes of annelids frequently occur. Some of these are made of cemented mud, fine sand, or of gravel; others, of parchment-like secretions. On the inshore plateau, and also in the deeper localities on the slope, there is usually more or less genuine mud or clay; but this is generally mixed with considerable fine sand, even in 300 to 600 fathoms. The sand, however, is often so fine as to resemble mud, and is frequently so reported when the preliminary soundings are made. In several localities the bottom was so 'hard,' in 65 to 125 fathoms, that the bulk of the material brought up consisted of sponges, worm-tubes, shells, etc., with some gravel, but with neither mud nor fine sand. Such bottoms were very rich in animal life. In many instances, even in our deeper dredgings (about 700 fathoms), and throughout the belt examined, we have taken numerous pebbles, and small, rounded bowlders of all sizes, up to several pounds in weight, consisting of granite, sienite, mica schist, etc. These are abundant in some localities, and covered with Actiniae, etc. Probably, while frozen into the shore-ice in winter and spring, they have been recently floated out from our shores and rivers, and dropped in this region, where the ice melts rapidly under the influence of the warmer Gulf-Stream water. Probably much of the sand, especially the coarser portions, may have been transported by the same agency.

Another way, generally overlooked, in which fine beach-sand can be carried long distances out to sea, is in consequence of its floating on the surface of the water after it has been exposed to the air, and dried on the beaches. The rising tide carries off a considerable amount of dry sand, floating in this way. In our fine towing-nets we often take more or less fine siliceous sand which is evidently floating on the surface, even at considerable distances from the shore. The vast sand-beaches, extending from Long Island to Florida, afford an inexhaustible supply of this fine sand.

The prevalence of fine sand along the Gulf-Stream slope in this region, and the remarkable scarcity of fine mud or clay deposits, indicate that there is here, at the bottom, a current usually sufficient to prevent, for the most part, the deposition of fine argillaceous sediments over the upper portion of the slope, in 65 to 150 fathoms. Such materials are probably carried along, for the greater part, till they eventually sink to greater depths, nearer the base of the slope, or beyond in the ocean-basin itself, where the currents are less active. Doubtless, there are also belts along which the northern current meets and opposes the Gulf Stream, causing less motion, and favoring the deposition of fine sediments. It is probable that motion of the water along the upper part of the slope may also be caused by tidal currents, which would modify the north-eastern flow of the Gulf Stream, both in direction and velocity. Currents produced by protracted storms might have the same effect. In depths

[1] Continued from No. 19.

greater than 200 fathoms on the outer slope, and in 25 to 60 fathoms on the inshore plateau, there is doubtless a slow, cold current to the south-west. It is not probable that these bottom-currents are strong enough to move even the fine sand after it has once actually reached the bottom; nor is it strong enough to prevent the general deposition of oceanic foraminifera, pteropods, etc.

The existence of actual currents in this region, sufficiently powerful to directly effect an erosion of the bottom, is hardly supposable. Such a result may be effected, however, in consequence of the peculiar habits of certain fishes and crustacea that abound on these bottoms. Many fishes, like the 'hake' (Phycis), of which three species are common here, have the habit of rooting in the mud for their food, which consists largely of Annelida and other mud-burrowing creatures. Other fishes, those with sharp tails especially, burrow actively into the mud or sand, tail first; and in all probability Macrurus, abundant on these slopes, has this habit. Several burrowing species of true eels and eel-like fishes are very abundant on these bottoms. Many of the crabs and other crustacea are active burrowers. Such creatures, by continually stirring up the bottom sediments, give the currents a chance to carry away the finer and lighter materials, leaving the coarser behind.

In many localities there are great quantities of dead shells, both broken and entire. A small proportion of the unbroken bivalves have been drilled by carnivorous gastropods, but there are large numbers that show no such injury. These have, for the most part, undoubtedly served as food for the star-fishes and large Actiniae, abundant on these grounds, and from which I have often taken many kinds of entire shells, including delicate pteropods. Many fishes, like the cod, haddock, hake, flounders, etc., have the habit of swallowing shells entire, and, after digesting the contents, they disgorge the uninjured shells. Such fishes abound here. Species of Octopus are also known to feed upon bivalves without breaking them, and O. Bairdii is common in these depths. The broken shells have probably been destroyed, in large part, by the large crabs and other crustaceans having claws strong enough to crack the shells. The large species of Cancer and Geryon, and the larger Paguri, abundant in this region, have strength sufficient to break most of the bivalve shells. Many fishes that feed on mollusca also crush the shells before swallowing them. Both fishes and crabs have, doubtless, thus helped to accumulate the broken shells that are often scattered abundantly over the bottom, both in deep and shallow water. Such accumulations of shells would soon become far more extensive than they are, if they were not attacked by boring sponges and annelids. Certain common sponges, belonging to the genus Cliona, very rapidly perforate the hardest shells in every direction, making irregular galleries, and finally utterly destroying them. On the outer grounds we dredge up rarely fragments of wood; but these are generally perforated by the borings of bivalves (usually Xylophaga dorsalis) and other creatures, and by them would evidently soon be destroyed.

We very rarely meet with the bones of vertebrates at a distance from the coast. Although these waters swarm with vast schools of fishes, while sharks, and a large sea-porpoise, or dolphin (Delphinus, sp.), often occur in large numbers, we very rarely dredge up any of their bones. In a few instances we have dredged a single example of a shark's tooth, and occasionally the hard otoliths of fishes. It is certain that not merely the flesh, but most of the bones also, of nearly all the vertebrates that die in this region, are very speedily devoured by the various animals that swarm on the bottom. Echini are very fond of fish-bones, which they rapidly consume. Fishes caught on the hooks in this region, and left down an hour or two, were nearly stripped of their flesh by small amphipod crustacea.

Relics of man and his works are of extremely rare occurrence at a distance from the coast, or even at a short distance outside of harbors, with the exception of the clinkers and fragments of coal thrown overboard from steamers with the ashes. As our dredgings are in the track of European steamers, such materials are not rare. A few years ago, even these would not have occurred. A rock forming on this sea-bottom would, therefore, not contain much evidence of the existence of man, nor even of the commonest fishes and cetaceans inhabiting the waters.

5. Fossiliferous magnesian limestone nodules.

At several localities in 234 to 640 fathoms, we dredged fragments and nodular masses or concretions of a peculiar calcareous rock, evidently of deep-sea origin, and doubtless formed at or near the places where it was obtained. These specimens varied in size from a few inches in diameter up to one irregular nodular or concretionary mass taken in 640 fathoms, which was 29 inches long, 14 broad, and 6 thick, with all parts well rounded. These masses differ much in appearance, color, texture, and fineness of grain; but they are all composed of distinct particles of siliceous sand, often very fine, cemented by more or less abundant lime and magnesia carbonates. Sometimes small quartz pebbles occur in them. The fine-grained varieties of the rock are often exceedingly compact, hard, and tough, usually grayish or greenish in color. They are often bored by annelids, sponges, etc., and are usually weathered brown, due to the presence of iron (probably in part as carbonate, sometimes as pyrite). The sand consists mainly of rounded grains of quartz, with some felspar, mica, garnet, and magnetite. It is like the loose sand dredged from the bottom in the same region. The calcareous cementing material seems to have been derived mainly from the shells of Foraminifera, abundantly disseminated through the sand just as we find the recent Foraminifera in the same region. In some cases, distinct casts of Foraminifera are visible in the rock. In some pieces of the rock, distinct fossil shells were found, apparently of recent species (Astarte, etc.). The larger masses appear to have been originally concretions in a softer deposit, which has been more or less worn away, leaving the hard nodules so exposed that the trawl could pick them up. The age of these rocks may be as great as the pleistocene, or even the pliocene, so far as the evidence goes. No rocks of this kind are found on the dry land of this coast. It is probable, however, that they belong to a part of the same formation as the masses of fossiliferous sandy limestone and calcareous sandstone, often brought up by the Gloucester fishermen from deep water on all the fishing-banks, from George's to the Grand Bank.

The chemical composition of these limestone nodules is of much interest geologically. Analyses made by Prof. O. D. Allen prove that they contain a considerable amount of magnesia. They are, therefore, to be regarded as magnesian limestones, or dolomites, of recent submarine origin. They also contain a notable quantity of calcium phosphate. The presence of the latter is not surprising when we consider the immense number of carnivorous fishes, cephalopods, etc., which inhabit these waters, and feed largely upon the smaller fishes, whose comminuted bones must, in part at least, be discharged in their excrements. In fact, it is probable that the greater part of all the mud and sand that cover these bottoms has passed more than once through the intestinal canals of living animals. The Echini, holothurians, and many of the star-fishes and worms, continually swallow large quantities of mud and sand for the sake of the minute organisms contained in it, and from which they derive their sustenance.

The following partial analysis by Prof. O. D. Allen gives the percentage of the most important constituents. The sample analyzed was a hard, compact, and very fine-grained magnesian limestone. Its color was yellowish green, with a darker green surface, weathered rusty brown in some places. It contained some minute specks of iron pyrite. Its specific gravity was 2.73.

Composition of a deep-water limestone.

	Per cent.
Lime	24.95

WATER-BOTTLES AND THERMOMETERS FOR DEEP-SEA RESEARCH AT THE INTERNATIONAL FISHERIES EXHIBITION.

It would naturally be expected that at an exhibition of this kind in England, where so much has been done in the past for deep-sea investigations, there would be found a good collection of the apparatus used in deep-sea work. Great Britain has, in fact, shown almost nothing of the kind; indeed, one may say, nothing whatever that especially relates to deep-sea investigation. After spending the not inconsiderable sum of money required to fit out the Challenger, the British government seems to have lost all interest in deep-sea exploration; and other nations are carrying on the work with greatly improved apparatus, while Great Britain rests content with the laurels already won.

The United States exhibit is the most complete of all, as regards apparatus of this kind. Denmark and Sweden have some apparatus for collecting specimens of water and observations of temperature, which, with the later forms used by the U.S. fish-commission and by the coast-survey, will form the main subject of this article.

The Swedish apparatus was devised by Prof. F. L. Ekman, principally for the use of the Swedish expedition of 1877, which carried out very thorough and systematic hydrographic investigations in the waters extending from the North Sea, through the Baltic, to the extreme end of the Gulf of Bothnia. Although the apparatus worked with entire satisfaction, it would scarcely be used at the present time, for it is unnecessarily heavy and large.

Two forms of apparatus for collecting samples of water from different depths are shown, both constructed on the same principle. The larger, having an ingenious means of closing, is chosen for description here. It consists of a brass cylinder open at both ends, about ten inches in length by four and a half in diameter, sliding freely through a space somewhat greater than its length, between three vertical brass rods or guides, which also constitute the frame of the apparatus. When the cylinder slides down, it encloses a vertical rod having a horizontal plate at the top, which forms a tight cover for the cylinder, similar to the end of a piston. The bottom of the cylinder falls into an annular groove in which a sheet-rubber ring is fitted, thus making a tight joint below. A rubber ring is also employed to make the upper joint tight. In the smaller instrument the lower groove is filled with a mixture of suet and wax; and the cylinder has an annular plate on top, the border of which extends inwards sufficiently to be bent downward so as to fit into a similar groove on the upper surface of the horizontal disk forming the top of the closed chamber. When the apparatus is sent down, the cylinder is suspended at the top. When it reaches the desired depth, the cylinder is released by a mechanism to be described, and falls, enclosing a sample of the water. In the smaller apparatus the cylinder is sustained during descent by the resistance offered by the annular plate above referred to, which is considerably larger than the diameter of the cylinder. On drawing up the apparatus, the plate also acts to force the cylinder well down into the grooves. In the larger instrument the cylinder is held up by a catch, actuated by a system of levers, which are connected with a turbine wheel enclosed in a brass case at the top. During descent the water passes through the case, entering and leaving it freely through strainers of brass gauze, and causes the turbine to revolve. The latter turns freely until the desired depth is reached. When ascending, the wheel makes a certain number of revolutions in the opposite direction, and soon acts upon the system of levers through a ratchet and ratchet-wheel, thus releasing the cylinder. This instrument has been successfully used in depths of three hundred metres. It is sufficiently good to enable the quantity of air contained in the water at different depths to be determined.

Arfwidson's water-bottle, exhibited by Denmark, is a simple cylinder of brass, shaped somewhat like a bell, closed by bottom and top plates with bevelled edges connected by a central stem. The bell falls. and the whole apparatus is drawn up by the central rod. The joints are made tight by grinding the plates and cylinder together. It is very simple, very light, and seems to be a good instrument. No information concerning its use is available at the present moment.

Another of Professor Ekman's instruments is used to collect samples of water, and also to enable the temperature to be correctly determined. Although quite different in construction from the others, it is the same in principle, except that it is made to protect the sample from any change of temperature while being drawn up, so that a thermometer may be introduced on deck to get the temperature of the stratum of water from which it was taken. The instrument has been found to give accurate results at depths of two hundred metres. It is not stated whether it has been used at greater depths.

In this instrument the cylinder is fixed between two galvanized iron rods, which, with four horizontal circular bands of the same material outside, constitute the frame, resembling a sort of cage. The top and bottom of the cylinder are formed by what may be described as two piston-heads connected together by a hollow rod, which slides up and down on another rod running vertically through the middle of the apparatus. The piston-heads are made of thick gutta-percha secured between brass plates. The connecting-rod is also covered with gutta-percha, and the cylinder itself is lined with it. Rubber is used to make the joints perfectly tight. The sample of water is thus protected by gutta-percha in every direction about two and a half centimetres in thickness. The upper piston-head carries a brass plate, which offers sufficient resistance to the water, while descending, to sustain it at the top of the apparatus. On hauling in, the water forces the piston down into the cylinder, enclosing the sample. The apparatus gives remarkably good results, if we may judge from some of the figures given in the case of a series of temperatures taken in the Baltic, where the alternations of cold and warm strata were quite remarkable. The temperatures were recorded to tenths of a degree of Celsius's scale, as, indeed, it was necessary that they should be, in order to make the results of unquestionable value; for the total variation in temperature between depths of 50 metres (when the temperature was 1°.8) and the bottom, 210 metres, was only 2°.1 C., yet there was a rise to 3°.9 at 100 metres, and a fall to 3°.1 at 210 metres.

No one would undertake to obtain such results with any deep-sea thermometer in use at that time. The Miller-Cassella instrument would utterly fail to record the temperatures at the bottom; and, even if it did record them, its readings would not be regarded as within half a degree F. of the exact temperature. The Siemens electric apparatus, which has been used on the Blake with great success, cannot be depended upon for greater accuracy than a quarter of one degree.

Fig. 1.

Capt. G. Rung of the Danish meteorological institute exhibits some thermometers enclosed within thick layers of cork, only the scales being exposed to view. In this way it is possible to obtain deep-water temperatures; for the instruments can be hauled upon deck, and readings made, before any heat can pass through the cork. This method, however, seems rather primitive; and, even if practicable, it is quite too slow to receive much commendation.

There can be no doubt that the best deep-sea thermometer is the latest Negretti and Zambra form, represented in fig. 1. It is so well known that a full description is not necessary; but as a reminder it may be said, that, when the instrument is upright, the mercury extends up into the tube to a height corresponding to the temperature. If then inverted, the mercury breaks at a particular point in the bend A, and runs down to the other end, where the temperature is read off. The small quantity of mercury in the bore does not appreciably change its length for slight variations of temperature. For a long time this has been the favorite instrument for taking deep-sea temperatures singly, but until lately no means had been devised for taking serial temperatures with it at a single cast. At the fisheries exhibition are shown three new methods of inverting the instrument at a given depth. The first we shall mention is exhibited by Capt. G. Rung of Denmark. It is scarcely worth while to describe this apparatus in detail; for, although it is undoubtedly an excellent device, the two other methods to be described are much better, because they are lighter and smaller. Capt. Rung inverts the thermometer by sending down a messenger along the line. By causing the inversion of each instrument to free a messenger to invert the next instrument below it, he obtains serial temperatures in the same manner as is done with the new device of Mr. W. L. Bailie, to be soon described.

Capt. Rung also exhibits a water-bottle and thermometer combined. A brass cylinder, perforated at the bottom with three small orifices, has a piston working air-tight within it. Within the piston-rod, which is perforated here and there, is a Negretti and Zambra thermometer, the bulb being at the outer extremity of the rod.

To use the apparatus, the piston is shoved in, and the end of the sounding-rope tied to the projecting end of the piston-rod. The apparatus is then inverted; and the lower end of the cylinder, being now uppermost, is secured to a catch a short distance up on the line. In this position it is lowered to the required depth, when a messenger is sent down which releases the cylinder. It falls, turns over, and the weight is then transferred to the piston-rod. The thermometer, being now bulb up, registers the temperature; while the weight of the cylinder causes it to pull the piston-rod out to the fullest extent, and, as the piston rises, it draws the water into the cylinder through the small holes in the bottom.

In figs. 2 and 3 we have illustrations of the ingenious apparatus devised by Commander Magnaghi of the Royal Italian navy, and exhibited by Messrs. Negretti and Zambra. It will be seen that the propeller-wheel C screws up or down as it revolves. During descent the propeller does not move, as the pin F is against the stop G. On reversing the motion, the propeller screws upward until the screw E releases the case, which then turns over, as in fig. 3, and is held in position by the spring K.

A still later form of this instrument has just been made, in which the thermometer-case is suspended on trunions at the lower end, instead of near the middle.

Another method for accomplishing the same result has been devised by Mr. W. L. Bailie, U S.N. In his arrangement the case of the thermometer is attached to the sounding-wire by a cam-catch at the bottom, and by two lateral spring jaws at the top, which encircle the wire.

A brass messenger is sent down the wire when the desired depth is reached, which opens the jaws, thus releasing the top of the case. The latter then falls over, turning on a swivel at the bottom. A hook at the bottom carries a second messenger, which is released as the case turns over, and falls down to invert the next instrument; and so on through the series. Instead of sending down a messenger on the wire, a propeller-wheel has also been arranged to open the jaws, so that either method may be employed.

The question arises, whether, with these excellent methods of using the instrument, the Negretti and Zambra thermometer cannot be made to record accurately to tenths of a degree. It would seem, that, by giving it a short range and a comparatively long tube,

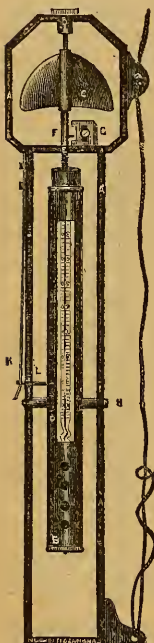

Fig. 2.

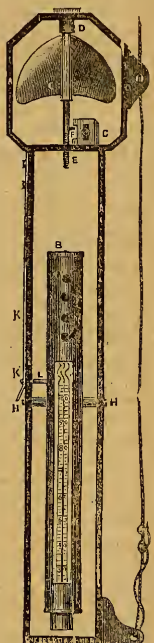

Fig. 3.

this might be done. If not, the most delicate observations for sub-surface temperatures will probably have to be made with some form of apparatus, which, like that used by Professor Ekman, brings the water to the surface in a case covered with a material through which heat cannot readily pass, or else by sending down a thermometer enclosed, like Capt. Rung's, in a thick case of non-conducting material.

R. Hitchcock.

London, June 1, 1883.

REAL ROOTS OF CUBICS.

THEOREM I.

[In the equation $x^3 + Ax^2 + B = 0$, when the roots are real, A and B have opposite signs; and simultaneously changing the signs of A and B changes signs of roots of equation.]

Assume $x = a$, $x = b$, $x = -\frac{ab}{a+b}$.

$$x^3 - \frac{1}{a+b}(a^2+ab+b^2)x^2 + \frac{1}{a+b}(a^2b^2) = 0; \quad (1)$$

and, changing signs of roots,

$$x^3 + \frac{1}{a+b}(a^2+ab+b^2)x^2 - \frac{1}{a+b}(a^2b^2) = 0. \quad (2)$$

Since the factors (a^2+ab+b^2) and (a^2b^2) are positive when the roots are real, whatever the sign of $\frac{1}{a+b}$, A and B will have opposite signs, and, from (1) and (2), simultaneously changing signs of A and B changes signs of roots of equation.

THEOREM II.

$\left[\frac{A^3}{27}\right.$ is greater than $\frac{B}{4}$ in quantity.$\left.\right]$

$$\text{Assume} \quad \left(\frac{a^2+ab+b^2}{3(a+b)}\right)^3 > \frac{a^2b^2}{4(a+b)} \quad (3)$$

$$\text{or} \quad \left(\frac{a^2+ab+b^2}{3}\right)^3 > a^2b^2\left(\frac{a+b}{2}\right)^2;$$

$$\text{but} \quad \left(\frac{a+b}{2}\right)^2 \geq ab \quad \text{(Algebra):}$$

hence inequality (3) is true.

From (1), omitting the term $\frac{A}{3}$,

$$\frac{x}{\left(-\frac{B}{4}+\frac{A^3}{27}\right)^{\frac{1}{3}}} = \left(1+\frac{\sqrt{\frac{B}{4}}}{\sqrt{-\frac{B}{4}+\frac{A^3}{27}}}\sqrt{-1}\right)^{\frac{2}{3}} + \left(1-\frac{\sqrt{\frac{B}{4}}}{\sqrt{-\frac{B}{4}+\frac{A^3}{27}}}\sqrt{-1}\right)^{\frac{2}{3}}; \quad (4)$$

and, from (2),

$$\frac{x}{\left(\frac{B}{4}\right)^{\frac{1}{3}}} = \left(1+\frac{\sqrt{-\frac{B}{4}+\frac{A^3}{27}}}{\sqrt{\frac{B}{4}}}\sqrt{-1}\right)^{\frac{2}{3}} + \left(1-\frac{\sqrt{-\frac{B}{4}+\frac{A^3}{27}}}{\sqrt{\frac{B}{4}}}\sqrt{-1}\right)^{\frac{2}{3}}. \quad (5)$$

In (4) the coefficient of $\sqrt{-1}$ may have any magnitude, and in (5) the coefficient of $\sqrt{-1}$ is the reciprocal of that magnitude. And since from any cubic (Theorem I.) (4) or (5) may be obtained, it follows, that, when the real part is unity, the coefficient of $\sqrt{-1}$ may be made less than unity, and real (Theorem II.).

Put n = coefficient of $\sqrt{-1}$, we have, by expansion,

$$(1+n)^{\frac{1}{3}} + (1-n)^{\frac{1}{3}} = 2-4\left(\frac{1}{3.6}\right)n^2 - 4\left(\frac{4.7}{3.6.9.12}\right)n^4 - 4\left(\frac{4.7.10.13}{3.6.9.12.15.18}\right)n^6, \text{ etc.}$$

The series, already converging, is made doubly converging by the high powers of n, since n has been made a fraction. Putting n, for example, no smaller than $\frac{1}{10}$, the correction for the sum of the series at the eighth term would be less than $\frac{1}{1,400,000,000,000,000,000}$. And, as the precision of the value of x is determined proportionally to the accuracy with which the series is summed, it follows that a good approximation to x may be obtained by using a very few first terms of the series.

A. M. SAWIN.

THE HABITS OF MURAENOPSIS TRIDACTYLUS IN CAPTIVITY; WITH OBSERVATIONS ON ITS ANATOMY.

THE Louisianian district of the Austroriparian region is a particularly rich field for the herpetologist. Thirty-six species of reptiles are known to be confined to its limits alone, not to mention a long list of others that range generally over the southern states; and to these we must add those species which are mentioned by the old French authors, but have not yet been taken by American naturalists, a knowledge of which fact always enhances the interest of a country in the eyes of the explorer, who pushes his way through its tangled jungles, or visits its unfrequented spots and its sultry forests, for the first time.

FIG. 1.—Life-size head of Muraenopsis tridactylus; adult. Drawn from the living specimen by the author.

After my arrival in New Orleans, the months that are included in the pseudo-winter of this sub-tropical land came and passed by, before my collection could boast of a single specimen representing the Amphiumida: indeed, it was not until April had almost made its appearance that a superannuated old negro presented himself one morning with a live but rather small specimen of the three-toed siren, the subject of this essay.

He called it a 'Congo eel,'—a name which is indifferently applied by every one here, intelligent as well as ignorant, to both this reptile and Amphiuma means. Long before this, reports had come to me from far and near of the dreaded 'Congo,' or 'lamprey' as it is often called. It was universally said that its bite was invariably fatal. To such an extent was this believed, that, I am told, a physician of the city, of undoubted reputation in his profession, and a capital chemist, but possessing nothing more than a general knowledge of natural science, was actually making experiments with the view of examining the venom of this innocent amphibian. When my aims became pretty thoroughly known throughout my section of the country, I applied a very different kind of analysis to this problem: a good round sum of money was offered to any one who would bring me the full record of a well authenticated case of death from the bite of the Congo snake, or eel. It is almost needless to add, that I never had to pay the reward. One person, more mercenary than well informed in such matters, did bring forward a case of an hysterical old colored woman who had been bitten several years ago by a Congo eel, and died *six months* after the infliction of the wound, in spasms!

The small one, which now came into my possession, was placed in water, in a large comfortable vessel, for observations upon his habits, before he was finally consigned to his tank of alcohol. In handling him, he rarely offered to bite, unless the examination was prolonged or roughly conducted; then he would curl up, slowly open his mouth, and make an awkward longe at the fingers or hand that held him. Sometimes he would only open his mouth, and hiss in a subdued manner. On one occasion, however, this reptile succeeded in getting out of his tub during the night. When I found him, in the morning, in a distant part of the room, he snapped at me quite savagely several times before he was retaken. It was amusing to see the way in which he succeeded in leaping out of his place of confinement, — a large tin bath-tub, with the water seven or eight inches below the brim. He swam round and round with increasing rapidity till the necessary impetus was acquired, when he would prettily make a sort of spring over the side of his tub on the floor, where he would squirm round like an eel until he was replaced. In such situations he uses his legs to the full extent to which they seem capable of being put; in the water, too, these members are constantly brought into use, — the fore-pair when he desires to move very slowly forward, in which case he may or may not, generally not, use the hind-pair in aiding the action. The fore-pair are also used alternately to push himself one way or another, when he wishes to change his course. A common use for the hind-pair, is to throw them forward, and brace them against the ground he may be passing over, in order to check his onward movement either partially or entirely. In swimming about he has all the appearance of the common eel; and during these times he draws both pairs of limbs close beside his body, when his action is graceful and interesting to behold.

When these sirens are at rest, they either stretch out in gentle curves, sluggishly along the bottom, or, what is not very uncommon for them to do, curl up tightly, in a spiral manner, the latter two thirds of their length, while the head and remaining third is protruded forward in a direct line. In this curious position they float near the surface, the head being lowermost. If two occupy the same vessel, they often curl about each other in a rather affectionate manner; but I have never witnessed them quarrel or fight. One time I threw a dead king-snake into the tub of my first small specimen, the snake being at least three times as long as the siren. Imagine my surprise to see him fly at the intruder, seize him just below the head, straighten out as stiff as he could, then rapidly whirl round, as a drill does, causing the dead snake to be spirally coiled about his body. A moment of quietude followed this strange manoeuvre, during which time one could see a crunching movement on the part of the jaws of the siren going on; but, finding his enemy showed no resistance, he slowly let go his hold, and, freeing himself from the dead snake's coils, swam about the tub without paying him any further attention. In a few moments, however, I repeated the experiment, when he made the same attack with just as much vigor as before; but all subsequent trials failed, and I could never induce him to take further heed of such a harmless enemy.

This siren will eat crayfish in confinement; but I could never induce one to take any thing else, although raw meat is the commom bait used by the negroes in catching them for me. Sometimes before a meal, or may be after, your captive will swim gracefully about his limited quarters, and occasionally rise to the surface, stick his nose out of the water, and give vent to a loud blowing sound, that may be heard anywhere in a large room, even if conversation be going on. As remarked above, my collectors usually took such specimens as were brought me, with the ordinary hook and line, baited with fresh meat; but very often they are captured in hand dip-nets, or even thrown out of a shallow drain or bayou with a stick. They are most numerous after heavy rains, when their usual places of resort are flooded over. When taken by others than those who are collecting for me, they are invariably despatched on the spot, and dreadfully and wantonly mutilated, so deep-seated is the detestation and dread of this harmless creature in the minds of all the people hereabout.

In a large, shallow tank of water, I have before me now two fine living specimens of this siren, which have been under my observation for nearly a fortnight. The larger of these two has a total length of eighty centimetres, with a mid-girth of fourteen centimetres. I have kept specimens alive that measured a hundred or more centimetres, but they have since been consigned to alcohol. The specimen now before me, just measured, is of a dark olivaceous brown above, and entirely so on all the parts beyond the hind-pair of limbs. A patch of this color is also found upon the throat. The color of the under parts is a dull, whitish leaden hue, being mottled with an intermediate shade as it joins the darker and more sombre color of the dorsal aspect of the body. This mottling grows denser as it approaches the hinder limbs, where finally it merges into the general tint of the upper surface, which is carried over the tail. A faint lateral crease is found along the mid-third of the body, with feeble corrugations crossing it vertically, that are quite evident as the creature writhes about, and the eel-like slime that naturally covers his entire body partially dries. The limbs are pretty well developed: each is three-fingered, or, better, each possesses three digits. The hinder limbs are larger than the fore ones, and stronger in every way. The body tapers to a tail beyond the genital fissure, but no well-marked constriction indicates to us its exact commencement, or attachment to the body. It is rounded beneath, and finished off along the median dorsal line with a thickened, feebly pronounced crest. Sections made through the body itself, between the fore and hind limbs, are elliptical, with the major axes in the horizontal plane. I have taken other measurements from this specimen, which I present in the form of a table.

Total length	80.0	cent.
Mid-girth	14.0	"
Length of fore-limb	1.7	"
" " hind-limb	2.5	"
" " head	6.5	"
Distance between the eyes	2.0	"
" " " nostrils	.6	"
" " mid-points bet'n eyes and nostrils,	2.2	"
Gill-cleft from eye	4.2	"
Fore-legs apart	3.1	"
Hind-legs "	2.2	"
Length of genital fissure	1.2	"
Commissure of jaw from gill-cleft	3.0	"
From a point midway between hind-limbs to tip of tail,	20.0	"

The nasal apertures are very small, and the eyes are black, round, a little more than a millimetre in diameter, and devoid of lids.

I may remark here, that, while engaged in taking these measurements, this specimen succeeded in seizing my thumb in his mouth, and immediately commenced his peculiar gyrations, turning himself in the long axis of his body; but I was too strong for him, and soon disengaged myself. The bite caused no more inconvenience than those I have received from alligators a month old.

The upper lips of the three-fingered siren are thin-edged and pendulous, extending from the commissure of the jaw to a point nearly opposite the nostril on either side, where they merge into the rounded snout. The lower lips do not meet in front by a centimetre. They are likewise thick and sharp-edged, overhanging the common integument of the lower jaw, and originating posteriorly within the commissure and beneath the upper lips. Minute glandular openings are seen on the head above, and in the maxillary space beneath, symmetrically arranged in rows, as on other parts of the body. We find the gill-clefts with two obliquely placed lips, with which they can be closed, the anterior one being the larger. The internal openings to the gill-clefts are far back in the pharynx, nearly opposite the rudimentary and partially cartilaginous larynx, which latter communicates directly with the superior extremities of the membranous pulmonary air-passages. A pair of normal lungs are among the most exquisite of structures in any vertebrate. Here they are particularly beautiful, being very long, cylindrical in form, extending far down into the abdomen, to terminate in pointed extremities. The right is thirteen centimetres longer than the left, and is carried nearly down to a point opposite the cloaca. From one end to the other, the alimentary tract is nearly or quite a straight tube. The oesophageal portion is rather small and tubular, with a few circular constrictions in its lower third. This division soon dilates into a spindle-shaped stomach of some size, which, in the specimen before me, is fourteen centimetres below the pharyngeal aperture. Below this last dilation the intestinal tract is carried straight to the cloaca, or rectal enlargement, into which the urinary and genital organs open. A very peculiar feature is noticeable in the circular constrictions that occur in the intestine at irregular intervals along its length. Very dark in color, the many-lobed liver is about twenty-six centimetres long, and covers at its lower tenth, or thicker extremity, an ellipsoidal gall-bladder of no small size. Many features of interest and importance present themselves in the circulatory and renal systems; but our space will not permit us to enter upon them here, as we have something to say about the osteology of Muraenopsis. Among other organs, a well-developed pancreas is to be observed; and the Wolffian bodies are present, and their dilated upper extremities are about opposite the lower end of the liver.

The tongue in this siren is in an extremely rudimentary stage of development. I will close this brief sketch of the anatomy of the soft parts — yet it can hardly be termed a sketch, for many structures have not even been alluded to — by calling the reader's attention to the remarkable length of time that nervous excitability, if I may apply such a term to the phenomenon, was kept up. My specimen was killed with chloroform. That of itself took a long time, forty minutes or more; but what is this, compared with the fact that its heart continued to pulsate in good rhythmical time during three hours and a half of my operations, and after the most extensive dis-

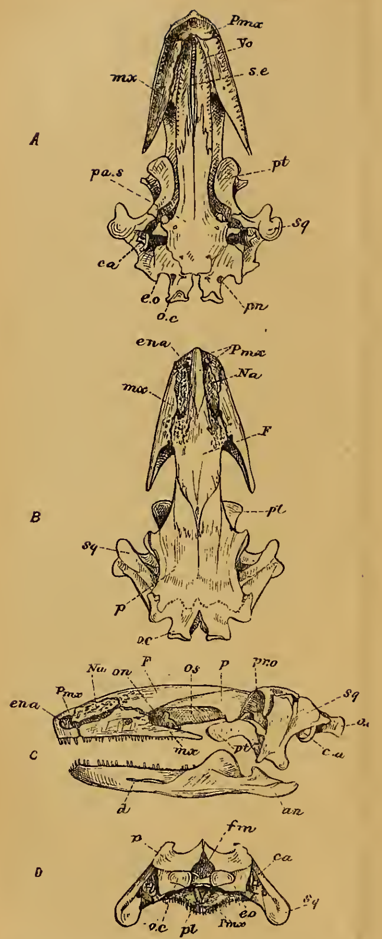

Fig. 2.—Dorsal, ventral, lateral, and posterior views of the skull of Muraenopsis tridactylus (life-size), respectively represented in A, B, C, and D, where like lettering has the same indication in each view. *Pmx*, premaxillary; *Vo*, vomer; *mx*, maxillary; *s. e*, splen-ethmoid; *pa. s*, parasphenoid; *pt*, pterygoid; *sq*, squamosal; *ca*, columella auris; *e. o*, exoccipital; o. c, occipital cordyle; *pn*, foramen for exit of pneumogastric and glosso-pharyngeal nerves; *ena*, external nasal aperture; *Na*, nasal; *F*, frontal; *p*, parietal; *on*, foramen for the passage of of the orbito-nasal nerve, the first division of the fifth pair, to the rhinal cavity; *os*, orbito-sphenoidal region; *pr. o*, pro-otic; *d*, dental element of mandible; *an*, angulae; *fm*, foramen magnum; *pl*, roof of the mouth.

sections had been made? And four hours and a half after, when all the organs had been removed, and inroads made upon the trunk, this creature would still writhe vigorously by simply pinching his tail, or close his jaws like a vice in a way that would put the hardiest of eels to shame, and crush any claim the latter might have in standing at the head of the list of those animals most tenacious of life. We find the cranium of Muraenopsis very thoroughly ossified, and many of the sutures observable only after close inspection. The teeth are of the pleurodont type, and may be seen in all stages of development in the deep grooves that exist in the mandible, the maxilla, the premaxilla (which usually supports twelve), and the entire inner margins of the descending plates of the vomers, which meet each other anteriorly (fig. 2, A). A long, slender, sphen-ethmoid is inserted between these last bones, quite distinctly seen on the inferior aspect.

The premaxilla throws backward a nasal process that overlaps the frontals above, and passes between the nasals. These latter segments are very much honeycombed and grooved, — a characteristic which is adopted by the anterior extremities of the frontals and the upper parts of the maxilla on either side. The coronal suture is seen beyond, a demi-lozenge shaped and elevated plate, developed by the united frontals, directed backward (fig. 2, B). Each outer margin of the parietal region is raised into a curling crest, as if pushed up by the unusually large squamosals, which lend to the lateral aspect of the skull of this creature such a massive appearance. As in other Urodela, a large columella auris is seen on either side, external to the extensive processes that project backward, to bear the occipital condyles (fig. 2, D). A pro-otic is well developed; but it is difficult to determine in the adult cranium whether a separate epiotic and opisthotic exist or not, though I am strongly inclined to think they do not. The pterygoids are completely ossified, and quite extensive, horizontally flattened, and curved plates of bone, their anterior extremities being prolonged with a fibrous tissue to form the floors of the orbits. The lower maxilla is very deep and solid; and, although the meeting of the dentary elements anteriorly is quite extensive, the symphysis is not firm. Nearly the entire basicranial region is occupied by the wide-spreading and anteriorly produced parasphenoid (fig. 2, A), which, with its serrated margin, articulates with the parallel vomerine plates beyond.

We have presented us for examination in

the hyoidean apparatus (fig. 3) two reniform hypo-hyals in cartilage, surmounted by a triple piece of the same material that occupies the usual site of the glosso-hyal. In the median line we have a thoroughly ossified basi-hyal; while curved bony cerato-hyals, with expanded cartilaginous anterior ends, are suspended from the hypo-hyals. Four branchial arches are represented; the first pair being long, curved bones, and the remaining ones cartilage. The gill-clefts open to the rear of the last pair on either side.

The spinal column of an adult Muraenopsis contains one hundred and ten well-ossified vertebrae. The second and third of these have suspended from their transverse processes free ribs, of which the anterior pair is the larger. A strongly marked intercondyloid process is formed between the two concave facets on the anterior aspect of the atlas. As a rule, all these vertebrae, except the first and the extremely rudimentary caudal ones, are of the amphicoelous type, with lofty neural spines,—far-spreading transversed processes that become horizontally broadened in mid-spinal region,—and with well-marked zygapophysial processes to link the series together. None of these vertebrae are modified to form a sacrum in con-

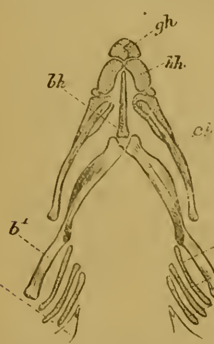

FIG. 3.—Hyoidean and branchial apparatus of Muraenopsis tridactylus; life-size; dotted parts in cartilage; *gh*, rudimentary glosso-hyal; *hh*, hypo-hyal; *ch*, cerato-hyal; b^1, b^2, b^3, and b^4, branchial arches; *gc*, gill-cleft.

nection with the pelvis in the precaudal region; beyond which, each segment throws down parial hypapophysial processes, which are not lost, as we proceed backwards, until we arrive at the ultimate nodules that complete the tip of the tail.

In my specimen the thirty-third and thirty-fourth vertebrae have coalesced in the most remarkable manner, forming one bone, with nearly all the parts double. The appendicular skeleton is represented by extremely rudimentary shoulder and pelvic girdles, supporting equally feebly developed limbs, with their segments arranged as seen in fig. 4. We find

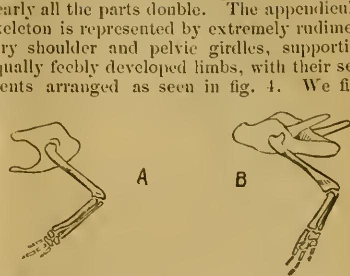

FIG. 4.—A, right fore-limb and rudimentary shoulder-girdle; B, right hind-limb and rudimentary pelvis, both slightly enlarged, of M. tridactylus. From dissections by the author.

the carpus has three cartilaginous elements in its structure,—two in the proximal row, and only one in the distal. This number is increased by an additional segment in the tarsus, which has two elements in each row, articulating with the digits, as shown in the figure.

Osseous tissue of an elementary character may be deposited in the humerus, the femur, and certain points in the pelvis, more particularly the projecting rod that appears to represent the pubic bone; otherwise all this part of the skeleton in our siren remains in cartilage throughout life.

R. W. SHUFELDT.

THE GREAT TERMINAL MORAINE ACROSS PENNSYLVANIA.[1]

AFTER describing the investigations which elsewhere had demonstrated the existence of a true terminal moraine to the glacier covering north-eastern America, the author stated, that having obtained the aid of the geological survey of Pennsylvania, and, during a portion of his work, the assistance of Prof. G. F. Wright, he had been able to follow and define the southern limit of glaciation for the first time in a continuous line four hundred miles in length, and to find that it was everywhere marked by a remarkable accumulation of glaciated material, which, winding across mountains and valleys, from the lowlands of the Delaware to the great Alleghany plateau, was continuous from end to end, and formed a true terminal moraine.

There is a marked distinction between the glaciated portion of Pennsylvania and that region south of glacial action. Although the general topography of the two regions is alike, the varied superficial features due to glacial agencies, the far travelled and scratched bowlders, the smoothed and striated

[1] Abstract of a paper before the American association for the advancement of science, in Montreal, August, 1882. By Prof. H. CARVILL LEWIS.

rock-exposures, the unstratified deposit of till, the many kames, and especially the numerous glacier-scratched fragments and pebbles, — all these deposits are in strong contrast with those south of the moraine, where all the gravels are stratified and the pebbles water-worn, where the rocks are never polished or striated, but, on the other hand, often decomposed to a great depth, and where, except near the seacoast, wide stretches of the more elevated regions are perfectly free from all drift.

The method employed in discovering the line of the moraine was to zigzag along its course from the glaciated into the non-glaciated region, and *vice versa*, going each time far enough on the one side to be fully satisfied of the absence of glaciation, and, on the other, to find undoubted traces of its action.

Nowhere south of the line of the terminal moraine had he found any traces of glacial action, *all statements by other geologists to the contrary notwithstanding*. When typically developed, the terminal moraine is characterized by peculiar contours of its own. A series of hummocks, or low conical hills, alternate with short straight ridges, and enclose shallow basin-shaped depressions, which, like inverted hummocks in shape, are known as *kettle-holes*. Large bowlders are scattered over the surface; and the unstratified till which composes the deposit is filled with glacier-scratched bowlders and fragments of all sizes and shapes. The average width of the moraine is about one mile.

At many places, however, the limit of glaciation is marked merely by an unusual collection of large transported bowlders. This is especially the case in front of a high mountain range which has 'combed out' the drift from the ice.

The general course of the moraine across Pennsylvania was defined as follows: appearing first in Northampton county, a mile below Belvidere, at latitude 40° 49′, it winds in a great curve, first westward and then northward, reaching the base of the Kittatinny Mountain, three miles east of the Wind-Gap.

Ascending to the top of the Kittatinny Mountain, sixteen hundred feet high, the moraine crosses the great valley between the Kittatinny and the Pocono, and then swings sharply back and around Pocono Knob, immediately afterwards to ascend the steep face of the mountain to the wide plateau on top, twenty-one hundred feet above the sea. Crossing this in a fine curve, and heaped up in an immense accumulation, it goes first north and afterwards west, reaching the gorge of the Lehigh River, some ten miles north of Mauch Chunk. It crosses the gorge at Hickory Run, and, without swerving from its general north-western course, ascends mountain range after mountain range, descends to the valley of the east branch of the Susquehanna, and crosses the river at Beach Haven.

Then, following the base of Huntington or Knob Mountain, it finally ascends it, and crossing its summit, at a height of fifteen hundred feet above the Susquehanna just below, descends the north slope of the mountain to the broad, undulating valley to the north. Taking a northerly course, it follows up on the east bank of Fishing Creek to the North or Alleghany Mountain, enters Lycoming county, passes westward along the base of the mountain, crossing in its course the Muncy and Loyalsock creeks, and then, near the village of Loyalsock, turns at right angles, and ascends the mountain.

Having reached the summit of the Alleghanies, over two thousand feet above the sea, it passes west through a wild, wooded region nearly as far as Pine Creek, where it begins a nearly straight north-westward course through the south-west corner of Tioga county, and the north-west part of Potter. In the high ground of Potter county, the moraine crosses a great continental watershed, from which the waters flow into the Gulf of Mexico, Lake Ontario, and Chesapeake Bay. The moraine is here finely shown at an elevation of twenty-five hundred and eighty feet, being higher than elsewhere in the United States.

It now enters the state of New York in the south-west corner of Allegany county. Passing still north-west, and entering Cattaraugus county, it twice crosses the winding course of the Allegheny River, east and west of Olean; then trending to a point five miles north of Salamanca, in latitude 42° 15′, it forms a remarkable apex, whence to the Ohio line its course is south-west. Turning at right angles to its former course, the moraine passes south-west through the south-east corner of Chautauqua county, and, keeping approximately parallel to the course of the Allegheny River, re-enters Pennsylvania in Pine Grove township, Warren county. It crosses the Conewango River seven miles north of Warren; then trending west, still at a general elevation of nearly two thousand feet above the sea, it crosses one gorge after another, and forms a line separating not only the glaciated from the non-glaciated region, but also the cultivated from the uncultivated and densely wooded region. It crosses the south-east corner of Crawford county, skirts the north-west and west boundary of Venango county, crosses Beaver River eight miles south of New Castle, and, traversing the extreme north-west corner of Beaver county, crosses the Ohio state line in the middle of Darlington township, thirteen miles north of the Ohio River.

The moraine thus leaves Pennsylvania at precisely the latitude at which it entered the state; and, if a straight line were drawn across the state between these two points, the line of the moraine would form with it a nearly right-angled triangle whose apex was a hundred miles distant perpendicularly from its base. The total length of the moraine, as here shown, is about four hundred miles. The moraine crosses the Delaware at an elevation of two hundred and fifty feet, the Allegheny at an elevation of fourteen hundred and twenty-five feet, and the Beaver at an elevation of eight hundred feet, above the sea, or two hundred and twenty-five feet above Lake Erie. Upon the high lands it rises higher by a thousand feet or more.

Coming to the details of the moraine, many of which are of great interest, reference was made to its fine development in Northampton county, west of

THE GREAT TERMINAL MORAINE ACROSS PENNSYLVANIA. by H. CARVILL LEWIS.

The Glaciated area is shaded

Bangor, where it forms a series of hummocky hills, which, a hundred to two hundred feet in height, and covered with transported and striated bowlders, rise abruptly out of a clayey plain to the west. Glacial striae upon exposed surfaces near Bangor point south-west, or towards the moraine. After following the moraine to the base of the Kittatinny Mountain, it became of great interest to know whether a great lobe of ice descended from New Jersey along the lower side of the mountain, or whether a tongue projected through the Delaware Water-Gap, or whether the glacier, even so close to its southern limit, came bodily over the top of the mountain, unchecked by it, and unchanged in its course. The last, the most improbable of these hypotheses, and certainly the least expected by the author, proved to be undoubtedly the true one. The author had been able to show that the moraine crossed the mountain near Offset Knob; that large bowlders, derived from lower elevations several miles northward, lie perched all along the summit, fourteen hundred feet above the sea; and that, as shown by the numerous striae on the northern slope of the mountain, running *up-hill*, the glacier moved diagonally up and across the mountain, uninfluenced in any way by the presence of the Water-Gap, and finally came to an end in the valley south of the mountain, as marked out by the terminal moraine. Huge bowlders of fossiliferous limestone, sometimes thirty feet long, were torn by the ice from their parent strata in Monroe county, on the north side of the mountain, lifted up a thousand feet, carried across the mountain, and dropped finally in the slate valley of Northampton county. The author had found one of these limestone bowlders upon the very summit of the mountain, where the jagged sandstone rocks had combed it out of the ice during its passage across. The journeys of these bowlders were short; but that of a well-rounded bowlder of Adirondack syenite, which the author had found in the same county, was about two hundred miles.

Another interesting point is in Monroe county, upon the summit of Pocono Mountain, over two thousand feet above the sea, where a great ridge of moraine hills twelve miles long, one mile wide, and a hundred or more feet high, composed of unstratified till, and bearing numerous bowlders of Adirondack gneisses and granites, rises out of the level, sandy plain of the Pocono plateau, and sweeps around from Pocono Knob into Carbon county. Known locally as 'Long Ridge,' its origin had never before been suspected. It encloses remarkable little 'moraine lakes' without inlet or outlet, and is heaped up into just such conical hills as may be seen in the moraine in southern Massachusetts. Nothing can more clearly show the continuity and uniformity of action of the great glacier than the identity of its moraine accumulations at such remote points.

In fact, the course of the moraine, as it winds from the top of the Kittatinny Mountain down to Cherry valley, and then up again on to the Pocono, is a complete vindication of the glacial hypothesis. It is in no sense a water-level, nor could it have been formed by floating ice. No other cause than that of a great glacier could form a continuous accumulation of glaciated material which contains no evidences of water-action, and which follows such a course. Neither on the mountains nor in the valley does the moraine rest against any defined barrier, as would be the case were it a shore-line.

The kames of Cherry valley, fine examples of which appear south of Stroudsburg, are interesting relics of sub-glacial water-action. They are composed of stratified water-worn gravel, having often an anticlinal structure, and as a series of conical hills and reticulated ridges, enclosing 'kettle-holes,' form conspicuous objects in the centre of the valley. They appear to have been formed by sub-glacial rivers, which, flowing from the moraine *backwards*, under or at the edge of the ice, emptied into the Delaware valley. They thus probably differ in origin from the longer kames in New England, and other regions more remote from the edge of the glacier.

The glacier had produced very slight effect upon the topography of Pennsylvania. It neither levelled down mountains nor scooped out cañons. The glacier passed bodily across the sharp edge of the Kittatinny Mountain without having any appreciable effect upon it, the glaciated part of the ridge being as high and as sharp as that part south of the moraine.

In describing the course of the moraine across Luzerne county, the author showed that it crossed several mountain chains in succession, by each of which it was locally deflected northward. At the point where the terminal moraine crosses Buck Mountain, in a line diagonally across the mountain, the moraine was so sharply defined that he was able to stand with one foot upon the glaciated and the other upon the non-glaciated region. It was interesting to find, that in *front* of a mountain chain, such as Huntington Mountain or the Alleghany Mountain, the moraine was poorly developed, as though the mountain had 'combed out' the drift from the ice.

He described an instructive portion of the moraine, where, three and one-half miles north-west of Berwick, it seems to abut against a high slate hill, which furnishes, therefore, a *section* of the end of the glacier. It shows that the extreme edge of the ice was here only about four hundred feet thick, and that, while the moraine and the scratched pebbles were carried along at the base of the ice, sharp fragments of sandstone were carried on top.

In speaking of the apex made by the moraine in New York, and of the high plateau region of Potter county, it was inferred, from the local influence already shown by the author to have been exerted by single mountain chains, that this region of high elevation had a decided influence upon the general course of the moraine.

Certain facts observed as to the gravel-ridges of the Allegheny River rendered it probable that the river flowed under a tongue of the glacier. ten miles broad and two miles long, through a sub-glacial channel, at the time of its greatest extension near Olean. He described a great natural dam across the valley of the Great Valley Creek, near Peth, where the moraine stretches across the valley from side to side: and he spoke of the contrast between the numerous drainage valleys which drained the waters of the melting ice into the Allegheny River, and those valleys which took their rise south of the moraine, and were free from all drift.

After giving some details of the western lobe of the ice-sheet, and dwelling upon the agricultural significance of the moraine, he spoke of some curious deposits of glaciated material which occurred in a narrow strip of ground immediately in front of the moraine, and which he had named the 'fringe.' These deposits consisted of bowlders of Canadian granite, and other rocks, which he found perched upon the summits of hills, sometimes as far as five miles in front of the moraine, though never farther. This glacial 'fringe,' confined to the western part of the state, was found to increase in width from two miles in Warren county to five miles on the Ohio line, and was at first a puzzling phenomenon. The hypothesis suggested was, that, like breakers on the seashore, the top of the ice overreached the lowest strata by the width of the 'fringe,' and that while the moraine marked the halting-place of the bottom of the ice, by which it was formed, the far-transported bowlders were carried on more rapidly in the top strata of the ice, and were dropped outside of the moraine to form the 'fringe.' It was stated that the striae in the western part of the state all pointed south-east, being at right angles to those in the eastern part of the state, but, like them, pointing always towards the moraine.

In conclusion, the author reviewed the more important facts discovered during his exploration of the line of the moraine, dwelling upon the character of the moraine where crossing river-valleys, the absence of proof of any tongues of ice down such valleys, the absence of glacial drift south of the moraine, the very slight erosion caused by the passage of the glacier, and especially upon the deflections, large and small, in the line of the moraine, which were inexplicable on any other hypothesis than that the moraine now described was pushed out at the foot of a continuous ice-sheet of immense extent.

LETTERS TO THE EDITOR.

Change of birds' notes.

For some years it has been known to many about here, that in one locality the cardinal bird (Cardinalis virginianus) has been in the habit of imitating the notes of the whippoorwill (Antrostomus vociferus). From articles I have read from time to time in various scientific journals, I infer that it is not generally known that birds ever, in the wild state (especially cardinalis), change their song. I therefore thought it well to report this case. I have in several instances known this bird to change its song, under confinement, for one entirely different; but this is the only case I have ever known where such a thing has occurred in the wild state. I have known of this case for about ten years.

F. O. Jacobs.

Newark, Licking county, O.

St. David's rocks and universal law.

The article with the above heading in Science of June 15, by Dr. M. E. Wadsworth, has just come under my observation; and, as it refers to questions which have arisen chiefly in consequence of my researches among those rocks, I shall deem it a favor if you will allow me space in Science for a few remarks in explanation. Professor Geikie's paper was written with, as he states, 'a sense of duty' to 'defend the views of his predecessors;' and it is perfectly certain, from the hasty manner in which the work was gone over by Professor Geikie and his two assistants, that the object was to vindicate the work of the Geological survey of thirty or forty years ago, rather than to apply the knowledge gained by the work of many independent observers since that time to correct the errors well known to have been committed by the surveyors, which remain as blots on the maps even now issued by the Geological survey. In the district of St. David's, these maps show a great intrusive mass passing under the city of St. David's, about eight miles in length, and with an average width of about a mile. The southern portion is called syenite, and the other felstone. The rocks lying along the north-western edge for about a mile in width are colored as altered Cambrian, presumably as the result of the intrusion; but on the south-east the rocks of the same age are supposed to be in contact with the mass in an unaltered condition, and without even a line of fault to separate them. These appearances were curiously anomalous if true: hence I felt it necessary to go very carefully into the question. My large acquaintance with the district, and the knowledge I had obtained in my explorations among the lower fossiliferous rocks of the area, enabled me to do this with some advantage. I had also, from time to time, much valuable assistance from Professors Harkness, Hughes, and Bonney, and from Mr. T. Davies of the British museum, Mr. Tawney, etc.

I found that under the same name, rocks of very different characters had been grouped together. The so-called syenite ridge was seen to consist in part of granitoid rocks, but also of quartz-felsites, of hälleflintas, of breccias, and of porcellanites freely traversed by intrusive dikes of various kinds. The so-called metamorphic Cambrian on the north-west was soon discovered to be an entirely distinct series from any Cambrian rocks known in the district, or, indeed, anywhere in Wales, and to be largely made up of volcanic rocks; and the basal Cambrian conglomerate, as marked on the survey-maps, was shown to overlie the granitoid, the quartz-felsite, hälleflinta, and the volcanic schistose and brecciated series unconformably, and to be mainly made up of fragments derived from those series. From the examination of the conglomerates also, it was seen that there were distinct evidences of their having been deposited along old coast-lines, and that their materials varied with the rocks upon which they reposed; also that these pre-Cambrian rocks must have been much in the condition in which they are now found, before the Cambrian conglomerates were deposited upon them. Curiously, also, I found that many of the masses colored as intrusive greenstones on the survey-maps were highly *acid* rocks, and others indurated volcanic ashes of pre-Cambrian age. Indeed, nearly all the so-called intrusive masses marked so abundantly on the survey-map among the older rocks in the St. David's area have been proved beyond doubt to be the result of erroneous observation; and yet we are told by the present director-general that little or no change is required in these maps, and that he feels it his duty to 'defend the views of his predecessors' as there indicated. There is a still larger area of the Dimetian rocks about ten miles to the east of St. David's; and there, as at St. David's, these granitoid rocks underlie the lowest Cambrian beds without producing the slightest alteration in the latter. Indeed, I have now found no less than six areas in Wales where typical Dimetian granitoid rocks occur under the Cambrian or pre-Cambrian rocks; and in neither of these areas, though several excellent observers have, in addition to myself, searched the boundaries carefully, have we found the slightest indications of their being intrusive in those rocks, though they are all colored as intrusive rocks in the survey-maps. In several of these areas the fact that they must be pre-Cambrian rocks is rendered perfectly certain, as large fragments of the granitoid rocks in exactly the same condition in which they are now found occur in the basal conglomerates of the Cambrian. In one area only, in Wales, have I found Dimetian rocks entirely surrounded by rocks newer than the Cambrian; and here the Llandovery conglomerates and sandstones repose upon them, and are largely made up of materials derived from the Dimetian. In the other areas newer rocks than the Cambrian are found occasionally in contact with limited portions of the Dimetian exposures; but these effects are clearly seen to have been produced by faults.

In his paper to the Geological society, referred to in Science, Professor Geikie maintained "that the 'Dimetian group' is an eruptive granite which has disrupted and altered the Cambrian strata, even above the horizon of the supposed basal conglomerate." The evidence adduced to support this view was from a section at Ogof-Llesugn, where, as he supposed, "the conglomerate had been torn off and enclosed in the granite, and has been intensely indurated so as to become a sort of pebbly quartzite." Professor Hughes and myself, along with a number of other competent observers, have since examined this spot; and we found that the conglomerate lies quite loosely upon the Dimetian, that at almost every point we could pass our hand between the conglomerate and the granitoid rock, and that the Cambrian conglomerate had no change whatever induced in it beyond that common to it in all parts of the district. Two other sections were mentioned, and drawings exhibited to show the 'Dimetian' intrusive in the Cambrian, and as having eaten deeply into the series at Porthclais. These sections I knew perfectly well, at the time, to be in the lines of faults; but for greater satisfaction I asked Professor Hughes and party to re-examine these with me. The result proved that I was entirely right, and that Professor Geikie and his assistants had mistaken a junction produced by well-marked faulting for an intrusion, and the beds which he supposed had been eaten away had simply been dropped by the fault. He could not produce a single specimen showing contact alteration between the granitoid (Dimetian series) and overlying rocks. His evidence, therefore, fails utterly, on examination; and the pre-Cambrian age of the granitoid rocks of St. David's is rendered, if possible, more than ever certain. An attempt was made to show that the quartz-porphyries which I had pointed out as being intrusive in the Pebidian rocks, which alter the rocks in their immediate vicinity, were just such rocks as might be apophyses of the 'granite,' but, with a curious want of knowledge of the fact that these quartz-porphyries are common to many other parts of the area far distant from the granitoid series, that they also actually in some places cut across the latter.

As Professor Geikie did not spend the time necessary to examine the area where the Arvonian rocks are chiefly exposed, but hastily arrived at the conclusion, without seeing them, that the hälleflintas, breccias, and porcellanites must be intrusive felstones, I need scarcely refer to Professor Geikie's views on this point. I shall refer fully to this question in my paper. in reply, to the Geological society. I may, however, mention, that I exhibited a series of magnificent breccias from this group, and showed large masses of the Cambrian basement conglomerates from Ramsey Island, consisting almost entirely of the rocks of the Arvonian group upon which they repose. The latter are colored in the survey-map as *intrusive* in beds high up in the Silurian (fossiliferous Arenig).

The Pebidian, Professor Geikie says, 'forms an integral part of the Cambrian system.' He acknowledges that it underlies the Cambrian conglomerate, but says the latter rests quite conformably upon the former. In the survey-map these Pebidian beds are supposed to be Cambrian beds higher than the conglomerate, but altered by the so-called intrusions. Here, therefore, some modification of the map is acknowledged to be necessary. Had Professor Geikie and his assistants used ordinary care in examining these conglomerates, they would have seen also that they are constantly in contact with different members of the underlying rocks, that they lie unconformably on the edges of those beds, and also that they are very largely made up of the rocks below.

Professor Geikie did not refer to North Wales in his paper; but as the facts are, if possible, clearer there than in South Wales, I may be allowed to call the attention of the readers of Science to some sections just published by the Geologists' association of London, preparatory to the visit to be paid by the members to Carnarvonshire and Anglesey, July 23–28. These sections show in a very clear manner how the Cambrian conglomerates creep over the Dimetian, Arvonian, and Pebidian rocks in that area. The rocks of the first two and lowest groups are in that area, as at St. David's, colored as intrusive rocks in the survey-maps, and the last as altered Cambrian and Silurian rocks.

The sections have been prepared by Prof. T. McK. Hughes (Woodwardian professor of geology at Cambridge, and formerly of the Geological survey), who has carefully worked out the geology of this district. He and I were the first to point out, in the year 1877, the similarity of the conditions exhibited here to those at St. David's; and since then he has devoted much time to the elucidation of the facts bearing upon the questions in that area.

In a diagram (no. 1) he shows how the basement conglomerate of the Cambrian, between Bangor and Carnarvon, creeps over no less than four sub-groups of the archean rocks: viz., at Bangor, over the Bryniau beds (Pebidian); at Brithdir, the Dinorwig beds (Arvonian ?); at another part farther south, the Crug beds (upper Dimetian); and at Tut Hill, the Carnarvon beds (lower Dimetian). In section 2, the unconformable overlap of the Cambrian over the Pebidian near Bangor is clearly shown; and in no. 3, a diagram section showing the sequence of the rocks from Carnarvon to Snowdon, the basement beds of the Cambrian are shown rolling over the Carnarvon and Dinorwig groups at different points.

Altogether, the evidence afforded by these sections is of the most conclusive kind; and it seems impossible to believe that the surveyors, when they have seen and examined these sections, and have had more experience with the Welsh rocks, can still cling to the antiquated faith that all these pre-Cambrian rocks

a, Conglomerate and sandstone (basement bed of Cambrian); b, Lower and middle portions of Cambrian, not subdivided, but probably including Harlech, Menevian, Lingula flags, and Tremadoc beds; c, Arenig; p, Pisolitic iron ore; d, Bala group, with subordinate volcanic beds; F, Faults; x, Broken ground; D, Dikes.

are merely intrusive masses or altered beds of Silurian and Cambrian age. The basal conglomerate in this area consists in places almost entirely of quartz-felsites, at other points of a mixture of granitoid (true Dimetian) and felsite rocks, and in some cases of schists. I may further mention with regard to the crystalline schists in Anglesey and in Scotland, supposed by the Geological survey also to be of Cambrian and Silurian age, that the recent researches of Bonney, Callaway, Lapworth, and myself, tend to make it certain that they are all, like the similar rocks in America described by Dr. Sterry Hunt and others, of pre-Cambrian age. Henry Hicks.

Silurian strata near Winnipeg.

Presuming that it may be of interest to some readers of Science to read something on the geology of a locality near Winnipeg, I take pleasure in furnishing information, hitherto unpublished, concerning an outcrop of Silurian strata in this part of the north-west. This interesting exposure occurs a short distance from Selkirk, situated some twenty-one miles north of Winnipeg on the Canadian Pacific railway, and near the Red River.

At this place a quarry was opened about a year ago, which, on examination, affords many attractions to a student of science. Fossils belonging to some sixteen species are readily obtained, not only in the solid rock, but also in the innumerable chippings that lie scattered about the quarry.

The rock is magnesian limestone, dresses readily, and, when burnt, supplies excellent lime. Stone from this place is shipped by rail to Winnipeg, where it is used for ordinary and ornamental building-purposes. Many of the fossils being in the form of casts, they frequently interfere with the successful dressing of the stone. About four feet of drift material overlies the rock; but at another quarry lately opened, nearer the river and a short distance farther north, the drift material attains a thickness of twenty feet. The rock is much the same, but apparently not so fossiliferous.

In the quarry first referred to, the remains of corals belonging to the genera Alveolaria, Halysites, and Zaphrentis, are very numerous. Some specimens obtained bear a close resemblance to the genus Favosites. Another group of very common fossils are representatives of the genera Orthoceras, Endoceras, Ormoceras, and Cyrtoceras.

An excellent specimen measuring eight inches in diameter, with three whorls, was found. The specific characters are much obliterated, but in general outline and appearance it bears a close resemblance to Trocholites ammonius of the Trenton.

Several imperfect specimens of Trilobites were found. One appears to be a member of the genus Illaenus. Fragments of Stromatopora are common, showing in all cases distinct lamination, and, in several, well-defined oscula; while in a few, conical elevations can be observed. The specimens obtained were found among the fragments of rock scattered about the quarry; but the characters of all are exceedingly uniform. The largest obtained measures 7 inches across, 5 in depth, and 2 in thickness. The laminae are well marked, numbering four to the line. They present a wave-like appearance, there being three crests in the section under examination. At the summit of each crest a large aperture is observed. Viewing the specimen from the top, six of these oscula are seen, all about the same distance apart. As yet, I have discovered no rods or pillars present; but there is no question regarding the presence of well-marked laminae and oscula.

I have read carefully the description of the species S. tuberculata, S. perforata, S. granulata, S. mammillata, and S. ostiolata, of Nicholson, and S. concentrica of Goldfuss, and none seem to embrace the species from this quarry. If any reader of Science can suggest the species to which this interesting fossil from Selkirk belongs, he will confer a great favor upon the writer. J. Hoyes Panton.

Pre-Bonneville climate.

In a critical notice of my preliminary report on Lake Bonneville (Science, no. 20), Mr. Davis points out that a certain conclusion as to the history of the basin is not sustained by the phenomena described. Since reading his comment, I have not been able to consult my text; but, if memory serves, his restriction is fully warranted. Still, the conclusion is not of necessity overthrown; for it is based in part on omitted data, the report aiming to present only an outline of the subject. Now that the matter is up for discussion, it may be well to indicate these.

The facts set forth are as follows. Above the Bonneville shore-line the topographic forms are those produced by sub-aerial agencies. Below the shore-line the details are of sub-aqueous origin, but the larger features are sub-aerial in type. Especially are the great alluvial cones constituting the pediments of some of the mountains continued beneath the old water-margin, their surfaces being lightly etched and embossed by lake agencies. Evidently these alluvial cones are of pre-Bonneville date; and evidently, too, the goal of drainage — 'the base level of erosion' — was lower when they were built than during the Bonneville epoch.

The questioned conclusion is, that the emptiness of the basin during the long pre-Bonneville, alluvial-cone epoch was due to aridity. Mr. Davis acutely perceives, that the adduced phenomena comport equally well with the alternative hypothesis that the pre-Bonneville condition of the basin was one of free drainage to the ocean, the present continuity of the basin's rim having been instituted either at or just before the beginning of the Bonneville epoch.

On this hypothesis, the place at which the drainage of the basin was discharged must have acquired the peculiar configuration of a river-channel; and since, as our observations show, alluvial accumulation has not been great in the region during Bonneville and post-Bonneville time, vestiges of this channel should remain. The fact that they have not been found goes far to show that they are not visible; for intelligent search has been made for them, our eyes having been trained for their recognition by the discovery of pre-Bonneville channels *within* the basin. All the low passes of the enclosing rim have been scrutinized. At whatever points, then, earlier drainage systems have intersected this rim, the channels appear to have been obliterated by the erosive and constructive agencies of land sculpture.

Again: the principal plain of the Bonneville basin is at heart mountainous. Its surface is level only because the alluvial mountain bases are deeply buried by later deposits. Of the nature of these deposits we know little more than that the uppermost is lacustrine, the Bonneville layer concealing all else. The deposit representing the pre-Bonneville or alluvial-cone epoch must be relatively heavy, and may be assumed to dominate in the determination of the general configuration of the plain. With the basin closed, a certain system of slopes would arise: with the basin open, there would arise a certain other system, definitely related to the point of discharge. The actual system of slopes is adjusted to the existing status, — a closed basin, with lacustral sedimentation.

Assuming that there was at some remote date a channel of outflow, and that the configuration of the plain was adjusted thereto, the period consumed in the obliteration of the one and the remodelling of the other must have been long as compared with the Bonneville epoch. The pre-Bonneville portion of the period — when the basin was closed, but contained no lake — was presumably characterized by a climate similar to the present.

The aridity of the pre-Bonneville epoch is one of the features associating the Bonneville history with glacial history; for, if it be disproved, the Bonneville flooding no longer demonstrates a climatic episode, and the apparent homology disappears. And the Bonneville oscillations have, of course, no climatographic value if they were orographically produced. It is well, therefore, to test thoroughly every link in the chain of evidence. G. K. Gilbert.

Nevada, July 15, 1883.

WARD'S DYNAMIC SOCIOLOGY.

III.

Mr. Ward presents a classification of the sciences differing from those proposed by August Comte and Herbert Spencer. The new classification is of great interest, and deserves especial mention. The classification of Comte was made prior to the great development of modern scientific research, and is imperfect. The classification of Spencer is, like much of his philosophy, a mixture of metaphysical speculation and positive knowledge. Does the classification of Ward meet the requirements of scientific philosophy?

He divides the subject-matter of all science into three parts, which he denominates the 'primary,' 'secondary,' and 'tertiary' aggregations. It is a classification of the objects of the cosmos by modes of aggregation. The primary aggregation is molecular, and gives an inorganic kingdom; the secondary is morphologic, and gives a biologic kingdom; the tertiary is sociologic, and is represented by human society.

A mountain is an aggregation of rocks, or geological formations, some of which may be crystalline, others detrital. It is an inorganic molar aggregate, and must fall into Mr. Ward's first class. But the earth itself is an aggregate of solids, fluids, and gases. Its solids are molar aggregates of detrital and crystalline rocks. These rocks at the surface are arranged in mountains, hills, and valleys, with intervening depressions filled with bodies of water, — seas, lakes, and rivers; and beneath, an unknown interior; and above, the atmosphere. The atmosphere is in motion. The water is carried into the air, and moves with it, and descends again upon the earth. The known solid portion of the earth is also in motion, rising and falling in its relation to the centre of the earth; while portions of the unknown interior of the earth are, by extravasation, coming to the surface, and the land portions of the earth are being carried by the waters into the sea.

Geology teaches us, then, that the earth is composed of interdependent parts; that the circulation of the air, of the waters, of the solids, and of the interior liquids is carried on by the action of the several interdependent parts; and the earth has been not inaptly compared by eminent geologists to a living or organized being. If we properly understand Mr. Ward, this aggregation also is to be relegated to his first class.

Again: the earth is one of a group of worlds composing the solar system, — the solar aggregation, composed of interdependent parts; and this aggregation is also to be included in the first class.

The inclusion of all of these modes of aggregation in the one class is tacit. He does not clearly set them forth, and his definitions are imperfect. It is difficult to understand from his discussion whether they were considered in his general scheme, or whether he would, if considering them, establish one or two more grand categories.

Again: psychology is included in the secondary aggregation as belonging to biology. As the term is now used by scientific men, 'psychology' includes a consideration of the biologic organ of the mind and its operations. Through these operations are produced languages, giving the science of philology; arts, giving the science of technology; societies, giving the science of sociology; and opinions, giving the science of philosophy. With Mr. Ward, philology, technology, and perhaps philosophy, are subordinate parts of sociology. Though he does not make direct statement to this effect, yet his presentation leads to this conclusion, in the same manner as his presentation of the subject of primary aggregation leads to the supposition that he intends to include molar and stellar aggregations therein.

Psychology has its biologic organ in the brain and nervous system; and mind is discovered in the lower orders of life, as well as in man. The genesis of psychology is manifestly in biology. In like manner, the organs of speech, active and passive, alike in oral, sign, and written language, are biologic; and language is also found in the lower orders of life. Language, therefore, has its genesis in biology. In the same manner, the organs of the arts are biologic; and rude arts are discovered in the lower orders of life. Technology, therefore, has its genesis in biology. The first step in sociologic organization is the biologic differentiation of the sexes, giving husband and wife, parent and child; and rude social organization is also found in the lower orders of life. Sociology, therefore, has its genesis in biology. The same considerations that would lead to the relegation of psychology to biology would also lead to the inclusion of philology, technology, and sociology, and perhaps of philosophy.

Now, these five sciences are so bound together that the absence of one would void all. They are interdependent anp co-ordinate in such a manner that the evolution of one is dependent on the evolution of all. Language is a means of communication between individual minds. Discrete minds could not develop language: it is produced by many co-existing individuals of each of a long series of generations. Society and mind were necessary to its production. The arts are produced by many persons in the same manner as languages, and involve also the operations of mind; but the arts could not have been developed without the concomitant development of language, for art is built on art, and that which remains in art must pass from person to person and from generation to generation by means of language. The arts of absolutely discrete men could make no progress.

For the evolution of society, language is necessary for the intercommunication of thought. The interdependence of men as integral parts of bodies politic would be impossible without language; and sociologic organization is dependent upon the differentiation of human activities, or the division of labor, and is therefore dependent upon the development of arts or technology. Philosophy, or the science of evolving opinion, is the final product of the mind, and is therefore dependent upon psychologic evolution. It is dependent upon philology, for language is the mould of thought, and determines its form. It is dependent upon technology, for by the arts men reach knowledge not otherwise attainable; and upon sociology, for it is the combined knowledge of many, accumulating through the generations.

Again: all that part of the evolution of psychology which distinguishes the human mind from that of the lower animals is due to the tertiary aggregation in the development of philology, technology, sociology, and philosophy. In philology the method of evolution is the survival of the economic in the struggle for expression; and the course of evolution is through the specialization of the grammatic processes, the differentiation of the parts of speech, and the integration of the sentence. The method of evolution in technology is the survival of the useful in the struggle to have; and the course of evolution is the employment of the forces and materials of nature for the benefit of mankind. The method of sociologic evolution is the survival of justice in the struggle for peace; and the course of evolution is the differentiation of the functions and organs of government, and the integration of tribes and nations. The method of evolution in philosophy is the survival of the true in the struggle to know; and the course of evolution is in the discernment and discrimination of phenomena, the relegation from analogic to homologic categories in classification, and the discovery of more and more complex sequences. In these psychologic sciences the struggle, i.e., the endeavor, i.e., the conation, is teleologic.

The primary method of psychologic evolution is the survival of the fittest in the struggle for existence, and is purely biologic. The struggling subject itself survives. The secondary or indirect method of psychologic evolution is by the agencies of the philologic, technologic, sociologic, and philosophic methods; and, combined, they constitute the successful struggle for happiness. All that part of the evolution of psychology which separates man from the lower animals is due to this secondary or indirect method, and is teleologic; and progress is due, not to the survival of the fittest of the struggling subjects, but to the survival of the object for which the struggle is made. These five sciences, therefore, constitute one group, through the fact that they belong properly to the tertiary aggregation of matter, and the further fact that the method or cause of evolution exhibited therein is radically different from the method or cause of evolution in biology. The five sciences are co-ordinate, reciprocal, and interdependent. As biology has its genesis through protoplasm and organic chemistry in the physical aggregation, so these five sciences of the tertiary aggregation have their genesis in biology, — in the biologic organs of mankind, and the beginnings of these sciences discovered among the lower animals.

Elsewhere Mr. Ward classifies phenomena in the manner shown in the table on the following page, which is copied from his work.

Of the four groups thus derived, the first, inorganic, corresponds to the group embraced in his primary aggregation; the second, organic, to the group embraced in his secondary aggregation, but excludes psychology, philology, technology, sociology, and philosophy. If we combine his direct and indirect teleologic phenomena into one group, the five great sciences which include the operations and products of the mind are thrown into one. Let the first, then, be called *physical phenomena* or phenomena of the primary aggregation, and the sciences which pertain thereto physical sciences; the second, *biologic phenomena* or phenomena of the secondary aggregation, and the sciences pertaining thereto biologic sciences. But what shall the third group be called? If the term psychology is used, it must be with a wider connoting than that which it has heretofore had. Psychology.

Phenomena are:

- Genetic; physical; unconscious: producing change through infinitesimal increments.
  - *Inorganic:* the result of physical or mechanical forces.
  - *Organic:* the result of vital or biological forces.
- Teleological; psychical; conscious: proceeding from volition and involving purpose.
  - *Direct:* proceeding according to the direct method of conation.
    - *Zoölogical:* as manifested by creatures below man.
    - *Anthropological:* as manifested by man. Domain of the social forces.
  - *Indirect:* proceeding according to the indirect method of conation.

Natural: taking place according to uniform laws, and produced by true natural forces; capable of prediction and modification.

Artificial: consisting of natural phenomena modified by the inventive faculty.

then, would include the operations of the mind, and the products, or results, of those operations. If we use anthropology, the term will not include the beginnings of psychology, philology, technology, and sociology, found among the lower animals; for they have mind, language, art, and society in a comparatively low form. On the other hand, anthropology has been used so as to include the biology of man. If we use sociology, following Comte, Spencer, and Ward, the term must include more than these authors design, and some other term must be selected for that differentiated science which forms one of the group of five, and which above has been designated as sociology. Altogether it seems better to use the term *anthropology*, which would then include psychology, philology, technology, sociology, and philosophy.

Mr. Ward does not relegate ethics to any place in his scheme. Moral science relates to that portion of human conduct in which the qualities of right and wrong inhere; and the moral quality depends upon the relations which exist between men and men: it is therefore a part of sociology; and the principal body of ethics at any time existing among a people is formulated as law, made by the court or the legislature. Mr. Spencer, in his essay on the classification of the sciences, gives it no place, but, in the elaborate scheme of philosophy embraced in his works, places it above sociology.

It may be asked, What place does logic take in the classification here proposed? The reply is, that the logic of the ancients has no place in science. To modern logic something else has been added; and this something else belongs to psychology. The logic of the ancients, and a large part of that of modern metaphysicians, is a system designed to discover truth by a form of words. If it be truthfully asserted that an object is white, no form of words can prove the truth of the assertion. If questioned, the questioner must perceive that the body is white in the same manner as it was perceived by the person making the assertion; and the assertor can only point out, i.e., demonstrate, the fact. And the same is true of any other fact, howsoever simple or complex. A truth or fact can be pointed out or demonstrated to the eye, or to the mind's eye, but cannot be proved by a logical form of statement. The idea of logical proof is a conception of a time when powers were occult; and logic divested of modern appurtenances is an occult art.

It would make this article too long to attempt to set forth fully the place of mathematics in this scheme; but quantitative relations, like qualitative relations, belong to all degrees of aggregations, to all complexities of phenomena, and to all stages of evolution; and, in the science of mathematics, relations of quantity are considered apart from other relations, and in the abstract.

Mr. Spencer, although he presents a classification of the sciences, does not use it in his philosophy of evolution, but practically uses the primary classification here set forth, under the terms 'inorganic,' 'organic,' and 'super-organic' evolution.

The defect in Mr. Ward's classification here pointed out seriously influences his presentation of the subject of dynamic sociology proper, appearing in the second volume. It also greatly narrows his view of the field of successful endeavor for organized society. Mankind has made progress, i.e., secured happiness, quite as much by the effort for peace and the establishment of justice as by the effort to know and the acquisition of truth. It can be shown in other and diverse ways that his view of successful human endeavor is philosophically narrow; and he sometimes uses the epithets of the pessimist in a manner unworthy the philosopher.

FRUIT-INSECTS.

Insects injurious to fruits. Illustrated with 440 cuts. By WILLIAM SAUNDERS. Philadelphia, *Lippincott*, 1883. 436 p. 8°.

THE author has enjoyed exceptional advantages for the preparation of the work he has undertaken. Not only has he been acquainted with the work of economic entomologists through his own participation in it, and as editor of one of our principal entomological periodicals, but for twenty years past he has been an extensive fruit-grower as well. He is thus entirely familiar with what is wanted, and has produced a practical book of considerable value. Not that it contains much that is original or of novel presentment: it is rather a plain and judicious statement of what is known, but accessible to few because scattered in periodical literature. One is surprised at the size of the book when he sees that no effort is made to fill it out with unnecessary matter: rarely are half a dozen pages given to any one insect, and more than two hundred and fifty harmful insects are discussed.

The insects are treated under the head of the plants they affect and the parts of the plant they attack, — an excellent method, first used in this country by Fitch. They are described in brief, untechnical language, almost invariably figured, and often in several stages; and the account of their injuries is followed by a short statement of the best remedies, with illustrations of the parasites or other natural foes which keep the insects more or less in check. The plants which receive most attention are the apple (64 insects, 127 pages), the grape (52 insects, 75 pages), and the orange (26 insects, 45 pages). Next after these in importance are the plum, pear, the various currants, the raspberry, and the strawberry, followed at a little distance by the peach; a few pages each suffice for the cherry, quince, gooseberry, melon, cranberry, olive, and fig.

The illustrations are familiar friends to entomologists, almost all of them having already done abundant service; but they are none the less valuable for the purpose of this work; and the paper on which they are now printed permits to many of them a respectability they must rejoice to attain after long familiarity with the crude workmanship of the various government presses under which they have been tortured. With a little more care in the printing, they would have shown at their best.

The only serious omission in the book is the absence of a systematic summary, or index, by which the insects of the same group attacking different plants should be brought together. This would the more readily serve to help the fruit-grower distinguish allied forms, and learn their different or similar habits. Such an index could have been so easily constructed, and would have occupied so little space, that its absence is the less excusable.

BREMIKER'S LOGARITHMIC TABLES.

Bremiker's Logarithmisch-trigonometrische tafeln mit sechs decimal-stellen. Neu bearbeitet von Dr. TH. ALBRECHT, professor and chief of section in the Royal Prussian geodetic institute. Tenth stereotype edition. Berlin, *R. Stricker*, 1883. 18+598 p. 8°.

BREMIKER'S six-figure logarithms were first published in 1852 with a Latin text and title: Nova tabula Berolinensis, etc. In 1860 a German edition was printed. Both these editions were printed from movable types. In 1869 a stereotyped edition was printed, with some changes in the contents of the work. The editions of 1852 and 1860 contained a capital table of the sines and tangents of small arcs, which was omitted in the stereotype edition; and in this latter edition a table of addition and subtraction logarithms was introduced. The omission of the table of the functions of small arcs was hardly an improvement; and, in fact, this omission caused the early editions to command a higher price than the later stereotyped one.

The present edition by Dr. Albrecht combines the excellences of both the preceding editions. It contains the table of the logarithmic sines and logarithmic tangents of arcs up to 5° for each 1″, and also includes the addition and subtraction tables.

The rest of the work is the same as the stereotype edition of 1869, except that four new pages of convenient constant logarithms are inserted, and that certain tables relating to units of weight and measure are omitted.

This collection of tables is a very practical and valuable addition to our present means of computation, and it will be welcomed as such. In the opinion of the writer, it is also the most satisfactory single collection of tables for students' use, although much can be said in favor of the best of the five-place tables for this purpose. EDWARD S. HOLDEN.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

Astrophysical observations of Jupiter. — Ricco publishes a fine series of eighteen drawings of the planet, made, with one exception, in 1881, 1882, and 1883, by means of the ten-inch telescope of the observatory of Palermo. He gives, also, a large number of micrometrical measures, and detailed descriptions of the appearance of the planet and its surface-markings, on forty-seven different dates. The effect of the 'red spot' upon the contour of the adjacent belts is well brought out. — (*Mem. soc. spettr. ital.*, May, 1883.) C. A. Y. [172

Photometric observations of eclipses of Jupiter's satellites. — Cornu and Obrecht give the results of some experiments upon artificial eclipses made to imitate the eclipses of Jupiter's satellites, using the method already referred to in these columns. They find that the probable error in determining the time when the light of the satellite is reduced to one-half its normal amount is about a hundredth of the total time of obscuration. They propose, also, the use of a polariscopic arrangement in place of the 'cat's-eye,' and, in this connection, append the following note: "We have recently learned that the astronomers of Harvard college employ an analogous arrangement — of which, however, the description is not known to us — for the purpose of determining the moment of disappearance (*pour arriver à définir l'époque de l'éclat nul*). If the apparatus is analogous, the method of observation is, as one sees, entirely different." They have evidently been misinformed; for the very essence of Prof. Pickering's plan consists in the determination, not of the moment of disappearance, but of half-brightness. — (*Comptes rendus*, June 25, 1883.) C. A. Y. [173

MATHEMATICS.

Surfaces of constant curvature. — M. Weingarten here deals with certain properties of the linear elements on surfaces with a constant measure of curvature. Certain considerations connected with the modern theory of functions, particularly that portion of the theory which deals with linear differential equations of the second order, have led him to conjecture that the determination of the geodetic lines upon a surface of constant curvature, by means of certain given linear elements, stands in a close relation to the theory of the linear differential equations of the second order. M. Weingarten makes the remark (which, though not new, is important here) that the extension of those properties of curved surfaces, studied and enunciated by Gauss, which depend upon a given form of the linear element, is much simplified by the introduction of certain functions of the position of a point upon the surface. The values of these functions are given in terms of the coefficients of the linear element in such a way, that, by the introduction of new (two) variables, we arrive again at the original linear element. The functions possessing this (invariantive) property are called flexion-invariants (*biegungsinvarianten*). As an example of flexion-invariants, we have the 'measure of curvature' of a surface. From the differential coefficients of a flexion-invariant, and the Gaussian coefficients, E, F, G, of a linear element of a surface, an indefinite number of new invariants can be formed, two only of which are independent. The author gives a brief account of Beltrami's work on these functions, and then considers particularly the surfaces of constant curvature. The paper is an exceedingly interesting one to the student of this particular branch of geometry, and is a valuable addition to the previous memoirs, by M. Weingarten, on this and cognate subjects. — (*Journ. reine ang. math.*, 1883.) T. C. [174

PHYSICS.

Density of the earth — Major R. v. Sterneck of the government Military-geographical institute of Vienna, last year, tried Airy's method of the determination of the earth's mean density in the St. Adalbert shaft of the silver-mines at Příbram, Bohemia, at depths of 516 and 972.5 metres. His average result was 5.65, which agrees closely with the values determined by other methods. On comparing his measures with Airy's, a curious agreement appears in the number of seconds gained by a clock at different depths, and a continual decrease in the deduced mean density as the depth increases. Airy found (1854), at a depth of 383 metres, that his clock gained $2^s.25$ a day, and the density was 6.57; v. Sterneck's figures are 516, $2^s.4$, and 6.28, and 972, $2^s.3$, 5.01, respectively: whence he concludes, "that, in the interior of the earth, the resultant of gravity, centrifugal force, and the attraction of the superincumbent mass, is constant." — (*Mitth. k.-k. milit.-geogr. inst. Wien*, 1882, ii. 77.) W. M. D. [175

Electricity.

Geographical variation of horizontal intensity. — F. Kohlrausch proposes to use a form of his local-variometer (described in *Ann. phys. chem.*, xviii. 545) in which the scale is at a distance A from the axis of suspension, and attached to the instrument, and obtains between the horizontal intensities at two different places the relation —

$$\frac{H' - H}{H} = \frac{\tan \phi}{4A}(n' - n) + \mu(t - t');$$

ϕ being the angle through which the frame of the instrument is turned, n and n' the deflections in scale-divisions, and μ a coefficient of the temperature, t. — (*Ann. phys. chem.*, xix. 130.) J. T. [176

Thermochemical properties of electromotive force. — Edlund investigates the thermal changes at the electrodes of a voltameter by placing the junctions of a thermopile in front of the electrodes, and enclosing both in a porous membrane. He finds, that, when the electrodes are copper and the liquid copper sulphate, the electromotive force between the metal and the liquid uses less heat for formation of current than is set free in the formation of copper sulphate.

The same law holds for zinc and zinc sulphate, cadmium with its acetate, and lead with its acetate; but for silver, with its sulphate, nitrate, and acetate, the law is reversed. In a Daniell cell, *a fortiori*, less heat is used for formation of current than is set free in the chemical action of the cell. — (*Ann. phys. chem.*, xix. 287.) J. T. [177

CHEMISTRY.

(*General, physical, and inorganic.*)

Speed of dissociation of brass. — Mr. E. Twitchell (under Prof. Robert B. Warder's direction) made the following determinations, which were suggested by Bobierre's method for the separation of copper and zinc in alloys. A piece of brass wire (no. 17) 150 mm. long and 1.43 mm. in diameter was heated to redness in a stream of hydrogen in a porcelain tube. The loss in weight, from hour to hour, is given in the following table: —

Time in hours.	Weight of alloy.	Loss per hour.	Zinc present.	A.
0	2.0570		.7409	
1	1.9128	.1442	.5967	92
2	1.8527	.0601	.5366	70
3	1.7855	.0672	.4694	66
4	1.7418	.0437	.4257	60
5	1.7168	.0250	.4007	53
6	1.6957	.0211	.3796	48
9	1.6624	.0111	.3463	37
12	1.6339	.0095	.3178	31

The figures given under A are proportional to the 'coefficient of speed,' as calculated from each observation, on the hypothesis that the zinc expelled at each moment is proportional to the whole quantity of zinc present. The steady decrease in the last column shows that this hypothesis does not obtain under the conditions of the experiment, but that an appreciable interval of time is required for the transfer of zinc from the central portion to the surface of the wire. Further experiments upon this *diffusion* of zinc are in progress. — (*Sect. chem. phys. Ohio mech. inst.; meeting* May 31.) [178

AGRICULTURE.

Influence of temperature and rainfall on the wheat-crop. — A comparison of the average temperature and the rainfall in England during the months of July and August for the last thirty-six years, with the corresponding wheat-crop, justifies the following conclusions: provided the stand of the crop at the beginning of July is promising, a temperature above the average for the succeeding two months insures more than an average crop as regards quantity, unless extraordinary circumstances, such as violent storms, intervene. Rainy weather may reduce the quality of the crop. On the other hand, however promising the crop may be at the end of June, a temperature below the average in July and August involves a small crop. If the weather is clear, the quality may be good, while, if cold and rain are united, the poorest crops are the result; such as those of 1879, when the temperature was 2.8° F. below the average, and the rainfall four inches above the average, or that of 1816 (the poorest crop on record), when the temperature was 4.8° F. below the average. — (*Bied. centr.-blatt.*, xii. 291.) H. P. A. [179

Effect of phosphatic manures in drought. — In the course of some field-experiments made during the very dry season of 1881, Emmerling observed that in one case manuring with ammonia alone produced a greater gain than manuring with ammonia and superphosphate. The result may have been accidental, as no duplicate trials seem to have been made; but Emmerling thinks that the manuring with phosphoric acid hastened the ripening of the plants, while the ammonia had the opposite effect of postponing the ripening, and keeping the plants green longer. (This effect of phosphoric acid has been observed in water-culture experiments, and silica also seems to exert a similar action.) — (*Bied. centr.-blatt.*, xii. 297.) H. P. A. [180

Damage to grain by wetting. — Märcker has examined a sample of barley which had been exposed to rain for fourteen days after it was cut. A considerable proportion of the starch had been converted into sugar. A loss of about six per cent of starch took place. The albuminoids were also altered, both the insoluble and soluble proteine having been partially converted into amides. The proportion of seed capable of germination was reduced from ninety-eight per cent to forty-five per cent. Kobus obtained similar results in an examination of damaged wheat. — (*Bied. centr.-blatt.*, xii. 326.) H. P. A. [181

MINERALOGY.

Enclosures in muscovite. — The occurrence of biotite and muscovite in one crystal is well known, and has been investigated by H. Carvill Lewis. He prepared cleavage-sections from one specimen, and arranged them in the order in which they occurred. The biotite contrasts strongly with the light-colored muscovite, and has often well-defined edges. The two micas are arranged symmetrically in relation to their prismatic planes, as may be shown by the crystal edges when they are well developed, or by the strike-figures which are parallel in the two micas in the same folia, making it probable that they have crystallized together out of the same solution. In examining a series of sections from one specimen, it is found that the proportion of the two micas varies in different parts of the crystal; the biotite, the more unstable of the two species, gradually giving way, and being changed into the more hardy muscovite.

Of a different nature are the superficial markings of magnetite, which occur from various localities. These markings form a series of branching lines, which run in three directions across the plates of the mica, crossing each other at angles of 60°, and have been regarded as repeated twinning around a dodecahedral axis. These lines, however, as shown by the author, bear a fixed relation to the axes of the mica, and are not due to any inherent property of the magnetite. If a crystal showing these markings be dissected, the lines of marking will all be found to lie in parallel direction; nor is there any direct connection with the markings on adjacent plates: one may be covered by the markings, the next free from them. The magnetite does not penetrate, but lies superficially upon the mica plates, and the lines follow the direction of the rays of the strike-figure. The author regards the magnetite as not derived from any external source, but from the muscovite itself, occurring, not along cracks or near the exterior of the crystals, but grouped in the interior of the same. — (*Proc. acad. nat. sc. Philad.*, Dec., 1882.) S. L. P. [182

GEOGRAPHY.

(Europe.)

Deformation of the earth's surface. — J. Girard calls attention to some interesting observations on apparent changes of level of neighboring points. One account attested by Girardet (*Exploration*, June, 1882) is of villages in the Jura which were hidden from each other at the beginning of the century, or even only forty years ago, but are now in sight. First the roofs, and later the walls, became visible by the slow warping of the ground. Another example is recorded in Bohemia, about thirty miles south of Karlsbad, where the people of Hohen Zedlisch are convinced that their village is rising; for thirty years ago they could see only the top of the church-spire in Ottenreuth, while now more than half of it is in view, and some roofs of lower buildings have also risen into sight. A line of levels has been run here to detect any further changes (*Congres sc. géogr.*, 1875). Girard does not attempt any criticism of these statements, but accepts them as proved. There would seem to be room for other explanations than the one suggested. — (*Rev. de géogr.*, 1883, 349.) W. M. D. [183

Maps of Norway. — The Norwegian geographical survey (Geografiske opmaaling) has published maps as follows: a guide-map, showing the progress of triangulation from 1779 to 1876 (only a small part of this work remains unfinished), — based upon this are several topographic maps on various scales: for the southern part of the country some are even 1 : 50,000 (or 1 : 10,000), in many sheets; the general map of southern Norway (1 : 400,000), in eighteen sheets; district-maps (1 : 200,000); and rectangle-maps (1 : 100,000), in fifty-four sections, with contours and mountain shading, and the larger bodies of water in blue. This serves as a basis for the geological survey under Prof. Th. Kjerulf. A general geological map (1 : 1,000,000) is also published. The coast-survey publishes charts of the southern shores on 1 : 50,000; of the northern, on 1 : 100,000. Thirty-two of the former and thirteen of the latter are completed. Besides these, there are a general coast-map (1 : 200,000) in thirteen sheets, and another on a smaller scale in five sheets, and fishery-maps (1 : 100,000) in eleven sheets. — (*Mitth. geogr. ges. Wien*, xxvi. 1883, 190.) W. M. D. [184

The Bavarian forest. — The physical features of this submountainous district, extending north of the Danube below Regensburg, are described under its topography and geology by Dr. C. W. von Gümbel, and its climatic relations by Dr. Ebermayer. The article is hardly susceptible of concentration, and we reproduce only what is said concerning the glaciation of the higher ground contemporaneous with that of the Alps. It is admitted that the diluvial deposits do not point with distinctness to glacial action, that striations and moraine-walls can hardly be recognized, and that the characteristic morainic landscape, so pronounced near the adjacent Alps, is absent here; but the numerous small lakes in the higher parts of the country (Arber-, Rachel-, Bestritzer-, Girgl-See and others), and the plentiful peat-swamps, the remains of extinct water-basins, are accepted as evidence of former glaciation. Among all the lakes, there is not one which cannot be explained as resulting either from local glacial erosion, or from obstruction of old valleys by drift-deposits. — (*Deutsche geogr. blätter*, vi. 1883, 21.) W. M. D. [185

(Asia.)

Telegraph-line in China. — Since the destruction of the short railroad from Shanghai to Wusung by the Chinese shortly after its building in 1877, it has been thought that there would be opposition to further introduction of foreign contrivances; and two years ago, when the construction of a telegraph-line was begun between Shanghai and Tientsin, a party of soldiers was detailed to guard the foreign engineers employed on it. The caution proved unnecessary; and the chief difficulties encountered were the numerous canals, some of which had to be crossed by cables. The want of good roads was a serious embarrassment when the line ran at a distance from the grand canal. The line is 938 miles in length, and required nearly twenty thousand poles. The construction was begun in June, 1881, at the two termini, and in December was opened to public use. — (*Pet. geogr. mitth.*, 1883, 231.) W. M. D. [186

Explorations in Cambodia. — Dr. Néis announces his arrival in Laos, on the border of Siam. From Sambok to Sombor the Mekong River is a continuous series of rapids, passable only for the native canoes. Thence above to Laos the left bank is encumbered with shoals. The country is chiefly covered with forests, which, along the river, are infested by Chinese pirates, who render river-traffic between Laos and Cambodia very limited. Laos contains some two hundred houses, and two thousand inhabitants, — Laotians and Chinese, who raise cotton and rice. The commerce is small, iron money is in use, and the Chinese are the chief traders. The ruins described by Garnier, to examine which was the chief object of the expedition, were visited. No inscriptions were found, and but a few interesting carvings. A sort of oven was filled with thousands of pieces of bark stamped, like medals, with three figures of Buddha: some retained traces of color and gilding. Some statuettes of Buddha of *faïence* were found in a vessel embedded in the cement of the oven. Dr. Néis found the fauna of Laos essentially the same as that of Cambodia. He intended, at the date of writing, to penetrate as far as Bassak, in Siam, where he would endeavor to obtain as complete collections as possible. — (*Comptes rendus soc. géogr.*, no. 11.) W. H. D. [187

BOTANY.

Influence of diminished atmospheric pressure on the growth of plants. — Experiments conducted by Wieler at Tübingen show, that, all other external conditions being the same, plants will grow more rapidly under *diminished* atmospheric pressure. Thus, if a specimen of the common Windsor bean (Vicia faba) be grown in a receptacle in which the pressure of the air can be controlled, it will be found to grow faster until the pressure has been diminished to 100–300 mm.; the normal pressure under which the ancestors of the plant have flourished being, of course, not far from 760 mm. If, however, the pressure is reduced below the smaller figure given above, the rate of growth diminishes. Wieler found that the curve of growth of the sunflower is about the same as that of the bean. It was further shown by his experiments, that growth is retarded by increased pressure until the minimum is reached at 2–2½ atmospheres, from which point there is again an increase. Although the short abstract of these interesting results so far published is meagre in the extreme, it indicates that the field entered upon by Wieler (and by Bert in France) may compel us to revise some notions now held in regard to the adaptation of plants to their surroundings in past ages, and at the present time upon high mountains. — (*Botan. zeit.*, July 6.) G. L. G. [188

Pollination of Cypella. — Two Brazilian species of this genus of Irideae have been studied from time to time by Fritz Müller, who finds a number of interesting peculiarities in their flowering. The flowers, like those of Cordia, etc., are produced in abundance only on certain days, which recur more or less regularly, and apparently independently of climatic conditions. Nectar is secreted in pockets on the three petals, which are flexible, so that when a Xylocopa or Bombus, to which the flowers seem well adapted, alights on one in quest of nectar, it bends over with the weight of the bee, whose back is brought in contact with a stigma and the underlying anther. Commonly the bee goes immediately to another flower without trying the other petals of the one on which it has first settled, so that crossing is effected by it. One of the species studied proves to have self-impotent pollen: the other is fertile with its own pollen. The stingless bees (Trigona), though not necessarily excluded by structural peculiarities from the nectar, do not obtain it readily; yet their visits for the protectively colored (pale-bluish) pollen are sufficiently numerous to prevent the larger bees from visiting the flowers in numbers. — (*Berichte deutsch. bot. gesellsch.*, April 3, 1883.) W. T. [189

ZOÖLOGY.

(General physiology and embryology.)

Influence of gravity on cell-division. — E. Pflüger, by placing fresh laid frogs' eggs in a watch-glass, and adding a little water with semen, and pouring it off in a few seconds, was able to impregnate the eggs without allowing the gelatinous envelopes time to swell. The eggs then adhered to the glass, and so could be brought into various positions. The first division occurs in three hours, and always in a vertical plane, no matter how the axis of the egg lies. When the axis of the egg (from dark to white pole) lies horizontally, the plane of division is still always vertical, but may form any angle with the ovic axis. The influence of gravity is also shown in that the upper pole divides more rapidly than the lower. If the position of the egg is exactly reversed, this still holds true, and development progresses; so that repeatedly the medullary furrow, with its high bordering ridges (nervous system), was found upon the *white* side when this was uppermost. Out of seventeen eggs, twelve developed so that the median plane of the body of the embryo coincided with that of the first division of the yolk. (This fact of a relation between the lines of cleavage and the axes of body is not novel, as Pflüger seems to think: there are many observations on various animals which prove such a relation.) From these experiments it results that the topography of the organs is not determined by the arrangement of the substance around the axes of the egg, but that the axis around which the organs are grouped is determined by gravity. — (*Pflüger's arch. physiol.*, xxxi. 311.) C. S. M. [190

Mammals.

Germ-layers of rodents. — A. Fraser finds in the common gray rat and the house mouse the same arrangement of the layers as in the guinea-pig. The *decidua* appears to differ in the mode of its formation from that which ordinarily obtains; and the very early, rapid, and voluminous formation of its solid mass appears to have some close and constant relation to the peculiar inversion of the blastodermic layers which is found in these rodents. — (*Journ. roy. micr. soc. Lond.*, June, 1883, 345.) C. S. M. [191

Intestinal absorption of fat by lymph-cells. — Zawarykin has studied the small intestine during active digestion, making sections stained with perosmic acid and picrocarmine. The material was obtained from dogs, rabbits, and white rats. The lymph-cells are found between the epithelial cells covering the follicle and in the underlying adenoid tissue, and finally in the mouths of the chylous vessels. These cells alone contain any fat, being charged with globules of various sizes. Their multifarious irregular forms, and the inconstant shape of the nucleus, indicate that they were performing active amoeboid movements when fixed by the osmic acid. From these appearances Zawarykin concludes that the lymph-cells (leucocytes) resorb the fat: they enter the epithelium, seize the particles of fat by amoeboid movements, then descend between the cylinder-cells, through the sub-epithelial endothelium and adenoid tissue, into the roots of the chylous vessels. In Peyer's patches the cells are present in crowds, and the resorption of fat seems particularly active at those points. (The presence of lymph-cells between the epithelial cells of the intestines has been known for some time, but the significance of their occurrence has not been heretofore understood. Sewall advanced the view that the immigrant cells remain and become epithelial cells; but that appeared highly improbable. The manner in which fat is absorbed has been much discussed of late years, but the explanation given by Prof. Zawarykin appears to us the first satisfactory one which has been offered.) — (*Pflüger's arch. physiol.*, xxxi. 231.) C. S. M. [192

ANTHROPOLOGY.

Brain-weight of boys and girls. — In the final result of the comparison of the two sexes in the human race, anatomical researches will form an important factor. Many anatomists have recognized this fact, and have instituted comparisons between the sexes from various points of view. M. Gustave le Bon reviews the work of M. Manouvrier and that of M. Budin, both of whom aver that "sex has no influence on brain-weight. With them the influence of sex is nothing more than the influence of height; and if the females as a whole exceed the males in brain-weight, it is simply because the weight of the body in the females is much below that of the males." M. le Bon puts the theory of his adversaries to the test in a very ingenious manner by comparing the brains of males and females having about the same weight. By this investigation it is shown that in the great majority of cases the male children surpass the females of the same weight in their cranial circumference. At the same age, height, and weight of body, the female brain is notably smaller than that of the male. — (*Bull. soc. anthrop. Paris*, v. 524–531.) J. W. P. [193

The Galibis. — The tribe of Galibis lives on the borders of the Sinamari, and not far from Cayenne, in French Guiana, and it consists of only a few families. A group of fifteen of them were sent to Paris in 1882; and several gentlemen, among them Mr. Manouvrier, have undertaken to study their physique, customs, language, etc. The Galibis were domiciled in their native fashion in the *jardin d'acclimatation*, and passed their time in their ordinary pursuits. The skin is reddish brown, but differs with individuals, owing partly to mixed blood: the true color is also disguised by the use of paint. The hair and eyes are jet black. The other physical characters, as well as their language and occupations, are given with the greatest minuteness. A single observation will show the extreme caution with which fine theories should be spun. M. Capitan studied carefully the processes of making pottery among the Galibis. Hamy took occasion to remark upon this as upon the greater rudeness of ornamentation in other respects, and concluded that the Galibis had much degenerated since they were first studied. But Mortillet recalled the discussion to a sober view by remarking that the specimens in our museums are choice objects, selected by travellers for their great beauty, while those made by the Galibis in the jardin were by rude workmen for daily use. They show us the cabin of the poor, while the voyagers had despoiled the homes of the rich. Theories of degeneration based upon Hamy's facts were therefore unsubstantial. — (*Bull. soc. anthrop. Paris*, v. 602.) J. W. P. [194

African psychology. — Max Buchner, writing to *Ausland*, speaks rather encouragingly of the Bantu negro character. "The negro in his native condition is not apparently of a lower grade of natural intelligence than the European of the common class. He probably excels the European in a kind of selfish cunning, while the restraints of moral scruples and of the finer feelings operate less strongly upon him. Yet he is not destitute of a sort of moral instinct, a kind of taboo conscience, that causes him to hesitate to do wrong. For this reason the negro is never an open thief." Mr. Jefferson used to say that his slaves were all honest, but they could beat the world finding things. The negro, says Buchner, is above every thing positivist, practical, materialist, and is inaccessible to intangible considerations. The question 'Has the negro a religion?' cannot be answered at once, either affirmatively or negatively. It must first be made clear what is to be understood by religion. He has a confused mixture of vague wants and superstitious impulses. A system of computing time can hardly be predicated of such a people; but they have a kind of superficial calendar of the months, which they make to help regulate their agricultural operations. The negro undoubtedly possesses all the capacities for education and civilization to at least as great an extent as our primitive ancestors. The fact that the psychical and intellectual, as well as the physical, differences between particular races of men are really insignificant, is destined to be made plainer, the more the subject is impartially studied; and the efforts of certain men, learned in distinctions of types, to set up fixed marks of separation between them, will not succeed. — (*Pop. sc. monthly*, July.) J. W. P. [195

NOTES AND NEWS.

The unexampled recent increase in the membership of the American association for the advancement of science, from a little over one thousand just before the Boston meeting of 1880, to nearly two thousand now, implies a considerable increase in its funds, and should imply direct participation by the association in the endowment of research, which its means have not hitherto permitted. No other way is now open for the association to advance science so securely.

We desire, therefore, to call the attention of the executive board of the association to the direct advantage which would certainly result in following the example of the British association by making an annual grant to the Naples zoölogical station, whose claims and advantages have already been so well stated in our columns by Miss Nunn and Dr. Whitman. The board would find no lack of applicants for the table thus secured, the cost of which would be four hundred dollars annually.

— Mr. George M. West of Escanaba, Mich., sends us a photograph of a hoe-shaped implement which is stated to have been made of native copper by hammering. The blade has a thin edge, and is said to be nearly nine inches long, about three inches wide, and one-half inch thick at the back where it joins the shank. The shank is an inch square at its union with the blade, six inches long, and half an inch square at its distal end. This implement was found in Brown County, Wis., and is, we believe, unique among the many copper objects found in North America, of which Wisconsin has yielded so large a proportion. While we have no reason to doubt the statement that this implement is made of native copper, we should rather have it placed in our hands for careful examination before committing ourselves as to its character and use. Should it prove to be all that the photograph suggests, we should like to give a description, with figures.

— In the first part of an article on 'Zoölogy at the Fisheries exhibition,' *Nature* of July 26 gives unstinted praise to the collections, public and private, exhibited by the United States, and admires the beauty of the marine objects shown by the Naples zoölogical station. Speaking of the collections shown by the U. S. fish-commission, it says, "It is not an exaggeration to say that this collection, both on account of the range and variety of its objects and the instructive way in which they have been disposed and treated by the American commissioner, Mr. Brown Goode, has been the admiration of all visitors."

— According to *Nature*, the Berlin academy of sciences has granted the following amounts from its Humboldt fund: 5,000 marks ($1,250) to Dr. Otto Finch, for working at the collection he made during his journey in Polynesia; 6,000 marks ($1,500) to Dr. Ed. Arning (Breslau), for researches on the leprosy epidemic in the Hawaiian Islands; the same amount to Dr. Paul Güssfeldt, to enable him to continue and extend his exploring tour in the Andes of Chili.

— The *Société industrielle de Mulhouse* has awarded its silver medal (*médaille d'argent hors concours*) to Mr. C. J. H. Woodbury of the Boston manufacturers' mutual fire-insurance company for his book, 'Fire protection of mills.'

— Dr. J. W. Mallet has resigned the professorship of chemistry in the University of Virginia.

SCIENCE.

FRIDAY, AUGUST 17, 1883.

THE AMERICAN ASSOCIATION AT MINNEAPOLIS.

The number of people who take an interest in scientific discovery is very great. We may assume that it far exceeds estimates based on the support given to scientific periodicals and societies. The question is not of thousands, but of hundreds of thousands. Of a report of Professor Tyndall's lectures on light in New York, there were sold over a half-million copies. That was ten years ago: the popular interest in science has vastly increased in the interval. This is shown by the gain of membership in the American association for the advancement of science, being within the last four years as great as in the previous thirty-one years.

Compared with what may be called the scientific following, the number of workers in science is small. Upon that following the workers must depend for recruits, and, directly or otherwise, for support. Science must lean on her friends: they are numerous, but few of them give help. There are large and rich communities where the local developments are on a par with the Pickwick club. The men and means for good work are not wanting, but the impulse is. 'Oh for the touch of a vanished hand,' like that of Louis Agassiz, to warm the dormant interest into life!

For this purpose the American association is an effective agency. It unites in one body the workers and those who are not professionally engaged in scientific pursuits. Its management should be and is favorable to the desires of both classes. In the social features of its meetings, all share alike, and perhaps with equal zest. But the workers regard the meetings chiefly as the occasions for hearing and reading 'papers.' Teachers, who form a large part of the membership, seek the most recent things of knowledge to add to their capacities for instruction. A majority of the attendants at the meetings come simply with a wholesome curiosity for the novelties of science.

The production and delivery of 'papers' at these meetings give rise to some queries. Is there any natural reason for expecting genius to burst into blossom in August rather than in any other month? If a man of science is diligently pursuing some line of research, may not the light that never was on sea or land break upon him in any other of the fifty-two weeks than the one when he can present it to the annual meeting? If he keeps back his announcement of progress or discovery, or if he brings it forward before he is fully prepared, does he not harm the cause of science and himself?

The 'papers' are of necessity often technical and uninteresting to all except experts in some special line. At one of the meetings a certain mathematician stated the case bluntly, thus: "I shall read my paper by title only, as there is nobody but myself here who can understand it." The rapidity with which a crowd of members thins out when the reading of a technical paper fairly begins, is at least suggestive. Nor should the departing crowd be denounced as simply unworthy of the pearls spread before them. They will stay if the paper has only a fair trace of popular interest. Doubtless many of those who leave the association in their first year of membership are disappointed. They had hoped for something not quite so 'dry.' Yet, if the reading of papers were dropped, the association would fail to gather the workers of science at its meetings.

Plans have at times been considered for securing addresses from men who are known as popular speakers, capable of attracting large audiences, especially if aided by suitable apparatus for the display of experiment. In various ways such a course might add largely to the resources and influence of the association. What is vastly more important, it would rouse an enthusiasm for science at the locality of the meeting, which, if rightly fostered, would give permanent results.

The association has sought to meet some of these wants and difficulties by creating a larger number of sections, each of which has a presiding officer, who is expected to deliver a formal address. This is an advance, but only a half-way measure. The papers increase in number every year; and the several sections must all work at once and arduously to finish their reading in the allotted time. To many a member, even to a specialist who may be engaged in two distinct lines of research, comes the disappointment of missing the hearing of valuable papers when two or three are delivered simultaneously.

Many of these features must appear prominently at the present meeting. The attendance will consist in greater proportion than usual of the popular element. The membership is now so large that there is no risk of the meeting being insignificant in size, as at Dubuque in 1872. But, since Minneapolis is the farthest point to the west yet tried, its distance must withhold many familiar faces. After this, we shall know better whether the kind invitations of San Francisco may be accepted two or three years hence. Next year the meeting should not be too far from the British association at Montreal.

At least eight addresses will be given by presidents of sections, — excellent in their kind, but not quite a substitute for thoughts that breathe and words that burn. If free and wide discussion could be encouraged at these meetings, the retiring president's address would now give abundant occasion. Dr. Dawson hits hard where he thinks he sees a crevice in the armor of the evolutionists or of the glacialists, and many will chafe if there is no immediate opportunity to return his thrusts. But, while it may fail of excitement, the meeting at Minneapolis is very enjoyable. The city and vicinity are picturesque and delightful. The hospitality of the west is as broad as its prairies

W. C. W.

THE IGLOO OF THE INNUIT.—I.

The Esquimaux of the arctic regions of North America call themselves 'Innuits,' and their winter-houses, built of ice and snow, 'igloos.' This short explanation may be needed to make clear my somewhat obscure title.

These strange huts have been incidentally described by many travellers in the accounts of their arctic explorations. But beyond the fact that they are rude domes of snow, in which these polar people live for the greater part of the year, little is known of the manner of their construction, their internal arrangement, or of the conditions which have led to their existence.

The many inquiries I have been called upon to answer in regard to these northern cabins, and the misconceptions I have found even among the better informed of my questioners, have led me to believe that an account of the igloo as I saw it during my life with the Innuits would be of interest.

The origin of the igloo can only be guessed from the few facts we know of early man. I will not discuss the ethnological problem which would identify the Innuit of the present day with the cave-men of Europe, but, assuming that it is true, will sketch a possible history of the ice-hut.

These cave-men are known to have existed along the edges of the *mer de glace*, which, during the ice period, overspread Europe, and buried it as Greenland is probably buried at the present day. What caused this great flow of frigidity to the south, or its retrogression to the north, it is needless to consider; suffice it to suppose that our hyperboreans followed it in all its migrations. The earliest evidences of their history are those they left in the caves of middle Europe when the glacier extended nearly to the Alps and Pyrenees, beyond which, with its outlying polar fauna of cave-men, cave-bears, cave-hyenas, mammoths, and reindeer, it never extended.

These caves were the work of nature. When these people lived in their vicinity, it is probable that they knew no other habitations, winter or summer, and disputed their possession with the many animals whose bones are found beside the implements and bones of the cave-men themselves.

As the *mer de glace*, with snail-like pace, withdrew northward, it was followed by these children of the cold (the cave-men), driven, as some suppose, by the more powerful river-drift men, or following that climate which was the more congenial.

The cave-men in their retreat, tightly held by other tribes or climatic temper, when they reached the older geologic formations which no longer gave them the welcome shelter of nature's rude houses (the dreary caves), must have looked for it from other means; and these were only stones and snow-banks. The former may have been used for their more permanent homes; but the cold interiors of stone huts in such a climate must soon have driven them to the more comfortable and easily built houses that can be excavated from a snow-bank, and so greatly resemble their old cave-homes.

During the first part of their retreat, the cave-men, cave-men no longer, were in a hilly, half-mountainous country, — a character of surface favorable to the formation of snow-drifts large enough to allow of pit or excavation, in which a family could comfortably reside. Here, then, was the first igloo, rudely cut into some protecting bank of snow, its walls knowing no other construction than that of nature. Such rough types of arctic architecture are still to be found among the mountains, where wood is unknown.

As the migrating sea of ice debouched upon the shores of the Arctic Sea, and withdrew its icy blanket from these more northern regions, the ancient arctic man found himself, as he reached those limits near the White Sea and the mouth of the Petchora, in a flatter country. The snow-drifts no longer lay in such colossal depths. They were direct functions of the surface, and flattened with it. It was no longer possible to construct a deep enough house by simple excavation. The problem was probably met by digging as far as possible, and completing the structure with banks, which in time were made of blocks of snow; for the snow of the arctic winter is not of that plastic nature which will allow one to fashion it at will, as schoolboys their forts and imitation-men, but dense and compact from the extreme cold and the packing wind. Such were the first typical and perfect igloos, a direct outgrowth of the level barren lands of the arctic zone, — features which yet determine its geographical limits.

Arctic man stopped on the shores of the sea, for in the rude means at hand he could follow the ice no farther. There was another migration to the north, which was to affect the character of his dwelling: this was the migration of the forests. As soon as wood reached his door, either by direct migration of the forests or by drifting down the great northward-trending rivers, he would naturally use it in the construction of his permanent houses, as we see to-day among the natives thus situated. The igloo was probably driven from Europe, then from Asia, and is now confined to certain localities of North America.

From writing of the igloos of the Innuits, the natural inference is, that the geographical boundaries of the two would be the same. The Innuits reach from Bering Straits (and even southward along the Alaskan coast and outlying islands) nearly to those of Belle Isle, following the sinuous coast of North America at irregular intervals. They populate the western shores of Greenland, and once occupied its eastern side. Yet this vast stretch of ocean-line must be shorn of the greater portion of its length before we can narrow it down to the part occupied by the igloo-building Innuits.

The data I have already given restricting the igloo to the barren grounds devoid of even driftwood, and the fact that nearly all Esquimaux tribes are a seacoast-abiding people, will assist us in a rough but fair approximation to its limits, — limits which can be readily made clear by reference to a map of the arctic regions of North America. The mouth of Mackenzie is about the dividing-line of the timber to the west and the barren country to the east. For considerable distances on both sides of its mouth, there is a good supply of driftwood. Where this driftwood ceases on the east is the western limit of the igloo, probably fifty to one hundred miles from the river. From this point they are found all along the coast, on the portions of the Parry Islands occupied by Esquimaux, the shores of Hudson's Bay and Straits as far as Marble Island, of Cumberland Gulf, and many of the estuaries of Baffin's Bay. The limit on the south is, I believe, Hudson's Strait, and on the east Baffin's Bay.

The time during which igloos may be built depends on the length of the winter. In summer the natives use a tent of seal or walrus skin.

The pole of greatest cold is placed by Bent to the north of the Parry Islands, nearly upon the eightieth parallel, and in about 100° W. longitude. I believe the thermometric observations made in the arctic regions, straggling as they have been, go far towards' showing that the magnetic and thermal poles are the same. This would bring the lowest temperatures six hundred miles to the south of the position assigned by Bent. Wherever it may be, there would the igloo have the longest existence for the year.

In the winter of 1878, being near Depot Island in North Hudson's Bay, we moved into igloos on the 1st of November. On King William's Land, next spring, we abandoned snow-houses, and took to tents on the 17th of June, having lived an igloo-life for seven months and seventeen days. That winter upon King William's Land we reared our first igloo on the 25th of September, being one month and five days earlier than at Depot Island the previous season. This would give a total of igloo-life for the southern part of King William's Land of eight months and twenty-two days, or nearly three-fourths of the year. This is the nearest to the pole of greatest cold (be it the magnetic pole or according to Bent) that any white men have lived *à la Innuit*. Assuming these two physical poles to be identical, and our position having been so near them, — being really only about a hundred miles distant, — we must have experienced about the maximum of annual igloo-life. Returning to North Hudson's Bay in the spring of 1880, we, as well as the majority of the Esquimaux living around Depot Island, moved into tents about the middle of May, giving igloo-life for North Hudson's Bay something over half the year, which is probably near the minimum.

While, of course, climatic causes principally determine the annual longevity of the snow-house, they are not the only ones. As soon as the spring thaws commence tumbling in the igloos, or making their structure insecure, the native would gladly avail himself of a tent; but this he cannot do, unless there be a clear spot somewhere near, on which it can be pitched. It may be a number of days from the time he would accept tent-life before the hilltops or ridges commence peeping through their winter covering. The inland ridges, higher and more marked, covered with black moss, which, once through the crust, makes sad havoc with the snow, appear much sooner than those facing the sea, which are flatter, enabling the inland reindeer hunters to occupy their tents earlier than the seal or walrus hunters of the coast. Some igloo-builders will wait until they can kill enough seal to make a new tent before using one. The Ooqueesik Salik Esquimaux of the Dangerous Rapids of the Great Fish River can be said to be practically without tents, securing nothing, or almost nothing, from which to make them. They hold to the shelter of an igloo late in the spring, and seek it as soon as one can be made in the early winter.

(*To be continued.*)

ON THE DEVELOPMENT OF THE PITUITARY BODY IN PETROMYZON, AND THE SIGNIFICANCE OF THAT ORGAN IN OTHER TYPES.

In the *Quarterly journal of microscopical science* (xxi. 750) I published a brief preliminary account of the development of the pituitary body in the lamprey, stating that it was formed from a part of the nasal sac. This account of a method of formation so entirely different from any thing that was known among the vertebrates was received with incredulity by Balfour, who says (Comp. embryology, ii. 358), "I have not myself completely followed its development in Petromyzon, but I have observed a slight diverticulum of the stomodaeum which I believe gives origin to it. Fuller details are in any case required before we can admit so great a divergence from the normal development as is indicated by Scott's statements." These fuller details have long been nearly ready for publication, but I have been prevented by circumstances from issuing them. I hope shortly to continue my series of studies on the embryology of Petromyzon, but, in the mean time, think it advisable to present this preliminary account.

My friend, Dr. Dohrn of Naples, has lately investigated this subject, and has come to the conclusion that neither Balfour nor myself can be correct, but that the pituitary body arises from an independent invagination of the epiblast between the nasal epithelium and the mouth (*Mitth. zool. stat. Neapel*, iv. 1 heft). On examining Dohrn's figures, however, I was much pleased to find that his disagreement with me is rather about terms than facts; for these drawings correspond almost exactly with those that I have already published, and many more as yet unpublished.

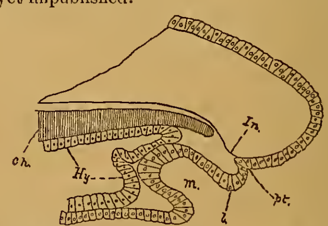

Fig. 1. — Sagittal section through head of lamprey embryo. *m*, mouth; *pt*, pituitary invagination; *In*, infundibulum; *Hy*, hypoblast of throat; *ch*, notochord; *l*, upper lip.

The development of the pituitary body, as far as I have been able to trace it, is as follows. Shortly before hatching, the mouth is formed by a deep invagination of the epiblast (see fig. 1, taken from my article in the *Morphol. jahrb.*, vii). The upper lip is somewhat rounded in longitudinal section, and bounded anteriorly by a very slight depression, which is the beginning of the pituitary body; but, as this is also the beginning of the invagination to form the nasal sac,[1] I have preferred not to separate them, as Dohrn has done. In the next stage (fig. 2)

Fig. 2. — Section through head of an older embryo just before hatching. *Olf*, olfactory epithelium. Other letters as in fig. 1.

the nasal epithelium has become much thickened, the pituitary involution deeper, and the upper lip elongated so as to become triangular in section. At this time the cranial flexure has reached its maximum; though it is far less than in most other groups, owing to the relatively small size of the fore and mid brains. The mouth is ventral in position, corresponding very closely to the selachian mouth in position and shape.

Shortly after this, the upper lip begins that remarkable series of transformations to which, as I long ago pointed out, many of the most striking peculiarities of the cyclostome organization are due. The posterior edge of the lip elongates rapidly, becoming triangular in section; while the whole anterior part of the head rotates forwards, thus tending to correct the cranial flexure, and bringing the mouth to point somewhat forward as well as downward. By this process the edge of the lip, which in fig. 2 is directed backwards, now comes to point downwards (fig. 3); at the same time, the opening of the nasal pit points forwards instead of downwards. The involution for the nasal passage and pituitary body has now become a long tube of cells, which transverse sections show us to be

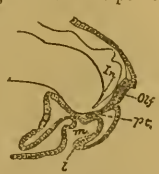

Fig. 3. — Section through head of a very young larva of the lamprey. Letters as before.

[1] By nasal sac, I mean the blind passage, as distinguished from the olfactory epithelium.

perforated by a small lumen. The end of this cellular tube reaches to the infundibulum, with which it lies in close contact. This portion will give rise to the pituitary body. Up to this time there has been no line of separation between the pituitary involution and the nasal epithelium; but when the process of rotation of the upper lip, and correction of the cranial flexure, is completed, the edge of the lip points directly forward, having passed through an angle of 180°, and the opening of the nasal sac is on the dorsal instead of the ventral surface of the head. At this time a fold appears below the olfactory epithelium, separating it distinctly from the pituitary passage.

The pituitary body is formed from part of the epithelium of this passage, and consists of solid follicles, separated by connective tissue. According to Dohrn (loc. cit., p. 178), this body is not constricted off from the passage or nasal sac at any time during larval life. I have not been able to satisfy myself, as yet, upon this point; but I am not inclined to agree with this view.

As to the morphological significance of the pituitary body, many views have been propounded, some of them bearing upon the question of the origin of the vertebrates. Some writers have contended that the conario-hypophysial tract through the brain is the remnant of the old mouth and gullet, which, in the ancestors of the vertebrates, passed through a ring of nervous tissue, as in the annelids. Space will not permit a discussion of this hypothesis; nor is such discussion necessary, as Balfour (Elasmobranch fishes, p. 170) has stated the insuperable objections to the view. Dohrn, in the pamphlet already quoted, adopts a view somewhat like one originally propounded by Götte, and adds a suggestion of his own. He considers the entire blind nasal sac of the lamprey to belong to the pituitary body, and that this sac has arisen from the coalescence of a pair of gill-slits. This hypothesis is but the carrying-out of the theory so ably advocated in the very suggestive pamphlet 'Ueber den ursprung der wirbelthiere.' But, until it can be shown that the vertebrate mouth is a new formation, the existence of pre-oral gill-clefts hardly merits discussion. I reserve for a later paper the consideration of the origin of the vertebrate mouth, — a question which is the turning-point of the solution of all these problems.

Balfour has suggested an explanation of the pituitary body. "It is," he says (p. 359), "clearly a rudimentary organ in existing craniate vertebrates; and its development indicates, that when functional it was probably a sense-organ opening into the mouth, or else a glandular organ opening into the mouth." It seems to me that the facts of its development in Petromyzon negative this hypothesis. It is there seen to have no connection with the mouth; nor is this mode of development so entirely exceptional as it would at first seem. Of all known embryos of craniate vertebrates, the lamprey has perhaps the smallest brain and the least cranial flexure; which state of things allows space for a distinct invagination from without to reach the infundibulum. In the Amphibia this is seen to a less degree: the invagination for the pituitary body is formed before the appearance of the

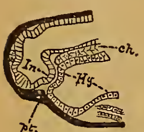

Fig. 4. — Section thro' head of embryo of Bombinator (after Götte). Letters as before.

Fig. 5. — Section through head of young tadpole of Bombinator (after Götte). Letters as before.

mouth, and just above it; so that, when the mouth appears, the two have an apparent connection, being crowded together by the increased cranial flexure. In other types — such as the selachian, bird, mammal, etc. — the brain acquires a very great size in early embryonic stages, and the cranial flexure is consequently very much increased. In these cases almost the only possible way for an epiblastic invagination to reach the infundibulum is from the epiblast of the mouth. If the reader will compare the figures given above for the lamprey with those from Götte (figs. 4 and 5) for the amphibian and that from Balfour for the selachian (fig. 6), these progressive changes will at once be clear. If embryological evidence counts for any thing, it would therefore seem extremely probable that the connection of the pituitary body with the mouth is only a secondary one, brought about by the greatly increased cranial flexure in the higher types. Assuming that the invagination originally took place independently of the mouth, such a secondary connection would be almost a mechanical necessity of the great brain-growth.

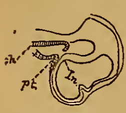

Fig. 6. — Section thro' head of embryo of Pristiurus (after Balfour). Letters as before.

Now, while I am not prepared to follow Dohrn in maintaining that the entire blind nasal sac below the olfactory capsule of Petromyzon really belongs to the pituitary body, yet I quite agree with him that the connection of the pituitary body with the olfactory organ is a secondary one. I have, in a former paper, stated the reasons for believing that the unpaired condition of the olfactory organ in the Cyclostomata is not primitive, but secondary, caused by the coalescence of two originally distinct pits. Now, if there were an independent invagination in the median line of the head, the causes which brought about the union of the two nasal sacs would also cause the latter to coincide with the pituitary involution. This is just what I conceive to have happened.

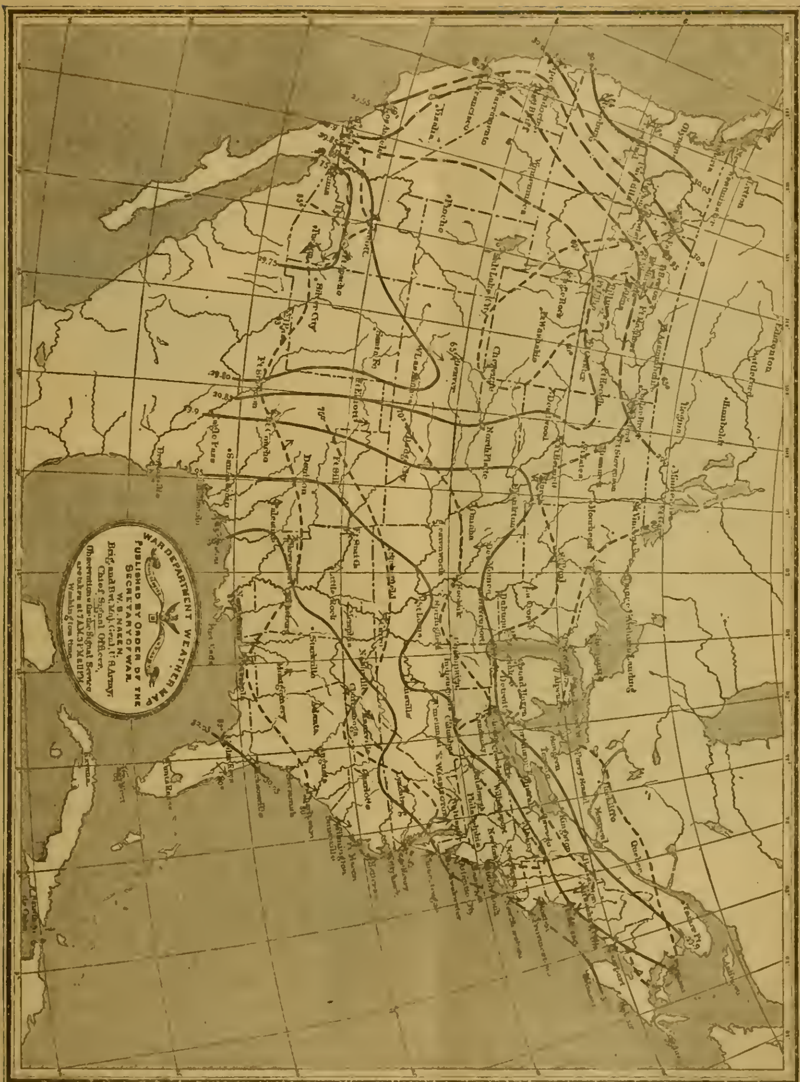
If the above reasoning be correct, the fact would seem clear, that the pituitary body is the remnant of some originally independent organ, which opened, not into the mouth, but on the surface of the head. Almost certainly this organ belonged to the invertebrate ancestor of the vertebrates. What its function was, is a difficult problem. Dohrn's hypothesis that it was formed by the coalescence of a pair of gill-clifts is untenable, not only for the reasons already given, but on account of the invariable epiblastic origin of this organ, while gill-clefts always arise in the vertebrates as outgrowths of the hypoblast. Perhaps we may modify Balfour's suggestion, and assume tentatively that it was a sense organ or gland which, having lost its function, has become rudimentary. At all events, it will be a step gained if we can establish the fact that the pituitary body is an organ originally independent both of the mouth and of the olfactory apparatus. W. B. Scott.

Morphological laboratory, Princeton, N.J., July 5, 1883.

THE WEATHER IN JUNE, 1883.

The monthly weather review of the U. S. signal-service contains in usual detail reports from all portions of the country of the weather conditions which characterized the month of June. There were no unusual meteorological features; the month exhibiting the 'average weather,' as far as this term can be realized. The destructive floods in the lower Missouri River, and in the Mississippi River between St. Louis and Cairo, the unusual rainfall in that section, and severe local storms in many of the states, are the special events of note.

The mean distribution of barometric pressure is illustrated by the accompanying chart, which also contains the mean isothermal lines,



MONTHLY MEAN ISOBARS, ISOTHERMS, AND WIND-DIRECTIONS, JUNE, 1883. REPRINTED IN REDUCED FORM BY PERMISSION OF CHIEF SIGNAL-OFFICER.

and arrows indicating the prevailing wind-directions. The pressure conditions are quite normal, the regions of highest mean pressure being the South Atlantic and Gulf states, and the North Pacific coast. Eight areas of low pressure have been traced over the United States, with an average velocity of 24.2 miles per hour. The discontinuance of telegraphic reports from stations west of the Rocky Mountains prevented the charting of the early portions of some of the storm-tracks. The passage of the low areas was accompanied by wide-extended and in many cases severe local storms, though they were not so numerous nor so violent as those which occurred in the month of May.

The departures from the normal temperatures were in no section large. On the Atlantic coast and west of the Rocky Mountains the temperature was slightly higher than the average, and over the interior districts slightly lower. Frosts occurred in many states in the first days of the month.

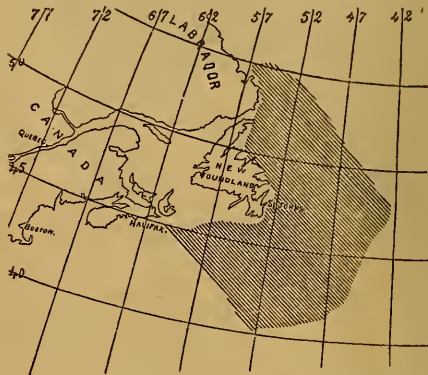
The following table contains the rainfall statistics for the month: —

Average precipitation for June, 1883.

Districts.	Average for June. Signal-service observations. For several years.	Average for June. Signal-service observations. For 1883.	Comparison of June, 1883, with the average for several years.
	Inches.	Inches.	Inches.
New England	3.60	3.36	0.24 deficiency.
Middle Atlantic states .	3.52	5.22	1.70 excess.
South Atlantic states . .	4.57	6.49	1.92 excess.
Florida peninsula . . .	5.70	4.80	0.90 deficiency.
East Gulf	4.29	4.91	0.62 excess.
West Gulf	3.37	3.73	0.36 excess.
Tennessee	4.34	3.49	0.85 deficiency.
Ohio valley	4.64	4.21	0.43 deficiency.
Lower lakes	3.26	4.04	0.78 excess.
Upper lakes	4.47	5.38	0.91 excess.
Extreme north-west . .	4.10	2.50	1.60 deficiency.
Upper Mississippi valley,	5.82	5.98	0.16 excess.
Missouri valley	6.06	7.98	2.92 excess.
Northern slope	2 53	3.43	0.90 excess.
Middle slope	2 01	2.27	0.26 excess.
Southern slope	3 26	1.70	1.56 deficiency.
Southern plateau . . .	0.40	0.03	0.37 deficiency.
North Pacific coast. . .	1.50	0.04	1.46 deficiency.
Middle Pacific coast . .	0.18	0.00	0 18 deficiency.
South Pacific coast . . .	0.02	0.04	0.02 excess.

On account of the excess of rain in the Missouri valley, disastrous floods occurred in the latter part of the month. At St. Louis the river reached the highest point since the establishment of the signal-service station. Much delay was experienced by the railways centring in St. Louis and Kansas City.

Three depressions only are charted upon the Atlantic Ocean in this month. All of these are in the eastern portion, and none are traced



ICE-CHART FOR JUNE, 1883.

from America to Europe. The weather over the North Atlantic was fair; but dense fogs prevailed from the coast of the United States eastward to the fortieth meridian. Ice was found as far east as 42° longitude, and as far south as 40°.5 latitude. During the month, icebergs drifted about three degrees eastward of the position in May. Compared with June, 1882, there is a marked decrease in the number of icebergs, and also in the amount of drifting field-ice. The accompanying chart shows the position of the ice in the month.

An interesting diagram is published in the review, showing the observations made on the steamship Assyria during her voyage from New York to Bristol, May 27 to June 11. Some of the symbols used are unexplained, however. The marked features are the rise in temperature immediately after leaving the Atlantic coast and the corresponding fall east of the fiftieth meridian, the agreement between the temperature and pressure curves, and the agreement between the temperatures of the air and sea-water.

Minor displays of auroras at various stations were reported during the month, and on the 30th an extensive but not brilliant display was noted. The number of sun-spots and groups was large. The record of halos, mirage, and meteors is large; and two water-spouts were reported, — one on Lake Erie, the other on Lake Monroe, Fla.

The verification of the tri-daily indications shows the average of 85.1 %. Of the cautionary signals displayed, 80.4 % were justified by winds exceeding twenty-five miles an hour at or within one hundred miles of the station.

THE FALL OF A BALLOON.[1]

In the August (1882) number of *l'Aeronaute*, accounts were given of the different ascents made on the 14th of July of that year. Among these ascents that of Cottin and Perron was of especial

Fig. 1.

Fig. 2.

interest, not because of the length of the voyage, but from its brevity, and on account of the fall which ended it. The balloon had barely started from Paris when a rent was formed in the upper part, and the balloon descended at Saint-Ouen. This occurrence is not entirely unknown; but that which does not

Fig. 3.

happen often is, that an artist, Mr. Jacque, chanced to be at his window, and was able to make rapid drawings of the balloon during its descent, and Mr. L. Gillon viewed the accident from the Place Wagram, and made three drawings.

Mr. Cottin, thinking that the aeronauts had not attached sufficient importance to his ascent, has published an account of it in a brochure, illustrating it with the drawings of Jacque and Gillon. He begins his statement, "It was sixteen minutes past four. The wind was blowing violently from the south-east. The temperature was 28° C. At starting, the voyagers felt nervous, and noticed some excitement in the movements of those who were assisting. Nevertheless, they started, saluting the crowd, who responded as only a sympathetic Parisian crowd knows how. They rose over the building which forms the corner of the Place Wagram. Thirty kilograms of ballast was thrown out; and, relieved of this weight, the balloon shot up. With one bound it was four hundred metres; another, and it had reached a height of six hundred metres. At this time it was just twenty-four minutes past four. The aeronauts felt that the balloon seemed to stop. They were told afterwards that they began to turn. Cottin felt a trembling of the basket. Some seconds passed. Then the noise of the flapping silk was heard."

Fig. 4.

[1] Taken, with the illustrations, from *l'Aeronaute*, June, 1883.

The balloon was torn when at a height of seven hundred and three metres, as shown by a pocket barometer which Cottin had with him, and saved in good condition. For the first hundred and twenty metres of the fall the motion was regular. Then a swinging motion began, and finally the fall

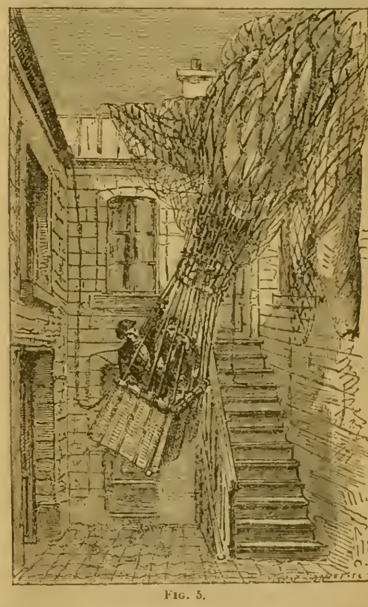


Fig. 5.

increased in speed. The oscillations increased enormously, and the basket swung through the air with a dizzying velocity. At times the balloon took up an almost horizontal position in the direction of the wind. This swinging continued till a point within a hundred and twenty or a hundred and thirty metres of the earth was reached. From this point the fall was nearly vertical, as the silk had formed itself into a parachute. During this period Mr. Perron threw out the last of the ballast, the guide-rope, and cut the cords of the anchor. Led by Perron's example, Cottin threw over a bottle of cold coffee, which, he remarks, 'might have injured or even disfigured them.'

Suddenly, without any shock, the basket seemed to drop from under their feet. A moment later they were violently thrown down by the sudden stopping of their fall. It was twenty-seven minutes past four. The ascension had lasted eleven minutes, and two minutes were occupied by the fall of seven hundred and three metres.

They found themselves suspended about two metres from the pavement in the courtyard of a house

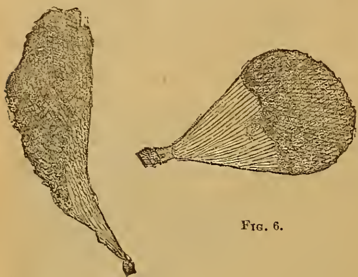

FIG. 6.

in Saint-Ouen, the ropes and material of the balloon having caught on the roof. The yard was not more than four metres long by three wide. To complete their good luck, there was a flight of steps which gave them an easy means of reaching the ground.

Mr. Jacque was in his studio, and saw the balloon in the air. Seeing that something unusual was happening, he seized a pencil, and hastily drew the successive forms which are reproduced in figs. 1 to 4. As to the drawings, he says, "I could only indicate very imperfectly the ropes and basket, which I could hardly see. It is necessary to remark, that the phases represented ought to be supposed as following closely one another, and constantly changing. I suppose that the time during which the fall was visible to me was about one minute, and the distance fallen five hundred metres. At the moment when I saw the balloon taking the last form (fig. 4), it was descending more rapidly, and disappeared behind the left slope of Montmartre. It did not seem more than one kilometre distant from me; but in this I was mistaken."

The sketches (fig. 6) of the fall as seen by M. L. Gillon are not accompanied by any explanation.

The figures are of interest as showing the form which a balloon takes when forming itself into a parachute, and give some indication of the resistance offered by the air. The parachute was doubtless of an imperfect form, and offered too great a resistance. It had, moreover, the fault of not having a central opening, on which account the air could only escape laterally, and gave rise to the fearful oscillations. In an actual parachute the central hole, of large size, allows easy escape to the air, and the oscillations are slight. It can almost be said that the resistance of a parachute increases with the size of the opening.

The balloon tore on its upper side on account of the disproportion in the ropes. The lower part, reversing, formed a closed parachute. It is not singular that the balloon should have taken such strange shapes while falling.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

ADDRESS OF THE RETIRING PRESIDENT, DR. J. W. DAWSON, AT MINNEAPOLIS, AUG. 15, 1883.

SOME UNSOLVED PROBLEMS IN GEOLOGY.

MY predecessor in office remarked, in the opening of his address, that two courses are open to the retiring president of this association in preparing the annual presidential discourse, — he may either take up some topic relating to his own specialty, or he may deal with various or general matters relating to science and its progress. A geologist, however, is not necessarily tied up to one or the other alternative. His subject covers the whole history of the earth in time. At the beginning it allies itself with astronomy and physics and celestial chemistry. At the end it runs into human history, and is mixed up with archeology and anthropology. Throughout its whole course it has to deal with questions of meteorology, geography, and biology. In short, there is no department of physical or biological science with which geology is not allied, or at least on which the geologist may not presume to trespass. When, therefore, I announce as my subject on the present occasion some of the unsolved problems of this universal science, you need not be surprised if I should be somewhat discursive.

Perhaps I shall begin at the utmost limits of my subject by remarking that in matters of natural and physical science we are met at the outset with the scarcely solved question as to our own place in the nature which we study, and the bearing of this on the difficulties we encounter. The organism of man is decidedly a part of nature. We place ourselves, in this aspect, in the sub-kingdom vertebrata, and class mammalia, and recognize the fact that man is the terminal link in a chain of being, extending throughout geological time. But the organism is not all of man; and, when we regard man as a scientific animal, we raise a new question. If the human mind is a part of nature, then it is subject to natural law; and nature includes mind as well as matter. On the other hand, without being absolute idealists, we may hold that mind is more potent than matter, and nearer to the real essence of things. Our science is in any case necessarily dualistic, being the product of the reaction of mind on nature, and must be largely subjective and anthropomorphic. Hence, no doubt, arise much of the controversy of science, and much of the unsolved difficulty. We recognize this when we divide science into that which is experimental, or depends on apparatus, and that which is observational and classificatory, — distinctions, these, which relate not so much to the objects of science as to our methods of pursuing them. This view also opens up to us the thought that the domain of science is practically boundless: for who can set limits to the action of mind on the universe, or of the universe on mind? It follows that science must be limited on all sides by unsolved mysteries: and it will not serve any good purpose to meet these with clever guesses. If we so treat the enigmas of the sphinx nature, we shall surely be devoured. Nor, on the other hand, must we collapse into absolute despair, and resign ourselves to the confession of inevitable ignorance. It becomes us, rather, boldly to confront the unsolved questions of nature, and to wrestle with their difficulties till we master such as we can, and cheerfully leave those we cannot overcome to be grappled with by our successors.

Fortunately, as a geologist, I do not need to invite your attention to those transcendental questions which relate to the ultimate constitution of matter, the nature of the ethereal medium filling space, the absolute difference or identity of chemical elements, the cause of gravitation, the conservation and dissipation of energy, the nature of life, or the primary origin of bioplasmic matter. I may take the much more humble *rôle* of an inquirer into the unsolved or partially solved problems which meet us in considering that short and imperfect record which geology studies in the rocky layers of the earth's crust, and which leads no farther back than to the time when a solid rind had already formed on the earth and was already covered with an ocean. This record of geology covers but a small part of the history of the earth and of the system to which it belongs, nor does it enter at all into the more recondite problems involved; still it forms, I believe, some necessary preparation, at least, to the comprehension of these.

What do we know of the oldest and most primitive rocks? At this moment the question may be answered in many and discordant ways; yet the leading elements of the answer may be given very simply. The oldest rock formation known to geologists is the lower Laurentian, the fundamental gneiss, the Lewisian formation of Scotland, the Ottawa gneiss of Canada. This formation of enormous thickness corresponds to what the older geologists called the fundamental granite, — a name not to be scouted, for gneiss is only a stratified granite. Perhaps the main fact in relation to this old rock is that it is a gneiss; that is, a rock at once bedded and crystalline, and having for its dominant ingredient the mineral orthoclase, — a compound of silica, alumina, and potash, — in which are embedded, as in a paste, grains and crystals of quartz and hornblende. We know very well, from its texture and composition, that it cannot be a product of mere heat; and, being a bedded rock, we infer that it was laid down layer by layer, in the manner of aqueous deposits. On the other hand, its chemical composition is quite different from that of the muds, sands, and gravels usually deposited from water. Their special characters are caused by the fact that they have resulted from the slow decay of rocks like these gneisses, under the operation of carbonic acid and water, whereby the alkaline matter and the more soluble part of the silica have been washed away, leaving a residue mainly siliceous and aluminous. Such more modern rocks tell of dry land subjected to atmospheric decay and rainwash. If they have any direct relation to the old gneisses, they are their grandchildren, not their parents. On the contrary, the oldest gneisses show no pebbles, or sand, or limestone — nothing to indicate that there was then any land undergoing atmospheric waste, or shores with sand and gravel. For all that we know to the contrary, these old gneisses may have been deposited in a shoreless sea, holding in solution or suspension merely what it could derive from a submerged crust recently cooled from a state of fusion, still thin, and exuding here and there through its fissures heated waters and volcanic products.

It is scarcely necessary to say that I have no confidence in the supposition of unlike composition of the earth's mass on different sides, on which Dana has partly based his theory of the origin of continents. The most probable conception seems to be that of Lyell; namely, a molten mass, uniform except in so far as denser material might exist toward its centre, and a crust at first approximately even and homogeneous, and subsequently thrown into great bendings upward and downward. This question has recently been ably discussed by Mr. Crosby in the London *Geological magazine*.[1]

In short, the fundamental gneiss of the lower Laurentian may have been the first rock ever formed; and in any case it is a rock formed under conditions which have not since recurred, except locally. It constitutes the first and best example of these chemico-physical, aqueous or aqueo-igneous rocks, so characteristic of the earliest period of the earth's history. Viewed in this way, the lower Laurentian gneiss is probably the oldest kind of rock we shall ever know, — the limit to our backward progress, beyond which there remains nothing to the geologist, except physical hypotheses respecting a cooling, incandescent globe. For the chemical conditions of these primitive rocks, and what is known as to their probable origin, I must refer you to my friend Dr. Sterry Hunt, to whom we owe so much of what is known of the older crystalline rocks,[2] as well as of their literature and the questions which they raise. My purpose here is to sketch the remarkable difference which we meet as we ascend into the middle and upper Laurentian.

[1] June, 1883. [2] Hunt, Essays on chemical geology

In the next succeeding formation, the true lower Laurentian of Logan, the Grenville series of Canada, we meet with a great and significant change. It is true, we have still a predominance of gneisses which may have been formed in the same manner with those below them; but we find these now associated with great beds of limestone and dolomite, which must have been formed by the separation of calcium and magnesium carbonates from the sea-water, either by chemical precipitation or by the agency of living beings. We have also quartzite, quartzose gneisses, and even pebble beds, which inform us of sand-banks and shores. Nay, more, we have beds containing graphite which must be the residue of plants, and iron ores which tell of the deoxidation of iron oxide by organic matters. In short, here we have evidence of new factors in world-building, — of land and ocean, of atmospheric decay of rocks, of deoxidizing processes carried on by vegetable life on the land and in the waters, of limestone-building in the sea. To afford material for such rocks, the old Ottawa gneiss must have been lifted up into continents and mountain masses. Under the slow but sure action of the carbonic dioxide dissolved in rain-water, its felspar had crumbled down in the course of ages. Its potash, soda, lime, magnesia, and part of its silica, had been washed into the sea, there to enter into new combinations, and to form new deposits. The crumbling residue of fine clay and sand had been also washed down into the borders of the ocean, and had been there deposited in beds.[1] Thus the earth had entered into a new phase, which continues onward through the geological ages; and I place in your hands one key for unlocking the mystery of the world when I affirm that this great change took place, this new era was inaugurated, in the midst of the Laurentian period.

Was not this time a fit period for the first appearance of life? Should we not expect it to appear, independently of the evidence we have of the fact? I do not propose to enter here into that evidence, more especially in the case of the one well characterized Laurentian fossil, Eozoon canadense. I have already amply illustrated it elsewhere. I would merely say here, that we should bear in mind that in this later half of the lower Laurentian, or, if we so choose to style it, middle Laurentian period, we have the conditions required for life in the sea and on the land; and, since in other periods we know that life was always present when its conditions were present, it is not unreasonable to look for the first traces of life in this formation, in which we find for the first time the completion of those physical arrangements which make life, in such forms of it as exist on our planet, possible.

This is also a proper place to say something of the doctrine of what is termed 'metamorphism.' The Laurentian rocks are undoubtedly greatly changed from their original state, more especially in the matters of crystallization and the formation of desseminated minerals by the action of heat and heated water. Sandstones have thus passed into quartzites, clays into slates and schists, limestones into marbles. So far, metamorphism is not a doubtful question; but, when theories of metamorphism go so far as to suppose an actual change of one element for another, they go beyond the bounds of chemical credibility; yet such theories of metamorphism are often boldly advanced, and made the basis of important conclusions. Dr. Hunt has happily given the name 'metasomatosis' to this imaginary and impossible kind of metamorphism, which may be regarded as an extreme kind of evolution, akin to some of those forms of that theory employed with reference to life, but more easily detected and exposed. I would have it to be understood, that, in speaking of the metamorphism of the older crystalline rocks, it is not to this metasomatosis that I refer, and that I hold that rocks which have been produced out of the materials decomposed by atmospheric erosion can never, by any process of metamorphism, be restored to the precise condition of the Laurentian rocks. Thus there is in the older formations a genealogy of rocks, which, in the absence of fossils, may be used with some confidence, but which does not apply to the more modern deposits. Still, nothing in geology absolutely perishes or is altogether discontinued; and it is probable, that, down to the present day, the causes which produced the old Laurentian gneiss may still operate in limited localities. Then, however, they were general, not exceptional. It is further to be observed, that the term 'gneiss' is sometimes of wide and even loose application. Beside the typical orthoclase and hornblendic gneiss of the Laurentian, there are micaceous, quartzose, garnetiferous, and many other kinds of gneiss; and even gneissose rocks, which hold labradorite or anorthite instead of orthoclase, are sometimes, though not accurately, included in the term.

The Grenville series, or middle Laurentian, is succeeded by what Logan in Canada called the upper Laurentian, and which other geologists have called the Norite or Norian series. Here we still have our old friends the gneisses, but somewhat peculiar in type; and associated with them are great beds rich in lime-felspar, — the so-called labradorite and anorthite rocks. The precise origin of these is uncertain, but this much seems clear; namely, that they originated in circumstances in which the great limestones deposited in the lower or middle Laurentian were beginning to be employed in the manufacture, probably by aqueo-igneous agencies, of lime-felspars. This proves the Norian rocks to be much younger than the Laurentian, and that, as Logan supposed, considerable earth-movements had occurred between the two, implying lapse of time.

Next we have the Huronian of Logan, — a series much less crystalline and more fragmentary, and affording more evidence of land elevation and atmospheric and aqueous erosion, than any of the others. It has great conglomerates, some of them made up of rounded pebbles of Laurentian rocks, and others of quartz pebbles, which must have been the remains of rocks subjected to very perfect erosion. The pure

[1] Dr. Hunt has now in preparation for the press an important paper on this subject, read before the National academy of sciences.

quartz rocks tell the same tale, while limestones and slates speak also of chemical separation of the materials of older rocks. The Huronian evidently tells of movements in the previous Laurentian, and changes in its texture so great, that the former may be regarded as a comparatively modern rock, though vastly older than any part of the paleozoic series.

Still later than the Huronian is the great micaceous series called by Hunt the Mont Alban or White Mountain group, and the Taconian or lower Taconic of Emmons, which recalls in some measure the conditions of the Huronian. The precise relations of these to the later formations, and to certain doubtful deposits around Lake Superior, can scarcely be said to be settled, though it would seem that they are all older than the fossiliferous Cambrian rocks which practically constitute the base of the paleozoic. I have, I may say, satisfied myself, in regions which I have studied, of the existence and order of these rocks as successive formations, though I would not dogmatize as to the precise relations of those last mentioned, or as to the precise age of some disputed formations which may either be of the age of the older eozoic formations, or may be peculiar kinds of paleozoic rocks modified by metamorphism. Probably neither of the extreme views now agitated is absolutely correct.

After what has been said, you will perhaps not be astonished that a great geological battle rages over the old crystalline rocks. By some geologists they are almost entirely explained away, or referred to igneous action or to the alteration of ordinary sediments. Under the treatment of another school, they grow to great series of pre-Cambrian rocks, constituting vast systems of formations, distinguishable from each other, not by fossils, but by differences of mineral character. I have already indicated the manner in which I believe the dispute will ultimately be settled, and the president of the geological section will treat it more fully in his opening address.

After the solitary appearance of Eozoon in the Laurentian, and of a few uncertain forms in the Huronian and Taconian, we find ourselves in the Cambrian, in the presence of a nearly complete invertebrate fauna of protozoa, polyps, echinoderms, mollusks, and crustacea; and this not confined to one locality merely, but apparently extended simultaneously throughout the ocean. This sudden incoming of animal life, along with the subsequent introduction of successive groups of invertebrates, and finally of vertebrate animals, furnishes one of the greatest of the unsolved problems of geology, which geologists were wont to settle by the supposition of successive creations. In an address delivered at the Detroit meeting of the association in 1875, I endeavored to set forth the facts as to this succession, and the general principles involved in it, and to show the insufficiency of the theories of evolution suggested by biologists to give any substantial aid to the geologist in these questions. In looking again at the points there set forth, I find they have not been invalidated by subsequent discoveries, and that we are still nearly in the same position with respect to these great questions that we were in at that time, — a singular proof of the impotency of that deductive method of reasoning which has become fashionable among naturalists of late. Yet the discussions of recent years have thrown some additional light on these matters; and none more so than the mild disclaimers with which my friend Dr. Asa Gray and other moderate and scientific evolutionists have met the extreme views of such men as Romanes, Haeckel, Lubbock, and Grant Allen. It may be useful to note some of these as shedding a little light on this dark corner of our unsolved problems.

It has been urged on the side of rational evolution, that this hypothesis does not profess to give an explanation of the absolute origin of life on our planet, or even of the original organization of a single cell or of a simple mass of protoplasm, living or dead. All experimental attempts to produce by synthesis the complex albuminous substances, or to obtain the living from the non-living, have so far been fruitless; and, indeed, we cannot imagine any process by which such changes could be effected. That they have been effected we know; but the process employed by their maker is still as mysterious to us as it probably was to him who wrote the words, 'And God said let the waters swarm with swarmers.' How vast is the gap in our knowledge and our practical power implied in this admission, which must, however, be made by every mind not absolutely blinded by a superstitious belief in those forms of words which too often pass current as philosophy!

But if we are content to start with a number of organisms ready made, — a somewhat humiliating start, however, — we still have to ask, How do these vary so as to give new species? It is a singular illusion in this matter, of men who profess to be believers in natural law, that variation may be boundless, aimless, and fortuitous, and that it is by spontaneous selection from varieties thus produced that development arises. But surely the supposition of mere chance and magic is unworthy of science. Varieties must have causes, and their causes and their effects must be regulated by some law or laws. Now, it is easy to see that they cannot be caused by a mere innate tendency in the organism itself. Every organism is so nicely equilibrated, that it has no such spontaneous tendency, except within the limits set by its growth and the law of its periodical changes. There may, however, be equilibrium more or less stable. I believe all attempts hitherto made have failed to account for the fixity of certain, nay, of very many, types throughout geological time; but the mere consideration that one may be in a more stable state of equilibrium than another so far explains it. A rocking stone has no more spontaneous tendency to move than an ordinary bowlder, but it may be made to move with a touch. So it probably is with organisms. But, if so, then the causes of variation are external, as in many cases we actually know them to be; and they must depend on instability or change in surroundings, and this so arranged as not to be too extreme in amount, and to operate in some determinate direction. Observe how remarkable the unity of the adjustments involved in such a supposition. How superior they must be to our rude and always more or less unsuccessful attempts to produce and carry forward varieties and races in definite directions! This cannot be chance. If it exists, it must depend on plans deeply laid in the nature of things, else it would be most monstrous magic and causeless miracle. Still more certain is this conclusion when we consider the vast and orderly succession made known to us by geology, and which must have been regulated by fixed laws, only a few of which are as yet known to us.

Beyond these general considerations, we have others of a more special character, based on paleontological facts, which show how imperfect are our attempts, as yet, to reach the true causes of the introduction of genera and species.

One is the remarkable fixity of the leading types of living beings in geological time. If instead of framing, like Haeckel, fanciful phylogenies, we take the trouble, with Barrande and Gaudry, to trace the forms of life through the period of their existence, each along its own line, we shall be greatly struck with this, and especially with the continuous existence of many low types of life through vicissitudes of physical conditions of the most stupendous character, and over a lapse of time scarcely conceivable. What is still more remarkable is, that this holds in groups which, within certain limits, are perhaps the most variable of all. In the present world no creatures are individually more variable than the protozoa; as, for example, the foraminifera and the sponges. Yet these groups are fundamentally the same, from the beginning of the palaeozoic until now; and modern species seem scarcely at all to differ from specimens procured from rocks at least half-way back to the beginning of our geological record. If we suppose that the present sponges and foraminifera are the descendants of those of the Silurian period, we can affirm, that, in all that vast lapse of time, they have, on the whole, made little greater change than that which may be observed in variable forms at present. The same remark applies to other low animal forms. In forms somewhat higher and less variable, this is equally noteworthy. The pattern of the venation of the wings of cockroaches, and the structure and form of land-snails, gally-worms, and decapod crustaceans, were all settled in the carboniferous age in a way that still remains. So were the foliage and the fructification of club-mosses and ferns. If at any time members of these groups branched off, so as to lay the foundation of new species, this must have been a very rare and exceptional occurrence, and one demanding even some suspension of the ordinary laws of nature.

Certain recent utterances of eminent scientific men in England and France are most instructive with reference to the difficulties which encompass this subject. Huxley, at present the leader of English evolutionists, in his 'Rede lecture'[1] delivered at Cambridge, England, holds that there are only two 'possible alternative hypotheses' as to the origin of species, — (1) that of 'construction,' or the mechanical putting-together of the materials and parts of each new species separately; and (2) that of 'evolution,' or that one form of life 'proceeded from another' by the 'establishment of small successive differences.' After comparing these modes, much to the disadvantage of the first, he concludes with the statement that "this was his case for evolution, which he rested wholly on arguments of the kind he had adduced;" these arguments being the threadbare false analogy of ordinary reproduction and the transformation of species, and the mere succession of forms more or less similar in geological time, neither of them having any bearing whatever on the origin of any species or on the cause of the observed succession. With reference to the two alternatives, while it is true that no certain evidence has yet been obtained — either by experiment, observation, or sound induction — as to the mode of origin of any species, enough is known to show that there are numerous possible methods, grouped usually under the heads of absolute creation, mediate creation, critical evolution, and gradual evolution. It is also true that almost the only thing we certainly know in the matter, is that the differences characteristic of classes, orders, genera, and species, must have arisen, not in one or two, but in many ways. An instructive commentary on the capacity of our age to deal with these great questions is afforded by the fact that this little piece of clever mental gymnastic should have been practised in a university lecture and in presence of an educated audience. It is also deserving of notice, that, though the lecturer takes the development of the Nautili and their allies as his principal illustration, he evidently attaches no weight to the argument in the opposite sense deduced by Barrande — the man of all others most profoundly acquainted with these animals — from the paleozoic cephalopods.

Another example is afforded by a lecture recently delivered at the Royal institution in London by Professor Flower.[1] The subject is, 'The whales, past and present, and their probable origin.' The latter point, as is well known, Gaudry had candidly given up. "We have questioned," he says, "these strange and gigantic sovereigns of the tertiary oceans as to their ancestors, — they leave us without reply." Flower is bold enough to face this problem; and he does so in a fair and vigorous way, though limiting himself to the supposition of slow and gradual change. He gives up at once, as every anatomist must, the idea of an origin from fishes or reptiles. He thinks the ancestors of the whales must have been quadrupedal mammals. He is obliged for good reasons to reject the seals and the otters, and turns to the ungulates, though here, also, the difficulties are formidable. Finally he has recourse to an imaginary ancestor, supposed to have haunted marshes and rivers of the mesozoic age, and to have been intermediate between a hippopotamus and a dolphin, and omnivorous in diet. As this animal is altogether unknown to geology or zoölogy, and not much less difficult to account for than the whales themselves,

[1] Report in *Nature*, June 21, corrected by the author.

[1] Reported in *Nature*.

he very properly adds, 'Please to recollect, however, that this is a mere speculation.' He trusts, however, that such speculations are 'not without their use;' but this will depend upon whether or not they lead men's minds from the path of legitimate science into the quicksands of baseless conjecture.

Gaudry, in his recent work, 'Enchainements du monde animal,'[1] though a strong advocate of evolution, is obliged in his final *résumé* to say, "Il ne laisse point percer le mystère qui entoure le developpement primitif des grandes classes du monde animal. Nul homme ne sait comment ont été formés les premiers individus de foraminifères, de polypes, d'étoiles de mer, de crinoides, etc. Les fossiles primaires ne nous ont pas encore fourni de preuves positives du passage des animaux d'une classe à ceux d'une autre classe."

Professor Williamson of Manchester, in an address delivered in February last before the Royal institution of Great Britain, after showing that the conifers, ferns, and lycopods of the paleozoic have no known ancestry, uses the significant words, "The time has not yet arrived for the appointment of a botanical king-at-arms and constructor of pedigrees."

Another caution which a paleontologist has occasion to give with regard to theories of life has reference to the tendency of biologists to infer that animals and plants were introduced under embryonic forms, and at first in few and imperfect species. Facts do not substantiate this. The first appearance of leading types of life is rarely embryonic. On the contrary, they often appear in highly perfect and specialized forms; often, however, of composite type, and expressing characters afterwards so separated as to belong to higher groups. The trilobites of the Cambrian are some of them of few segments, and, so far, embryonic; but the greater part are many-segmented and very complex. The batrachians of the carboniferous present many characters higher than those of their modern successors, and now appropriated to the true reptiles. The reptiles of the Permian and trias usurped some of the prerogatives of the mammals. The ferns, lycopods, and equisetums of the Devonian and carboniferous were, to say the least, not inferior to their modern representatives. The shell-bearing cephalopods of the paleozoic would seem to have possessed structures now special to a higher group, that of the cuttle-fishes. The bald and contemptuous negation of these facts by Haeckel and other biologists does not tend to give geologists much confidence in their dicta.

Again: we are now prepared to say that the struggle for existence, however plausible as a theory, when put before us in connection with the productiveness of animals, and the few survivors of their multitudinous progeny, has not been the determining cause of the introduction of new species. The periods of rapid introduction of new forms of marine life were not periods of struggle, but of expansion, — those periods in which the submergence of continents afforded new and large space for their extension and comfortable subsistence. In like manner it was continental emergence that afforded the opportunity for the introduction of land animals and plants. Further, in connection with this, it is now an established conclusion, that the great aggressive faunas and floras of the continents have originated in the north, some of them within the arctic circle; and this in periods of exceptional warmth, when the perpetual summer sunshine of the arctic regions co-existed with a warm temperature. The testimony of the rocks thus is, that not struggle, but expansion, furnished the requisite conditions for new forms of life, and that the periods of struggle were characterized by depauperation and extinction.

But we are sometimes told that organisms are merely mechanical, and that the discussions respecting their origin have no significance, any more than if they related to rocks or crystals, because they relate merely to the organism considered as a machine, and not to that which may be supposed to be more important; namely, the great determining power of mind and will. That this is a mere evasion, by which we really gain nothing, will appear from a characteristic extract of an article by an eminent biologist, in the new edition of the Encyclopedia Britannica, — a publication which, I am sorry to say, instead of its proper *rôle* as a repertory of facts, has become a strong partisan, stating extreme and unproved speculations as if they were conclusions of science. The statement referred to is as follows: "A mass of living protoplasm is simply a molecular machine of great complexity, the total results of the working of which, or its vital phenomena, depend on the one hand on its construction, and, on the other, on the energy supplied to it; and to speak of vitality as any thing but the name for a series of operations is as if one should talk of the horologity of a clock." It would, I think, scarcely be possible to put into the same number of words a greater amount of unscientific assumption and unproved statement than in this sentence. Is 'living protoplasm' different in any way from dead protoplasm, and, if so, what causes the difference? What is a 'machine'? Can we conceive of a self-produced or uncaused machine, or one not intended to work out some definite results? The results of the machine in question are said to be 'vital phenomena;' certainly most wonderful results, and greater than those of any machine man has yet been able to construct. But why 'vital'? If there is no such thing as life, surely they are merely physical results. Can mechanical causes produce other than physical effects? To Aristotle, life was 'the cause of form in organisms.' Is not this quite as likely to be true as the converse proposition? If the vital phenomena depend on the 'construction' of the machine, and the 'energy supplied to it,' whence this construction, and whence this energy? The illustration of the clock does not help us to answer this question. The construction of the clock depends on its maker, and its energy is derived from the hand that winds it up. If we can think of a clock which no one has made and which no one winds, — a clock constructed by chance, set in harmony with the universe by chance,

[1] Paris, 1883.

wound up periodically by chance, — we shall then have an idea parallel to that of an organism living, yet without any vital energy or creative law; but in such a case we should certainly have to assume some antecedent cause, whether we call it 'horologity' or by some other name. Perhaps the term 'evolution' would serve as well as any other, were it not that common sense teaches that nothing can be spontaneously evolved out of that in which it did not previously exist.

There is one other unsolved problem, in the study of life by the geologist, to which it is still necessary to advert. This is the inability of paleontology to fill up the gaps in the chain of being. In this respect, we are constantly taunted with the imperfection of the record; but facts show that this is much more complete than is generally supposed. Over long periods of time and many lines of being, we have a nearly continuous chain; and, if this does not show the tendency desired, the fault is as likely to be in the theory as in the record. On the other hand, the abrupt and simultaneous appearance of new types in many specific and generic forms, and over wide and separate areas at one and the same time, is too often repeated to be accidental. Hence paleontologists, in endeavoring to establish evolution, have been obliged to assume periods of exceptional activity in the introduction of species, alternating with others of stagnation, — a doctrine differing very little from that of special creation as held by the older geologists.

The attempt has lately been made to account for these breaks by the assumption that the geological record relates only to periods of submergence, and gives no information as to those of elevation. This is manifestly untrue. In so far as marine life is concerned, the periods of submergence are those in which new forms abound for very obvious reasons already hinted. But the periods of new forms of land and fresh-water life are those of elevation, and these have their own records and monuments, often very rich and ample; as, for example, the swamps of the carboniferous, the transition from the cretaceous subsidence to the Laramie elevation, the tertiary lake-basins of the west, the terraces and raised beaches of the pleistocene. Had I time to refer in detail to the breaks in the continuity of life, which cannot be explained by the imperfection of the record, I could show at least that nature, in this case, does advance *per saltum*, — by leaps, rather than by a slow continuous process. Many able reasoners, as LeConte in this country, and Mivart and Collard in England, hold this view.

Here, as elsewhere, a vast amount of steady conscientious work is required to enable us to solve the problems of the history of life. But, if so, the more the hope for the patient student and investigator. I know nothing more chilling to research, or unfavorable to progress, than the promulgation of a dogmatic decision that there is nothing to be learned but a merely fortuitous and uncaused succession, amenable to no law, and only to be covered, in order to hide its shapeless and uncertain proportions, by the mantle of bold and gratuitous hypothesis.

So soon as we find evidence of continents and oceans, we raise the question, "Have these continents existed from the first in their present position and form, or have the land and water changed places in the course of geological time?" In reality both statements are true in a certain limited sense. On the one hand, any geological map whatever suffices to show that the general outline of the existing land began to be formed in the first and oldest crumplings of the crust. On the other hand, the greater part of the surface of the land consists of marine sediments which must have been derived from land that has perished in the process, while all the continental surfaces, except, perhaps, some high peaks and ridges, have been many times submerged. Both of these apparently contradictory statements are true; and, without assuming both, it is impossible to explain the existing contours and reliefs of the surface.

In the case of North America, the form of the old nucleus of Laurentian rock in the north already marks out that of the finished continent, and the successive later formations have been laid upon the edges of this, like the successive loads of earth dumped over an embankment. But in order to give the great thickness of the paleozoic sediments, the land must have been again and again submerged, and for long periods of time. Thus, in one sense, the continents have been fixed; in another, they have been constantly fluctuating. Hall and Dana have well illustrated these points in so far as eastern North America is concerned. Professor Hull of the Geological survey of Ireland has recently had the boldness to reduce the fluctuations of land and water, as evidenced in the British Islands, to the form of a series of maps intended to show the physical geography of each successive period. The attempt is probably premature, and has been met with much adverse criticism; but there can be no doubt that it has an element of truth. When we attempt to calculate what could have been supplied from the old eozoic nucleus by decay and aqueous erosion, and when we take into account the greater local thickness of sediments towards the present sea-basins, we can scarcely avoid the conclusion that extensive areas once occupied by high land are now under the sea. But to ascertain the precise areas and position of these perished lands may now be impossible.

In point of fact, we are obliged to believe in the contemporaneous existence in all geological periods, except perhaps the very oldest, of three sorts of areas on the surface of the earth: 1. Oceanic areas of deep sea, which must always have occupied the bed of the present ocean, or parts of it; 2. Continental plateaus, sometimes existing as low flats or as higher tablelands, and sometimes submerged; 3. Areas of plication or folding, more especially along the borders of the oceans, forming elevated lands rarely submerged, and constantly affording the material of sedimentary accumulations.

Every geologist knows the contention which has been occasioned by the attempts to correlate the earlier paleozoic deposits of the Atlantic margin of North America with those forming at the same time on the interior plateau, and with those of intervening lines of plication and igneous disturbance. Stratigraphy, lithology, and fossils are all more or less at fault in dealing with these questions; and, while the general nature of the problem is understood by many geologists, its solution in particular cases is still a source of apparently endless debate.

The causes and mode of operation of the great movements of the earth's crust which have produced mountains, plains, and tablelands, are still involved in some mystery. One patent cause is the unequal settling of the crust toward the centre; but it is not so generally understood as it should be, that the greater settlement of the ocean-bed has necessitated its pressure against the sides of the continents in the same manner that a huge ice-floe crushes a ship or a pier. The geological map of North America shows this at a glance, and impresses us with the fact that large portions of the earth's crust have not only been folded, but bodily pushed back for great distances. On looking at the extreme north, we see that the great Laurentian mass of central Newfoundland has acted as a protecting pier to the space immediately west of it, and has caused the Gulf of St. Lawrence to remain an undisturbed area since paleozoic times. Immediately to the south of this, Nova Scotia and New Brunswick are folded back. Still farther south, as Guyot has shown, the old sediments have been crushed in sharp folds against the Adirondack mass, which has sheltered the tableland of the Catskills and of the Great Lakes. South of this again, the rocks of Pennsylvania and Maryland have been driven back in a great curve to the west. Nothing, I think, can more forcibly show the enormous pressure to which the edges of the continents have been exposed, and at the same time the great sinking of the ocean-beds. Complex and difficult to calculate though these movements of plication are, they are more intelligible than the apparently regular pulsations of the flat continental areas, whereby they have alternately been below and above the waters, and which must have depended on somewhat regularly recurring causes, connected either with the secular cooling of the earth, or with the gradual retardation of its rotation, or with both. Throughout these changes, each successive elevation exposed the rocks for long ages to the decomposing influence of the atmosphere. Each submergence swept away, and deposited as sediment, the material accumulated by decay. Every change of elevation was accompanied with changes of climate and with modifications of the habitats of animals and plants. Were it possible to restore accurately the physical geography of the earth in all these respects, for each geological period, the data for the solution of many difficult questions would be furnished.

It is an unfortunate circumstance, that conclusions in geology arrived at by the most careful observation and induction do not remain undisturbed, but require constant vigilance to prevent them from being overthrown. Sometimes, of course, this arises from new discoveries throwing new light on old facts; but when this occurs it rarely works the complete subversion of previously received views. The more usual case is, that some over-zealous specialist suddenly discovers what seems to him to overturn all previous beliefs, and rushes into print with a new and plausible theory, which at once carries with him a host of half-informed people, but the insufficiency of which is speedily made manifest.

Had I written this address a few years ago, I might have referred to the mode of formation of coal as one of the things most surely settled and understood. The labors of many eminent geologists, microscopists, and chemists in the old and the new worlds had shown that coal nearly always rests upon old soil surfaces penetrated with roots, and that coal-beds have in their roofs erect trees, the remains of the last forests that grew upon them. Logan and I have illustrated this in the case of the series of more than sixty successive coal-beds exposed at the South Joggins, and have shown unequivocal evidence of land-surfaces at the time of the deposition of the coal. Microscopical examination has proved that these coals are composed of the materials of the same trees whose roots are found in the underclays, and their stems and leaves in the roof-shales; that much of the material of the coal has been subjected to sub-aerial decay at the time of its accumulation; and that in this, ordinary coal differs from bituminous shale, earthy bitumen, and some kinds of cannel, which have been formed under water; that the matter remaining as coal consists almost entirely of epidermal tissues, which, being suberose in character, are highly carbonaceous, very durable, and impermeable by water,[1] and are hence the best fitted for the production of pure coal; and finally that the vegetation and the climatal and geographical features of the coal period were eminently fitted to produce in the vast swamps of that period precisely the effects observed. All these points and many others have been thoroughly worked out for both European and American coal-fields, and seemed to leave no doubt on the subject. But several years ago certain microscopists observed on slices of coal layers filled with spore-cases, — a not unusual circumstance, since these were shed in vast abundance by the trees of the coal-forests, and because they contain suberose matter of the same character with epidermal tissues generally. Immediately we were informed that all coal consists of spores; and, this being at once accepted by the unthinking, the results of the labors of many years are thrown aside in favor of this crude and partial theory. A little later, a German microscopist has thought proper to describe coal as made up of minute algae, and tries to reconcile this view with the appearances, devising at the same time a new and formidable nomenclature of generic and specific names, which would seem largely to represent mere fragments of tissues. Still later, some local facts in a French coal-field have induced an eminent botanist of that country to revive the drift theory of coal, in opposition to that of growth *in situ*. A year or two ago, when my friend Professor Williamson of Manchester informed me that he was preparing a large series of slices of coal with the view of revis-

[1] Acadian geology, third edition, supplement, p. 68.

ing the whole subject, I was inclined to say, that after what had been done by Lyell, Goeppert, Logan, Hunt, Newberry, and myself, this was scarcely necessary; but, in view of what I have just stated, it may be that all he can do will be required to rescue from total ruin the results of our labors.

An illustration of a different character is afforded by the controversy now raging with respect to the so-called fucoids of the ancient rocks. At one time the group of fucoids, or algae, constituted a general place of refuge for all sorts of unintelligible forms and markings; graptolites, worm-trails, crustacean tracks, shrinkage-cracks, and, above all, rill-markings, forming a heterogeneous group of fucoidal remains distinguished by generic and specific names. To these were also added some true land-plants badly preserved, or exhibiting structures not well understood by botanists. Such a group was sure to be eventually dismembered. The writer has himself done something toward this,[1] but Professor Nathorst has done still more;[2] and now some intelligible explanation can be given of many of these forms. Quite recently, however, the Count de Saporta, in an elaborate illustrated memoir,[3] has come to the defence of the fucoids, more especially against the destructive experiments of Nathorst, and would carry back into the vegetable kingdom many things which would seem to be mere trails of animals. While writing this address, I have received from Professor Crié of Rennes a paper in which he not only supports the algal nature of Rusichnites, Arthrichnites, and many other supposed fucoids, but claims for the vegetable kingdom even Receptaculites and Archaeocyathus. It is not to be denied that some of the facts which he cites, respecting the structure of the Siphoniae and of certain modern incrusting algae, are very suggestive, though I cannot agree with his conclusions. My own experience has convinced me, that, while non-botanical geologists are prone to mistake all kinds of markings for plants, even good botanists, when not familiar with the chemical and mechanical conditions of fossilization, and with the present phenomena of tidal shores, are quite as easily misled, though they are very prone, on the other hand, to regard land-plants of some complexity, when badly preserved, as mere algae. In these circumstances it is very difficult to secure any consensus, and the truth is only to be found by careful observation of competent men. One trouble is, that these usually obscure markings have been despised by the greater number of paleontologists, and probably would not now be so much in controversy were it not for the use made of them in illustrating supposed phylogenies of plants.

It would be wrong to close this address without some reference to that which is the veritable *pons asinorum* of the science, the great and much debated glacial period. I trust that you will not suppose, that, in the end of an hour's address, I am about to discuss this vexed question. Time would fail me even to name the hosts of recent authors who have contended in this arena. I can hope only to point out a few landmarks which may aid the geological adventurer in traversing the slippery and treacherous surface of the hypothetical ice-sheet of pleistocene times, and in avoiding the yawning crevasses by which it is traversed.

No conclusions of geology seem more certain than that great changes of climate have occurred in the course of geological time; and the evidence of this in that comparatively modern period which immediately preceded the human age is so striking that it has come to be known as pre-eminently the ice age, while, in the preceding tertiary periods, temperate conditions seem to have prevailed even to the pole. Of the many theories as to these changes which have been proposed, two seem at present to divide the suffrages of geologists, either alone, or combined with each other. These are, (1) the theory of the precession of the equinoxes in connection with the varying eccentricity of the earth's orbit, advocated more especially by Croll; and (2) the different distribution of land and water as affecting the reception and radiation of heat and the ocean-currents, — a theory ably propounded by Lyell, and subsequently extensively adopted, either alone or with the previous one. One of these views may be called the astronomical; the other, the geographical. I confess that I am inclined to accept the second or Lyellian theory for such reasons as the following: 1. Great elevations and depressions of land have occurred in and since the pleistocene, while the alleged astronomical changes are not certain, more especially in regard to their probable effect on the earth; 2. When the rival theories are tested by the present phenomena of the southern polar region and the North Atlantic, there seem to be geographical causes adequate to account for all except extreme and unproved glacial conditions; 3. The astronomical cause would suppose regularly recurring glacial periods of which there is no evidence, and it would give to the latest glacial age an antiquity which seems at variance with all other facts; 4. In those more northern regions where glacial phenomena are most pronounced, the theory of floating sheets of ice, with local glaciers descending to the sea, seems to meet all the conditions of the case; and these would be obtained, in the North Atlantic at least, by very moderate changes of level, causing, for example, the equatorial current to flow into the Pacific, instead of running northward as a gulf stream; 5. The geographical theory allows the supposition not merely of vicissitudes of climate quickly following each other in unison with the movements of the surface, but allows also of that near local approximation of regions wholly covered with ice and snow, and others comparatively temperate, which we see at present in the north.

If, however, we are to adopt the geographical theory, we must avoid extreme views; and this leads to the inquiry as to the evidence to be found for any such universal and extreme glaciation as is demanded by some geologists.

[1] Footprints and impressions on carboniferous rocks, *Amer. journ. sc.*, 1873.

[2] Royal Swedish academy, Stockholm, 1881.

[3] Apropos des algues fossiles, Paris, 1883.

The only large continental area in the northern hemisphere supposed to be entirely ice- and snow-clad is Greenland; and this, so far as it goes, is certainly a local case, for the ice and snow of Greenland extend to the south as far as 60° N. latitude, while both in Norway and in the interior of North America the climate in that latitude permits the growth of cereals. Further, Grinnel Land, which is separated from North Greenland only by a narrow sound, has a comparatively mild climate, and, as Nares has shown, is covered with verdure in summer. Still further, Nordenskiöld, one of the most experienced arctic explorers, holds that it is probable that the interior of Greenland is itself verdant in summer, and is at this moment preparing to attempt to reach this interior oasis. Nor is it difficult, with the aid of the facts cited by Woeickoff and Whitney,[1] to perceive the cause of the exceptional condition of Greenland. To give ice and snow in large quantities, two conditions are required, — first, atmospheric humidity; and, secondly, cold precipitating regions. Both of these conditions meet in Greenland. Its high coast-ranges receive and condense the humidity from the sea on both sides of it and to the south. Hence the vast accumulation of its coast snow-fields, and the intense discharge of the glaciers emptying out of its valleys. When extreme glacialists point to Greenland, and ask us to believe that in the glacial age the whole continent of North America as far south as the latitude of 40° was covered with a continental glacier, in some places several thousands of feet thick, we may well ask, first, what evidence there is that Greenland, or even the antarctic continent, at present shows such a condition; and, secondly, whether there exists a possibility that the interior of a great continent could ever receive so large an amount of precipitation as that required. So far as present knowledge exists, it is certain that the meteorologist and the physicist must answer both questions in the negative. In short, perpetual snow and glaciers must be local, and cannot be continental, because of the vast amount of evaporation and condensation required. These can only be possible where comparatively warm seas supply moisture to cold and elevated land; and this supply cannot, in the nature of things, penetrate far inland. The actual condition of interior Asia and interior America in the higher northern latitudes affords positive proof of this. In a state of partial submergence of our northern continents, we can readily imagine glaciation by the combined action of local glaciers and great ice-floes; but, in whatever way the phenomena of the bowlder clay and of the so-called terminal moraines are to be accounted for, the theory of a continuous continental glacier must be given up.

I cannot better indicate the general bearing of facts, as they present themselves to my mind in connection with this subject, than by referring to a paper by Dr. G. M. Dawson on the distribution of drift over the great Canadian plains east of the Rocky Mountains.[2] I am the more inclined to refer to this, because of its recency, and because I have so often repeated similar conclusions as to eastern Canada and the region of the Great Lakes.

The great interior plain of western Canada, between the Laurentian axis on the east and the Rocky Mountains on the west, is seven hundred miles in breadth, and is covered with glacial drift, presenting one of the greatest examples of this deposit in the world. Proceeding eastward from the base of the Rocky Mountains, the surface, at first more than four thousand feet above the sea-level, descends by successive steps to twenty-five hundred feet, and is based on cretaceous and Laramie rocks, covered by bowlder clay and sand, in some places from one hundred to two hundred feet in depth, and filling up pre-existing hollows, though itself sometimes piled into ridges. Near the Rocky Mountains the bottom of the drift consists of gravel not glaciated. This extends to about one hundred miles east of the mountains, and must have been swept by water out of their valleys. The bowlder clay resting on this deposit is largely made up of local *débris*, in so far as its paste is concerned. It contains many glaciated bowlders and stones from the Laurentian region to the east, and also smaller pebbles from the Rocky Mountains; so that at the time of its formation there must have been driftage of large stones for seven hundred miles or more from the east, and of smaller stones from a less distance on the west. The former kind of material extends to the base of the mountains, and to a height of more than four thousand feet. One bowlder is mentioned as being forty-two by forty by twenty feet in dimensions. The highest Laurentian bowlders seen were at an elevation of forty-six hundred and sixty feet, on the base of the Rocky Mountains. The bowlder clay, when thick, can be seen to be rudely stratified, and at one place includes beds of laminated clay with compressed peat, similar to the forest beds described by Worthen and Andrews in Illinois, and the so-called interglacial beds described by Hinde on Lake Ontario. The leaf-beds on the Ottawa River, and the drift-trunks found in the bowlder clay of Manitoba, belong to the same category, and indicate that throughout the glacial period there were many forest oases far to the north. In the valleys of the Rocky Mountains opening on these plains there are evidences of large local glaciers now extinct, and similar evidences exist on the Laurentian highlands on the east.

Perhaps the most remarkable feature of the region is that immense series of ridges of drift piled against an escarpment of Laramie and cretaceous rocks, at an elevation of about twenty-five hundred feet, and known as the 'Missouri coteau.' It is in some places thirty miles broad and a hundred and eighty feet in height above the plain at its foot, and extends north and south for a great distance; being, in fact, the northern extension of those great ridges of drift which have been traced south of the Great Lakes, and through Pennsylvania and New Jersey, and which figure on the geological maps as the edge of the continental glacier, — an explanation obviously inappli-

[1] Memoir on glaciers, Geol. soc. Berlin, 1881. Climatic changes, Boston, 1883.

[2] SCIENCE, July 1, 1883.

cable in those western regions where they attain their greatest development. It is plain that in the north it marks the western limit of the deep water of a glacial sea, which at some periods extended much farther west, perhaps with a greater proportionate depression in going westward, and on which heavy ice from the Laurentian districts on the east was wafted south-westward by the arctic currents, while lighter ice from the Rocky Mountains was being borne eastward from these mountains by the prevailing westerly winds. We thus have in the west, on a very wide scale, the same phenomena of varying submergence, cold currents, great ice-floes, and local glaciers producing icebergs, to which I have attributed the bowlder clay and upper bowlder drift of eastern Canada.

A few subsidiary points I may be pardoned for mentioning here. The rival theories of the glacial period are often characterized as those of land glaciation and sea-borne icebergs. But it must be remembered, that those who reject the idea of a continental glacier hold to the existence of local glaciers on the high lands more or less extensive during different portions of the great pleistocene submergence. They also believe in the extension of these glaciers seawards and partly water-borne, in the manner so well explained by Mattieu Williams; in the existence of those vast floes and fields of current- and tide-borne ice whose powers of transport and erosion we now know to be so great; and in a great submergence and re-elevation of the land, bringing all parts of it and all elevations up to five thousand feet successively under the influence of these various agencies, along with those of the ocean-currents. They also hold, that, at the beginning of the glacial submergence, the land was deeply covered by decomposed rock, similar to that which still exists on the hills of the southern states, and which, as Dr. Hunt has shown, would afford not only earthy *débris*, but large quantities of bowlders ready for transportation by ice.

I would also remark, that there has been the greatest possible exaggeration as to the erosive action of land-ice. In 1865, after a visit to the alpine glaciers, I maintained that in these mountains glaciers are relatively protective rather than erosive agencies, and that the detritus which the glacier streams deliver is derived mostly from the atmospherically wasted peaks and cliffs that project above them. Since that time many other observers have maintained like views, and very recently Mr. Davis of Cambridge and Mr. A. Irving have ably treated this subject.[1] Smoothing and striation of rocks are undoubtedly important effects, both of land-glaciers and heavy sea-borne ice; but the levelling and filling agency of these is much greater than the erosive. As a matter of fact, as Newberry, Hunt, Belt, Spencer, and others have shown, the glacial age has dammed up vast numbers of old channels which it has been left for modern streams partially to excavate.

The till, or bowlder clay, has been called a 'ground moraine,' but there are really no alpine moraines at all corresponding to it. On the other hand, it is more or less stratified, often rests on soft materials which glaciers would have swept away, sometimes contains marine shells, or passes into marine clays in its horizontal extension, and invariably in its embedded bowlders and its paste shows an unoxidized condition, which could not have existed if it had been a sub-aerial deposit. When the Canadian till is excavated, and exposed to the air, it assumes a brown color, owing to oxidation of its iron; and many of its stones and bowlders break up and disintegrate under the action of air and frost. These are unequivocal signs of a sub-aqueous deposit. Here and there we find associated with it, and especially near the bottom and at the top, indications of powerful water-action, as if of land-torrents acting at particular elevations of the land, or heavy surf and ice action on coasts; and the attempts to explain these by glacial streams have been far from successful. A singular objection sometimes raised against the sub-aqueous origin of the till is its general want of marine remains, but this is by no means universal; and it is well known that coarse conglomerates of all ages are generally destitute of fossils, except in their pebbles; and it is further to be observed, that the conditions of an ice-laden sea are not those most favorable for the extension of marine life, and that the period of time covered by the glacial age must have been short, compared with that represented by some of the older formations.

This last consideration suggests a question which might afford scope for another address of an hour's duration, — the question how long time has elapsed since the close of the glacial period. Recently the opinion has been gaining ground that the close of the ice age is very recent. Such reasons as the following lead to this conclusion: the amount of atmospheric decay of rocks and of denudation in general, which have occurred since the close of the glacial period, are scarcely appreciable; little erosion of river-valleys or of coast-terraces has occurred. The calculated recession of waterfalls and of production of lake-ridges lead to the same conclusion. So do the recent state of bones and shells in the pleistocene deposits, and the perfectly modern facies of their fossils. On such evidence the cessation of the glacial cold and settlement of our continents at their present levels are events which may have occurred not more than six thousand or seven thousand years ago, though such time estimates are proverbially uncertain in geology. This subject also carries with it the greatest of all geological problems, next to that of the origin of life; namely, the origin and early history of man. Such questions cannot be discussed in the closing sentences of an hour's address. I shall only draw from them one practical inference. Since the comparatively short post-glacial and recent periods apparently include the whole of human history, we are but new-comers on the earth, and therefore have had little opportunity to solve the great problems which it presents to us. But this is not all. Geology as a science scarcely dates from a century ago.

[1] *Proc. Bost. soc. nat. hist.*, xxii. *Journ. geol. soc. Lond.*, Feb., 1883.

We have reason for surprise in these circumstances, that it has learned so much, but for equal surprise that so many persons appear to think it a complete and full-grown science, and that it is entitled to speak with confidence on all the great mysteries of the earth that have been hidden from the generations before us. Such being the newness of man and of his science of the earth, it is not too much to say that humility, hard work in collecting facts, and abstinence from hasty generalization, should characterize geologists, at least for a few generations to come.

In conclusion, science is light, and light is good; but it must be carried high, else it will fail to enlighten the world. Let us strive to raise it high enough to shine over every obstruction which casts any shadow on the true interests of humanity. Above all, let us hold up the light, and not stand in it ourselves.

LETTERS TO THE EDITOR.

**** Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Kalmias and rhododendrons.

June 16 of the present summer I chanced to be floating down Crossweeksung Creek in my canoe; and, at a bend in the stream, found myself at the foot of a steep bluff some seventy feet high, which was densely covered with a luxuriant growth of kalmias and rhododendrons in full bloom. The former were laden with magnificent clusters of white, waxy flowers; and the more gorgeous pink rhododendron-blossoms were scattered through them. It was the most beautiful floral display I had ever seen.

On my return home, I turned to the description by Kalm of the smaller of these shrubs, to which Linné gave the generic name it now bears in honor of its discoverer. Kalm writes, "Linnaeus, conformable to the peculiar friendship and goodness which he has always honored me with, has been pleased to call this tree Kalmia." He further says, "The spoon-tree, which never grows to a great height, we saw this day in several places. The Swedes here have called it thus, because the Indians, who formerly lived in these provinces, used to make their spoons and trowels of the wood of this tree. In my cabinet of curiosities I have a spoon made of this wood by an Indian." Again he says, "About the month of May they begin to flower in these parts (central New Jersey), and then their beauty rivals that of most of the known trees in nature. The flowers are innumerable, and sit in great bunches," etc.

Kalm was visiting in New Jersey when he wrote the above; and it may be that where he was at the time (Swedesboro, Gloucester county), the rhododendron is not found. At all events, he nowhere mentions this shrub, which is here known as 'mountain laurel' to distinguish it from the true kalmia. In calling the latter the 'spoon-tree,' has he confounded the two? Certainly his remarks on the character of the wood, and the use to which it was formerly put by the Indians, lead to that conclusion. At present, it would be difficult to find a sufficiently large growth of kalmia to enable an Indian to whittle from it a spoon or trowel of respectable size. From rhododendron-stocks, implements of considerable size can be made; and Professor Kalm's description of kalmia wood is equally applicable to it. He describes it as "very hard, may be made very smooth, and does not easily crack or burst."

In Britton's Flora of New Jersey, Kalmia latifolia is called 'spoon-wood,' which name, I suppose, is derived from the remarks made by Kalm, as above quoted. I suggest that it is a misnomer, and that the remarks on the uses of the wood made by the distinguished Swedish naturalist refer really to the rhododendron.

Considering that Kalm was so careful an observer, was particularly interested in botany, and further, not only enjoyed the friendship of Bartram, but frequently visited him, in whose celebrated garden was a rhododendron-grove, it is strange that no mention is made, in his 'Travels in North America,' of the larger 'laurel,' so called; yet such appears to be the case.

This is an unimportant matter perhaps, but, if I am right, should not go uncorrected.

Charles C. Abbott, M.D.

Trick of the English sparrow.

A curious freak of the imported sparrow recently came to my notice at Basin Harbor, on Lake Champlain, in Vermont.

The eaves-swallows had attached their mud 'retorts,' as usual, in line under the eaves of the farmer's barn, anticipating, no doubt, a successful and happy house-keeping, notwithstanding a colony of feathered foreigners had encamped about the premises.

At sight of these 'bottle-nosed' dwellings, now arriving at completion, it occurred to the little tramps that these were exactly the thing they wanted; but, as the apartments were not to let, a battle ensued, which resulted in the rout of Lunifrons. The sparrows then took possession of the mud-houses, and furnished them to their own taste. But some of the 'masons' made a successful resistance, and still held the castle; so that often a swallow-family had their arch enemy at next door.

Thus in more ways than one does the impudent little urchin, which has come to us from over the sea, merit the name of *parasite*. Now that the bird has become not only a general nuisance, but a sore annoyance to our native and useful birds, it is no wonder if the cry goes up all over the land, '*The sparrow must be blotted out!*'

F. H. Herrick.

Achenial hairs of Senecio.

In a paper read before the American association for the advancement of science at Montreal, Professor Macloskie referred to the achenial hairs of some of the Compositae. The paper was afterward published in the *American naturalist* for January, 1883; and here we find a figure showing the tubes issuing from the hairs of Senecio. A beautiful experiment showing these tubes, or rather threads, can be made with the achenes of S. Douglasii. Scraping a few of the hairs from an achene, and placing them on a slide under the microscope with a two-thirds objective, and applying a drop of water to the slide, the threads are seen to uncoil. As soon as the water touches the hairs, the tips seem to burst, and allow the threads to emerge, rapidly twisting round and round in a very snake like manner. The experiment is a most satisfactory one, and can be readily made. These threads were noticed long ago, as Lindley (Veg. king., p. 701–705) speaks of Decaisne having seen them. Lindley says in regard to them, "On placing one of these papillae in water, it immediately separates into two lips, and these emit mucilaginous tubes, which issue forth like wires, spirally unrolling themselves, and finally much exceed the papillae from which they proceed. These tubes are apparently formed by a very considerable number of threads placed one upon the other in the manner of a skein of thread." I do not know of any explanation of the use of these threads. Can any of your readers suggest a purpose for them?

Jos. F. James.

Cincinnati, O., Aug. 2, 1883.

Seeds of Lepidium.

I regret to observe, by your issue of July 27, that my employment of the expression 'mucilaginous threads' as to the seeds of Lepidium has led your reviewer to understand that I referred to something like the seed-fibres of Collomia. Spiral fibres embedded in mucilage are found on the seeds of Collomia; radiating processes consisting of mucilage, each tipped by a facet of cuticle, are emitted by the seeds of Lepidium virginicum. This is shown on the application of water with staining-fluid to ripe seeds. Other species of Lepidium (including L. ruderale) show the same phenomenon, though the experiment may fail with immature seeds or old herbarium specimens.

G. Macloskie.

Princeton, N.J., Aug. 3, 1883.

["The exotest may bear long hairs (cotton) or spiral threads. . . . In Lepidium (pepper-grass), on being moistened, it darts out mucilaginous threads" It certainly may be gathered from this that the 'spiral threads' and the 'mucilaginous threads' are not the very same. But the darting-out of mucilaginous threads so well describes what one sees in Collomia-seeds and the like, and so poorly answers to what takes place in those of Lepidium, that the reviewer supposed there might be some mixing up of cases. But he simply asked whether the author was sure of the threads in Lepidium. We find nothing to which the name of 'mucilaginous threads' can with any exactness be applied; nor do we think that the term now used of 'radiating processes,' though not widely amiss, gives a clear idea of the case, which we should describe thus: —

A superficial pellicle of the seed-coat of Lepidium consists of a single and continuous layer of cells, the thick walls of which are at maturity converted into mucilage, or into an isomer of cellulose, which swells up into mucilage 'upon the application of water.' But the water acts so promptly in forming the *limbus* around the seed or its section, that we fail in that way to get an intelligible view of the structure and the nature of the process. To do this, however, we have only to soak thin sections of the seed in strong alcohol, examine in them the unaltered mucilage-cells, and then add a little water by degrees. The cells then swell up slowly, push outward radially (for mutual pressure prevents lateral expansion at the beginning), become wedge-shaped or pear-shaped as they farther protrude, and at length form the well-known mucilaginous *limbus*. Dr. Macloskie will be interested in repeating this experiment, and will accept our apology for partially misunderstanding him.]

KONKOLY'S ASTRONOMICAL INSTRUMENTS.

Praktische anleitung zur anstellung astronomischen beobachtungen, mit besonderen rücksicht auf die astrophysik, nebst einer modernen instrumentenkunde. Von Nicolaus von Konkoly. Braunschweig, *Vieweg*, 1883. 912 p., 345 illustr. 8°.

This is an important but at the same time a disappointing work. It contains the description and representation of nearly all the principal modern astronomical instruments, and presents such a comprehensive summary as can be found in no other existing book. The numerous illustrations, largely derived from the business catalogues of leading instrument-makers, are generally excellent, and the mechanical execution and press-work are admirable. Undoubtedly the book is one which must have a place in every astronomical library.

At the same time, the work is far from exhaustive, omitting all mention of many of the latest and most useful improvements; and it is not always accurate in its description of those it does notice. Nor does it deal in any thorough or satisfactory manner with the theory of the instruments described. It is so full and so good, that it is a great pity that it is not still better and still more complete, as it easily might have been.

The first chapter, on time-keepers (*uhren*), describes, among clock-escapements, only the old Graham dead-beat and a duplex of Jürgensen's. There is no notice of Airy's detached escapement, now in use at Greenwich, nor of any of the numerous and excellent gravity-escapements now so common in England and this country. The account of electric make and break circuit apparatus is for this reason unsatisfactory, since only escapements of the detached class admit of a simple break-circuit which does not affect the pendulum. The author treats the subject rather extensively, describing no less than twelve different forms of contact apparatus, some of them very elaborate and complicated. The antiquated contrivances of Locke and Mitchell are described as if they continued to be in use.

The second chapter, a short one, deals with the different forms of levels and level-testers, and appears to be in all respects satisfactory.

The third chapter treats of instruments for the determination of time. Under this head are included not only transits and transit-circles, but all forms of theodolites, sextants, passage-prisms, etc. There is also a certain amount of information respecting the graduation of circles and the methods of testing their accuracy, i.e., the optical and mechanical arrangements; the mathematical theory remaining untouched.

The next chapter, the fourth, is by far the most extensive and full of any, occupying two hundred and forty-six pages. It treats of equatorials and their mounting, and describes and illustrates nearly all the important modern telescopes. For the most part, it is well done, especially the portion relating to driving-clocks.

It is evident, however, that the author does not fully grasp all the principles involved in these machines, or he would hardly have spoken so disparagingly of the 'spring-governor' of Bond, which is unquestionably, when properly adjusted, one of the most perfect of all. In so full a treatment of the subject, one would naturally expect to find some notice of the ingenious arrangement by which the clock-work of the Dun Echt equatorial is brought under the electric control of the standard timepiece; but it is missing, though Grubb's less perfect apparatus for the same purpose is fully described.

The fifth chapter, dealing with micrometers, calls for no special notice, beyond the remark that it strikes one as a curious classification which treats of *chronographs* in this connection.

The sixth chapter is a short one, describing the different forms of helioscopes and solar eye-pieces, and the most convenient arrangements for making drawings of sun-spots and determining their position.

The seventh chapter is intended to be a full and elaborate description of the different forms of astronomical spectroscopes, with their accessories. It does describe and figure a great many; but there are several mistakes (as, for instance, on p. 656, where the temporary device which Professor Young employed in observing the eclipse of 1869 is said to have been used with a heliostat, and is spoken of as if it were now used at Princeton), and there is the capital omission of failing even to mention the use of diffraction-gratings in spectroscopic work. It strikes one as very surprising that the author should not have learned that for solar observations the grating has almost entirely supplanted the prism in many if not most observatories. The remarkable apparatus of Thollon is alluded to, but not described with any fulness.

The remaining chapters of the book treat of apparatus for celestial photography, photometry, and the measure of solar radiation.

Similar remarks apply to these as to the preceding. There are many excellent descriptions and illustrations, many important omissions, and a few mistakes. We call special attention to the fine representation of the most ingenious mounting — devised by Hansen, and constructed by Repsold — for the photoheliographs employed by the German transit of Venus parties, — a contrivance which we have never seen described elsewhere. But in the chapter on photography, neither the name of H. Draper nor of Common appears; and Rutherford's photographs of the spectrum are said (on p. 827) to have been made with an apparatus he never even saw, the instrument figured being a spectroscope which was used at Dartmouth college in attempting to photograph the solar prominences, while the description given is incorrect in several particulars. In the chapter on the measurement of radiation the apparatus of Pouillet and Secchi appears, but nothing later, — none of the instruments of Violle or Crova, and, of course, not the bolometer of Langley. The chapter on photometers is much better brought up to date.

On the whole, the book is rather a provoking one. There is a great deal in it of real value, collected from various more or less inaccessible sources, and very neatly presented; but the *lacunae* are serious, and a few detected mistakes leave a sense of insecurity as to accuracy in other details.

BURNHAM'S LIMESTONES AND MARBLES.

History and uses of limestones and marbles. With forty-eight chromolithographs. By S. M BURNHAM. Boston, *S. E. Casino & Co.*, 1883. 15 + 392 p. 8°.

THE separate crystals of our rocks, when they lend themselves to decoration in the form of gems, afford a capital opportunity for the book-maker. Superstition, tradition, a host of human activities, have gathered about them, that, in the hands of writers of skill, have been worked into very readable books. But, when the author of 'Limestones and marbles' tries to take something of the same book-maker's way with the coarser though still beautiful marbles, he leaves the field of thoroughly humanized things, and finds himself in a dreary sea of unrelated facts. A writer thoroughly conversant with the architectural history of building and ornamental stones could probably give us a book which would, from its connection with the most economic of the fine arts, be very readable. A skilled lithologist who would furnish us a careful discussion of the nature of those changes which give beauty, strength, and endurance to rocks, would thereby furnish us with a needed essay; but in this book we have no trace of these capacities, but only the ordinary patience of the devoted compiler.

As a piece of unwearied compilation, unenlivened with any higher quality, this is a very remarkable book. In the list of limestones of the United States we have evidence of a most universal but most uncritical ransacking of authorities; for the element of personal knowledge is entirely wanting. Nor has the compilation the value it might have had if authorities had been quoted. Although the book is apparently by a New-Englander, he omits the limestones of Smithfield, R.I., and the serpentines of Lynnfield, Mass., — both interesting, though, as yet, little-used stones. Any personal knowledge of the subject would have supplied a host of such facts, which are not to be found in books, though well known to geologists. The same absence of personal knowledge leads to such misleading statements as that the fossils around Prague are identical with those of the same age in Scandinavia, Russia, Great Britain, and North America. While the book is padded with thirty-eight pages on classification of fossils, nothing is given to the arts of quarrying or of dressing stones, — most important and most relevant matters.

The chromolithographic plates are fairly well done: they fail to give the peculiar effect of depth or translucency, which is beyond this art, but which is the greatest charm of the finest decorative stones.

The style is not altogether bad, though it is frequently inverted; and the author often gets into the subject very much as John Phoenix 'backed the transit' into the plane of the meridian. Now and then it is strikingly epigrammatic, as in the following phrase: 'One of the caprices of nature is to anticipate the works of art.'

It is a pity that so much faithful labor should have been given to this work. The printing of the book, and the index, are very satisfactory. Despite its defects, the book will have a certain value to those interested in the subject; for, as a compilation, it is, in its way, remarkable.

A PRIMER OF VISIBLE SPEECH.

Visible-speech reader for the nursery and primary school. By Alex. Melville Bell, F.E I S., etc. Cambridge, *King*, 1883. 4 + 52 p. 16°.

The science of phonetics made, perhaps, its greatest advance through Bell's Visible speech, though it has by no means remained stationary since that book appeared. It is this system which this primer seeks to bring into practical use in teaching, and its alphabet is a great improvement over that which we now use. It cannot be said, however, that the phonetic analysis on which it is based has received in all respects the approval of phoneticians. With some changes, the vowel system has now won wide acceptance, but the analysis of consonants has met with serious objections; for instance, for such sounds as *f*, *th*, *s*, *sh*, in English. A discussion of the system itself would necessitate reference to recent work on phonetics, especially to Sweet's paper on Sound notation in the Transactions of the philological society for 1880–81, and to Sievers's Grundzüge der phonetik, and such a discussion would hardly be in place here. One may wish, however, that some of Sweet's changes of the Visible-speech alphabet could have been adopted. Still, the imperfections of the system might never attract a child's notice, and he would probably accept unquestioningly the signs given for *f* and *th*, without understanding why they were made to resemble the sign for *l*. For the scientific study of living languages, and of the phenomena of linguistic change, some such phonetic system as Visible speech, we may hope, will be agreed upon, at least provisionally, whether it is found of practical value in teaching children to read or not. The test of practice must show whether this ingenious alphabet will do better than other phonetic primers the work of teaching a child to read ordinary printed books. The primer is divided into three parts, — first, pictured words, containing pictures of a few common objects, with their names and some phrases; next, sentences in rhythmical form; and lastly, a vocabulary of common words arranged according to the initial sound, beginning with labial consonants, and ending with vowels. All this is printed only in Visible-speech letters. These three parts are preceded by some directions to the teacher; and at the end a key is added for the teacher's use, containing the usual forms in Roman type of all the words in the primer. Exclusive of the key, the whole contains thirty-five pages. At the beginning of the key are given a few 'notes,' which speak of the syllabic *l* and *n*, as in *castle*, *listen*, and of the glides, that is, the vowel vanishes, or final diphthongal elements in such words as *hear* (the sound represented by *r*), *day*, *go*. It must surprise an American student of phonetics to see that American pronunciation is credited by Mr. Bell with pure long vowels in the last two of these words, instead of with diphthongs, especially if his own experience and observation with foreign languages have shown him how hard it is for most Americans to learn the pure long sounds of *e* and *o* as pronounced on the continent of Europe. Possibly the American vanishing vowel in these cases is less prominent than in England, and it may be that some Americans do pronounce simple long vowels in such cases. In this primer these two glides are not used with $\bar{a}$ and $\bar{o}$. To call the *r* glide, as in *hear*, a very soft *r* is misleading, as most of us in the eastern United States pronounce absolutely no *r* at all in such words.[1] Here, too, what is said of American pronunciation is inexact; for surely we all have an *r* glide in words like *hearing*, while an English reader of Mr. Bell's words would suppose that Americans pronounce *hear* as he does, but *hearing* like *he-ring*. The American rule for the *r* glide may be thus stated for some, perhaps most of us: when the *r* glide is present at the end of a word, it is retained before any ending of derivation or inflection, the consonant *r* being pronounced in addition after the glide if the ending begins with a pronounced vowel. Thus the glide is heard in *boor, boorish, beer, beery, soar, oaring, store, storing, stored;* but there is no *r* glide in *Mary, story, fury.* Cases like these last seem to have been excluded from the book.

[1] See Whitney, The elements of English pronunciation, in his Oriental and linguistic studies, second series.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

CHEMISTRY.

(General, physical, and inorganic.)

New explosive. — S. H. Hinde proposes a new explosive mixture composed of 64 parts of nitro-glycerine, 12 ammonium citrate, 0.25 ethyl palmitate, 0.25 calcium carbonate, 23 coal, 0.50 sodium carbonate. — (*Chem. techn. repert.*, 1883, 153.) C. E. M. [196

Compressed cartridges. — H. Güttler makes cartridges of compressed blasting-powder, which are bound together by dextrine. For this purpose he uses a hard burned charcoal (brown-red), which he claims has the formula $C_8H_4O_2$. The mixture of charcoal, sulphur, and nitre are incorporated with the solution of dextrine, corned in grains of one to two millimetres; and after drying they are pressed into perforated cylinders. These cylinders are then dried and shellacked. The reaction due to explosion is represented, when India nitre is used, by $C_8H_4O_2 + 8\,KNO_3 + 4\,S = 8\,CO_2 + 2\,H_2O + 8\,N + 2\,K_2SO_4 + 2\,K_2S$. — (*Chem. techn. repert.*, 1883, 154.) C. E. M. [197

Fulminating compound. — B. G. and F. L. Benedict have invented a mixture for use in primers, in place of fulminating mercury, consisting of 2 parts amorphous phosphorus, 8 of minium, and 2 of potassium chlorate. The oxides of mercury or manganese may be used in place of the minium. — (*Chem. techn. repert.*, 1883, 153.) C. E. M. [198

AGRICULTURE.

Soluble and insoluble phosphates. — In experiments on potatoes, Swanwick and Prevost obtained a larger yield on plots manured with superphosphate than on those manured with the same phosphate simply ground. A slight increase in the percentage of starch was observed in the potatoes manured with superphosphate. — (*Bied. centr.-blatt.*, xii. 250; *Trans. highl. agric. soc.*, 1882.) H. P. A. [199

Value of artificial butter. — There are, according to Ad. Mayer, three principal points to be regarded in judging of the worth of an article of diet; viz., harmlessness, taste, and physiological utility. That artificial butter is harmful can hardly be seriously claimed; while, as regards its taste, the very magnitude of the industry shows that the imitation is very successful. The physiological utility of artificial butter depends essentially on its digestibility; and on this point Mayer has experimented, using as subjects a man, and a boy nine years old. But slight differences were observed between natural and artificial butter; but the former was digested a trifle better. When the artificial butter was used in preparing potatoes, it proved to be almost uneatable; and the author suggests that this fact may prove of use in detecting the presence of the former. — (*Landw. vers.-stat.*, xxix. 215.) H. P. A. [200

Butt and tip kernels of corn. — The vegetation of the butt, central, and tip kernels of corn in the field has corroborated the results already published as gained in the greenhouse. The figures of vegetations stand as below: —

Planted.	Butt kernels.		Central kernels.		Tip kernels.	
	June 1	June 4.	June 1.	June 4.	June 1.	June 4.
1 A 1, May 16	446	533	551	581	564	600
1 A 2, "	478	531	515	564	564	583
1 A 3, "	497	558	490	570	500	549
1 A 4, "	428	496	463	560	519	587
1 A 5, "	362	467	456	526	428	526
Total vegetated	2211	2588	2485	2801	2575	2845
Total planted	3420	3420	3420	3420	3420	3420
Per cent vegetated . .	64	75	72	82	75	83

— (*N. Y. agric. exp. stat., bull.* xlvii.) H. P. A. [201

Chemistry of asparagin. — B. Schulze finds that asparagin is not decomposed to any notable extent by heating with water, even under a pressure of three to four atmospheres, and in the presence of acid plant-juices. Consequently, when fodders containing asparagin, of which there are many, are cooked, this substance is unaltered; and, since its nutritive value has been established, the knowledge of this fact is of some importance. When heated with alkalies, asparagin yields asparaginic acid and ammonia, while a portion of the acid is further acted on, and malic acid is formed. — (*Landw. vers.-stat.*, xxix. 233.) H. P. A. [202

METEOROLOGY.

Observations on Ben Nevis. — A permanent observatory is to be established at the summit of this mountain by the Scottish meteorological society. A road to the summit has been begun: the building will be erected this summer, and it is expected that regular observations will be made after Nov. 1. The records will be kept hourly, not only at the summit, 4,406 feet above sea-level, but also at Fort William, which is situated twenty-eight feet above the sea, and at the base of the mountain. Since June 1, 1881, simultaneous observations at these points have been made at frequent intervals of the day, in the summer-time, by Mr. and Mrs. C. L. Wragge, the former of whom made the ascent every day until the storms of October rendered this impossible. The results obtained have been discussed by Mr. Buchan sufficiently to warrant the permanent establishment of the observatory. — W. U. [203

The origin of lightning. — In explaining satisfactorily the phenomenon of lightning, a difficulty is encountered in accounting for the enormous electric tensions which are necessary to explain the great length of the spark often observed. The theory is advanced by A. Fick, that the high tensions are produced by the sudden concentration of electricity already existing in a free state. This concentration is caused by the formation of large drops of rain from the small vesicles of moisture existing in the clouds, by which the surface upon which the electricity exists is greatly diminished. The sudden formation of drops of water from the mass of aqueous vapor may be due to the advance of cold-air currents. The author endeavors to answer two objections which may be urged against his theory: 1. That in every rain-storm lightning ought to be seen; 2. That it ought to rain whenever it lightens. To the first objection he replies, that the drops may be formed gradually, and not suddenly, in which case the tensions would be dissipated gradually; and, to the second, that drops are always formed in connection with lightning, but that in falling to the earth they sometimes encounter a layer of dry air, and are absorbed in their passage. — (*Naturforscher*, June 23.) W. U. [204

GEOGRAPHY.

(*Arctic.*)

News from Bering Sea. — News to July 8 has been received from the North Pacific whaling-fleet. The promise of a late spring had been fulfilled to date. Large quantities of drift-ice were afloat in Bering Sea some distance south of Bering Strait as late as the end of June. The whalers had taken but few whales, — only nine for the whole fleet. St. Lawrence Bay did not open until July 1. The Leo, bound for Point Barrow to relieve the party at the U. S. international polar station, had arrived at Plover Bay July 5. During the last few days of June strong southerly winds prevailed, driving the ice northward, so that at least one of the steam-whalers was able to reach ten leagues north of Cape Lisburne. The Corwin had not arrived. The bark Mary and Susan had been nipped, and was leaking badly; and the steam-whaler Balaena had returned to Plover Bay with the loss of her propeller-blades. Most of the fleet met south of St. Paul Island, in latitude 57° N., in April, and were fast in the ice from forty to eighty days, encountering very heavy ice and severe cold. The whales in their northward migration passed Cape Chaplin about July 9. The bark Hunter had been injured by a serious fire in the forecastle. A small number of walrus had been taken in default of larger game. Notwithstanding the unfavorable spring, a few weeks suitable weather may change the conditions sufficiently to enable the fleet to make a fair season's catch; but it must be confessed that the prospect of this, as well as for the Leo's reaching Point Barrow, and securing the desired observations there, are not encouraging. — W. H. D. [205

(*Africa.*)

Revoil's journey to Somali-land. — M. G. Revoil, recently intrusted with the direction of an expedition to Somali-land by the French ministry of public instruction, left Zanzibar about the first of May. During detentions at Aden and Zanzibar, collections of natural history and ethnology were obtained, and the members of the party instructed in the methods of work. Friendly relations were established with several chiefs of the Somali coast, who were on an annual visit to Zanzibar, and recommendations to various tributary chieftains obtained from the sultan. M. Revoil intended to enter the country with Arab guides at Mogadoxo. and to ascend the Wabbi River to Geledi, whence, after a short stay, he would proceed to Gananeh on the Juba River, which he would endeavor to map, while obtaining collections of all kinds. After this the Juba would be ascended to the region of the Ugadines toward the west, or he would enter the Galla country toward Kaffa and Shoa, where it is thought the friendly relations of the French with King Menelik would insure him a favorable reception. It is expected that the journey will terminate by traversing the country to Harrar, and thence to Zeila on the Gulf of Aden. — (*Comptes rendus soc. géogr.*, no. 11.) W. H. D. [206

ZOÖLOGY.

Mollusks.

Existence of a shell in Notarchus. — Vayssière has demonstrated the existence of a minute internal spiral shell in Notarchus. Taken into consideration with a similar discovery by Krohn in Gasteropteron, the author thinks it very probable that both are persistent embryonic shells (in Notarchus it is about one-fiftieth as long as the animal itself), and that an analogous appendage will be found eventually in most tectibranchs, which, up to the present time, have been considered shell-less. — (*Journ. de conchyl.*, xxii. 4.) W. H. D. [207

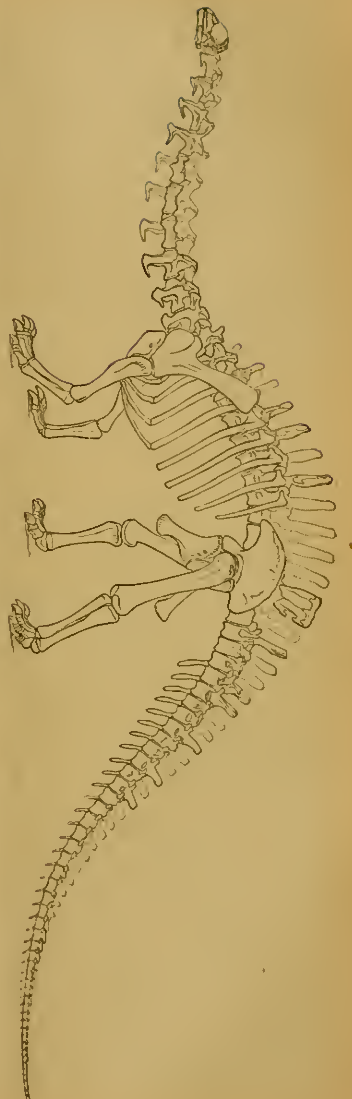
New abyssal mollusks. — Fischer describes a number of new species from the deep-sea dredgings of the Travailleur in 1882. They belong to the genera Dentalium, Mitra, Sipho, Pseudomurex, and Belomitra. The latter is a new genus resembling Bela, but with numerous small plications on the columella.

One species, Mitra cryptodon, comes from a depth of 1,900 metres in the Atlantic, — probably the greatest depth recorded for any species of that genus up to the present time. — (*Journ. de conchyl.*, xxii. 4.) W. H. D. [208

VERTEBRATES.

Reptiles.

Restoration of Brontosaurus. — In the continuation of his papers on Sauropoda, Marsh gives the accompanying restoration of Brontosaurus almost entirely from a single individual about fifty feet long. "The head was remarkably small; the neck was long, and, considering its proportions, flexible, and was the lightest portion of the vertebral column; the body was quite short, and the abdominal cavity of moderate size; the legs and feet were massive, and the bones all solid; the feet were plantigrade, and each footprint must have been about a square yard in extent; the tail was large, and nearly all the bones solid." Special attention is drawn to the head, which is "smaller in proportion to the body than in any vertebrate hitherto known," the entire skull weighing and measuring less than the fourth or fifth cervical vertebra. The animal is estimated to have weighed more than twenty tons, was more or less amphibious, probably fed on aquatic plants, and was doubtless a 'stupid, slow-moving reptile,' wholly wanting any offensive or defensive weapons. — (*Amer. journ. sc.*, Aug.) [209



RESTORATION OF BRONTOSAURUS.

Mammals.

Influence of pressure on heart-beat. — Many observers have noticed that the mammalian heart, after the death of the animal, will, under certain conditions, continue to beat spontaneously for some hours, especially if artificial inflation of the lungs is kept up. Ewald and Kobert have made some observations on this subject, inflating the heart directly with air, and find that hearts which have ceased to beat spontaneously, or after the application of mechanical stimuli, will again give contractions when the pressure within their cavities is raised. They come to the conclusion that one of the conditions which the blood must fulfil, in order to maintain the heart in activity, is, that it must exert a certain pressure on the heart-walls. — (*Pflüger's archiv*, xxxi. 187.) W. H. H. [210

Epiphyses on the centra of the vertebrae of the manatee. — M. Albrecht describes these rudimentary epiphyses at length. He believes that the presence of crests and furrows upon the intervertebral faces is a sure indication of epiphyses; but he goes further, and describes these processes. They are 'partially ossified in a peripheral zone, particularly in the dorsal region.' He also forms the hypothesis that the epiphyses are the remnants of more perfect ones, basing it upon the fact of the presence of the ridges and grooves upon the faces of the centra. — (*Bull. mus. hist. nat Belg.*, ii. 1883, 38.) F. W. T. [211

ANTHROPOLOGY.

The skulls of assassins. — A short time since, attention was called to the investigations made upon criminals and delinquents, with a view to study the early stages of humanity. The discussion is kept up by the French society, and most elaborate measurements are reported. M. Dally is not quite satisfied with the methods, however, and makes the following remarks. It is very wrong to confound things different *inter se* under one abstract term, and to study them as a natural group. Assassins, murderers, criminals, and even the assassinated, constitute juridical categories; but surely they are not philosophic. Highwaymen, ravishers, the jealous, monomaniacs, avengers, nihilists, etc., may be assassins; yet they have nothing in common, except that their actions lead to the same result. The organic conditions which lead to murder are quite different in each case. Again: every one knows that nothing is more rare than a perfectly symmetrical skull. Before establishing the proportions of anomalous crania among criminals, it is necessary to fix the standard among the virtuous. In fact, all men who have heavy lower jaws are not necessarily assassins; nor can we assume that all crime is evidence of atavism, and argue, hence, that in the anatomy of murderers we have the portraits of our prehistoric ancestors. — (*Bull. soc. anthrop. Paris*, v. 778.) J. W. P. [212

Easter Island. — Commander Bouverie F. Clark, in June last, visited the Easter Island, landing at the village of Malaveri, where the vessel was boarded by Mr. Alexander Salmon, agent of the Maison Brander of Tahiti, who purchased the property of the missionaries four years ago. The latter then left for the Gambier Archipelago, taking three hundred natives with them. The natives now number a hundred and fifty, and are decreasing. About five hundred were shipped to Tahiti eight years ago, to work on the plantations of the Maison Brander. Among the remaining people are no traces of the missionary work. They are divided into several small clans; and their chief quarrels are about the first eggs of the 'wide-awake' every year from Needle rock. The myth or tradition of their arrival is given by Commander Clark, who also speaks hopefully of the fertility of the island, as well as its value as a provision station. — (*Proc. roy. geogr. soc.*, v. 40.) J. W. P. [213

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

PUBLIC AND PRIVATE INSTITUTIONS.

University of Michigan.

Central laboratory for microscopy and general histology. — Instruction is given in this laboratory in the following subjects. 1. Microscopical technics, or the science and art of microscopy, comprising, (*a*) the theory and construction of the instrument and its various accessories; (*b*) the methods of determining magnifications; (*c*) the methods of microscopic drawing, microscopic photography, and microscopic projections; (*d*) the preparation of objects of various classes. 2. Human histology. 3. Comparative histology. 4. Vegetable histology. 5. Dental histology. 6. Pathological anatomy. 7. Completion of microscopic study in such other subjects as may be desired by professors in charge.

The following is the plan pursued in the principal divisions: —

Normal human histology. — This course consists of thirty lectures in the amphitheatre on the use of the microscope and on histology. In laboratory work the student is taught the manipulation of the instrument, use of accessories, etc. Then follows the study of such subjects as blood, epithelium, bone, tooth, cartilage, elastic tissue, muscle, kidney, stomach, liver, intestine, brain, spinal cord, and various miscellaneous subjects, as the oesophagus, tongue, skin, etc. The students are given instruction in mounting, so that each specimen is preserved as it is studied. The average number of mounts per student is about twenty. Each student is required to have at least twelve mounts, and some ambitious ones mount as high as fifty or sixty. Over six thousand mounts are carried away each year by students in this department. The object of the course is, first, to make the student better acquainted with the structure of tissues, and, second, that he may become familiar enough with the microscope and its manipulations to work to advantage without the aid of an instructor.

Vegetable histology. — The first course consists of work in structural botany for a term of twenty weeks. Special attention is given to the correct representation of microscopic objects on paper. Sixty accurate drawings of the various structures examined during the course are required of each student, the specimens being prepared by the students themselves. Vegetable protoplasm is studied with the special view of ascertaining the effects of the various reagents employed in general laboratory work. Then follow lessons on the vegetable cells, diatoms, and other miscellaneous subjects.

Course two in vegetable histology consists of work in pharmaceutical botany, three forenoons of laboratory work each week for twenty weeks. At the close of the course each student chooses a particular drug, studies it thoroughly, and presents the results of his labors in the form of a thesis.

Advanced normal and pathological histology. — Any student who has completed the primary course in the histological laboratory, or who has performed an equivalent amount of work in some other institution, can enter the class for advanced work. The first work here is in testing objectives with test-plates and diatoms, and in becoming more familiar with a few useful accessories. The art of injecting is then taken up, and the frog and cat are experimented upon, as well as individual organs from larger animals. Each student then chooses some particular organ or tissue, and prepares it in as many ways as possible for study. He thus becomes familiar with the various methods of hardening, cutting, and staining. Pathological structures are now carefully studied. This includes the study of inflammation and its results, the study of diseased organs and tissues, and of the non-inflammatory new formations.

Embryology. — A study of the development of the chick, including microscopic sections of the same.

Urinalysis. — A course of six weeks in the chemical analysis of the urine, including the use of the microscope in determining the character of the various deposits and crystals.

NOTES AND NEWS.

Dr. H. Newell Martin, professor of biology in Johns Hopkins university, has been appointed Croonian lecturer of the Royal society of London for the current year. The Croonian lecture was founded by Lady Sadlier, in fulfilment of a plan of her former husband, Dr. Croone, one of the founders and the first registrar of the Royal society. By her will, made in 1701, she devised "one-fifth of the clear rent of the King's-Head Tavern, in or near Old Fish Street, London, at the corner of Lambeth Hill, to be vested in the Royal society, for the support of a lecture and illustrative experiment on local motion." For many years past there has been no formal delivery of the lecture. The council of the Royal society select from the papers presented to them during the preceding twelve months that one dealing with animal motion which they think most noteworthy, and publish it as the Croonian lecture, sending to the author the sum derived from Lady Sadlier's bequest. The amount of money is trivial, but the appointment as Croonian lecturer is a highly prized distinction. The paper by Professor Martin, which is to be printed as the Croonian lecture for 1883, is on the Effect of changes of temperature on the beat of the heart. It is interesting to note that the first Croonian lecture, delivered by Dr. Stuart in 1738, was on the Motion of the heart.

— *Nature* of Aug. 2 prints the following telegram from the Swedish party which wintered at Spitzbergen, and was last heard from in October. "Cape Thordsen, July 4, 1883. This message will be forwarded to-morrow to Capt. Startschin, with the boat fetching our first mail this year. The wintering of the expedition has in every respect been attended with success, particularly as the scientific researches have throughout been carried on exactly in accordance with the regulations formulated by the International polar commission. Hydrographical and magnetic studies have also been pursued on the ice in the Ice Fjord, as well as parallax measurements of clouds, and observations as to the temperature of the air, the snow, and the earth. The winter has, on the whole, been mild; the greatest cold occurring on Jan. 2, when the thermometer registered 35.5° C. below freezing-point. Storms have been few. Since September last the following buildings have been erected: a hut on a mountain at an elevation of 270 metres, containing the anemometer and the windfan, which were read by a self-registering electrical apparatus; two astronomical observatories; another magnetic hut; a bath-house, a forge, and a wood storehouse. The dwelling-house and working-room have also been enlarged. The following game was shot during the winter: 61 ptarmigans, 9 reindeer, 18 wild geese, 20 foxes, and some wild fowl. With continuous labor, plenty of food and drink, and frequent baths, the members of the expedition have throughout enjoyed excellent health. Descriptions of the nature of our labor and life here during the wintering will follow."

— The new biological laboratory of the Johns Hopkins university, which will be opened next September, has been especially constructed with reference to providing opportunity for advanced work in experimental physiology. It contains two large rooms for general advanced work in animal physiology, in addition to others specially designed for work with the spectroscope, with the myograph, for electrophysiological researches, and for physiological chemistry. It also contains a special room constructed for advanced histological work, and well supplied with apparatus and reagents, a room for microphotography, and rooms for advanced work in animal morphology.

Prof. C. H. F. Peters of Clinton, N.Y., announces to Harvard college observatory the discovery of a new planet by him on the night of Aug. 12. Its position at time of discovery was as follows: Aug. 12, 13 hours, 49 minutes, 27 seconds, Clinton mean time; right ascension, 21 hours, 20 minutes, 48.17 seconds; declination, south, 12 degrees, 29 minutes, 8.2 seconds. The daily motion of the object is − 36 seconds in right ascension, and in declination 20 minutes and 50 seconds south. It is unusually bright for an asteroid, being of the ninth magnitude.

— The *Nation* for Aug. 2 calls attention to a very interesting feature of the table of ages (table XLII.) in the compendium of the tenth census. The table exhibits an astonishing preponderance of persons whose age is a 'round number,' i.e., a multiple of five or ten. One of the instances mentioned is, that while, according to the table, there are 1,094,324 persons at the age of 30, there are only 621,852 persons of 29 years, and only 492,530 persons of 31 years. There is a less powerful but still very marked and constant attraction to even numbers as compared with odd: for example, 42 claims 458,949, while 43 is content with 384,259; 47 is credited with 349,512, but 48 with 400.549. These are from the table of aggregates for the United States. The peculiarities are, of course, much more strongly marked in the columns referring to the classes and localities where there is most ignorance. Thus the number of the colored females in Mississippi who are put down as 30 years of age is 10,619, while the years immediately preceding and following are given only 2,253 and 1,236 respectively.

The writer of the interesting note in the *Nation* attributes the phenomenon to conjectural statements by people who did not know their own ages; but probably only a small part of it is due to that cause, at least in the more intelligent portions of the population. In so intelligent a state as Rhode Island, for instance, we find for the years 29, 30, 31, the numbers 3,965, 6,550, 3,112; which is not much better than in the aggregate of the United States. How much is due to guessing by relatives, servants, masters, etc., and especially to suggestions and guesses by the census-gatherers themselves, — who, of course, do not regard the exact ages as important, and most of whom have probably no strong views on the subject of the 'personal equation,' — no one can tell, but probably very much more than to people's ignorance of their own ages. An examination and comparison of the original note-books of the various census-takers would furnish materials for an interesting exercise, if nothing more, in statistical research, and might reveal approximately the extent to which the personal qualities of the census-takers has affected the result; while a comparison of the table with well-established tables of mortality might enable us to estimate the force of the tendency to understate age which would doubtless be found to exist. The whole thing makes a very pretty problem, and serves to illustrate in a rather gross and exaggerated way the complexity of statistical investigations.

—We learn from *Nature* that a meeting which may have an important result upon science and art instruction in England has been inaugurated at Manchester. An association has been established to effect the general advancement of the profession of science and art teaching by securing improvements in the schemes of study, and the establishment of satisfactory relations between teachers and the Science and art department, the city and guilds of London institute, and other public authorities. It proposes also to collect such information as may be of service to teachers professionally; and it will endeavor, by constant watchfulness, to advance the status and material interests of science and art teachers in all directions. The president of the new association is Professor Huxley, and the vice-presidents are Dr. H. E. Roscoe, Mr. Norman Lockyer, Professor Boyd Dawkins, Professor Gamgee, Professor Ayrton, Professor Silvanus Thompson, Dr. John Watts, Mr. S. Leigh-Gregson, Mr. John Angell, Mr. W. Lockett Agnew, Mr. C. M. Foden, and Mr. J. H. Reynolds. Mr. W. E. Crowther, of the Technical school and mechanic's institution, Manchester, is the honorary secretary; and all communications should be addressed to him, especially by those who are desirous of forming affiliated unions in other districts. We believe that branches are already being established at Newcastle-upon-Tyne and Liverpool.

—The attorney-general of the United States has approved the title to the proposed site of the fish-commission establishments at Wood's Holl, Mass.; and the contracts for the work on the breakwater, pier, and basin, will, it is expected, soon be made.

—King's Dictionary of Boston, after the manner of Dickens's Dictionary of London, has recently been published. Edwin M. Bacon is the editor. A short introduction is written by George E. Ellis, D.D. The brief notices of the libraries and scientific associations of Boston are satisfactory, and well brought down to date.

—For the last two years a couple of buck mountain sheep have been running with the flock of Mr. Bailey of Bull Run Basin, Nevada; and there are now between twenty and thirty half-breed lambs in the lot. According to the Tuscarora mining news, they are mostly covered with hair, although there is some wool amongst it. They carry their heads high, like the wild sheep, but are as easily herded as those of pure domestic blood. They are of no value for shearing, but are said to make excellent mutton.

—The subsidence of land in the Cheshire salt-districts of England is again becoming alarming. The bed of the river Weaver has widened out below Northwich, forming a lake of about two miles square, called the Flashes. Crater-like holes suddenly fall in, forming in a day or two deep ponds of saltish water. In one instance, two years ago, the river itself flowed backwards into the subsidence for the space of two minutes, filling up several old rock-salt mines in the neighborhood: from these the water is now pumped, and used as brine. Land-owners in the neighborhood brought a bill into Parliament during the session of 1882, to obtain compensation for the damage done by the salt-works; but it was argued that subsidence would occur by natural filtration, even if the brine were unworked, and the bill was thrown out.

—Mr. Albert Marth, F.R.A.S., has succeeded Dr. W. Doberck as astronomer at Col. Cooper's observatory, Markree, Ireland.

SCIENCE.

FRIDAY, AUGUST 24, 1883.

THE LESSONS OF THE MEETING.

The question as to the distance from the eastern seaboard to which the American association for the advancement of science can carry its annual assemblages is partly solved by the meeting at Minneapolis. That has registered about three hundred members in attendance; a small number, indeed, as compared with the Boston and Montreal meetings, but larger than was at first anticipated. One-third came from the Atlantic and New-England states. Astronomy and physics are fairly represented in the list; geology, as was expected, claimed the largest proportion; of botanists, there were over twenty-five — this was a surprise; the ethnologists were in considerable force; in all other branches of science, the attendance was somewhat meagre.

This, therefore, has not been one of the large meetings. Its addresses and papers have not contained any very striking feature that appealed to the interest of the general public. On the other hand, all that was presented, with few exceptions, though not brilliant, was above mediocrity. Looking over the list of papers, we find fewer than usual of the kind that brings sorrow to the hearts of scientific students; that provokes the question, How did such things ever pass the standing and sectional committees?

The merits and the disadvantages of the present system of conducting these meetings have been placed in very sharp light. Excellent addresses were delivered by most of the presidents of sections; in fact, these productions this year are a credit to the association. But the strain of obtaining such representative addresses from so many sections will soon be apparent: it may prove difficult to find the men to deliver them, within a very few years, especially if the number of sections continues to increase. The delivery of two or more of these addresses simultaneously, and the completion of the delivery of all of them in one afternoon, was felt to be a matter of grave injustice, both to speakers and hearers. To our readers we shall offer the only remedy now possible for this injustice, by printing the addresses in full, and by detachments.

Local committees, in cities to which the association will hereafter be invited, may learn some valuable lessons from the experience at Minneapolis. There was no lack of hospitable intention: the hearty courtesies of a western community were liberally extended. But the generous intentions were not carried out in the minor details that are essential to comfort if not to success. The meetings were held at a distance from the city, at the extreme end of a one-horse car route. Consequently the conveyances were overcrowded, much time was lost in going and coming, and — worse than all — few of the citizens of Minneapolis attended the sessions. We do not remember a meeting of the association at which the local interest, so far as audiences indicate it, was so deficient. The hotel selected for headquarters was not agreeable, because not exactly suitable. Members scattered to distant points, finding delicious havens of rest and recreation at summer-hotels on the lakes, but having to take yet longer time to attend the daily sessions. Free railroad transportation was provided to these distant resorts, but there was a confusing uncertainty about late trains that caused many embarrassments. These things may be trifles, but they are apt to be remembered when the lavishness of entertainment is forgotten.

As was anticipated, the association has chosen Philadelphia for its next session, where we may look again for the great numbers which attended the Boston and Montreal meetings. The exact date for holding it has been wisely left in the hands of the executive board, pending the choice of time by the British association for their Montreal meeting. A preference, however, has been indicated for the week beginning Sept. 3, — a date earlier than usual, but welcome to all who know how warm Philadelphia can be in August.

W. C. W.

RELIABILITY OF THE EVIDENCE OBTAINED IN THE STUDY OF CONTAGIA.

There is certainly a disposition, among some of our scientific men, to doubt the possibility of making direct and satisfactory demonstrations of the *rôle* played by the schizophytes, or microbia, in the production of disease, and that which they may be compelled to take in its prevention. Recent publications by accepted authorities have tended rather to confirm these doubts than to remove them, and we are frequently asked if our results are not founded on probabilities rather than on definite and conclusive facts. While this uncertainty is still felt, it is well to occasionally review the connection between the facts established and the conclusions drawn from them.

Though the schizophytes are the smallest of living organisms, that is not an insurmountable obstacle to their careful study, as is proved by the well-known investigations of the Bacillus anthracis by Koch. His demonstration that this exists in two forms (a vegetating filament and a spore), and that the latter survives unfavorable conditions which destroy the former, enabled him to trace a connection between the activity of the virus and the life of the parasite, which other investigators had failed to establish. Thus, the blood of anthrax victims, which contained only Bacillus rods, lost its power to reproduce the disease after a few days' putrefaction; while that which contained spores remained virulent an indefinite time. A certain degree of cold, and also an insufficient supply of oxygen, prevent the formation of spores; and, the filaments being short-lived, the organism loses its vitality in a few days under such conditions. If spores had formed before the liquid was exposed to these conditions, however, they were unaffected, and were capable of germination after weeks or months. Again: if a virulent liquid was largely diluted, the filaments were destroyed, but the spores survived. In all these cases the activity of the virus disappeared with the death of the organism, and was retained whenever the formation of spores had enabled this to resist the unfavorable conditions.

Here was a proof of the pathogenic character of the schizophyte much more satisfactory than the mere demonstration of its presence in all cases of the disease, or the additional evidence that it might be passed through a certain number of cultivation-flasks; the liquid in the last being as virulent as in the first.

Since Koch's paper was published, Pasteur has added observations of an equally convincing character. The liquid part of the virus may be freed from the organism either by filtering through plaster or by decanting after it has stood in a constant temperature for a few days to allow the germs to gravitate to the bottom of the flask. In either case the liquid is harmless, and the separated germs still produce the disease. Again: compressed oxygen destroys the filaments, but does not affect the spores; and a virus containing only the former loses its activity when treated with this agent, while one in which spores have formed retains its virulence.

We are able to say, therefore, that, in the disease known by the French as charbon and by the English as anthrax, no liquid is virulent unless it contains the living Bacillus anthracis, and that the death of this organism always coincides with the destruction of the virulence.

This demonstration of the pathogenic action of the Bacillus cannot but be regarded as equally satisfactory with what is obtained by investigations in other departments of biological science. If the observations of these gentlemen are accurate, and they have been confirmed too often to be doubted, then there is no escaping the conclusion that the Bacillus anthracis is the essential and only cause of anthrax.

It is not to be denied, however, that the size of the parasite in anthrax, and the fact of its existence under two forms having such unequal resistance to unfavorable conditions, were characters which greatly facilitated the demonstration of its pathogenic relation to the disease. Is it possible to obtain equally satisfactory evidence in regard to the smallest of the schizophytes, and one which only exists in the vegetating condition?

The micrococcus of chicken-cholera is of this kind, and it is consequently very interesting to see just what progress we have made in demonstrating its identity with the virulent principle. We know from Pasteur's investigations that it is always present in this disease; that it may be cultivated, and passed from flask to flask for many times, without losing its virulence. The filtered liquid loses its activity; that from which the germs are separated by gravitation is equally harmless. Taking up the study here, I have proved that the exact degree of heat which, in a given time, kills the micrococcus (132° F. for 15 minutes), destroys the virulence at precisely the same point; also that the proportion of carbolic acid, of sulphuric acid, and of a solution of chlorides (Platt's), which destroys the virulence in from two to four hours, corresponds with the proportion which is required to kill the organism in the same time.

The effect of heat and of these disinfectants on the virus was determined by inoculation experiments. The point at which the micrococcus is killed was learned by placing a drop or two of virus in the sterilized liquid of a cultivation-tube after the proper proportion of disinfectant had been added. In a given time a drop was taken from this tube, and placed in a second one which contained a favorable medium for the growth of the germs. If the schizophytes had been destroyed by the disinfectant, there would be no multiplication; while, if they had resisted it, they would certainly reveal the fact by developing in their usual manner. The exact correspondence which exists between the results of the two series of experiments in every case, is also an evidence of the reliability of the method.

While it might be conceived, that, even though the virulent agent consisted of something entirely different from the micrococcus, both might be destroyed by the same degree of heat in the same time, it is not conceivable that this would also occur from the effect of three different chemical agents. If it were necessary, this line of evidence could probably be increased indefinitely; but it is already equal to what is usually considered necessary to demonstrate a point in other departments of science.

It is possible, then, by present methods of research, to determine satisfactorily whether a given organism is the cause of a certain disease, or whether it is an epi-phenomenon; and, if there is still much doubt in regard to some of these, it would seem to be owing to the fact that observers have relied too implicitly upon the microscope, and neglected the cultivation and inoculation experiments, that are essential to definite and reliable conclusions.

D. E. SALMON.

SPONGE-CULTURE IN FLORIDA.

THE U. S. national museum has lately received from Messrs. McKesson and Robbins, sponge-importers of New York, an interesting contribution representing the first successful attempts at sponge-cultivation on the American coast. It consists of only four specimens, all of the finest or sheep's-wool variety, which were raised from cuttings at Key West, Fla., by the agent of the above-named firm. The localities in which the sponges were planted were not the most favorable for sponge-development, and their growth was therefore less rapid and perfect than might otherwise have been the case. They were fastened to the bottom, in a depth of two feet and a half, by means of wires or sticks running through them, and allowed to remain down a period of about six months before they were taken up. Fully four months elapsed before they recovered from the injury done them in the cutting, which removes the outer 'skin' along the edges of the section; and the actual growth exhibited was for about two months only. The original height of each of the cuttings was about two inches and a half. One was planted in a cove or bight where there was little or no current, and its increase in size was very slight. The other specimens were placed in tide-ways, and have grown to from four to six times their former bulk, which certainly promises well for the future of sponge-propagation. Two hundred and sixteen specimens in all were planted at the same date, and, at the last accounts, those which remained were doing finely.

The chief obstacle to the artificial cultivation of sponges at Key West arises from the fact that the sponge-fishermen infest every part of the region where sponges are likely to grow, and there is no legal protection for the would-be culturist against intruders. The enactment of judicious laws bearing upon this subject by the state of Florida, or the granting of special privileges conferring the right to occupy certain prescribed areas for sponge-propagation, would undoubtedly tend to increase the annual production of this important fishery, which has remained at a standstill for several years past, mainly because of the partial exhaustion of several of the most extensive sponging-areas.

Accompanying these artificial growths was a collection of over a hundred specimens of the various grades of Florida sponges of different sizes, each labelled with its supposed age, based upon estimates of the average rate of growth, by the sponge-collectors. This entire collection now forms a part of the American exhibit at the great London fisheries exhibition.

R. RATHBUN.

THE CONDITIONS NECESSARY FOR THE SENSATION OF LIGHT.

It is generally assumed that the only condition necessary for the production of the sensation of light by the action of radiant energy is, that the radiant energy must be of a certain wave-length within the limits of wave-length of the visible spectrum, namely, between wave-lengths 7.604×10^{-5} centimetres and 3.933×10^{-5} centimetres; that, when the eye perceives nothing, none of these wave-lengths can be present. It is worth while, therefore, to examine those physical conditions that result in giving the sensation of light to ascertain whether such assumption is warranted. As to the eye itself, it will not make any difference so far as this question is concerned, whether one accepts the Young-Helmholtz theory of vision, the Herring theory, or any other. The only important fact is, that, in either, *energy* is required and is expended in the eye; but it is important to know how to measure the energy, and to have a tolerably clear idea about its form. Without any question, a ray of radiant energy, such as is emitted by a heated molecule or atom of hydrogen, consists of a single line of undulations of a definite wave-length, for the molecule cools (that is, loses its heat-energy) by imparting it to the ether; and a 'wave-length' is simply the distance to which such a disturbance in the ether will be propagated during the time of a single vibration of the molecule. As each vibration of the latter imparts some of its energy to the moving ether, it follows that the energy of a ray of light must depend upon the number of vibrations per second; or, what is the same thing, the energy of the ray is proportional to its length. As all rays move with the same velocity in the ether, it follows that any object that should receive such radiant energy would receive an amount proportional to the time.

Suppose, now, that an atom of hydrogen be made to vibrate, no matter how, so as to give a wave-length $C = 6.562 \times 10^{-5}$ centimetres. If such a ray falls upon the eye, it will produce the sensation of redness, and, if the eye receives the vibrations for one second, it will receive 4.577×10^{14} vibrations; that is to say, it will receive as many undulations from the ether as the generating atom made in the interval of one second. Now, we know experimentally that the eye can perceive when the interval is as small as the millionth of a second, when the number of vibrations of such a ray as the above would be 4.577×10^{8}, a very respectable number. It would seem probable that that number might be considerably reduced, and still leave a sufficient number to affect the eye. If the time-interval should be made so short as the one ten-billionth of a second, there would then be 45,770 such undulations that would enter the eye. But there must be a limit to the number needed to produce the sensation; and it is also probable that this limit will differ in different persons. Admitting this time-limit, it follows that undulations of proper wave-length may exist about us, and yet not be sufficient in time-quantity to affect the eye. If other vertebrates or insects possess a shorter limit than man, it is certain that they will see when man cannot. But the energy of vibrations varies as the square of the amplitude; and hence, if one of two rays of equal length has a greater amplitude than the other, the latter might be seen, while the former might not, although they had the same wave-length.

According to the kinetic theory of gases, the molecules are in incessant motion, in which collisions result in changing the directions of the free paths of each of the molecules, and also in making each to vibrate, because molecules are elastic. This vibratory motion proper, being a change of form of the molecule, is what constitutes its heat-energy. The interval between encounters gives opportunity to each molecule to vibrate in its own periodic time or some of its harmonics. Maxwell computed the number of impacts per second for several gases,[1] and gives, for hydrogen, $17,750 \times 10^{6}$. If, then, we divide the number of vibrations per second by the number of impacts, we shall have the number of vibrations between impacts: $\frac{4.577 \times 10^{8}}{177.50 \times 10^{6}} = 25,700.$ This is on the supposition that the vibrations produced are all of the wave-length of the C hydrogen-line.

It is highly probable that this hydrogen-line is not due to the fundamental vibrations of the hydrogen molecule, but that it is some harmonic (the twentieth, according to Stoney). Whatever its harmonic relation may be, it must be highly probable that it will frequently be produced when the conditions are as they are in ordinary gas; but, in normal conditions as to temperature, that gas is not luminous. If this reasoning be right, the reason it is not luminous at ordinary temperatures and pressures is due solely to the slight amplitude of the vibrations of proper wave-length, not to their entire absence. When the gas is heat-

[1] *Nature*, Sept. 25, 1873.

ed, or is impelled with great energy from the terminal of an induction-coil in a Geisler's tube, it is not necessary to assume that the molecules are made to vibrate in wholly new periods, but that the amplitude of their vibrations in any and all periods has been increased, thereby giving greater amplitude, and consequent energy, to the radiant undulations emitted, sufficient to affect the eye.

When one considers the kinetic energy of molecules due to their temperature, it seems probable that all bodies — solid and liquid, as well as gaseous — must be vibrating in all possible periods continuously; but in solid sand in liquids the shortness of the free paths makes interference too frequent to allow any molecule to vibrate many times between impacts, and hence the harmonics suffer most, and are destroyed before they can have given rise to undulations in sufficient number or in amplitude to perform any optical service. By heating a solid, greater amplitude is given to all the vibrations, and we see the red or longer undulations first during the process of heating, because such are less easily destroyed by impact than the shorter ones, which cannot have at best so great an amplitude. This statement assumes that it is with molecules as it is with visible masses of matter: the greater the number of vibrations possible to it, the less the possible amplitude.

With these conditions as stated, it is readily seen why common objects are not at all times visible, that is to say, are not luminous. It is because our eyes are not sensitive enough to respond to the slight energy of the undulations due to both lack of amplitude and shortness of the rays, not because those rays are absolutely wanting. A. E. Dolbear.

RADIOMETERS WITH CURVED VANES.

Among the radiometers in a collection which I have recently examined were two with curved vanes of silver. The radius of curvature was less than 2 cm. When placed in front of a lamp, the concave side moves towards the source of heat. I have found no satisfactory explanation of these movements. According to a recent article by Dr. Pringsheim, the convex side of these vanes is supposed to be at a higher temperature than the concave side. The grounds for such an hypothesis are not obvious; and it would seem hardly possible that an appreciable difference could exist between the surfaces of a thin sheet of silver.

It is more probable that the air on one side of the vane is hotter than that on the other. Since the 'kick' of a molecule depends on its increase in temperature, the vane will move towards the side on which the air is the warmer.

Dr. Pringsheim mentions an experiment in which he brought the heat to a focus inside the radiometer at a point in front of the vane. He found that the air gave no evidence of being heated. I repeated the experiment with solar heat, using a lens of three inches diameter and four inches focal length. The heat in air was sufficient to ignite instantly a common parlor match. When the focus was kept in front of the vane of an ordinary radiometer for two minutes, no appreciable effect was observed: the instant it touched the vanes, however, they gave a start, and began to revolve. This experiment shows that the effects observed with curved vanes cannot be attributed to concentration of heat-rays from the vanes.

According to the kinetic theory, this rotation is set up only if the molecules arriving on the convex side of the vane receive a greater positive increment to their velocity than those arriving on the concave side. These conditions are satisfied in this way: if the vanes are warmer than the air, the particles leaving the vane in both directions have an increased velocity; but take, for instance, the particles moving in lines parallel to the axis of the concavity towards the vane from either side, those on the convex side are scattered by reflection, those on the concave side are brought to a focus at a distance (in this instrument) of less than 1 cm. from the vertex of the concavity. The molecules in the vicinity of this focus receive an increase of kinetic energy; and similar reasoning holds for the sets of molecules moving parallel to each other in any other direction. Hence the molecules on the concave side are hotter than those on the convex side, though not necessarily so hot as the vane itself. Since the molecules on the concave side receive a smaller increase of velocity from the vane, they give it a smaller reactive push.

The action of the case in a radiometer is very prettily shown by wetting it with cold water. The action is best examined with curved vanes, or with vanes of metal covered on one side with mica. The rotation is at first in the same direction as on heating, showing that the air has become cooled by contact with the glass, but is after a time reversed, showing, that, by quasi-conduction through the air, the vanes have become cool, while the glass is regaining its original temperature.

George W. Evans.

THE IGLOO OF THE INNUIT.[1]—II.

AMONG the natives of North Hudson's Bay, the first huts of the season, if there is a scarcity of compact snow, are made of ice. Rectangular slabs, three to four by six or six and one-half feet, are cut from some neighboring fresh-water lake where the ice has formed to a thickness of six inches. As a rough approximation, these slabs may be said to be about the size of an ordinary door. The slabs are placed almost upright, resting on their ends, and joined so as to form a circular pen of from ten to fifteen feet in diameter. Over the top of this the summer seal-skin tent (toó-pik) is spread for a roof; being supported by the tent-poles crossing at convenient places, and held in place by a lashing of seal-skin about a foot below the top of the ice-slabs.

In one of the slabs, generally on the side facing the south, a large opening is cut, which is further protected by a smaller storm-igloo having an entrance-hole no larger than the girth of the most corpulent Innuit of that particular village.

As an aid in cutting, a rectangle is marked on the surface of the ice, having a width equal to the length of the proposed slabs, and from it they are cut with an ice-chisel (toó-oke). This chisel is generally a heavy mortising-chisel, securely lashed to the end of a pole from six to seven feet long. I have seen bayonets, sabre or sword points, or sharpened files made to serve the same purpose. The Esquimaux around King William's Land used the spikes from the wrecked ships of Sir John Franklin's ill-fated expedition. The large ice-slabs weigh nearly half a ton. When dragged from the lake, they are turned on edge, and a hole cut through their centre. By means of a strong seal-skin line passed through this hole, two strong men can handle a slab with considerable ease, moving or sliding it long distances. It takes four or five persons to put the first two together, the slight inclination which is given them holding them up when once in position. After this, two or three are all that are needed to add each slab, until the house is completed. When two slabs are abutted against each other, the edges are trimmed with a snow-knife to give as much bearing-surface as possible; and, when permanently set, snow dipped in water is applied to the joint inside and out, completely closing all crevices, and, when frozen, binding the two as solidly as if but one. A handful is also put in the central hole, which held the seal-skin thong, and the ice-pen is practically air-tight around its sides. The floor of snow has become packed by the treading of the builders; and over it are laid flat stones, on which are spread a great many coarse robes of reindeer, musk-ox, and polar-bear skins, and over these the finer reindeer-skins that make the bed, which occupies over half the floor.

MAKING AN ICE-IGLOO.

These ice-igloos are as transparent as glass; and before they are covered by the drifting snow, or their interiors dimmed by the smoking of the sooty lamps, a night-scene in one of these villages, especially if it be large, with the brilliant burning stone lamps in full blaze, is one of the most beautiful sights I have ever witnessed, especially in this dreary land. Could one imagine the little Lilliputs living in flat candy-jars with drumhead covers, he would

[1] Continued from No. 28.

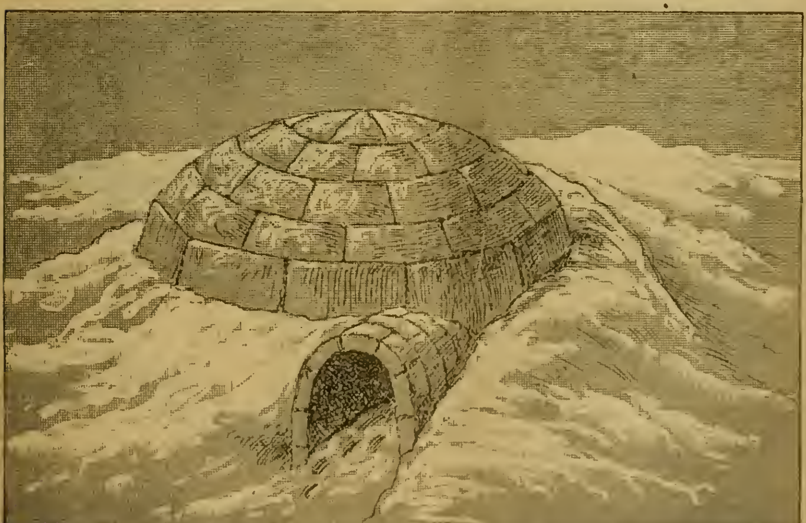
have a fair miniature representation of an ice-village.

Our canvas tent becoming very uncomfortable on account of the intense cold, which had sunk to nearly — 30° F., we had a large ice-igloo constructed, into which we moved on the 1st of November. 1878. and found it decidedly more habitable.

If the village be small, they generally construct an ice-house per day, all working, either cutting out the slabs, hauling them to the igloo site, putting them into shape, or chinking the cracks with wet snow; and this is continued until all are housed. If a large village, they divide into parties.

Sometimes the Innuits will retain their ice-igloo, even after the snow has become fit for building-purposes, the seal-skin tent being removed, and a new dome-shaped roof made of snow-blocks. Such cases, however. are extremely rare; and unless this combination igloo is covered in thoroughly with deep snow-drifts, or with snow thrown upon it to a depth of at least four to six feet, it will not compare in comfort with that of snow alone. The relative conductivity of the two materials, snow and ice, readily explains the reason. The ice also condenses the moisture of the breath, and the steam from cooking, more readily upon its cold, smooth surface; and this becomes at last an almost unbearable annoyance. — an annoyance which can be comprehended without explanation. The advantage of this igloo of ice is in its straight upright walls, which give more room than the slanting sides of the snow-house, while it is also easier to build, the ice portion being already constructed. We lived in such an igloo during the winter of 1878–79; but none of the Innuits around us retained theirs, and often complained of the cold when in ours, and referred it to its peculiar construction. I might add. however, that our three bedrooms or bed-igloos. which were attached to and communicated with the main one of ice, were wholly of snow.

As the reader must have already surmised from the hints given from time to time, the true igloo is built of snow, those already described being used but a very small portion of the year. It is used on all their winter journeys, even for a single night: and, as contrary to the prevailing belief, the Innuits travel the most during this season, one can see that a person sharing their life and travels would have many opportunities, during two long winters with them, to see igloo-building and igloo-life in nearly all its aspects.



AN ICE-IGLOO WITH SNOW CAPPING.

When the native has decided to relinquish his house of ice for one of snow, or on a sledge-journey has decided to go into camp,—in short, is going to build an igloo, — the first thing done is to get out the 'snow-testers,' with which they determine the compactness, depth, and general availability for building-purposes of the snow-drifts. The ancient style of snow-tester, *a*, and

SNOW-TESTERS, ANCIENT AND MODERN.

those yet used by the Esquimaux who have no trading communications with the whalers and explorers, is one made from reindeer-horn, about the diameter of a little finger, and probably three feet long. One end is sharpened, and the other, formed as a button about the size of a quarter of a dollar, is held in the palm of the hand. The modern tester, *b*, is simply the iron rod of the seal-spear with the barb removed.

Having halted on some lake that they know by certain signs has not yet frozen to the bottom,[1] the men scatter out like skirmishers along the deep snow-drifts near the shore, and commence prodding with their testers. Finally a shout from one shows that he has been successful; and, leaving the tester sticking in the snow to mark the spot, he and the others return to the sledges, which are then brought up, and the building commences.

It takes considerable experience, coupled with good judgment, to pick out the best building-site; and, while the constant prodding with the testers oftentimes looks foolish to a spectator, it is no inconsiderable part of the performance. Snow which looks perfect on the crust may be friable beyond use a few inches deeper, and this the tester will reveal. Soft drifting snow may cover a bank of splendid building-material. Again, the drift may be freely interspersed with hidden stones and bowlders, which the testers will bring to light if freely used. This testing for good snow generally occupies from ten minutes to a quarter of an hour: but I have seen it drawn out to an hour, or so long as it takes to build the igloo itself; and, in fact, I have seen them compelled to abandon the most favorable looking lake after having skirted its whole outline, and move on to the next.

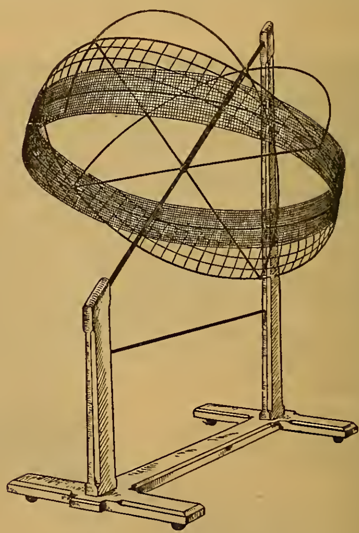
[1] This is generally done by lying flat on the ice, and placing their eyes as close to it as the nose will allow, when some varying peculiarities of the ice-colors decide their conjectures.

(*To be continued.*)

ILLUSTRATIVE APPARATUS FOR ASTRONOMY.

THE accompanying figure represents an apparatus designed for use in teaching astronomy. It is mounted so that the axis on which it rotates is parallel to the earth's axis. Two circles represent the equinoctial and ecliptic, and on the latter is a strip of wire cloth to represent the zodiac. The circles are of such a size that the meshes of the cloth (in this case a half-inch) are one degree in size, and larger meshes of five degrees are made, extending to the circle of the equinoctial. The northern halves of the two colures help to hold all in position. The lower part of these latter circles are dispensed with, so that one may conveniently stand near the centre, the frame being of such a height as to bring the centre nearly on a level with the eye.

It helps the beginner to obtain a clear conception of the fundamental circles so often referred to, of their actual position in the



heavens, and their apparent diurnal change of motion. It enables him also to represent the sun, moon, and planets in their correct positions at any time, their right ascensions and declinations (or longitudes and latitudes) being given. For this purpose I use disks of cardboard, with small hooks attached by which they may be readily fastened to the wires. It is, besides, very convenient to use in the explanation of many questions and topics that arise in the course of the subject. A light rod or wire attached to a standard serves as a horizon when required.

The apparatus grew out of the need felt of something besides the celestial globe and the usual means of illustration for use in the lecture-room. The idea of it was suggested by a description of something like it which some one had seen; but the description was so vague, I am unable to say how nearly similar is this design, or whether it is any improvement or not on what may be used elsewhere. But I have found it to serve a very good purpose in the lecture-room, and think it may be serviceable to other teachers. G. B. Merriman.

HELL'S OBSERVATIONS OF THE TRANSIT OF VENUS IN 1769.

Professor Newcomb has lately taken advantage of a visit to the Imperial observatory of Vienna to make, with the consent and support of its director, Prof. E. Weiss, an examination of Father Hell's manuscript record, with reference to deciding on the alleged falsification of these observations by Hell himself. The result of his examination was so different from that generally accepted, that Professor Newcomb prepared and presented to the Royal astronomical society a statement of the evidence and his conclusions. The story of Hell's supposed tampering with his observations of the transit, made at Wardhus in 1769, is, in substance, that he delayed publishing them so long as to give rise to the suspicion of intending to alter them; that he showed them to no one until after he had received the observations made at other stations; that a cloud was thus thrown over their genuineness; that the suspicions thus excited were confirmed in 1835 through the discovery and publication by Littrow of Hell's original manuscript journal, which its author had neglected to destroy; and that the examination of this journal showed numerous cases of alteration and erasure of the original observed figures, including the seconds of first interior contact, which had been completely erased, and replaced by new numbers inserted with different ink at some subsequent time. And the reason for all this was supposed to be, that Hell desired to publish, not his true observations, but results which should be in the best possible accordance with the observations of others. More precise statements on some points are these: the transit occurred 1769, June 3; Hell's party sailed from Wardhus, June 27, but meeting with delays from adverse weather, and stopping to make observations, they did not reach Drontheim until Aug. 30; after some stay here and in Christiania, Copenhagen was reached on Sept. 17; the observations were communicated to the Danish academy of sciences in November or December; the printing commenced Dec. 13, and on Jan. 13, 1770, Hell received twenty printed copies. Professor Newcomb remarks that he does not know the original authority for the statement that Hell was loudly called upon for his observations before he would consent to their publication.

The document which Professor Newcomb has scrutinized is a thin manuscript volume in folio, containing twenty-seven finely written pages, and nearly as many blank ones, bearing the heading "Observationes Astronomicae et Caetera in Itinere litterario Viennâ Wardöehusium factae. 1768. A. M. Hell." This volume is assumed to be in Hell's own writing, and to be his original journal of his observations. Littrow apparently treats of it as the actual first record of the observations, but to Professor Newcomb this seems very improbable. He concludes that the writing of this journal was done at the observing-station, probably at the close of each day's work or each set of observations. What Hell sent to press in December, 1769, was not a transcript of this journal, but a more copious account, containing eighty-one printed pages, with only an occasional identity of language. But, with a single unimportant exception, the numbers are all printed without change from the original manuscript journal, whether corrected or uncorrected in that journal. It is very clear to Professor Newcomb that nearly all the alterations were made at the station — two, at least, before the ink got dry. And he further concludes, that, *whatever the sources from which the corrections were derived, the numbers as printed by Hell were all but one or two obtained at Wardhus.* Going into these manuscript corrections more in detail, it seems quite clear to Professor Newcomb that the alterations in the numbers representing the observations of first contact were made with the same ink as the original; and he regards only one conclusion as certain, — that the corrections were made at the time of writing, and without the slightest intention of giving any thing but the actually observed moment when Venus was first seen.

Coming now to the much disputed observations of internal contact, the figures of seconds seem at first sight to be corrected. Littrow says that the paper bears marks of having been scraped, and that the original figures of seconds had been carefully erased, the ink, in consequence, spreading in the paper. Professor Newcomb remarks, that one sees at a glance that the latter statement is erroneous; and he applies to the question of erasure the test of viewing the paper by oblique sunlight, and proves the texture of the surface to be still uninjured. The evidence thus leads to the certain conclusion, that no different figures from those now visible were ever written there. If, then, they are in any way the result of calculation from other observations, the place must have been left blank until Hell got back to Copenhagen, and made the necessary calculations, — an hypothesis too fanciful for serious discussion. Another part of the record looks more suspicious, — a line, 'fulmen 9 32 48,' is not only an interlineation, but is written in decidedly different ink from all the original manuscript. The original journal, up to the time that Hell left Wardhus, being all written in one kind of ink, we conclude that the insertion was made after he reached Copenhagen, and after he had seen the observations of others. Two hypotheses are before us as to how the insertion was determined, — we may suppose that Hell, when he found he had omitted what other observers considered an important phase, tried to remember how long after the recorded contact he first saw the sun's limb continuous, and wrote the result in his journal; or we may suppose that he made a memorandum at the time of the observation, but omitted to copy it in the journal, either through inadvertence, or because he deemed it too late for contact. When he found the phase important, he merely copied the omitted record in his journal. The use of the queer word 'fulmen,' which appears only in the manuscript, seems to Professor Newcomb to give color to the latter hypothesis. He can hardly conceive of one using it deliberately, after six months, to express the formation of the thread of light; whereas, at the moment of observation, in the excitement and hurry, it would be a very natural single word to designate the rapid increase of the effulgence of solar light around the following limb of Venus, which follows true contact at ingress. It is a strong confirmation of this view, that Mr. Stone, without apparently having made any comparison with Hell's printed observations, reached this same conclusion as to the probable use of the word 'fulmen.'

With regard to the egress of the planet, the times of Hell's notes of the 'gutta nigra' are each increased by two seconds; but obviously this correction was made at the time of writing. More serious is a correction of the time of observation by Sajnovics, the companion and assistant of Hell. They, no doubt, discussed their times; and, in consequence of such discussion, Sajnovics concluded that his times were late. In the exterior contacts, the only corrections are such as were made at the time of writing, and to which Professor Newcomb attaches no importance.

Regarding certain collateral circumstances which have been supposed to cast suspicion upon Hell's intentions, not only does Professor Newcomb see no suspicious delay in making known his observations (for the whole paper, containing an account of his instruments, observations, and results, including an investigation of his quadrant and clocks, a discussion of his latitude, longitude, and time, and a full statement of his observations, was written, printed, and ready for distribution, four months after his return to Copenhagen), but it seems difficult for him to suppose that Hell could have had time to make so complete a reduction of the observations of others as to be able to compare them with his own. That his observed times of the contacts were not published in advance, as were those of many other observers, but appeared first in an official form under the imprint of the Academy of sciences, seems to Professor Newcomb in accord with very proper feeling, as the observations were made under the auspices of the king of Denmark, and dedicated to him; and furthermore, owing to the position of the station being unknown, publication in advance could have served no useful purpose.

In his discussion, Professor Newcomb makes but slight allusion to the absence of many circumstances which might be expected to accompany manufactured observations; but he has presented all the positive evidence within reach so fully as to enable every one to draw his own independent conclusions. His own conclusions are, —

First, The belief that there was any suspicious delay in the publication of Hell's observations, or any thing in his course to give reasonable ground for a suspicion that he intended to tamper with his observations, is a pure myth.

Second, Excepting the time of formation of the thread of light at ingress; excepting, also, a discrepancy of one second in the time of internal contact, and a change of two seconds in one of Sajnovics's times, — it is proved, not only negatively and presumptively, but by positive evidence and beyond serious doubt, that all the essential numbers of observation given by Hell, whether relating to the transit, time, or longitude, are printed as concluded upon and written in his journal at Wardhus, before there was any possibility of communication with other observers.

Third, The addition of the time of the formation of the thread of light was suggested by the accounts of other observers; but the time itself is Hell's own, obtained possibly from estimation and memory, but more probably from a memorandum made at the time of observation, which he neglected to insert in his journal.

Fourth, The alterations in Sajnovics's time of second internal contact were probably made, because Sajnovics himself afterward concluded that his recorded time was too late; but it may be assumed, that, in reaching this conclusion, he was influenced by Hell's observations.

Professor Newcomb adds, respecting his own proceedings in investigating this subject, that, in commencing the examination of Hell's journal, he had no hope of doing more than deciding whether it was or was not safe to use Hell's numbers as actual results of observations, and no thought of doubting the commonly received view of the case. He soon became perplexed to find himself differing entirely from the conclusions of Littrow. Before the latter had found the manuscript, suspicion had rested upon Hell's truthfulness; so that when he looked into the manuscript, and saw such extensive alterations, the indictment seemed so clearly proven that Littrow's only duty was to make the facts which proved it known to the world. He thus unconsciously assumed the tone of a public prosecutor, and saw all the circumstances from an accuser's point of view.

LETTERS TO THE EDITOR.

Errata in catalogues of stars.

The Washburn observatory possesses a nearly complete collection of such star-catalogues as have been printed since the year 1800. A list of them is given below. It will be noticed that this list does not include the very expensive British association catalogue. Oeltzen's Argelander's Northern zones is also missing from the list, as I have been unable to buy it in Europe during the past two years. Another very scarce catalogue (Weisse's Bessel's Zones from + 15° to − 15°) I have just obtained after two years' delay.

In each one of these catalogues, I have had every erratum known to me inserted in its proper place, so that the set of catalogues really represents what is known, freed from an enormous mass of misprints and real errors.

I am not able to say how many material errors have been corrected, but certainly not less than twelve thousand. I think those who use star-catalogues most will be most surprised at the amazing number of material errors which still remain in the catalogues which they employ daily.

I have called attention to these errors in order to say that I will engage to have any of the catalogues of the following list corrected completely, in all respects like my own, for any observatory, or for any astronomer who may desire it.

The catalogue should be sent by American express, prepaid, addressed to me, and accompanied by a note asking that the work be done. The book, when corrected, will be returned by express at the owner's expense.

The corrections will be made by one of my assistants, under my direction, and an account kept of the number of hours spent on the work. The work will be charged for at the rate of fifty cents per hour. I may say that the sum so received will be paid to the copyist.

It has appeared to me, that, after the large amount of labor which has been expended on my own catalogues, I was under obligations to give the benefit of such work to others, and this I willingly do.

The first list following gives the names of the catalogues owned by the Washburn observatory; the second gives the sources from which the errata have been derived. I shall be much indebted for references to errata not there mentioned.

EDWARD S. HOLDEN.

Washburn Observatory, Madison, Wis.,

The search for Crevaux.

Apropos of your recent weekly summary of the progress of geography under the titles of the Death of Crevaux, etc., I may say that a member of the French geographical society, M. Thouars, accompanied the U. S. solar eclipse expedition from Panama to Callao, March 12–21, of this year. M. Thouars had familiarized himself with explorations in South America by extensive travels in Columbia and elsewhere, and intended to penetrate the Pilcomayo region, in search of the relics of the Crevaux expedition, alone, or with only one companion, the two disguised as Catholic priests. The attempt seems foolhardy; and, for my part, I am glad to know that M. Thouars intends to carry a revolver under his priest's robe, and that he is a brave man and an excellent shot.

If he has not abandoned his daring project, we should hear of him during the early part of 1884.

EDWARD S. HOLDEN.

Madison, Aug. 6, 1883.

Occurrence of the swallow-tailed hawk in New Jersey.

Early in the evening of July 28 I was standing on the brow of the bluff overlooking the Delaware River, near Bordentown, N.J., when my attention was called to a large bird sailing in comparatively small circles high overhead. Fortunately there was a dark blue-black cloud behind it, so that I had an excellent opportunity to observe the bird. It was the swallow-tailed hawk (Nauclerus forficatus). It remained in nearly the same position for over an hour, when it altered its flight, and, with steady wing-strokes, flew rapidly in a north-west direction.

The appearance of this hawk here is one of the rarest events in the experience of New Jersey ornithologists. CHAS. C. ABBOTT, M.D.

A reckless flier.

ONE might think a tragic end would await such birds as the Swifts, so bold and persistent their flight; and doubtless such is in store for many, though they seem to steer clear of most obstacles.

A case in point came recently to hand, — that of an unfortunate bird impaled to the spear-point of a lightning-rod above a chimney. There it remained until shot off with a gun, — a warning and a ghastly one, indeed, to all this *swift* race. F. H. HERRICK.

Swallows in Boston.

I saw on the 4th of this month the first swallow in Boston, at the extreme end of City Point, South Boston. I have been on the lookout for them since April. Two friends, good observers, report that they have not seen one this season.

CARL REDDOTS.

Boston, Aug. 7, 1883.

'HAS any one seen a swallow this summer in Boston?' inquires a correspondent in SCIENCE, Aug. 3. Yes: I saw six last week, perched on the state-house. Prior to this I had also raised the query. Whether it was the pugnacious sparrows, or legislature, that had banished these aerial visitors from the capitol, their old haunt, was and is a query.

LEANDER WETHERELL.

Boston, Aug. 11.

WARD'S DYNAMIC SOCIOLOGY.

IV.

IT is Mr. Ward's theory, that the more complex sciences should be based upon the less complex. This he avowedly derives from

Comte, but himself defends at length; and his work is constructed consistently therewith. The part which relates to sociology, therefore, is based upon principles derived from the physical and biologic sciences and psychology, which he treats as a biologic science. Some general mention is made of languages, arts, and opinions, in various portions of the book; but no systematic treatment of these subjects is presented. The same is true with respect to all that body of facts which, if systematized, the author would call static sociology. He only attempts to treat, at length and in order, the forces of society. This theory is but a half-truth, and the method of treatment resulting therefrom has sometimes led to conclusions that are erroneous. The most important failure in this respect is Mr. Ward's presentation of what he denominates the four stages of society: viz., "(1) the solitary or antarchic stage; (2) the constrained aggregate or anarchic stage; (3) the national or politarchic stage; and (4) the cosmopolitan or pantarchic stage." The first or solitary stage is that which Mr. Ward supposes to exist among animals. In the second stage he supposes mankind to have multiplied in great numbers, to have been widely spread throughout the earth, and to have been aggregated without organization. The third stage is represented by the organized tribes and nations of the earth. The fourth stage is a prophecy, when all men shall be organized in one body politic.

It will be well to compare this scheme with that of Morgan in his 'Ancient society.' Morgan attempts to establish what he denominates ethical periods. The three grand periods are savagery, barbarism, and civilization; and savagery and barbarism are subdivided. The following is his scheme: —

I. Lower status of savagery . . .	From the infancy of the human race to the commencement of the next period.
II. Middle status of savagery . .	From the acquisition of a fish subsistence and a knowledge of the use of fire to the commencement of the next period.
III. Upper status of savagery . . .	From the invention of the bow and arrow to the commencement of the next period.
IV. Lower status of barbarism . .	From the invention of the art of pottery to the commencement of the next period.
V. Middle status of barbarism . .	From the domestication of animals on the eastern hemisphere, and in the western from the cultivation of maize and plants by irrigation, with the use of adobe-brick and stone, to the commencement of the next period.
VI. Upper status of barbarism . .	From the invention of the process of smelting iron ore, with the use of iron tools, to the commencement of the next period.
VII. Status of civilization	From the invention of a phonetic alphabet, with the use of writing, to the present time.

It will be seen, that Ward's scheme is consistent with his philosophy, and based on method of aggregation, while Morgan's scheme is based on the development of arts. Ward is right in his philosophic plan, but altogether wrong in its execution: Morgan is wrong in his plan, or method, but more nearly right in his final conclusions; for the three grand stages which he endeavors to establish can with some modification be fully based on the method of aggregation, i.e., on the data of sociology as distinguished from technology. This will be briefly set forth.

The inception of social organization is in the biologic differentiation of the sexes, giving husband and wife, parent and child, brother and sister, and other relations of affinity and consanguinity. At that time, when the species now known as man had made no farther progress than have some of the lower animals at the present time, this elementary organization existed; and a greater or less development of this organization is discovered among many species of the lower animals. On it the subsequent organization was built. The importance of this fundamental organization seems to have escaped Mr. Ward.

Archeologic evidence is now abundant to show, that man was widely scattered throughout the earth at a very early stage in the development of art, i.e., in the paleolithic age. Again: there is abundant linguistic evidence to show, that man was widely scattered throughout the earth at the inception or beginning of the development of articulate, i.e., organized, speech. In this condition he must have had at least something of the social organization which is based on sex. The stories which have been told, to which Mr. Ward refers without giving full credence, of men living in utterly discrete conditions, are but idle tales, and have no place in the data of scientific anthropology. Mr. Ward says, "The second stage embodies none of the elements of permanency, and cannot be expected to be found extensively prevailing at any age of the world. It is essentially a transition stage, and, like transition forms in biology, is characterized by an ephemeral duration. Nevertheless, it has numerous living representatives among the lower existing tribes, particularly among the Fuegians, interior Australians, Wood-Veddas, and Bushmen." The illustrations given of this second stage are also idle tales. These people must also have had the organization mentioned above as based on sex; and it is now known that some of them at least, especially the Australians, have a highly organized system of social aggregation based on kinship. These people are, in fact, organized as tribes. In the presence of facts, the first and second periods of Mr. Ward disappear.

Travellers among savage peoples, seeking for the institutions with which they were themselves acquainted among civilized men, have found them not, and have sometimes reported the peoples to be without institutions, and at other times have completely misinterpreted what they did discover. If we accept such statements, we must believe that some tribes were without organization, and some had the institutions and governments of civilization. And if we compare the statements of a number of travellers about the same people, we shall discover that most of the savage tribes of the earth have been reported, now as being destitute of government and sociologic institutions, and now as having kings, aristocracies, and the elaborate paraphernalia of civilized governments. None of these accounts are true: all are to be rejected. But there yet remains a body of sociologic data relating to the lower tribes of mankind, collected by scientific anthropologists, chiefly during the last two or three decades. We owe much of this knowledge to Morgan's researches, and the investigations of others which have grown out of his suggestions. We now know something of the organization of almost every tribe on the face of the earth, though in many cases our knowledge is exceedingly meagre and fragmentary. Yet perhaps enough is known to warrant the assertion, that there is no tribe so low but that it has a sociologic organization highly developed in comparison with that mentioned above as based on sex and exhibited among the lower animals. The outlines of this plan of organization must be set forth.

The tribes of mankind, as distinguished from nations, have each an organization based on kinship. This system of kinship invariably recognizes grades, based primarily on degrees of affinity and consanguinity, and secondarily on relative age, or the series of generations which may be extant among a people at any given time. All of the relations which exist among such a people, and which may be denominated as rights and duties, are determined by the kinship relations recognized in their social organization, and expressed in their language. This subject is too vast for thorough exposition here, and a single illustration must suffice. Among all such tribes age gives authority, but no method of determining the absolute age of any individual exists among them. Dates of birth are soon forgotten. But there is in the language of every such tribe a device by which relative age is invariably expressed; for every man, woman, and child accosts and designates every other man, woman, and child within the tribe by a term which in itself expresses relative age. Thus, in these languages there is no term for *brother;* but there is one term for *elder brother*, and another for *younger brother*. A man cannot speak of his 'brother' as such simply: he must use a term which says 'my elder brother,' or 'my younger brother,' as the case may be. In the same manner, if he speaks to or of any other person in the tribe, the term by which that person is designated will itself show the relative ages of the persons speaking and spoken to or of. Age gives authority, and this authority is so important and so universal that it is woven into the texture of every tribal language. Every tribe is organized as a great family, — a system of kindred.

From this plan of early tribal organization, there is a great development exhibited in many ways; for tribes are differentiated into classes, or clans, or gentes, which are interdependent bodies politic.

This tribal organization, so briefly characterized, has its fundamental idea in kinship; and the minds of the people in this stage can conceive of no other form of organization. If two or more tribes form an alliance, temporary or permanent, for defensive or offensive purposes, one or both, the same thought prevails. In a council for such an alliance, one of the first propositions to be settled is, 'What shall be the kinship relations existing between us?' and, before the alliance can be consummated, this must be settled.

Once upon a time the Cherokees, Choctaws, Chickasaws, Muskokees, and other tribes met in council for the purpose of forming an alliance against the upper Mississippi tribes of the Dakota stock; and it was decided, that, as the Cherokees lived at the sources of the streams that watered the country occupied by the other tribes, they, the Cherokees, should be called 'elder brothers,' and the tribes living on the lower courses of the streams should come in order from east to west as second, third, fourth, fifth, and sixth born sons, because such was the course of the sun as it travelled over their lands. Then the people of one tribe called the people of another 'elder' or 'younger' brothers, and took precedence and authority in council and war therefrom.

This plan of organization is a distinct method of aggregation, designated as kinship, or tribal; but it gradually developed into something else. As tribes, by alliance, by conquest, and various other processes, enlarged, it was done by establishing artificial kinship, — by what Sir Henry Maine denominates a 'legal fiction;' and in many cases it came to be that the whole organization was chiefly a legal fiction. Kinship ties were chiefly artificial. Under these circumstances the kinship bond, composed of marriage-ties and streams of kindred blood, was found to be but a rope of sand; and gradually, by many steps, the basis of aggregation was changed to territory, and the bonds of society became the organs of government for the regulation of relations arising from property. But, before a territorial system of aggregation is fully established, intermediate stages are discovered. First, the tribal organization occupies a distinct territory, but the territorial organization is latent; then aggregations partly by territory and partly by kinship supervene; and finally, by many steps, kinship organization is abandoned, and territorial organization remains. This gives two very distinct methods of aggregation or plans of social organization, viz., kinship and territorial society, or tribal and national government; and the two are objectively discovered, and not simply theoretical. The first in its simplest state is Morgan's Status of savagery; the second in its simplest state is Morgan's Status of civilization. His Status of barbarism includes the higher forms of kinship organization and the transition forms mentioned above. If we confine his Status of barbarism to the transition forms, we will then have savagery, barbarism, and civilization established properly on modes of aggregation; but barbarism will merely be a transition stage, and comparatively ephemeral.

Of Mr. Ward's fourth stage, it is simply necessary to say that he himself recognizes it as an ideal of the future; but it is properly based upon history, and is in the manifest course of social evolution. Of the myriads of languages once existing, and of many of which we now have but mere glimpses, few remain, and of these few a very small number are rapidly predominating. The many have become few, and the few will be completely unified, for such is the course of philologic evolution. Of the myriads of tribes scattered by the shores of the seas, on the margins of the lakes, and along the streams of all the habitable earth, but few remain. They have been gradually integrated into larger tribes, and finally, with the most advanced, into nations; and the time will come when there will be but one body politic, for such is the course of sociologic evolution. Every tribe of the myriads that have spoken distinct languages has each for itself developed a mythologic philosophy. These mythologic philosophies are rapidly disappearing, and now are comparatively but few; and the time will come when but one philosophy will remain, — the philosophy of science, the truth, — for such is the course of philosophic evolution. The fourth stage of society — the cosmopolitan or pantarchic — is a legitimate induction, a qualitative but not a quantitative prophecy, for who shall say when it shall come?

Morgan's method of basing his stages upon the arts is unphilosophic: it was simply stages of art development, not stages of social organization. But, because art and society have evolved interdependently together, it very nearly represents the truth; but the actual condition of the progress of any given society or body politic can be determined with less accuracy from its arts than from any other department of anthropology, and this from the fact that art is expressed in material form that can be easily imitated. Its use is at once apparent; and a people may easily borrow an art, or an aggregate of arts, without passing through the stage necessary for its invention. Arts, therefore, travel beyond the boundaries of tribes, languages, and philosophies, and are rapidly spread throughout the world. Tribes that to-day use the bow and arrow may to-morrow use the gun, though they have no knowledge of chemistry and metallurgy. The attempts of the archeologists of modern times to trace migrations, or to connect peoples by a genetic tie, have been to a large extent rendered vicious by the failure to recognize this principle. Tribes and nations, peoples, bodies politic, cannot be classified by arts: but the evolution of arts may be marked off in stages, as done by Morgan; and his stages are the best yet proposed, though he failed as an ethnologist in the attempt to classify races.

In the same manner, but to a less degree, scholars have failed to classify peoples by languages; for languages only to a limited extent represent genetic connections of peoples. Tribes speaking diverse languages have coalesced; and languages have thus been compounded, and language has supplanted language. A linguistic classification, therefore, is not completely ethnic, but it comes nearer to the truth than the technologic classification. If a classification by philosophies were attempted, it also would fail, though it would be superior to the philologic; for opinions last longer than words. A sociologic classification of peoples also fails to exhibit genetic relationships. Arts, languages, states, philosophies, may be classified, each to show genetic relationships; but they each and all together fail to classify mankind in a fundamental and philosophic manner.

Scholars have devoted much time and ingenuity to classify mankind by biologic characteristics, sought for in the color of the skin, the texture of the hair, the form of the skull, the relative proportion of parts, etc. These attempts have all failed. It is probable that in the early history of mankind biologic differentiation progressed so far as to produce some well-marked varieties; but the biologic method of evolution by the survival of the fittest was more and more repealed as the anthropologic methods of evolution gained ground, and the scattered and discrete tribes were more and more commingled by the union here and there of distinct streams of blood, by the spread of arts, that placed all peoples under conditions of artificial environment, and made them more and more independent of natural environment, and by various other anthropologic conditions too numerous and complex to be here set forth. But, altogether, the tendency to differentiate into distinct biologic peoples has been overcome, and the tendency to unification has been steadily increasing: so that the distinctions of biologic varieties of mankind, of which we now have but hints in the biologic characteristics remaining, are gradually being obliterated; and we may confidently predict that in the fourth stage, yet to be reached, race distinctions will be utterly lost.

In the short articles of this review an attempt has been made to give a synopsis of the work in question, to show the relation of 'Dynamic sociology' to current philosophy, and to point out its more important defects. Little space is left for that commendation which its intrinsic merits deserve. Mr. Ward's presentation of the subject is simple, clear, systematic, and courageous. For its preparation he has explored vast fields of thought; and his conclusions, however they may be questioned, cannot be ignored by those who are interested in modern philosophy. Ward's Dynamic sociology is America's greatest contribution to scientific philosophy.

ELEMENTARY METEOROLOGY.

Elementary meteorology, with meteorological charts and illustrations. By R. H. Scott. London, *Kegan Paul, Trench, & Co.*, 1883. 408 p. 8°.

This volume, the latest English contribution to the science of meteorology, is not a treatise, as the title indicates. It is, however, an excellent work, treating the subject from a modern stand-point, and sweeping away many untenable theories. We especially note the chapters on the barometer and on the formation of rain and hail. The descriptive chapters collecting all known facts relating to wind and ocean currents are very valuable and well presented.

Our author rejects the once seemingly satisfactory theory, attributing the south-west monsoon winds of India to the rising of heated air above the plains to the north-east of the Himalaya range, and also the theory that the existence of sea-breezes is due to the rising of heated air upon the land near oceans. He, however, adopts this theory of ascending currents of heated air in explaining the formation of cumulus-clouds. It is difficult to see how the atmosphere can be heated, save gradually, in strata parallel to the earth's surface, except on mountain sides. This is the theory adopted by Hann, who regards the cumulus-cloud as simply indicating the layer at which the air has the temperature of the dew-point.

Mr. Scott seems to indorse the theory that there is an ascending current in the centre of a barometric depression, though his storm-chart on p. 355 shows all the wind-directions near the low centre tangent to the isobars. This shows that the air-motion, which at the outside of the storm is directed more or less toward the centre, gradually becomes circular as it approaches the centre. Such a whirl moving over the earth's surface, losing a part of the air in its path, does not require any ascending current at its centre. The same may be said of our author's theory that rain can be formed by rising currents of heated air. In this case, not only is there the doubtful assumption of an ascending current, but the formation of rain under these circumstances seems disproved, in another place, by the author himself, who rejects the theory that any considerable precipitation can be produced by the mixture of masses of hot and cold air. Mr. Scott acknowledges that nothing definite is known as to the origin of atmospheric electricity; but his conjecture that the coalescence of cloud-droplets into rain-drops may be due to electricity will hardly be accepted by meteorologists at present. The description of a peculiar electrical manifestation observed in the Alps, July 10, 1863, is very similar to that given by Siemens while on Cheops pyramid, April 14, 1859.

The division of thunder-storms into heat and cyclonic is hardly applicable to the United States, where it appears as if no thunder-storms occur, except as largely influenced by, or directly dependent on, the presence of a barometric depression.

The error of more than forty million square miles in the earth's surface between the equator and 30° north latitude should be corrected in the next edition.

The statement, that at great depths in the ocean a probable uniform temperature of 32° F. prevails, has been disproved by the researches of Professor Verrill and the U. S. fish-commission.

We notice on p. 362 the surprising statement, that, as the central office of the U. S. weather bureau is in the eastern part of the country, there is a great advantage to those predicting storms by the use of the telegraph.

The chart of mean January isobars does not incorporate Stelling's work in Siberia, published in 1879, and accepted by Mohn in the last edition of his Meteorology. Mohn's chart shows a mean pressure over central Siberia of 780 mm. (30.79 in.), while the highest figure in Scott for the same region is 30.4 inches.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The thirty-second annual meeting of the American association was opened in the halls of the university of Minnesota, Minneapolis, Aug. 15, at 10.30 A.M. Dr. J. W. Dawson, the retiring president, introduced the president elect, Prof. C. A. Young, who briefly and gracefully expressed his thanks to the association for the distinction they had offered him. After welcomes spoken by the governor of the state and the mayor of the city, the principal address was made by the acting president of the university, Dr. W. W. Folwell, on behalf of the local committee. From his address we print the closing sentences: —

I should do a wrong to my city if I should leave upon you the impression that we are so overwhelmed and engrossed with our material labors as to have no care for the things of the mind and the higher life. If that were true, why should we welcome with so much sincere ardor the assemblage of your association? From the villages of New England, and the farmhouses of the Middle states, our people have brought that perennial curiosity, that thirst for knowledge, that intense though sombre imagination, which have given American civilization and American literature a cast and hue of its own. I must, in a word, praise our system of public schools, both city and state, which under able management and popular support cannot, we believe, be ranked below those of any communities of our size in the Union. Minnesota is the first place which has organized its secondary as well as its primary education, and offered to every child in the state a free course of studies, from the alphabet to the degree of master of arts. Our churches, goodly in size and number, may speak for the interests of religion. The future will attest the diligence and the fidelity of those who love music and the sister arts, of whom far older cities might be proud. It is thus, however, Mr. President, that we Minneapolitans, alert, pre-occupied, pause in the midst of our labors to welcome your already venerable association. We hail you as the survivors of a generation of great investigators, — the Sillimans, the Baches, the Morses, the Rogerses, who have made their own country famous and their own names as imperishable as science herself. We hail you as the worthy successors of such a generation, perpetuating and enlarging their work. In common with civilized people, we recognize the immense debt of the modern world to science; yet often, no doubt, while we are filling the sky with applause to some lucky inventor, we are not remembering the years, perhaps generations, of inconspicuous and painful labors, carried on in our studies and laboratories, which made the invention possible. Let the inventor have his glory and his profit without envy and without stint; but let us not fail to build the cenotaph of a thousand nameless geometers, star-gazers, and natural philosophers, who, working in silence and obscurity, without thought of fame or hope of reward, put it in his power to bless and captivate the world. We are grateful, therefore, to science for the telegraph and the microscope, for chloroform, for the photograph, for all the nameless applications of electricity. To science we owe that magnificent apparatus of transportation which is the crowning and distinctive feature of modern material life. To science we owe the thousand appliances which yield comfort and even elegance to the humblest household. Immense as are these contributions of science to material comfort and happiness, she has still, I think, performed greater services to mankind. The scientific method developed in the study of nature has spread to all branches of investigation. It has permeated all our education: it has boldly leaped the boundary between physics and metaphysics. It has even penetrated into industry and business and common life. The modern man first collects what knowledge he can about his enterprise or adventure, and assures himself of its value. He then makes the best quest he can in regard to the future. Then he assembles new facts, and, as the facts require, revises and amends his theory, till at length it becomes a working rule, maxim, and principle. He knows not merely how to know, but how to guess. The penetration of the scientific method into the operations of trade in great commercial centres is very conspicuous. We even endeavor to gamble scientifically. No Drew, or Armour, or Gould ever forms his corner without a most careful study of the situation; and his venture is his bet on the correctness of his theory. The farther extension of the scientific method, till it shall become the guide of conduct in the every-day life of all men, is now the chief problem in education.

In the next place, I think science may at length fairly claim to have wrought out, under great difficulties, a working hypothesis of our universe in the nebular hypothesis and its almost necessary corollary, 'evolution.' It cannot be denied that we are all, in some sense, evolutionists, — some of us against our prepossessions, some of us by insensible but progressive lapses. I am not competent to argue out this great theme. I feel bound to admit that the evolution doctrine, in one form or other, has quietly taken possession of the modern mind. Why may we not gladly accept it as a most useful working hypothesis of the mode of creation? I say, of the mode of creation; for the mystery of creation will forever mock the powers of man. Only this we know: that unless human consciousness is a juggle, and human language a mockery, there can never be to man a creation without a creator, nor an evolution without an evolver.

Another great service of science is the maintenance in the world of a body of men, a lay priesthood, devoted to the search for truth for its own sake and its own value. In a mercenary age, when, in the opinion of a distinguished contemporary, mercantilism has become a huge disease and excrescence on society, the example of such a body of men is of supreme value in the training of the new generations. Youth are formed, a wise Greek has taught us, not so much by schools as by the example of distinguished men.

A still greater benefit of science to mankind is the emancipation it has wrought for us, in the last generation, from superstition and the dominion of imaginary powers. It is no long time since it was generally believed by civilized men, that human affairs were under the control of the spirits of the air, good or evil. Men walked in cringing terror, by day and night, of demons and goblins damned. The earthquake, the tornado, the lightning's stroke, they looked upon as instruments of punishment for the sins of rulers and peoples. Thanks to science, the modern world has emerged from this cloud of gloom. We have some certain knowledge. Knowledge is not merely qualitative, but quantitative. Truth ever makes free. Above all, we know that all things in nature are governed by law, — law, "whose seat is in the bosom of God, whose voice is the harmony of the world." The beautiful conception of the Greeks of the universe as a kosmos, that is, an embodiment of divine and perfect order, is pervading modern thought. We now know that the phenomena of nature have no relation to human conduct, the impartial rain falling alike on the just and unjust. Men walk the earth erect and free, fearing no bogies, or warlocks, or demons of any kind. How vast and how blessed the relief to childhood! In dispelling superstition, science has incidentally wrought her greatest service to mankind in the purification of religion. The time is coming when grateful thanks will be rendered by the minister of religion for the emancipation which science has wrought for the faith; when the conflict of science and religion will only be remembered as the antagonism of crude theories on the one hand, and cruder superstitions on the other. Grateful we are for the knowledge which science has collected and collated and perpetuated to our use. All honor to the men who are consecrated to truth in her service! We may not know what marvels, far surpassing all the gifts of the past, the science of the future may reveal. Still, we must remember that the human mind is finite, while truth is infinite. The vast unknown engirdles our little circle of light. The mystery of life and death, no son of earth has ever penetrated. Welcome, then, the faith which points to the continuance of life in a land where study will be no weariness to the soul, where no veil of flesh will cloud the vision, where science and religion shall be forever one, where men shall know even as they were known.

To welcome you as a body of scientists, lovers and seekers after truth from love of it and of your kind, would be well worth our while, were it our only motive to improve and inspire the children and youth of our city. In doing you honor, we give them a lesson no books nor masters could impart. For their sake we renew our welcome.

President Young briefly responded: —

Gentlemen, — On behalf of my fellow-members of the association, I return you my sincerest thanks for the hearty welcome we have received to this magnificent state, this young and beautiful city, this vigorous, energetic, warm-hearted community. When you first invited us here, it was not in our power to come; but your second invitation we have accepted most gladly, and hope and believe that our meeting here will prove a benefit and pleasure to all concerned. Some of us have known you personally before, and most of us have long been more or less familiar at second hand with your state and city; and yet, I think, to many of us it is something like a new revelation to see for ourselves what a few years have accomplished. I am not enough of a Latin scholar to quote my Virgil well; but I have been all the time most forcibly reminded of the passage in which Æneas first comes in sight of rising Carthage. Most emphatically the work 'hails' here. We see no drones or sluggards; but every shoulder is at the wheel, and every thing is moving. It may, perhaps, seem to you sometimes, when in our sectional meetings we discuss some question about the stars, or some hypothesis as to the formation of rock-strata, or the structure of some worm or insect, that we are out of the current, and contributing nothing to the advancement of the world. But you know it is not so, and your invitation to hold our meeting here shows that you know it. The world advances, not on one line only, but on many, — on lines material, intellectual, spiritual. To some extent, the movements are indeed independent, but not very far. Any true advance on either line implies corresponding movement on each of the others, if not absolutely simultaneous, yet surely consequent. There is no need to ask you here how much this city owes to modern science, when I see on every side, in your streets and storehouses and mills, the practical application of the highest engineering, mechanical, and electric art; and in the future it is almost certain that science is to contribute still more liberally to business. But not mainly for this reason do I claim your regard to science; but because, made in the image of God as we are, knowledge and understanding are as truly wealth and power as lands and food and money.

I need not add that, as you have invited us here, so we on our part cordially invite you to attend all our meetings, to listen to the papers and their discussion. We cannot promise that every paper will be interesting to all, but each one, I think, will be able to select certain ones he will be glad to hear; and if any of you choose to join us, and enroll yourselves as promoters of the advancement of science, our membership is open on easy terms. Once more, gentlemen, we thank you for the cordial welcome, and address ourselves to our business, in the hope and confidence that our meeting here is to be in the highest degree pleasant and successful.

PROCEEDINGS OF SECTION A. — MATHEMATICS AND ASTRONOMY.

ADDRESS OF WILLIAM A. ROGERS, OF CAMBRIDGE, MASS., VICE-PRESIDENT OF THE SECTION, AUG. 15, 1883.

THE GERMAN SURVEY OF THE NORTHERN HEAVENS.

The illustrious Argelander was accustomed to say, in the quaint form of speech which he often employed, "The attainable is often not attained if the range of inquiry is extended too far." In no undertaking is there greater need of a judicious application of this sound maxim than in the systematic determination of the exact positions of all the stars in the visible heavens which fall within the reach of telescopes of moderate power.

The first subject which engaged the attention of the Astronomische gesellschaft, at its formation in 1865, was the proposition to determine accurately the co-ordinates of all the stars in the northern heavens down to the ninth magnitude. To this association of astronomers (at first national, but since become largely international, in its character and organization) belongs the credit of arranging a scheme of observations by which, through the co-operation of astronomers in different parts of the world, it has been possible to accomplish the most important piece of astronomical work of modern times. With a feasible plan of operations, undertaken with entire unity of purpose on the part of the observers to whom the several divisions of the labor were assigned, this great work is now approaching completion. While it is yet too early to speak with confidence concerning the definitive results which the discussion of all the observations are expected to show, we may with profit consider the object sought in the undertaking, the general plan of the work, the difficulties which have been encountered, and the probable bearing which the execution of the present work will have upon the solution of a problem concerning which we now know absolutely nothing with certainty, — a problem of which what we call universal gravitation is only one element, if, indeed, it be an element, — a problem which reaches farther than all others into the mysteries of the universe, — the motion of the solar and the sidereal systems in space.

Our first inquiry will be with respect to the condition of the question of stellar positions at the time when this proposal was made by the gesellschaft in 1865. All the observations which had been made up to this time possess one of two distinct characteristics. A portion of them were made without direct reference to any assumed system of stellar co-ordinates as a base, but by far the larger part are differential in their character. This remark holds more especially with reference to right ascensions. Nearly all of the observations of the brighter stars made previous to about 1830 were referred to the origin from which stellar co-ordinates are reckoned by corresponding observations of the sun; but since that date it has been the custom to select a sufficient number of reference stars, symmetrically distributed both in right ascension and declination, and whose co-ordinates were supposed to be well known. The unequalled Pulkova observations for the epoch 1845 form, I believe, the only exception to this statement. From the assumed system of primary stars are derived the clock errors and instrumental constants which are employed in the reduction of all the other stars observed. The positions of these secondary stars, therefore, partake of all the errors of the assumed fundamental system, in addition to the direct errors of observation.

The following list comprises the most important of the catalogues which have been independently formed; viz., Bessel's Bradley for 1755, the various catalogues of Maskelyne between 1766 and 1805, Gould's D'Agelet for 1783, Piazzi for 1800, Auwer's Cacciatore for 1805, Bessel for 1815, a few of the earlier catalogues of Pond, Brinkley for 1824, Bessel for 1825, Struve for 1825, Bessel for 1827, Struve for 1830, Argelander for 1830, and Pulkova for 1845.

The important catalogues of secondary stars published previous to 1865 are comprised in the following table.

[*Table omitted.*]

An analysis of these catalogues reveals four important facts:—

First, that a large share of the observations relate to bright stars, at least to stars brighter than the eighth magnitude.

Second, that in a large number of cases the same star is found in different catalogues, but that no rule is discoverable in the selection.

Third, that with the exception of the polar catalogues of Fedorenko, Groombridge, Schwerd, and Carrington, the double-star observations of Struve, and the zone observations of Bessel and Argelander, the observations were not arranged with reference to the accomplishment of a definite object.

Fourth, that each catalogue involves a system of errors peculiar to the observers, to the character of the instrument employed, and to the system of primary stars selected, but that thus far there had been no attempt to reduce the results obtained by different observers to a homogeneous system. In estimating the value of these observations it will be necessary to refer to the researches which have been made subsequent to 1865.

The systematic deviations of different catalogues in right ascension *inter se* were noticed at an early date by several astronomers; but the first attempt to determine the law of these variations seems to have been made by Safford in a communication to the monthly notices of the Royal astronomical society in 1861 (xxi. 245), 'On the positions of the Radcliffe catalogue.' I quote the equation derived by Safford, since it appears to be the first published account of a form of investigation almost exclusively followed since that time. It is as follows:—

Diff. of R. A. (Greenw. 12 Year cat. — Rad.) = $-0.38^s. + 0.32^s. \sin (\alpha + 5\text{ h. } 32\text{ m.})$. Extending this expression to terms of the second order, it may be put under the form, $\Delta = a$ constant $+ (m \sin \alpha + n \cos \alpha) + (m' \sin 2\alpha + n' \cos 2\alpha) +$, etc.

Safford also seems to have been the first to notice the connection between the observed residuals, and the errors in position of the primary stars employed. He remarks, "In investigating the causes which would give rise to such systematic discrepancies, I was struck with the fact that the same or nearly the same variations were apparent in the assumed places of the time stars for the years since 1845; that, if the correct positions of the time stars had been assumed, the resulting positions would have been free from these small errors." That the relation given by Safford should have been observed at all, is the more remarkable, since the primary stars upon which the Radcliffe positions depend are nearly the same as those employed at Greenwich. In reality, the systematic errors of both catalogues have since been found to be considerably greater than is here indicated, and the deviation pointed out by Safford is in the nature of a second difference. The speaker has shown (*Proc. Amer. acad.*, 1874, 182) that the weight of the errors of the provisional catalogue assumed, fell between the first and the third quadrants in the Radcliffe observations for 1841–42, on account of the omission of certain clock stars which were used at Greenwich.

Since the discordances which exist between two catalogues may arise from errors in either one or in both, it is clearly impossible either to determine the nature of the erorrs, or to assign their true cause, until a fundamental system has been established which is free both from accidental and from periodic errors,—from accidental errors, since a few abnormal differences may easily invalidate the determination of the errors which are really periodic; from periodic errors, because a relative system can only become an absolute one when one of the elements of which it is composed becomes absolute.

We owe to the researches of Newcomb, published in 1869–70, a homogeneous system of stellar co-ordinates in right ascension, which are probably as nearly absolute in their character as it is possible to obtain from the data at present available. He determined the absolute right ascensions of thirty-two stars of the first, second, and third magnitudes, and comprised between the limits —30° and + 46° declination. A comparison of the places of these stars for a given epoch, with the same stars in any catalogue for the same epoch, enables us to determine with considerable precision the system of errors inherent in that catalogue. Several circumstances prevent the exact determination of this relation. Among them may be mentioned the fact that Newcomb's system cannot safely be extended far beyond the limits in declination of the stars composing the system, that the stars are not symmetrically distributed in declination, and that the system of errors derived from bright stars is probably not the same as that derived from stars of less magnitude.

To a certain extent all of these objections have been met in the later discussion by Auwers, to which reference will presently be made. The substantial agreement of these two systems, independently determined, furnishes satisfactory evidence that we have at last obtained a foundation system with which it is safe to make comparisons, from which we may draw conclusions with comparative safety. When the catalogues which were formed between 1825 and 1865 are compared with Newcomb's fundamental system, through the medium of these thirty-two stars, the following facts are revealed.

a. The only catalogues in which there is freedom from both accidental and periodic errors are Argelander's Äbo catalogue for 1830, and the Pulkova catalogue for 1845. One is reminded, in this connecnection, of the remark of Pond, that "we can hardly obtain a better test of our power of predicting the future positions of stars than by trying by the same formula how accurately we can interpolate for the past. In a variety of papers which I have submitted to the Royal society, I have endeavored to show, that, with us, the experiment *entirely* fails."

b. During this interval the constant differences between the earlier catalogues and Newcomb's system vary between $+0.17^s$ for Pond, 1820; and -0.19^s for Pond, 1830: and for later catalogues, between $+0.07^s$ for Cambridge, 1860; and $+.02^s$ for Greenwich, 1860.

c. All the right ascensions determined at English observatories, and especially those which depend upon the positions published by the British Nautical almanac, are too large in the region of five hours, and too small in the region of eighteen hours. The general tendency of the constant part of the deviation from Newcomb's system is to neutralize the periodic errors in the region of five hours, and to augment them in the region of eighteen hours, where, in the case of a few catalogues, the error becomes as great as 0.10^s, — a quantity which can be readily detected from the observations of two or three evenings with an indifferent instrument, if it relates to a single star.

The right ascensions determined at French observatories exhibit systematic errors, which follow nearly the same law as those which characterize English observations.

Distinctively German observations are nearly free from systematic errors. As far as they exist at all, their tendency is to neutralize the errors inherent in distinctively English and French observations.

d. In the case of several catalogues, residual errors of considerable magnitude remain after the systematic errors depending upon the right ascensions have been allowed for. These errors are found to be functions of the declination of the stars observed, and without doubt have some connection with the form of the pivots of the instrument with which the observations were made. This statement holds true, especially with respect to the observations at Paris, Melbourne, and Brussels, between 1858 and 1871; and to the Washington observations between 1858 and 1861.

e. The systematic errors which exist in observations previous to 1865 follow the same law, and have nearly the same magnitude, as the errors of the same class which are inherent in the national ephemerides of the country in which they were made.

The British Nautical almanac and the Connaisance des temps are largely responsible for the perpetuation of this class of errors. For a few years before and after 1860, the ephemerides of the Nautical almanac were based upon the observations of Pond, which contain large periodic errors. It is found that the errors of this system have been transferred without sensible diminution to every catalogue in which the observations depend upon Nautical almanac clock stars. At English observatories it has been the custom to correct the positions of the fundamental stars by the observations of each successive year; but this has produced no sensible effect on the diminution of the periodic errors, which belong to the fundamental system. The periodic errors of the American ephemeris follow nearly the same law as the errors of the Nautical almanac, but their magnitude is somewhat reduced. The error of equinox is also less.

Wolfer's *Tab. reg.*, upon which the Berliner jahrbuch is based, has no well-defined systematic errors; and the correction for equinox is nearly the same in amount as in the American ephemeris, but with the opposite sign. The accidental errors seem to be rather larger than in the system of the American ephemeris.

f. A general estimate may be formed of the relative magnitudes of the errors of secondary catalogues by comparing the average error for each star of the primary catalogue. The numbers given below represent the average deviation for each star, expressed in hundredths of seconds, after the various catalogues have been reduced to a common equinox.

		Average error for each star.
Argelander	1830	1.1
Pulkova	1845	1.1
Greenwich	1845	2.0
Greenwich	1860	2.0
D'Agelet (Gould)	1783	2.2
Cape of Good Hope (Henderson)	1833	2.2
Greenwich	1850	2.2
Greenwich	1871	2.2
Paris	1867	2.4
Washington	1846-52	2.5
Struve	1830	2.5
Cape of Good Hope	1856	2.8
Radcliffe	1860	3.1
Greenwich	1840	3.1
Bessel	1825	3.2
Pond	1830	3.7
Gillis	1840	3.8
Madras (Taylor)	1830	3.9
Cape of Good Hope (Fallows)	1830	3.9
Radcliffe	1845	4.5
Armagh	1840	5.0
Piazzi	1800	5.3
Bessel's Bradley	1755	7.9
Lalande	1800	13.2
Lacaille	1750	24.9

It is obvious from these relations, that previous to about 1825 the magnitude of the accidental errors of observation, combined with the errors of reduction, prevent any definite conclusions with respect to the periodic errors inherent in these early observations. It is probable, also, that early observations of stars of the eighth and ninth magnitudes are subject to a class of errors peculiar to themselves, the nature of which it is now well-nigh impossible to determine.

The systematic errors in declination which belong to the various secondary catalogues named are even more marked than those in right ascension. The experience of Pond in 1833 is the experience of every astronomer who has attempted to compare observations of the same star made at different times, under different circumstances, with different instruments, and by different observers. He says, "With all these precautions, we do not find, by comparing the present observations with those of Bradley made eighty years ago under the same roof, and computed by the same table of refractions, that we can obtain by interpolation any intermediate catalogue which shall agree with the observations within the probable limits of error."

We owe to the investigations of Auwers (*Astron. nachr.*, nos. 1532–1536), the first definite system of declinations which is measurably absolute in its character. Yet the deviations of this system from that derived by the same author, but from much additional data in publication xiv. of the gesellschaft, is no less than 1.2″. The present difference outstanding between the Pulkova and the Greenwich systems at 10° south declination is 1.7″.

Within the past five years, the labors of Auwers, of Safford, of Boss, and of Newcomb, have resulted in the establishment of a mean system of declinations from which accidental errors may be considered to be eliminated in the case of a large number of stars; but the different systems still differ systematically *inter se* by quantities which are considerably greater than the probable error of any single position.

When the discussion of the question of a uniform determination of all the stars in the northern heavens to the ninth magnitude was taken up by the gesellschaft at its session in Leipzig in 1865, Argelander, who was then president of the society, appears to have been the only astronomer who had a clear apprehension of the difficulties of the problem. He alone had detected the class of errors whose existence subsequent investigations have definitely established. He alone had found a well-considered plan by which these errors might be eliminated, as far as possible, from future observations.

Argelander, however, always claimed for Bessel the first definite proposal of the proposition under consideration (see *Astron. nachr.*, i. 257). It was in pursuance of this plan that the zones between − 15° and + 15° in declination were observed. These zones were to form the ground-work of the Berlin charts; and Argelander, in the execution of the Bonn Durchmusterung, simply carried out the second part of Bessel's recommendation.

With the exception of the observations of Cooper at Makree observatory, and the charts of Chacornac, these two great works — the second being a continuation of the first, under a better and more feasible plan — are the only ones in existence which give us any knowledge of the general structure of the stellar system.

The observations of stars to the ninth magnitude, found in the catalogues of Bessel, Lalande, and Piazzi, form the ground-work of these charts. The co-ordinates in right ascension and declination of the stars found in these authorities were first reduced to the epoch 1800; the resulting right ascension being given to seconds of time, and the declination to tenths of minutes of arc. With these places as points of reference, all other stars were filled in, down to the ninth magnitude, by observations with equatorial instruments. The work was divided into zones of one hour each. Bremiker undertook five zones; Argelander and Schmidt, two; Wolfers, three; and Harding, two. The remaining zones were undertaken by different astronomers in widely separated localities.

The work seems to have been performed with somewhat unequal thoroughness, some zones containing nearly all the stars to the ninth magnitude, while in others a large number of stars having this limit in magnitude are wanting.

The Durchmusterung undertaken by Argelander at Bonn was a far more serious and well-considered undertaking. This unequalled work consists in the approximate determination of the co-ordinates of 324,198 stars situated between − 2° and + 90° declination. It includes stars to the 9.5 magnitude, the co-ordinates being given to tenths of minutes of time, and the declinations to tenths of minutes of arc.

The first definite proposal of this work undertaken by the gesellschaft, however, appears to have been made by Bruhns. In the course of a report upon the operations of the Leipzig observatory, he stated, that, in his view, the time had come for undertaking a uniform system of determinations of the places of stars to the ninth magnitude in the northern hemisphere by means of meridian circles; but he proposed, at the same time, that the positions of stars fainter than the ninth magnitude should be determined by means of differential observations with equatorial instruments. After explaining certain plans and arrangements relating particularly to his own observatory, he introduced the following resolution: —

"The Astronomische gesellschaft regards it as needful that all the stars to the ninth magnitude, occurring in the Durchmusterung, should be observed with meridian circles, and commissions the council to arrange for the execution of the work."

This proposal occasioned a long and somewhat animated discussion, in which Argelander, Hirsch, Bruhns, Förster, Schönfeld, and Struve took part.

Argelander declared himself surprised at this proposal, which called for the rapid realization of a plan of organization which he had been considering for years with the greatest care, the difficulties of which he had maturely considered, and the execution of which still demanded the most careful deliberation and preparation. One of the necessary preliminary steps was a plan which he had already prepared, published and presented to the society in an informal way, which provided for contemporaneous and corresponding observations of the brighter stars. As president of the society, he felt unequal to undertaking the charge which the acceptance of the resolution proposed would involve; as this procedure seemed to him premature without previous preparation. He would admit, however, that every call to action of this kind tended to stimulate enthusiasm, and should therefore be encouraged; but he felt obliged to ask the society not to require from him the immediate execution of the plan, but to intrust the serious consideration of it, and the preparation for it, to his zealous friends in the council.

Upon the motion of Struve, the society by a rising vote, expressed its confidence in the assurance of the president that he would bring forward his plan at the proper time, as soon as the means for its execution could be assured.

At the meeting held at Bonn in 1867, Argelander again brought up the subject in a communication which appears to have been an exhaustive discussion of the whole problem. This paper is not printed in the proceedings of the gesellschaft; but at its conclusion a committee was appointed to take definite action with respect to the recommendations which it contained. The committee reported at the same session; and their report, which is published in the place of the paper presented by Argelander, is probably identical in substance with it. The plan proposed and adopted was finally published in the form of a programme, in which the details of the work are arranged with considerable minuteness. As this programme has been widely distributed, it seems unnecessary to give any thing more than a general abstract of it. Since it differs in a few minor points from the first report of the committee at the Bonn meeting, the essential features of this report will be given instead of an abstract of the programme itself.

They are as follows: —

a. The limits in declination of the proposed series of observations are — 2° and + 80°. The first limit was chosen on account of the lack of suitable fundamental stars south of the equator. It is probable, also, that Argelander had a suspicion of the fact, since proven, that the uncertainty with respect to the systematic errors of southern stars is, of necessity, considerably greater than for northern stars, and that on this account it would be better to defer this part of the work until further investigations in this direction could be made.

The limit + 80° was chosen because the repetition of Carrington's observations between 81° and 90° was considered superfluous, and Hamburg had already undertaken the extension of Carrington's observations from 81° to 80°.

b. Within these limits, all stars in the Durchmusterung to the ninth magnitude, and, in addition, all stars which have been more exactly observed by Lalande, by Bessel at Koenigsberg, and by Argelander at Bonn, are to be observed.

c. The observations are to be differential. The clock errors are not to be found from the fundamental stars usually chosen for this purpose, and the equator point corrections are not to be derived from observations at upper and lower culminations, but these elements are to be derived from a series of 500 or 600 stars, distributed as uniformly as possible over the northern heavens. The exact co-ordinates of these stars are to be determined at Pulkova,. thus securing the unity necessary in order to connect in one system the observations of different zones.

d. Every star is to be observed twice. If the two observations differ by a quantity greater than ought to be expected, a third observation will be necessary.

e. In order to facilitate the work, it will be desirable to use only three or four transit threads, and only one or two microscopes. In order to facilitate the reductions to apparent place, the working-list of stars should be comprised within narrow limits.

f. Before the commencement and after the close of each zone, two or three fundamental stars are to be observed upon the same threads and with the same microscopes as were used in the zone observations. When the seeing is not good, and when for any other cause it seems desirable, one or more fundamental stars may be observed in the course of the zone. The number and selection of the stars will depend upon the character of the instrument employed. If it remains steady for several hours, and has no strongly marked flexure or division errors, or if these errors have been sharply determined, the fundamental stars may be situated ten degrees or fifteen degrees away from the zone limits. However, there must remain many things for which no general rule can be given, and which must be left to the judgment of the observer, aided by an accurate knowledge of his instrument.

g. With a Repsold or a Martin instrument, one microscope will be sufficient, if its position with respect to the whole four can be determined. It will be sufficient, if the change in position during the observations can be interpolated to 0.2″.

h. It will be desirable to divide beforehand the zones into such time intervals that the observations can be easily made.

i. Zones exceeding one and one-half or at the most two hours are not advisable, first, because the zero points will be too far apart, and, second, because a longer duration will involve too much fatigue physically and mentally.

At the conclusion of this report, all the astronomers present who were willing to take part in this work were requested to communicate with the council, stating the region of the heavens which they preferred to select for observation.

At this meeting, Berlin, Bonn, Helsingfors, Leipzig, and Mannheim signified their intention to share in the work. Leiden also expressed its intention of taking part as soon as the work already undertaken should be completed.

When the stars to be observed had been selected from the Durchmusterung, it was found that the number would not vary much from 100,000, requiring rather more than 200,000 observations. Preparations for the work of observation were immediately commenced; and, by the time of the next report in 1869, considerable progress had been made.

In the report for this year, the provisional places of a catalogue of 539 fundamental stars were published. This catalogue is composed of two parts. The list of hauptsterne consists of 336 stars to the fourth magnitude, observed at Pulkova by Wagner with the large transit instrument, and by Gyldén with the Ertel vertical circle. The list of zusat-sterne consists of 203 stars fainter than the fourth magnitude. As the details of the work in the formation of the provisional places of the stars of this list are not given in the report, it is not quite clear upon what authority they rest. The work assigned to the Pulkova observatory by thé zone commission was the exact determination of the places of the stars of this list. The observations were undertaken by Gromadski with the Repsold meridian circle. In accordance with the plan adopted, each star was observed eight times, — four times in each position of the instrument. The observations were differential with respect to the hauptsterne.

The results were published by Struve in 1876; and the places there given were used in the first reduction of the Harvard-college observations for 1874–75, and perhaps in some other cases.

About this time a change seems to have been made in the original plan with respect to the formation of the final catalogue of fundamental stars, of which I have been unable to find a clear account. The original intention was to make the positions depend entirely upon the observations at Pulkova. The zone commission established by the gesellschaft, however, committed the formation of this catalogue to Auwers; and it is to him that we owe the most complete and the most perfect catalogue of fundamental stars yet published. The Pulkova system for 1865 was adopted as the basis; but, in order to obtain greater freedom from accidental errors for individual stars, the final catalogue was obtained by combining with the Pulkova series, the Greenwich observations from 1836 to 1876, the Harvard-college observations for 1871–72, the Leipsic observations, in declination only, between 1866 and 1870, and the Leiden observations in declination between 1864 and 1870. Before this combination was made, however, these observations were all reduced to the Pulkova system.

The following observatories have taken part in the zone observations: —

Observatories.	Limits of zones in declination.	Observatories.	Limits of zones in declination.
Nicolajeff . . .	− 2° to + 1°	Lund	+35° to +40°
Albany	+ 1 " + 5	Bonn	+40 " +50
Leipsic	+ 4 " +10	Harvard college .	+50 " +55
Leipsic	+10 " +15	Helsingfors . .	+55 " +60
Berlin	+15 " +25	Christiana . . .	+65 " +70
Cambridge (Eng.)	+25 " +30	Dorpat	+70 " +75
Leiden	+30 " +35	Kasan	+75 " +80

The zone between −2° and +1° was originally undertaken at Palermo, that between +1° and +4° at Neuchâtel, that between +4° and +10° at Mannheim, and that between +35° and +40° at Chicago.

In the latter case, the great fire at Chicago crippled the resources of the observatory to such an extent, that Safford was compelled to relinquish the work, which was at that time quite far advanced.

The chief items of interest in connection with this work are found in the following tabular statement: —

[*Table omitted.*]

Attention was called, at an early date, to the importance of continuing the survey of the northern heavens beyond the southern limit fixed by Argelander. The preparation necessary for the execution of this work consisted in the extension of the Durchmusterung to the tropic of Capricorn. This was undertaken by Schönfeld at Leipsic.

In the report to the gesellschaft at the meeting held at Stockholm in 1877, he has given an account of this work, in which he stated that it was sufficiently near completion to invite the consideration of the question of the meridian circle determinations of the places of stars to the ninth magnitude. The lack of southern fundamental stars whose positions were well determined was still a hinderance to the immediate commencement of the work. Relatively more stars of this class are required than in the northern observations, in order to eliminate the inequalities due to refraction. Schönfeld stated, that, while the burden of the determination of the places of these southern fundamental stars must rest mainly upon southern observations, it seemed necessary to connect them with the Pulkova system by a connecting link (mittelglied), through observations at some observatory well situated for this purpose. At this meeting Sande Bakhuysen, at Leiden, gave notice of intention to take part in this work. Gyldén urged the importance of securing the co-operation of Melbourne; and Peters suggested the advantage of securing Washington as an additional 'mean term' (V. J. S. 1877, p. 265).

The next reference to this work is contained in the vierteljahrsschrift for 1881, xv. p. 270. A list of 303 southern stars is here given, whose exact places were at that time being determined at Leiden and at the Cape of Good Hope. This list was selected by Schönfeld and Sande Bakhuysen, in a way to meet the requirements referred to in previous discussions.

A final catalogue of 83 southern fundamental stars by Auwers appears in this number of the vierteljahrsschrift. The places depend upon the same authorities as for the northern stars, with the addition of the Cape of Good Hope catalogue for 1860, Williamstown, Melbourne for 1870, and Harvard college (Safford) for 1864. For stars not observed at Pulkova, the general catalogue of Yarnall (1858–1861), and the Washington observations, with the new meridian circle between 1872 and 1875, were employed. As in the case of the northern stars, these observations are all reduced to the Pulkova system for 1865. It is understood that the co-ordinates of the list of 303 stars are to depend upon this extension of the general system of publication xiv. to the limits required by the southern Durchmusterung of Schönfeld.

It would be surprising if all the conditions of success were fulfilled in the first execution of a work having the magnitude, and involving the difficulties, of the scheme of observations undertaken under the auspices of the gesellschaft. The extent of the discordances which are to be expected between the results obtained by different observers can only be ascertained when the observations by which the different zones are to be connected have been reduced. Each observer extended the working-list of his own zone 10′ north and south; and it is expected that a sufficient number of observations of this kind has been made to determine the systematic relations existing between the co-ordinates of each zone with those of its neighbor.

It is probable, however, that the experience of Gill will be repeated on a larger scale. In 1878 he solicited the co-operation of astronomers in the determination of the co-ordinates of twenty-eight stars, which he desired to employ in the reduction of his heliometer observations of the planet Mars for the purpose of obtaining the solar parallax. The results obtained at twelve observatories of the first class are published in vol. xxxix. p. 99, of the monthly notices of the Royal astronomical society. Notwithstanding the fact that the final values obtained at each observatory depend upon several observations, the average difference between the least and the greatest results, obtained by different observers for each star, is 0.24ˢ. in right ascension and 2.3″ in declination. In four cases the difference in right ascension exceeds 3.0, and in four cases the difference in declination exceeds 3.0.″

Even after the results are reduced to a homogeneous system, the following outstanding deviations from a mean system are found: —

Authority.	Δ α	Δ δ	Authority.	Δ α	Δ δ
	s.	″		s.	″
Koenigsberg . .	+.005	−0.71	Leiden	−.053	−0.19
Melbourne . . .	+.026	−0.49	Paris	+.055	+0.01
Pulkova	+.005	+0.36	Washington . .	−.120	+0.78
Leipsic	+.049	+0 40	Harvard college,	−.072	+0 09
Greenwich . . .	+ 009	−0.56	Cordoba . . .	−.032	−0.20
Berlin	+.044	+0.67	Oxford	+.076	+0.21

The observations of a second list of twelve stars, one-half of the number being comparatively bright, and the remaining half faint, showed no marked improvement, either with respect to the magnitude of errors which could be classed as accidental, or in regard to the systematic deviations from a mean system.

This discussion revealed one source of discordance which will doubtless affect the zone observations; viz., the difference between right ascensions determined by the eye-and-ear method, and those determined with the aid of the chronograph.

The programme of the gesellschaft makes no provision for the elimination of errors which depend upon the magnitude of the stars observed; but special observations have been undertaken at several observatories for the purpose of defining the relation between the results for stars of different magnitudes. At Harvard-college observatory, the direct effect of a reduction of the magnitude has been ascertained by reducing the aperture of the telescope by means of diaphragms. Beside this, the observations have been arranged in such a manner that an error depending upon the magnitude can be derived from an investigation of the observations upon two successive nights.

At Leiden, at Albany, and perhaps at other observatories, the effect of magnitude has been determined by observations through wire gauze. But notwithstanding all the precautions which have been taken in the observations, and which may be taken in the reductions, it will undoubtedly be found that the final results obtained will involve errors which cannot be entirely eliminated.

In the experience of the speaker, two other sources of error have been detected. It has been found, that there is a well-defined equation between the observations, which is a function of the amount, and the character of the illumination of the field of the telescope. It has also been found that observations made under very unfavorable atmospheric conditions differ systematically from those made under favorable conditions. When the seeing was noted as very bad, it is found that the observed right ascensions are about .08ˢ too great, and that the observed declinations are about 0.8″ too great.

There are doubtless other sources of error which the discussion of the observations will bring to light. The effect of the discovery of these and other errors will probably be to hasten the repetition of the zone observations under a more perfect scheme, framed in such a manner as to cover all the deficiencies which experience has revealed, or may yet reveal. One would not probably go far astray in naming the year 1900 as the mean epoch of the new survey. If the observations are again repeated in 1950, sufficient data will then have been accumulated for at least an approximate determination of the laws of siderial motion.

What is the present state of our knowledge upon this subject? It can be safely said that it is very limited. First of all, it cannot be affirmed that there is a sidereal system in the sense in which we speak of the solar system. In the case of the solar system, we have a central sun about which the planets and their satellites revolve in obedience to laws which are satisfied by the hypothesis of universal gravitation. Do the same laws pervade the inter-stellar spaces? Is the law of gravitation indeed universal? What physical connection exists between the solar system and the unnumbered and innumerable stars which form the galaxy of the heavens? Do these stars form a system which has its own laws of relative rest and motion? or is the solar system a part of the stupendous whole? Does the solar system receive its laws from the sidereal system? or has Kepler indeed pierced the depths of the universe in the discovery of the laws which gave him immortality? Are we to take the alternative stated by Ball, — either that our sidereal system is not an entirely isolated object, or its bodies must be vastly more numerous or more massive than even our most liberal interpretation of observations would seem to warrant? Are we to conclude, for example, that stars like 1830 Groombridge and α Centauri, "after having travelled from an infinitely great distance on one side of the heavens, are now passing through our system for the first and only time, and that after leaving our system they will retreat again into the depths of space to a distance which, for any thing we can tell, may be practically regarded as infinite"? Can we assert with Newcomb, that in all probability the stars do not form a stable system in the sense in which we say that the solar system is stable, — that the stars of this system do not revolve around definite attractive centres? Admitting that the solar system is moving through space, can we at the present moment even determine whether that motion is rectilinear, or curved, to say nothing of the laws which govern that motion? How much of truth is there in the conjectures of Wright, Kant, Lambert, and Mitchel, or even in the more serious conclusions of Moedler, that the Alcyone of the Pleiades is the central sun about which the solar system revolves?

These are questions which, if solved at all, must be solved by a critical study of observations of precision accumulated at widely separated epochs of time. The first step in the solution has been taken in the systematic survey of the northern heavens undertaken by the gesellschaft, and in the survey of the southern heavens at Cordoba by Dr. Gould. The year 1875 is the epoch about which are grouped the data which, combined with similar data for an epoch not earlier than 1950, will go far towards clearing up the doubts which now rest upon the question of the direction and the amount of the solar motion in space; and it cannot be doubted that our knowledge of the laws which connect the sidereal with the solar system will be largely increased through this investigation. The basis of this knowledge must be the observed proper motions of a selected list of stars, so exactly determined that the residual mean error shall not affect the results derived; or, failing in this, of groups of stars symmetrically distributed over the visible heavens, sufficient in number to affect an elimination of the accidental errors of observation, without disturbing the equilibrium of the general system.

For an investigation of this kind, a complete system of zone observations, at widely separated intervals, will afford the necessary data, if the following conditions are fulfilled.

First: The proper motions must be derived by a method which does not involve an exact knowledge of the constants of precession. In every investigation with which I am acquainted, the derived proper motions are functions of this element.

Second: The general system of proper motions derived must be free from systematic errors. Errors of this class may be introduced either through the periodic errors inherent in the system of fundamental stars employed in the reduction of the zone observations, or in a change in the constants of precession. It is in this respect that the utmost precaution will be required. If from any cause errors of even small magnitude are introduced into the general system of proper motions at any point, the effect of these errors upon the values of the co-ordinates at any future epoch will be directly proportional to the interval elapsed. We can, therefore, compute the exact amount of the accumulated error for any given time.

When this test is applied to the fundamental stellar systems independently determined by Auwers, Safford, Boss, and Newcomb, we find the following deviations *inter se* at the end of a century.

	Maximum mean deviation in a century.		Maximum systematic deviation in a century.	
	$\Delta\alpha$	$\Delta\delta$		
Auwers *minus* Safford . . .	-0.22^s	$+0.2''$	0.23^s	$1.1''$
Auwers *minus* Boss	–	+0.8	–	2.1
Auwers *minus* Newcomb . .	−0.09	+0.8	0.06	2.2

It is the common impression, that both the direction and the amount of the motion of the solar system in space are now well established. The conclusions of Struve upon this point are stated in such explicit language that it is not surprising that this impression exists. He says, "The motion of the solar system in space is directed to a point in the celestial sphere situated on the right line which joins the two stars measured from π and ω Herculis. The velocity of this motion is such that the sun, with the whole cortége of bodies depending on him, advances annually in the direction indicated, through a space equal to one hundred and fifty-four million miles."

It must be admitted that there is a general agreement in the assignment by different investigators of the co-ordinates of the solar apex. This will be seen from the following tabular values.

Authorities.	Right ascension.	Declination.
Herschel, 1783	257° 00′	+25° 00′
Prevost	230 00	+25 00
Klugel, 1789	260 00	+27 00
Herschel, 1805	245 52	+49 38
Argelander, 1837	257 49	+28 50
Lundahl	252 24	+14 26
Struve	261 22	+37 36
Galloway	260 01	+34 23
Mädler	261 38	+39 54
Airy	256 54	+34 29
	261 29	+26 44
Dunkin	261 14	+32 55
	263 44	+25 00

In estimating the value which should be attached to these results, several considerations must be taken into account.

(*a*) All of the results except those of Galloway depend practically upon the same authorities at one epoch, viz., upon Brodley.

(*b*) The deviations *inter se* probably result, in a large measure, from the systematic errors inherent in one or both of the fundamental systems from which the proper motions were derived. For example, Lundahl employed Pond as one of his authorities, and it is in Pond's catalogue that the most decided periodic errors exist.

(*c*) Brot in 1812, Bessel in 1818, and Airy in 1860, reached the conclusion that the *certainty* of the movement of the solar system towards a given point in the heavens could not be affirmed.

(*d*) The problem is indirect. In the case of a member of the solar system, exact data will determine the exact position in orbit at a given time; but here we have neither exact data, nor can we employ trigonometrical methods in the solution. We simply find that the observed proper motions are probably somewhat better reconciled under the hypothesis of an assumed position of the apex of the solar motion. The method of investigation employed by Safford, who has of late years given much attention to this subject, consists in assuming a system of co-ordinates for the pole of the solar motion, from which is determined the direction each star would have if its own proper motions were zero. Comparing this direction with the observed direction as indicated by the observed proper motion, equations of condition are formed from which a correction is found to the assumed position of the apex, by the methods of least squares.

It must always be kept in mind, that the quantities with which we must deal in this investigation are exceedingly minute, and that the accidental errors of observation are at any time liable to lead to illusory results. The weak link in the chain of Mädler's reasoning is to be found here. I think we can assume 0.2″ as the limit of precision in the absolute determination of the co-ordinates of any star, however great the number of observations upon which it depends. Beyond this limit it is impossible to go, in the present date of instrumental astronomy.

It is safe to say, that there is not a single star in the heavens whose co-ordinates are known with certainty within this limit. Do not misunderstand me. Doubtless there are many stars in which the error will at some future time be found to fall within this limit. The law of probabilities requires this, if the maximum limit falls within 1″. But who is prepared to select a particular star, and say that the absolute position of this star in space cannot be more than 0.2″ in error?

e. At present an arbitrary hypothesis is necessary in the discussion of the problem. Airy assumed that the relative distances of the stars are proportional to their magnitudes; and he found slightly different results according to different modes of treatment. Safford assumed that the distances are, at least approximately, in inverse proportion to the magnitude of the proper motions. The general result of his investigations, up to this point, is, that there is some hope of using the solar motion as a base, to advance our knowledge of stellar distances. Later investigations have been made by De Ball, but the details have not yet come to hand. It is understood, however, that his results coincide in a general way with those previously obtained.

It is clear from this brief review, that we have here a field of investigation worthy of the highest powers of the astronomer. The first step has been taken in the survey of the heavens carried on under the auspices of the gesellschaft. It remains for the astronomers of the present generation to solve the difficulties which now environ the problem, and prepare the way for a more perfect scheme of observation in the next century.

PAPERS READ BEFORE SECTION A.

The total solar eclipse of May 6, 1883.

BY EDWARD S. HOLDEN, OF WASHBURN OBSERVATORY, MADISON, WIS.

THIS eclipse had the longest totality of any which has been observed.

An expedition was sent by the National academy of sciences and the U. S. coast-survey jointly, under direction of a committee from the former. Expenses were met by an appropriation of $5,000 by congress and by the National academy of sciences from a fund left by Professor Watson. The navy department also placed the U. S. steamer Hartford at the disposal of the academy, to transport the expedition from Peru to Caroline Island, where the eclipse was to be observed, and thence to Honolulu.

The efforts of Mr. Rockwell to provide money by private subscription for this undertaking, though directly unsuccessful, prepared the way by drawing public attention.

Professor Young was the chairman of the committee of the National academy of sciences: it was at one time hoped that he would take charge of the observing-party, but this proved impracticable. The reports of different members of the party are to be submitted to the National academy of sciences in November. Mr. Holden has, however, permission of the academy to present an account of the observation before the American association. It is understood that the present is not by any means a final report. This especially applies to the observations of Dr. Hastings, from which that gentleman concludes that the solar corona is chiefly a phenomenon due to the diffraction of the solar light at the moon's limb. The computations to demonstrate this are not yet at hand, but are to be completed in a few weeks.

The American party consisted of Edward S. Holden, director of Washburn observatory, Madison, Wis.; Charles S. Hastings, professor of physics in the Johns Hopkins university, Baltimore, Md.; Charles H. Rockwell, Tarrytown, N.Y.; E. D. Preston, aid U. S. coast and geodetic survey, Washington, D.C.; Winslow Upton, U.S. signal-office, Washington, D.C.; and Ensign S. J. Brown, U.S.N., U. S. naval observatory, Washington, D.C.

The original six members of the party were joined, on April 20, by four volunteer observers, all officers of the U. S. ship Hartford: these were Lieut. E. F. Qualtrough, U.S.N.; Passed assistant-surgeon W. S. Dixon, U.S.N.; Midshipman W. S. Fletcher, U.S.N.; and Midshipman J. G. Doyle, U.S.N.

On March 11 the party was strengthened by the joining (at Colon) of the two English gentlemen who were sent out by the Royal society of London to make photographic observations of the eclipse, under instructions from J. Norman Lockyer, Esq., F.R.S., and Capt. W. de W. Abney, R.E., of the science and art department of the South Kensington museum. These were H. A. Lawrance, London, Eng., and C. Ray Woods, London, Eng.

During the stay of the party on Caroline Island

(April 21 to May 9), ten petty officers and men of the Hartford remained, and rendered very intelligent assistance.

In all, the party on the island consisted of twenty-two persons.

After giving details of the proceedings of the expedition, its arrival, and the preparations for the eclipse, Mr. Holden states, as to the event itself, that the following atmospheric conditions prevailed: The sky proved clear at first contact, cloudy at intervals till near totality, clear during totality except a slight haze in its first minutes, cloudy a few minutes after third contact, and finally clear at fourth contact.

The meteorological observations (for which due credit is given to the members of the party that had them in charge) are noteworthy. In two weeks, April 25 to May 9, twenty showers were recorded; but the rainfall in each was very small, the total in the two weeks being about 8 inches. Half of this fell during the only considerable disturbance of the weather, which took place May 4, when it rained from midnight to 9.50 A.M.

The barometer was notably uniform. Its diurnal movements were plainly marked; the maxima being at 9 A.M. and P.M., the minima at 3 A.M. and P.M. The indications of the thermometer were very constant. The daily range was 9.3°, the highest reading 89.3°, the lowest 72.4°, the daily maximum at noon, the minimum at 6 A.M. The relative humidity ranged from 70 per cent at midday to 84 in early morning, and at no time fell below 61. The island lies in the region of the south-east trades, but the wind (which was very steady) blew constantly between north and east. The average velocity of the wind was 6.05 miles; the largest during twenty-four hours was 212 miles, the least 59 miles; the highest velocity, registered in a squall, was 16 miles per hour.

The botanical and zoölogical observations are not yet ready for publication. During the voyage a series of observations was made by Mr. Upton on southern variable stars. Dr. Hastings and Mr. Holden, while on the island, discovered twenty-three new double stars, a list of which has appeared in SCIENCE.

In preparing for the eclipse, Mr. Holden assigned to each observer a single duty, not requiring him to move from one instrument to another. The excellent photographic apparatus, prepared under the direction of Prof. W. Harkness of the U.S. naval observatory, was not used: the entire field of photography was left to the English party accompanying our own, and to the French party under M. Janssen, who were very successful in photographing the corona.

The combination of polariscope and telescope was used, but not with successful results, the apparatus proving unsuitable. Dr. W. S. Dixon, who attended to a telescopic examination of the details of the inner corona, will report on the same separately, giving a drawing of the corona. With the spectroscope, the chief point of observation was as to the relative lengths of the line 1474 east and west of the sun. At second contact, this line was 12′ longitude east and 3′ west. The length of 1474 east diminished, while 1474 west increased. At mid-totality these were equal. Before the third contact, the appearances were reversed: 1474 west was longer and brighter than 1474 east.

At the beginning of totality, the lines C, D_3, F, and (near G) were seen brilliant but very short. At mid-eclipse the spectrum was deliberately examined. On a continuous spectrum, two lines only were seen: 1474 *bright*, and the D line *dark*. C, E, b, F, were certainly wanting. Near the end of totality, C, D_3, and F appeared again, very short. Five seconds after second contact, four curved lines were seen, — C, D_3, 1474, F. A light cloud passed over the sun; and on its disappearance the spectrum showed a small line, of about one-third the height of the others, between 1474 and F. One hundred seconds after second contact, three coronal rings took the place of the lines: they were red, yellowish-green, and green, and are supposed to be C, D_3, and 1474. Two hundred seconds after second contact, the red ring was decidedly the brightest, and it continued to increase in brightness during sixty seconds. Two hundred and ninety seconds after second contact, the four curved lines, C, D_3, 1474, F, appeared. The reversal of the bright lines at third contact was observed. The change was instantaneous, or nearly so. The reversal of the Fraunhofer lines was not seen. The only bright line seen for the first 190 seconds was 1474. A dark line was seen, which was probably D.

Mr. Rockwell, using a Rutherford grating and a narrow slip tangential to the limb, reported that 1474 K was not seen until a minute and a half had passed. It was followed 4′ or 5′ west of the limb, twice; and it was seen only on the western side of the moon. Two green lines were also seen, each brighter and broader than 1474, but much shorter.

Due credit is given by Mr. Holden to each of the observers of the party. His own observations were confined to a search for the planet Vulcan, reported to exist by Professors Watson and Swift. Mr. Holden's search continued during the whole of totality (five minutes and twenty-five seconds), with a six-inch telescope with a power of 44 and field of 57′ in declination. He saw every star on the map which he had previously published in SCIENCE (Feb. 23, 1883), down to the sixth magnitude, inclusive, except the thirty-sixth magnitude stars nearest to the sun; and he saw only these stars. One of the stars of the map was of the same magnitude as Watson's 'Vulcan.' This was a conspicuous object. No star half so bright as this could possibly have escaped observation. Mr. Holden is therefore confident that Vulcan did not exist within the limits swept over. Mr. Holden also determined the direction of the motion of the diffraction bands before and after totality. This was an observation which he could not make successfully in Colorado in 1878, and which he believes has not been before made.

A new method of investigating the flexure corrections of a meridian circle.

BY PROF. W. A. ROGERS OF CAMBRIDGE, MASS.

THE error due to refraction, the flexure of the circle itself, and the astronomical flexure, the three being functions in themselves, are most prolific errors respecting flexures of a meridian circle.

The theory which suggested itself was arrived at from the use on the telescope of a level of a different construction from any the author had ever seen. He had been a disbeliever in a level, but this device converted him into an advocate of the level. The level tube is attached to a plate, and the plate attached to the cube of the telescope. Then set the telescope at the north point, and reverse it to the south, reading the circle north and south. It would be much better were the point fixed upon a ring so that it can be readily placed at any inclination.

Results of tests with the almacantar, in time and latitude.

BY S. C. CHANDLER, OF CAMBRIDGE, MASS.

THE instrument which has been named the 'almacantar' was described and figured in a paper presented to the association at its meeting in 1880. In its general nature it is an equal altitude instrument. A hollow rectangular trough containing mercury revolves horizontally on an upright central pillar. The trough contains a float which is perfectly free to obtain equilibrium, while it is constrained to revolve with the trough. The float carries a telescope which turns on a horizontal axis, and can be clamped at any desired altitude. When this instrument is revolved on its vertical axis, any given point in the field of view describes a horizontal small circle, or almacantar, in the heavens. The transits of stars over a series of horizontal lines will thus afford means of determining the altitude of the instrument, the error of the clock, the latitude or the declinations of stars, by a proper distribution of the observations in azimuth.

A higher degree of accuracy is attainable by this instrument than by a transit or a zenith telescope of same size. The author's comparison of results is as follows: The probable error of a single star in determining the clock error is only $\pm0.05^s$ or $\pm0.06^s$. With a transit instrument of the same size, the quantity is not less than $\pm0.08^s$. With the almacantar the probable error in determining the latitude of a single star is $\pm0.55''$, including the error of the star's place. This is about equal to the probable error of a pair of stars by Talcott's method, with the larger telescopes of the United-States coast-survey.

The instrument was a small one, — $1\frac{3}{4}$ inches aperture and 25 inches focus. It was constructed for experiment only, in a provisional way, at a cost of $150. There are obvious defects in design and construction: when these are remedied, the error can be much reduced.

A series of observations with this instrument are given by the author, for the latitude of a pier about 80 feet north of the Harvard-college observatory. The value obtained by averaging these is $0.7''$ less than given by Professor Peirce in his discussion of the prime vertical transit observations taken by the Messrs. Bond, and adopted as the standard value of the latitude of the observatory. The author concludes that Professor Peirce's value is too large by fully three-quarters of a second. By way of proof the author gives a series of observations on the five stars used by Professor Peirce. These are compared with those of Auwers and Boss, and the correction of the hitherto accepted value of the latitude now indicated by the almacantar is thereby confirmed.

The clock errors of two nights selected at random, as given by the almacantar, were exhibited by the author. The results both in time and latitude would be considered satisfactory with an ordinary instrument of two or three times the size. The almacantar can be made much larger than the one under trial, certainly of five or six inches aperture, with corresponding increase of precision along with greater optical power. Its mechanical construction is simple, and reduces the sources of error. Thus in the older instruments there are involved: 1°. The accurate construction of parts, as of pivots, level, graduated circles. 2°. Fixity of mounting, to avoid a shifting of the instrumental plane. 3°. Rigidity of the instrument itself, to secure constancy of collimation and flexure. In the almacantar only the last condition has to be satisfied, and it is by far the easiest of the three to be attained mechanically.

The author regards the principle of flotation adopted as being as delicate an indication of the direction of gravity as is obtained by the spirit-level.

The almacantar gives promise of a new instrumental resource in the higher practical astronomy. It is competent to deal with the most delicate problems. It will evade some of the minute sources of error that still cling to meridian instruments. Especially, it furnishes a method for obviating difficulties, hitherto regarded as almost insuperable, connected with flexure and refraction, in observations with the meridian circle.

Internal contacts in transits of the inferior planets.

BY J. R. EASTMAN, OF WASHINGTON, D.C.

THE author began by reviewing the different values obtained in observing transits of Venus, and by computations thereon since 1761. Eventually it became certain that the differences of these values depended chiefly upon the computer's interpretation of the observer's record. The phenomenon known as the 'black drop' began to be considered as an element in the calculation. Stone regarded it as a necessary phenomenon. He gave an explanation of its origin, and stated that the moment when a dark ligament appears to connect the apparent limbs of the sun and Venus is the time of *real* internal contact. The second phase, when the limbs of Venus and the sun appear in contact, Stone says, is 'the *apparent* internal contact.'

In 1876 M. André, the astronomer in charge of the French expedition to Nouméa, in 1874, announced that "the bridge, black ligament, or black drop, as it is variously called, is a necessary phenomenon under certain circumstances, and not merely accidental." He noticed, however, that "it is always possible to get rid of the ligament, and reduce the phenomenon to geometrical constants, either (*a*) by reducing sufficiently the intensity of the source of light, or augmenting the absorbing power of the dark glass employed; or (*b*) by covering the object-glass with a dark diaphragm composed of rings alternately full and empty, all very thin, and bearing a certain proportion to the focal length of the lens."

These results and opinions of M. André were not generally known at the time of the transit of Mercury in 1878; although his theories were confirmed by his observations at Utah at that date, the results being published by him in 1881. The black drop was seen and recognized in 1878 by many observers of Mercury; some evidently regarding their success in finding it as a proof of accuracy of observation, others apologizing for failing to perceive the phenomenon.

The author of this paper regards it as noteworthy, that every observer, so far as ascertained, who got, by means of shade-glasses, the best definition of the sun's limbs, with an illumination less than the eye could easily bear, did not see any trace of the black drop. Before seeing any account of M. André's experiments, and having given little attention to his deductions announced by Father Perry, the author became independently convinced, after observation of the transit of Mercury in 1878, that the theory of a *necessary* black drop was fallacious.

While, in 1874, many American observers perceived the black drop, none appear to have seen it, among the eight American parties organized by the transit-of-Venus commission of 1882.

The paper winds up with an account of the observations of contact at the transit-of-Venus station at Cedar Keys, Fla., last December. The observation of first contact was prevented by a cloud covering a part of the sun's disk. On the disappearance of the cloud, the illumination was reduced by a sliding shade-glass, till easily endured by the eye. The definition of the sun's limb was perfect. When haze or cirri interfered, a less density of shade-glass was permitted; the steadiness and definition of the limb remaining, and that of Venus being 'all that could be desired,' with no modification, at the edge of the disk, of its dense black color.

Before the second contact, the entire disk of Venus was visible for several minutes. The portion beyond the sun's disk was bordered by a narrow line of light much less bright than the limb of the sun, and of a lighter tint. About one minute before contact, the apparent motion of the cusps of the sun, as they closed around the planet, noticeably increased, although the movement was perfectly steady. The cusps swept around the planet in a line of sunlight of the same tint as adjacent parts of the sun. This line was as narrow as could be seen with the power used, — 216 diameters, — and was free from tremors or pulsations. There was no agitation in the limb of either body near the point of contact, no trace of black drop, ligament, or band, no change of tint or color on the limb of Venus, and no indication of any clinging of the limbs. The contact was as easily, and perhaps as accurately, observed as the transit of a star within 8° of the pole, under the best conditions. The uncertainty of noting the time of the visible contact could not have been greater than three-tenths of a second. The phenomena at the third contact were similar to those at the second, but, of course, in a reversed order.

In conclusion, the author urges his belief, founded upon his own experience as well as on study of the work of other observers, that, with a properly arranged telescope and shade-glass, no observer need have trouble from any phase of the 'black drop.' To attain this end satisfactorily, the observer of contacts must have no other purpose in view than such observation. The study of any branch of solar physics, or searching for some new thing, may, and probably will, detract from the accuracy of his work, which should be confined to obtaining the record of a good definition of the sun's limb, as a reference-point in the passage of the limb of the planet.

An improved method of producing a dark-field illumination of lines ruled upon glass.

BY PROF. W. A. ROGERS OF CAMBRIDGE, MASS.

By repeated and careful tests the author found that by letting the light, which is held at an angle of 45°, into the telescope, and then splitting the rays by means of two opposite mirrors, throwing them on the horizontal line, an almost perfect light is secured. Thereby it becomes practicable to see with distinctness stars of the smaller magnitudes upon a dark field.

Other astronomers present expressed a preference for the use of red light. Professor Rogers claimed that his method was better for minute observation.

Physical phenomena on the planet Jupiter.

BY G. W. HOUGH OF CHICAGO, ILL.

The rapid motion of revolution of the planet, by changing the positions of the markings on the surface to our line of sight, makes great apparent differences in their shapes and sizes. This has perhaps been the occasion of reports of sudden and great changes upon the surface. The changes are not sudden, but are gradual; and many of the features are permanent. Minor changes are constantly in progress in the equatorial belts. The author recently observed the belt drifting down toward the red spot; but although it partly surrounded it, they did not coalesce, and the spot forced a scallop into the belt, — a very curious phenomenon. The author saw a satellite pass over this red spot, though the satellites are not visible when on the white part of the disk. He had also had a chance to compare shadows of satellites on the disk and on the spot, and both are dark. The red spot has seemingly retrogaded during the past four years; that is to say, the rotation of Jupiter has seemingly increased from 9 h. 55 m. 33 s., to 9 h. 55 m. 38 s. The future observer should attend more carefully to what he sees, and theorize afterward.

French observations on the solar eclipse of May 6, 1883.

BY DR. J. JANSSEN OF PARIS, FRANCE.

A LETTER from the French astronomer Dr. Janssen, who passed through this country on his return from an eclipse expedition, was addressed by him for the use of the association to Professor Eastman, who translated it, and read the translation in Section A. It was thus entered as one of the papers. Dr. Janssen says, —

"The principal object of the observations was the study of the dark rays in the corona. The visibility of these rays depends more on the light-power of the instrument than upon the perfection of the images. At first the ordinary brilliant rays which the corona presents were recognized; but what was new, and more complete than ever expected, was that the background of the coronal spectrum presented the Fraunhofer's spectrum. All the dark rays were theoretically visible. Phenomena were observed, which indicated that there were some portions of the corona which reflected, much more abundantly than others, the light emanating from the solar sphere: this would indicate the existence of cosmic matter circulating around the sun. The rings of Rispighi were not found arranged symmetrically around the sun. The light of the corona was strongly and radially polarized. All these things were associated with the problem of circumsolar cosmic matter. The observations went to show that no important intra-mercurial planet exists."

Some hitherto undeveloped properties of squares.

BY O. S. WESTCOTT OF CHICAGO, ILL.

THE paper began by ascribing due credit to a method for obtaining squares and square roots, described by Samuel Emerson in 1865. The principles and details of that method were briefly summarized. Mr. Westcott then stated the general principles of his own method, which is very expeditious. He first shows that the tens and units figures of all perfect squares of numbers, from 26 to 49 inclusive, are the same as the tens and units figures of perfect squares of numbers from 24 to 1 inclusive. A table is presented as follows:

$(24)^2 = 576$, add 100, $= 676 = (26)^2$
$(23)^2 = 529$, add 200, $= 729 = (27)^2$
$(22)^2 = 484$, add 300, $= 784 = (28)^2$

and so on, to

$(1)^2 = 1$, add 2400, $= 2401 = (49)^2$

To determine the square of any number between 25 and 50, find the corresponding number below 25, and augment its square by the number of hundreds indicated by its remoteness from 25. Or, more conveniently, take the excess above 25 as hundreds, and augment by the square of what the number lacks of 50.

Thus: $(43)^2 = (43 - 25) . 100 + (50 - 43)^2$
$= \quad 1800 \quad + \quad 49 \quad = 1849$

Conversely: To obtain the square root of 1764. The root is plainly between 25 and 50. The tens and units figures indicate 8. Therefore the square root of 1764 is $50 - 8 = 42$.

It is further observable, that the tens and units figures of perfect squares of numbers from 51 to 99 inclusive, are the same as the tens and units figures of the squares of numbers from 49 to 1 inclusive. Since $4 \times$ any number of hundreds + 25, 50, or 75, gives an exact number of hundreds, it follows that the tens and units figures of the squares of numbers less than 25 represent all the possible combinations of figures in those orders of units for *all* square numbers. The terminations of all perfect square numbers are 22 in all: viz., 00, 01, 04, 09, 16, 21, 24, 25, 29, 36, 41, 44, 49, 56, 61, 64, 69, 76, 81, 84, 89, 96.

The following rule is then deduced: To square any number from 50 to 100, take twice the excess above 50 as hundreds, and augment by the square of what the number lacks of 100.

Thus: $(89)^2 = 200\,(89 - 50) + (100 - 89)^2$
$= \quad 7800 \quad + \quad 121 \quad = 7921$

Conversely, $\sqrt{3249}$: The root is plainly between 50 and 60; the tens and units figures indicate 7; therefore $\sqrt{3249} = 50 + 7 = 57$.

For greater convenience it is noted, that in such a case as $\sqrt{7921}$ the root is $50 + 39$ or $100 - 11$, and it is easier to use the latter form. That is, if the root is in the fourth quarter of the hundred, subtract the number indicated by the tens and units from 100, and the difference is the root. Thus $\sqrt{8281} = 100 - 9 = 91$.

To square any number from 100 to 200, take four times the excess above 100 as hundreds, and augment by the square of what the number lacks of 200.

To square any number from 125 to 250, take one-half the excess above 125 as thousands, and augment by what the number lacks of 250.

By a series of steps of this character, the author gives methods for squaring higher numbers, and conversely for obtaining their square roots. A choice of methods is also indicated. The facility which was obtained by such means was deftly illustrated on the blackboard by the author, who in a few seconds performed such exploits as raising 5 to the 16th power, and then showed in detail the processes which he had mentally executed. The paper sets forth the reason for each rule, deducing it from the usual binomial theorem, with almost obvious simplicity.

The demonstrations were received by the section with hearty applause. In response to an inquiry, Mr. Westcott stated, that he had been very successful in teaching this method in classes, about a tenth of his pupils becoming rapid experts in the methods of solution, which were especially useful in handling quadratic equations, and determining at a glance whether a given number is or is not a perfect square.

PROCEEDINGS OF SECTION B. — PHYSICS.

ADDRESS OF H. A. ROWLAND OF BALTIMORE, MD., VICE-PRESIDENT OF SECTION B, AUG. 15, 1883.

A PLEA FOR PURE SCIENCE.[1]

THE question is sometimes asked us as to the time of year we like the best. To my mind, the spring is the most delightful; for nature then recovers from the apathy of winter, and stirs herself to renewed life. The leaves grow, and the buds open, with a suggestion of vigor delightful to behold; and we revel in this ever-renewed life of nature. But this cannot always last. The leaves reach their limit; the buds open to the full, and pass away. Then we begin to ask ourselves whether all this display has been in vain, or whether it has led to a bountiful harvest.

So this magnificent country of ours has rivalled the vigor of spring in its growth. Forests have been levelled, and cities built, and a large and powerful nation has been created on the face of the earth. We are proud of our advancement. We are proud of such cities as this, founded in a day upon a spot over which, but a few years since, the red man hunted the buffalo. But we must remember that this is only the spring of our country. Our glance must not be backward; for however beautiful leaves and blossoms are, and however marvellous their rapid increase, they are but leaves and blossoms after all. Rather should we look forward to discover what will be the outcome of all this, and what the chance of harvest. For if we do this in time, we may discover the worm which threatens the ripe fruit, or the barren spot where the harvest is withering for want of water.

I am required to address the so-called physical section of this association. Fain would I speak pleasant words to you on this subject; fain would I recount to you the progress made in this subject by my countrymen, and their noble efforts to understand the order of the universe. But I go out to gather the grain ripe to the harvest, and I find only tares. Here and there a noble head of grain rises above the weeds; but so few are they, that I find the majority of my countrymen know them not, but think that they have a waving harvest, while it is only one of weeds after all. American science is a thing of the future, and not of the present or past; and the proper course of one in my position is to consider what must be done to create a science of physics in this country, rather than to call telegraphs, electric lights, and such conveniences, by the name of science. I do not wish to underrate the value of all these things: the progress of the world depends on them, and he is to be honored who cultivates them successfully. So also the cook who invents a new and palatable dish for the table benefits the world to a certain degree; yet we do not dignify him by the name of a chemist. And yet it is not an uncommon thing, especially in American newspapers, to have the *applications* of science confounded with pure science; and some obscure American who steals the ideas of some great mind of the past, and enriches himself by the application of the same to domestic uses, is often lauded above the great originator of the idea, who might have worked out hundreds of such applications, had his mind possessed the necessary element of vulgarity. I have often been asked, which was the more important to the world, pure or applied science. To have the applications of a science, the science itself must exist. Should we stop its progress, and attend only to its applications, we should soon degenerate into a people like the Chinese, who have made no progress for generations, because they have been satisfied with the applications of science, and have never sought for reasons in what they have done. The reasons constitute pure science. They have known the application of gunpowder for centuries; and yet the reasons for its peculiar action, if sought in the proper manner, would have developed the science of chemistry, and even of physics, with all their numerous applications. By contenting themselves with the fact that gunpowder will explode, and seeking no farther, they have fallen behind in the progress of the world; and we now regard this oldest and most numerous of nations as only barbarians. And yet our own country is in this same state. But we have done better; for we have taken the science of the old world, and applied it to all our uses, accepting it like the rain of heaven, without asking whence it came, or even acknowledging the debt of gratitude we owe to the great and unselfish workers who have given it to us. And, like the rain of heaven, this pure science has fallen upon our country, and made it great and rich and strong.

To a civilized nation of the present day, the applications of science are a necessity; and our country has hitherto succeeded in this line, only for the reason that there are certain countries in the world where pure science has been and is cultivated, and where the study of nature is considered a noble pursuit. But such countries are rare, and those who wish to pursue pure science in our own country must be prepared to face public opinion in a manner which requires much moral courage. They must be prepared to be looked down upon by every successful inventor whose shallow mind imagines that the only pursuit of mankind is wealth, and that he who obtains most has best succeeded in this world. Everybody can comprehend a million of money; but how few can comprehend any advance in scientific theory, especially in its more abstruse portions! And this, I believe, is one of the causes of the small number of persons who have ever devoted themselves to work of the higher order in any human pursuit. Man is a gregarious animal, and depends very much, for his happiness, on the sympathy of those around him; and it is

[1] In using the word 'science,' I refer to physical science, as I know nothing of natural science. Probably my remarks will, however, apply to both, but I do not know.

rare to find one with the courage to pursue his own ideals in spite of his surroundings. In times past, men were more isolated than at present, and each came in contact with a fewer number of people. Hence that time constitutes the period when the great sculptures, paintings, and poems were produced. Each man's mind was comparatively free to follow its own ideals, and the results were the great and unique works of the ancient masters. To-day the railroad and the telegraph, the books and newspapers, have united each individual man with the rest of the world: instead of his mind being an individual, a thing apart by itself, and unique, it has become so influenced by the outer world, and so dependent upon it, that it has lost its originality to a great extent. The man who in times past would naturally have been in the lowest depths of poverty, mentally and physically, to-day measures tape behind a counter, and with lordly air advises the naturally born genius how he may best bring his outward appearance down to a level with his own. A new idea he never had, but he can at least cover his mental nakedness with ideas imbibed from others. So the genius of the past soon perceives that his higher ideas are too high to be appreciated by the world: his mind is clipped down to the standard form; every natural offshoot upwards is repressed, until the man is no higher than his fellows. Hence the world, through the abundance of its intercourse, is reduced to a level. What was formerly a grand and magnificent landscape, with mountains ascending above the clouds, and depths whose gloom we cannot now appreciate, has become serene and peaceful. The depths have been filled, and the heights levelled, and the wavy harvests and smoky factories cover the landscape.

As far as the average man is concerned, the change is for the better. The average life of man is far pleasanter, and his mental condition better, than before. But we miss the vigor imparted by the mountains. We are tired of mediocrity, the curse of our country. We are tired of seeing our artists reduced to hirelings, and imploring congress to protect them against foreign competition. We are tired of seeing our countrymen take their science from abroad, and boast that they here convert it into wealth. We are tired of seeing our professors degrading their chairs by the pursuit of applied science instead of pure science; or sitting inactive while the whole world is open to investigation; lingering by the wayside while the problem of the universe remains unsolved. We wish for something higher and nobler in this country of mediocrity, for a mountain to relieve the landscape of its monotony. We are surrounded with mysteries, and have been created with minds to enjoy and reason to aid in the unfolding of such mysteries. Nature calls to us to study her, and our better feelings urge us in the same direction.

For generations there have been some few students of science who have esteemed the study of nature the most noble of pursuits. Some have been wealthy, and some poor; but they have all had one thing in common, — the love of nature and its laws. To these few men the world owes all the progress due to applied science, and yet very few ever received any payment in this world for their labors.

Faraday, the great discoverer of the principle on which all machines for electric lighting, electric railways, and the transmission of power, must rest, died a poor man, although others and the whole world have been enriched by his discoveries. And such must be the fate of the followers in his footsteps for some time to come.

But there will be those in the future who will study nature from pure love, and for them higher prizes than any yet obtained are waiting. We have but yet commenced our pursuit of science, and stand upon the threshold wondering what there is within. We explain the motion of the planet by the law of gravitation; but who will explain how two bodies, millions of miles apart, tend to go toward each other with a certain force?

We now weigh and measure electricity and electric currents with as much ease as ordinary matter, yet have we made any approach to an explanation of the phenomenon of electricity? Light is an undulatory motion, and yet do we know what it is that undulates? Heat is motion, yet do we know what it is that moves? Ordinary matter is a common substance, and yet who shall fathom the mystery of its internal constitution?

There is room for all in the work, and the race has but commenced. The problems are not to be solved in a moment, but need the best work of the best minds, for an indefinite time.

Shall our country be contented to stand by, while other countries lead in the race? Shall we always grovel in the dust, and pick up the crumbs which fall from the rich man's table, considering ourselves richer than he because we have more crumbs, while we forget that he has the cake, which is the source of all crumbs? Shall we be swine, to whom the corn and husks are of more value than the pearls? If I read aright the signs of the times, I think we shall not always be contented with our inferior position. From looking down we have almost become blind, but may recover. In a new country, the necessities of life must be attended to first. The curse of Adam is upon us all, and we must earn our bread.

But it is the mission of applied science to render this easier for the whole world. There is a story which I once read, which will illustrate the true position of applied science in the world. A boy, more fond of reading than of work, was employed, in the early days of the steam-engine, to turn the valve at every stroke. Necessity was the mother of invention in his case: his reading was disturbed by his work, and he soon discovered that he might become free from his work by so tying the valve to some movable portion of the engine, as to make it move its own valve. So I consider that the true pursuit of mankind is intellectual. The scientific study of nature in all its branches, of mathematics, of mankind in its past and present, the pursuit of art, and the cultivation of all that is great and noble in the world, — these are the highest occupation of mankind. Commerce, the applications of science, the accumulation of wealth, are necessities which are a curse to those with high ideals, but a blessing to that portion of the world which has neither the ability nor the taste for higher pursuits.

As the applications of science multiply, living becomes easier, the wealth necessary for the purchase of apparatus can better be obtained, and the pursuit of other things beside the necessities of life becomes possible.

But the moral qualities must also be cultivated in proportion to the wealth of the country, before much can be done in pure science. The successful sculptor or painter naturally attains to wealth through the legitimate work of his profession. The novelist, the poet, the musician, all have wealth before them as the end of a successful career. But the scientist and the mathematician have no such incentive to work: they must earn their living by other pursuits, usually teaching, and only devote their surplus time to the true pursuit of their science. And frequently, by the small salary which they receive, by the lack of instrumental and literary facilities, by the mental atmosphere in which they exist, and, most of all, by their low ideals of life, they are led to devote their surplus time to applied science or to other means of increasing their fortune. How shall we, then, honor the few, the very few, who, in spite of all difficulties, have kept their eyes fixed on the goal, and have steadily worked for pure science, giving to the world a most precious donation, which has borne fruit in our greater knowledge of the universe and in the applications to our physical life which have enriched thousands and benefited each one of us? There are also those who have every facility for the pursuit of science, who have an ample salary and every appliance for work, yet who devote themselves to commercial work, to testifying in courts of law, and to any other work to increase their present large income. Such men would be respectable if they gave up the name of professor, and took that of consulting chemists or physicists. And such men are needed in the community. But for a man to occupy the professor's chair in a prominent college, and, by his energy and ability in the commercial applications of his science, stand before the local community in a prominent manner, and become the newspaper exponent of his science, is a disgrace both to him and his college. It is the deathblow to science in that region. Call him by his proper name, and he becomes at once a useful member of the community. Put in his place a man who shall by precept and example cultivate his science, and how different is the result! Young men, looking forward into the world for something to do, see before them this high and noble life, and they see that there is something more honorable than the accumulation of wealth. They are thus led to devote their lives to similar pursuits, and they honor the professor who has drawn them to something higher than they might otherwise have aspired to reach.

I do not wish to be misunderstood in this matter. It is no disgrace to make money by an invention, or otherwise, or to do commercial scientific work under some circumstances. But let pure science be the aim of those in the chairs of professors, and so prominently the aim that there can be no mistake. If our aim in life is wealth, let us honestly engage in commercial pursuits, and compete with others for its possession. But if we choose a life which we consider higher, let us live up to it, taking wealth or poverty as it may chance to come to us, but letting neither turn us aside from our pursuit.

The work of teaching may absorb the energies of many; and, indeed, this is the excuse given by most for not doing any scientific work. But there is an old saying, that where there is a will there is a way. Few professors do as much teaching or lecturing as the German professors, who are also noted for their elaborate papers in the scientific journals. I myself have been burdened down with work, and know what it is; and yet I here assert that all *can* find time for scientific research if they desire it. But here, again, that curse of our country, mediocrity, is upon us. Our colleges and universities seldom call for first-class men of reputation, and I have even heard the trustee of a well-known college assert that no professor should engage in research because of the time wasted! I was glad to see, soon after, by the call of a prominent scientist to that college, that the majority of the trustees did not agree with him.

That teaching is important, goes without saying. A successful teacher is to be respected; but if he does not lead his scholars to that which is highest, is he not blameworthy? We are, then, to look to the colleges and universities of the land for most of the work in pure science which is done. Let us therefore examine these latter, and see what the prospect is.

One, whom perhaps we may here style a practical follower of Ruskin, has stated that while in this country he was variously designated by the title of captain, colonel, and professor. The story may or may not be true, but we all know enough of the customs of our countrymen not to dispute it on general principles. All men are born equal: some men are captains, colonels, and professors, and therefore all men are such. The logic is conclusive; and the same kind of logic seems to have been applied to our schools, colleges, and universities. I have before me the report of the commissioner of education for 1880. According to that report, there were 389,[1] or say, in round numbers, 400 institutions, calling themselves colleges or universities, in our country! We may well exclaim that ours is a great country, having more than the whole world beside. The fact is sufficient. The whole earth would hardly support such a number of first-class institutions. The curse of mediocrity must be upon them, to swarm in such numbers. They must be a cloud of mosquitoes, instead of eagles as they profess. And this becomes evident on further analysis. About one-third aspire to the name of university; and I note one called by that name which has two professors and 18 students, and another having three teachers and 12 students! And these instances are not unique, for the number of small institutions and schools which call themselves universities is very great. It is difficult to

[1] 364 reported on, and 25 not reported.

decide from the statistics alone the exact standing of these institutions. The extremes are easy to manage. Who can doubt that an institution with over 800 students, and a faculty of 70, is of a higher grade than those above cited having 10 or 20 students and two or three in the faculty? Yet this is not always true; for I note one institution with over 500 students which is known to me personally as of the grade of a high school. The statistics are more or less defective, and it would much weaken the force of my remarks if I went too much into detail. I append the following tables, however, of 330 so-called colleges and universities: —

218	had from	0 to 100	students.
88	" "	100 " 200	"
12	" "	200 " 300	"
6	" "	300 " 500	"
6	over	500	

Of 322 so-called colleges and universities: —

206	had	0 to 10	in the faculty.
99	"	10 " 20	" "
17	"	20 or over	" "

If the statistics were forthcoming, — and possibly they may exist, — we might also get an idea of the standing of these institutions and their approach to the true university idea, by the average age of the scholars. Possibly also the ratio of number of scholars to teachers might be of some help. All these methods give an approximation to the present standing of the institutions. But there is another method of attacking the problem, which is very exact, but it only gives us the *possibilities* of which the institution is capable. I refer to the wealth of the institution. In estimating the wealth, I have not included the value of grounds and buildings, for this is of little importance, either to the present or future standing of the institution. As good work can be done in a hovel as in a palace. I have taken the productive funds of the institution as the basis of estimate. I find: —

234	have below	$500,000.
8	"	between $500,000 and $1,000,000.
8	"	over $1,000,000.

There is no fact more firmly established, all over the world, than that the higher education can never be made to pay for itself. Usually the cost to a college, of educating a young man, very much exceeds what he pays for it, and is often three or four times as much. The higher the education, the greater this proportion will be; and a university of the highest class should anticipate only a small accession to its income from the fees of students. Hence the test I have applied must give a true representation of the possibilities in every case. According to the figures, only 16 colleges and universities have $500,000 or over of invested funds, and only one-half of these have $1,000,000 and over. Now, even the latter sum is a very small endowment for a college; and to call any institution a university which has less than $1,000,000, is to render it absurd in the face of the world. And yet more than 100 of our institutions, many of them very respectable colleges, have abused the word 'university' in this manner. It is to be hoped that the endowment of the more respectable of these institutions may be increased, as many of them deserve it; and their unfortunate appellation has probably been repented of long since.

But what shall we think of a community that gives the charter of a university to an institution with a total of $20,000 endowment, two so-called professors, and 18 students! or another with three professors, 12 students, and a total of $27,000 endowment, mostly invested in buildings! And yet there are very many similar institutions; there being 16 with three professors or less, and very many indeed with only four or five.

Such facts as these could only exist in a democratic country, where pride is taken in reducing every thing to a level. And I may also say, that it can only exist in the early days of such a democracy; for an intelligent public will soon perceive that calling a thing by a wrong name does not change its character, and that truth, above all things, should be taught to the youth of the nation.

It may be urged, that all these institutions are doing good work in education; and that many young men are thus taught, who could not afford to go to a true college or university. But I do not object to the education, — though I have no doubt an investigation would disclose equal absurdities here, — for it is aside from my object. But I do object to lowering the ideals of the youth of the country. Let them know that they are attending a school, and not a university; and let them know that above them comes the college, and above that the university. Let them be taught that they are only half-educated, and that there are persons in the world by whose side they are but atoms. In other words, let them be taught the truth.

It may be that some small institutions are of high grade, especially those which are new; but who can doubt that more than two-thirds of our institutions calling themselves colleges and universities are unworthy of the name? Each one of these institutions has so-called professors, but it is evident that they can be only of the grade of teachers. Why should they not be so called? The position of teacher is an honored one, but is not made more honorable by the assumption of a false title. Furthermore, the multiplication of the title, and the ease with which it can be obtained, render it scarcely worth striving for. When the man of energy, ability, and perhaps genius is rewarded by the same title and emoluments as the commonplace man with the modicum of knowledge, who takes to teaching, not because of any aptitude for his work, but possibly because he has not the energy to compete with his fellow-men in business, then I say one of the inducements for first-class men to become professors is gone.

When work and ability are required for the position, and when the professor is expected to keep up with the progress of his subject, and to do all in his power to advance it, and when he is selected for these reasons, then the position will be worth working for, and the successful competitor will be honored accordingly. The chivalric spirit which prompted Faraday to devote his life to the study of nature may actuate a few noble men to give their life to scientific work; but, if we wish to cultivate this highest class of men in science, we must open a career for them worthy of their efforts.

Jenny Lind, with her beautiful voice, would have cultivated it to some extent in her native village; yet who would expect her to travel over the world, and give concerts for nothing? and how would she have been able to do so if she had wished? And so the scientific man, whatever his natural talents, must have instruments and a library, and a suitable and respectable salary to live upon, before he is able to exert himself to his full capacity. This is true of advance in all the higher departments of human learning, and yet something more is necessary. It is not those in this country who receive the largest salary, and have positions in the richest colleges, who have advanced their subject the most: men receiving the highest salaries, and occupying the professor's chair, are to-day doing absolutely nothing in pure science, but are striving by the commercial applications of their science to increase their already large salary. Such pursuits, as I have said before, are honorable in their proper place; but the duty of a professor is to advance his science, and to set an example of pure and true devotion to it which shall demonstrate to his students and the world that there is something high and noble worth living for. Money-changers are often respectable men, and yet they were once severely rebuked for carrying on their trade in the court of the temple.

Wealth does not constitute a university, buildings do not: it is the men who constitute its faculty, and the students who learn from them. It is the last and highest step which the mere student takes. He goes forth into the world, and the height to which he rises has been influenced by the ideals which he has consciously or unconsciously imbibed in his university. If the professors under whom he has studied have been high in their profession, and have themselves had high ideals; if they have considered the advance of their particular subject their highest work in life, and are themselves honored for their intellect throughout the world, — the student is drawn toward that which is highest, and ever after in life has high ideals. But if the student is taught by what are sometimes called good teachers, and teachers only, who know little more than the student, and who are often surpassed and even despised by him, no one can doubt the lowered tone of his mind. He finds that by his feeble efforts he can surpass one to whom a university has given its highest honor; and he begins to think that he himself is a born genius, and the incentive to work is gone. He is great by the side of the molehill, and does not know any mountain to compare himself with.

A university should not only have great men in its faculty, but have numerous minor professors and assistants of all kinds, and should encourage the highest work, if for no other reason than to encourage the student to his highest efforts.

But, assuming that the professor has high ideals, wealth such as only a large and high university can command is necessary to allow him the fullest development.

And this is specially so in our science of physics. In the early days of physics and chemistry, many of the fundamental experiments could be performed with the simplest apparatus. And so we often find the names of Wollaston and Faraday mentioned as needing scarcely any thing for their researches. Much can even now be done with the simplest apparatus; and nobody, except the utterly incompetent, need stop for want of it. But the fact remains, that one can only be free to investigate in all departments of chemistry and physics, when he not only has a complete laboratory at his command, but a friend to draw on for the expenses of each experiment. That simplest of the departments of physics, namely, astronomy, has now reached such perfection that nobody can expect to do much more in it without a perfectly equipped observatory; and even this would be useless without an income sufficient to employ a corps of assistants to make the observations and computations. But even in this simplest of physical subjects, there is great misunderstanding. Our country has very many excellent observatories: and yet little work is done in comparison, because no provision has been made for maintaining the work of the observatory; and the wealth which, if concentrated, might have made one effective observatory which would prove a benefit to astronomical science, when scattered among a half-dozen, merely furnishes telescopes for the people in the surrounding region to view the moon with. And here I strike the keynote of at least one need of our country, if she would stand well in science; and the following item which I clip from a newspaper will illustrate the matter: —

"The eccentric old Canadian, Arunah Huntington, who left $200,000 to be divided among the public schools of Vermont, has done something which will be of little practical value to the schools. Each district will be entitled to the insignificant sum of $10, which will not advance much the cause of education."

Nobody will dispute the folly of such a bequest, or the folly of filling the country with telescopes to look at the moon, and calling them observatories. How much better to concentrate the wealth into a few parcels, and make first-class observatories and institutions with it!

Is it possible that any of our four hundred colleges and universities have love enough of learning to unite with each other and form larger institutions? Is it possible that any have such a love of truth that they are willing to be called by their right name? I fear not; for the spirit of expectation, which is analogous to the spirit of gambling, is strong in the American breast, and each institution which now, except in name, slumbers in obscurity, expects in time to bloom out into full prosperity. Although many of them are under religious influence, where truth is inculcated, and where men are taught to take a low seat at the table in order that they may be honored by being called up higher, and not dishonored by being thrust down lower, yet these institutions have thrust themselves into the highest seats, and cannot probably be dislodged.

But would it not be possible to so change public opinion that no college could be founded with a less endowment than say $1,000,000, or no university with less than three or four times that amount? From the report of the commissioner of education, I learn that such a change is taking place; that the tendency towards large institutions is increasing, and that it is principally in the west and south-west that the multiplication of small institutions with big names is to be feared most, and that the cast is almost ready for the great coming university.

The total wealth of the four hundred colleges and universities in 1880 was about $40,000,000 in buildings, and $43,000,000 in productive funds. This would be sufficient for one great university of $10,000,000, four of $5,000,000, and twenty-six colleges of $2,000,000 each. But such an idea can of course never be carried out. Government appropriations are out of the question, because no political trickery must be allowed around the ideal institution.

In the year 1880 the private bequests to all schools and colleges amounted to about $5,500,000; and, although there was one bequest of $1,250,000, yet the amount does not appear to be phenomenal. It would thus seem that the total amount was about five million dollars in one year, of which more than half is given to so-called colleges and universities. It would be very difficult to regulate these bequests so that they might be concentrated sufficiently to produce an immediate result. But the figures show that generosity is a prominent feature of the American people, and that the needs of the country only have to be appreciated to have the funds forthcoming. We must make the need of research and of pure science felt in the country. We must live such lives of pure devotion to our science, that all shall see that we ask for money, not that we may live in indolent ease at the expense of charity, but that we may work for that which has advanced and will advance the world more than any other subject, both intellectually and physically. We must live such lives as to neutralize the influence of those who in high places have degraded their profession, or have given themselves over to ease, and do nothing for the science which they represent. Let us do what we can with the present means at our disposal. There is not one of us who is situated in the position best adapted to bring out all his powers, and to allow him to do most for his science. All have their difficulties, and I do not think that circumstances will ever radically change a man. If a man has the instinct of research in him, it will always show itself in some form. But circumstances may direct it into new paths, or may foster it so that what would otherwise have died as a bud now blossoms and ripens into the perfect fruit.

Americans have shown no lack of invention in small things; and the same spirit, when united to knowledge and love of science, becomes the spirit of research. The telegraph-operator, with his limited knowledge of electricity and its laws, naturally turns his attention to the improvement of the only electrical instrument he knows any thing about; and his researches would be confined to the limited sphere of his knowledge, and to the simple laws with which he is acquainted. But as his knowledge increases, and the field broadens before him, as he studies the mathematical theory of the subject, and the electro-magnetic theory of light loses the dim haze due to distance, and becomes his constant companion, the telegraph-instrument becomes to him a toy, and his effort to discover something new becomes research in pure science.

It is useless to attempt to advance science until one has mastered the science: he must step to the front before his blows can tell in the strife. Furthermore, I do not believe anybody can be thorough in any department of science, without wishing to advance it. In the study of what is known, in the reading of the scientific journals, and the discussions therein contained of the current scientific questions, one would obtain an impulse to work, even though it did not before exist. And the same spirit which prompted him to seek what was already known, would make him wish to know the unknown. And I may say that I never met a case of thorough knowledge in my own science, except in the case of well-known investigators. I have met men who talked well, and I have sometimes asked myself why they did not do something; but further knowledge of their character has shown me the superficiality of their knowledge. I am no longer a believer in men who could do something if they would, or would do something if they had a chance. They are impostors. If the true spirit is there, it will show itself in spite of circumstances.

As I remarked before, the investigator in pure science is usually a professor. He must teach as well as investigate. It is a question which has been discussed in late years, as to whether these two functions would better be combined in the same individual, or separated. It seems to be the opinion of most, that a certain amount of teaching is conducive, rather than otherwise, to the spirit of research. I myself think that this is true, and I should myself not like to give up my daily lecture. But one must not be overburdened. I suppose that the true solution, in many cases, would be found in the multiplication of assistants, not only for the work of teaching but of research. Some men are gifted with more ideas than they can work out with their own hands, and the world is losing much by not supplying them with extra hands. Life is short: old age comes quickly, and the amount one pair of hands can do is very limited. What sort of shop would that be, or what sort of factory, where one man had to do all the work with his own hands? It is a fact in nature, which no democracy can change, that men are *not* equal, — that some have brains, and some hands. And no idle talk about equality can ever subvert the order of the universe.

I know of no institution in this country where assistants are supplied to aid directly in research. Yet why should it not be so? And even the absence of assistant professors and assistants of all kinds, to aid in teaching, is very noticeable, and must be remedied before we can expect much.

There are many physical problems, especially those requiring exact measurements, which cannot be carried out by one man, and can only be successfully attacked by the most elaborate apparatus, and with a full corps of assistants. Such are Regnault's experiments on the fundamental laws of gases and vapors, made thirty or forty years ago by aid from the French government, and which are the standards to this day. Although these experiments were made with a view to the practical calculation of the steam-engine, yet they were carried out in such a broad spirit that they have been of the greatest theoretical use. Again, what would astronomy have done without the endowments of observatories? By their means, that science has become the most perfect of all branches of physics, as it should be from its simplicity. There is no doubt, in my mind, that similar institutions for other branches of physics, or, better, to include the whole of physics, would be equally successful. A large and perfectly equipped physical laboratory with its large revenues, its corps of professors and assistants, and its machine-shop for the construction of new apparatus, would be able to advance our science quite as much as endowed observatories have astronomy. But such a laboratory should not be founded rashly. The value will depend entirely on the physicist at its head, who has to devise the plan, and to start it into practical working. Such a man will always be rare, and cannot always be obtained. After one had been successfully started, others could follow; for imitation requires little brains.

One could not be certain of getting the proper man every time, but the means of appointment should be most carefully studied so as to secure a good average. There can be no doubt that the appointment should rest with a scientific body capable of judging the highest work of each candidate.

Should any popular element enter, the person chosen would be either of the literary-scientific order, or the dabbler on the outskirts who presents his small discoveries in the most theatrical manner. What is required is a man of depth, who has such an insight into physical science that he can tell when blows will best tell for its advancement.

Such a grand laboratory as I describe does not exist in the world, at present, for the study of physics. But no trouble has ever been found in obtaining means to endow astronomical science. Everybody can appreciate, to some extent, the value of an observatory; as astronomy is the simplest of scientific subjects, and has very quickly reached a position where elaborate instruments and costly computations are necessary to further advance. The whole domain of physics is so wide that workers have hitherto found enough to do. But it cannot always be so, and the time has even now arrived when such a grand laboratory should be founded. Shall our country take the lead in this matter, or shall we wait for foreign countries to go before? They will be built in the future, but when and how is the question.

Several institutions are now putting up laboratories for physics. They are mostly for teaching, and we can expect only a comparatively small amount of work from most of them. But they show progress; and, if the progress be as quick in this direction as in others, we should be able to see a great change before the end of our lives.

As stated before, men are influenced by the sympathy of those with whom they come in contact. It is impossible to immediately change public opinion in our favor; and, indeed, we must always seek to lead it, and not be guided by it. For pure science is the pioneer who must not hover about cities and civilized countries, but must strike into unknown forests, and climb the hitherto inaccessible mountains which lead to and command a view of the promised land, — the land which science promises us in the future; which shall not only flow with milk and honey, but shall give us a better and more glorious idea of this wonderful universe. We must create a public opinion in our favor, but it need not at first be the general public. We must be contented to stand aside, and see the honors of the world for a time given to our inferiors; and must be better contented with the approval of our own consciences, and of the very few who are capable of judging our work, than of the whole world beside. Let us look to the other physicists, not in our own town, not in our own country, but in the whole world, for the words of praise which are to encourage us, or the words of blame which are to stimulate us to renewed effort. For what to us is the praise of the ignorant? Let us join together in the bonds of our scientific societies, and encourage each other, as we are now doing, in the pursuit of our favorite study; knowing that the world will some time recognize our services, and knowing, also, that we constitute the most important element in human progress.

But danger is also near, even in our societies. When the average tone of the society is low, when the highest honors are given to the mediocre, when third-class men are held up as examples, and when trifling inventions are magnified into scientific discoveries, then the influence of such societies is prejudicial. A young scientist attending the meetings of such a society soon gets perverted ideas. To his mind, a mole-hill is a mountain, and the mountain a molehill. The small inventor or the local celebrity rises to a greater height, in his mind, than the great leader of science in some foreign land. He gauges himself by the molehill, and is satisfied with his stature; not knowing that he is but an atom in comparison with the mountain, until, perhaps, in old age, when it is too late. But, if the size of the mountain had been seen at first, the young scientist would at least have been stimulated in his endeavor to grow.

We cannot all be men of genius; but we can, at least, point them out to those around us. We may not be able to benefit science much ourselves; but we can have high ideals on the subject, and instil them into those with whom we come in contact. For the good of ourselves, for the good of our country, for the good to the world, it is incumbent on us to form a true estimate of the worth and standing of persons and things, and to set before our own minds all that is great and good and noble, all that is most important for scientific advance, above the mean and low and unimportant.

It is very often said, that a man has a right to his opinion. This might be true for a man on a desert island, whose error would influence only himself. But when he opens his lips to instruct others, or even when he signifies his opinions by his daily life, then he is directly responsible for all his errors of judgment or fact. He has no right to think a molehill as big as a mountain, nor to teach it, any more than he has to think the world flat, and teach that it is so. The facts and laws of our science have *not* equal importance, neither have the men who cultivate the science achieved equal results. One thing is greater than another, and we have no right to neglect the order. Thus shall our minds be guided aright, and our efforts be toward that which is the highest.

Then shall we see that no physicist of the first class has ever existed in this country, that we must look to other countries for our leaders in that subject, and that the few excellent workers in our country must receive many accessions from without before they can constitute an American science, or do their share in the world's work.

But let me return to the subject of scientific societies. Here American science has its hardest problem to contend with. There are very many local societies dignified by high-sounding names, each having its local celebrity, to whom the privilege of describing some crab with an extra claw, which he found in his morning ramble, is inestimable. And there are some academies of science, situated at our seats of learning, which are doing good work in their locality. But distances are so great that it is difficult to collect men together at any one point. The American association, which we are now attending, is not a scientific academy, and does not profess to be more than a gathering of all who are interested in science, to read papers and enjoy social intercourse. The National academy of sciences contains eminent men from the whole country, but then it is only for the purpose of advising the government freely on scientific matters. It has no building, it has no library; and it publishes nothing except the information which it freely gives to the government, which does nothing for it in return. It has not had much effect directly on American science; but the liberality of the government in the way of scientific expeditions, publications, etc., is at least partly due to its influence, and in this way it has done much good. But it in no way takes the place of the great Royal society, or the great academies of science at Paris, Berlin, Vienna, St. Petersburgh, Munich, and, indeed, all the European capitals and large cities. These, by their publications, give to the young student, as well as the more advanced physicist, models of all that is considered excellent; and to become a member is one of the highest honors to which he can aspire, while to write a memoir which the academy considers worthy to be published in its transactions excites each one to his highest effort.

The American academy of sciences in Boston is perhaps our nearest representation of this class of academies, but its limitation of membership to the State deprives it of its national character.

But there is another matter which influences the growth of our science.

As it is necessary for us still to look abroad for our highest inspiration in pure science, and as science is not an affair of one town or one country, but of the whole world, it becomes us all to read the current journals of science and the great transactions of foreign societies, as well as those of our own countries. These great transactions and journals should be in the library of every institution of learning in the country, where science is taught. How can teachers and professors be expected to know what has been discovered in the past, or is being discovered now, if these are not provided? Has any institution a right to mentally starve the teachers whom it employs, or the students who come to it? There can be but one answer to this; and an institution calling itself a university, and not having the current scientific journals upon its table or the transactions of societies upon its library-shelves, is certainly not doing its best to cultivate all that is best in this world.

We call this a free country, and yet it is the only one where there is a direct tax upon the pursuit of science. The low state of pure science in our country may possibly be attributed to the youth of the country; but a direct tax, to prevent the growth of our country in that subject, cannot be looked upon as other than a deep disgrace. I refer to the duty upon foreign books and periodicals. In our science, no books above elementary ones have ever been published, or are likely to be published, in this country; and yet every teacher in physics must have them, not only in the college library, but on his own shelves, and must pay the government of this country to allow him to use a portion of his small salary to buy that which is to do good to the whole country. All freedom of intercourse which is necessary to foster our growing science is thus broken off; and that which might, in time, relieve our country of its mediocrity, is nipped in the bud by our government, which is most liberal when appealed to directly on scientific subjects.

One would think that books in foreign languages might be admitted free; but to please the half-dozen or so workmen who reprint German books, not scientific, our free intercourse with that country is cut off. Our scientific associations and societies must make themselves heard in this matter, and show those in authority how the matter stands.

In conclusion, let me say once more, that I do not believe that our country is to remain long in its present position. The science of physics, in whose applications our country glories, is to arise among us, and make us respected by the nations of the world. Such a prophecy may seem rash with regard to a nation which does not yet do enough physical work to support a physical journal. But we know the speed with which we advance in this country: we see cities springing up in a night, and other wonders performed at an unprecedented rate. And now we see physical laboratories being built, we see a great demand for thoroughly trained physicists, who have not shirked their mathematics, both as professors and in so-called practical life; and perhaps we have the feeling, common to all true Americans, that our country is going forward to a glorious future, when we shall lead the world in the strife for intellectual prizes as we now do in the strife for wealth.

But if this is to be so, we must not aim low. The problems of the universe cannot be solved without labor: they cannot be attacked without the proper intellectual as well as physical tools; and no physicist need expect to go far without his mathematics. No one expects a horse to win in a great and long race who has not been properly trained; and it would be folly to attempt to win with one, however pure his blood and high his pedigree, without it. The problems we solve are more difficult than any race: the highest intellect cannot hope to succeed without proper preparation. The great prizes are reserved for the greatest efforts of the greatest intellects, who have kept their mental eye bright and flesh hard by constant exercise. Apparatus can be bought with money, talents may come to us at birth; but our mental tools, our mathematics, our experimental ability, our knowledge of what others have done before us, all have to be obtained by work. The time is almost past, even in our own country, when third-rate men can find a place as teachers, because they are unfit for every thing else. We wish to see brains and learning, combined with energy and immense working-power, in the professor's chair; but, above all, we wish to see that high and chivalrous spirit which causes one to pursue his idea in spite of all difficulties, to work at the problems of nature with the approval of his own conscience, and not of men before him. Let him fit himself for the struggle with all the weapons which mathematics and the experience of those gone before him can furnish, and let him enter the arena with the fixed and stern purpose to conquer. Let him not be contented to stand back with the crowd of mediocrity, but let him press forward for a front place in the strife.

The whole universe is before us to study. The greatest labor of the greatest minds has only given us a few pearls; and yet the limitless ocean, with its hidden depths filled with diamonds and precious stones, is before us. The problem of the universe is yet unsolved, and the mystery involved in one single atom yet eludes us. The field of research only opens wider and wider as we advance, and our minds are lost in wonder and astonishment at the grandeur and beauty unfolded before us. Shall we help in this grand work, or not? Shall our country do its share, or shall it still live in the almshouse of the world?

PAPERS READ BEFORE SECTION B.

Determination of the relation between the imperial yard and the metre of the archives.

BY WILLIAM A. ROGERS OF CAMBRIDGE, MASS.

THIS paper was a continuation of one upon the same subject presented at the Montreal meeting. The mean result of the determinations up to that time was as follows: Imperial yard + 3.37015 inches = Metre des archives.

The writer stated at that time, that he should not like to be held to a very strict account with regard to the last decimal figure, or even the last two decimal figures, on account of the difficulty of obtaining the requisite data.

Since the meeting last year, additional data have been obtained. In February of the present year, a combined yard and metre was received from Paris. The yard was compared with the imperial yard, in 1880, by Mr. Chaney, the warden of the imperial standards. During the interval between 1880 and February of the present year, this metre has received repeated comparisons with the metre of the International bureau, under the direction of Dr. Pernet. According to his report, this metre is 310 mikrons too short at 0° centigrade; for the same temperature, the yard was found by Mr. Chaney to be 20.7 mikrons too short.

Comparing the metre and the yard upon this bar with the bronze yard and metre described at Montreal, and combining the results with those previously found, the relation was found as follows: Imperial yard + 3.37039 inches = Metre des archives.

The magnetophone, or the modification of the magnetic field by the rotation of a perforated metallic disk.[1]

BY PROF. H. S. CARHART OF EVANSTON, ILL.

THE experiments of Bell, Preece, and others, on the radiaphone, suggested the possibility of interrupting, or at least periodically modifying, the lines of force proceeding from the poles of a magnet, by means of a disk of sheet-iron, perforated with a series of equidistant holes, and rotated so that the holes should pass directly in front of the magnetic pole. It is well known that the armature placed on the poles of a permanent magnet diminishes the strength of the external field of force by furnishing superior facilities for the formation of polarized chains of particles from pole to pole. This is the case even when the armature does not touch the poles, but is in close proximity to them.

If a piece of sheet-iron be placed over the poles of a magnet without touching, and magnetic curves be developed on paper above the iron, they will be found to exhibit less intense and less sharply defined magnetic action than when the sheet-iron is removed. If, however, a small hole be drilled directly over each magnetic pole, the screening action of the sheet-iron is modified in much the same way as when a hole is

[1] This paper will shortly be published in SCIENCE in full.

made in a screen opaque to light; for the developed curves show distinctly the outline of the holes. If, therefore, the sheet-iron in the form of a circular plate, pierced with a number of holes, be rapidly rotated between the poles of a magnet and small induction bobbins, the action of the magnet on the core of the bobbins will be periodically modified, because of the passing holes: and hence induced currents will flow through a circuit including the bobbin. A disk of sheet iron was pierced with two circles of quarter-inch holes concentric with the disk, the number of holes in the two circles being thirty-two and sixty-four respectively. On one side of the disk was placed a horseshoe magnet with its poles very near the rows of holes; on the other side were arranged two corresponding induction bobbins. The circuit was completed through a telephone and either bobbin at pleasure. Upon rotating the disk rapidly, a clear musical sound was produced in the telephone, the pitch rising with the rapidity of rotation. Moreover, the bobbin opposite the circle of sixty-four holes gave the octave above the other, and each gave a note of the same pitch as was produced by blowing a stream of air through the corresponding holes.

Magnetic survey of Missouri.

BY F. E. NIPHER OF ST. LOUIS, MO.

In the spring of 1878 a survey of Missouri was begun, which was expected to determine all points in regard to terrestrial magnetism: 160 points have been covered. The work was undertaken under private auspices, most of the money tendered unasked, and the work has been carried on successfully until the present time. The first three years were spent in making a preliminary survey. In the early part of the survey we labored under great difficulties, because I supposed that the lines of equal value, laid down upon the observations given in the coast-survey charts, were substantially correct; so that time was frequently lost in repeating values at stations left behind, in order to be certain that no error had been committed. But when we settled down to the conclusion that we really knew nothing about the matter, we had very much less trouble. At first, intensity determinations were made at each station; but in later years, since the magnets have proved so satisfactory, the plan was adopted of making absolute determinations only at regular intervals during the summer. The temperature corrections for the magnet were made twice, — once in 1878, and once two years ago, — and they agreed very closely with each other.

The dip circle was a large one, such as was formerly much used, and which was found to be an excellent instrument, though rather clumsy to carry. The charts which have been prepared show what the results were. In a former communication to the association at Cincinnati, I suggested an explanation of the peculiar flexures of the isogonic lines, as being due to earth-currents which seemed to be deflected by the moist river-valleys. The map upon which that hypothesis was based represented observations taken over the entire state. By re-determination we have found that those observations were all correct; but more detailed work shows that this explanation is not admissible. There is no explanation of the fact that contour has any thing to do with the deviation of the needle from the normal values. Similar flexures are also seen in the lines of equal inclination and the lines of intensity. One and perhaps two years will be required to accomplish the work properly. There is nothing new in the subject, except the rather unexpected flexures which we found in these lines. It shows very clearly that the isogonic lines which are published for the use of surveyors are of no earthly use. Work ought to be done in a detailed way over the whole country; and I hope we shall some time be able to combine with these determinations a series of magnetic values at ten or twelve different stations in the state of Missouri, and also simultaneous determinations of earth-currents upon lines making angles with each other at the different stations. Similar variations would probably be found in the states of Illinois and Iowa.

In the discussion which followed, President Rowland said, that with respect to the earth-currents, he himself never saw any experiments which gave steady earth-currents. Earth-currents are usually supposed to vary very quickly. They do not pass in a steady direction anywhere; and therefore he would inquire whether Professor Nipher has any reason to suppose there are such earth-currents, and, further, whether these local changes of these lines may not be due to hidden mines of iron, or something or other, rather than to earth-currents.

The question was also asked, whether, in comparing earlier observations with the later, there are variations from year to year which would soon invalidate any survey that could be made, and render it comparatively of no value.

I suppose, replied Professor Nipher, that, over rather large areas of country, the annual change does not vary very rapidly in space. In the western states, so far as I know at present, it is pretty nearly constant, though I do not know as we have any reason to say that it is really constant. Replying to the president's last question, I should say that the determination to which I have referred, as regards earth-currents, was not for the purpose of testing the theory which I formerly had, but simply for the purpose of examining a cause which certainly has some effect. I think it is well enough known that it is a fact, and it is well to investigate it, since we found so many unexpected things. I should suppose that the explanation, that it is due to magnetic matter under the surface of the earth, is the much more probable one, as the case stands now. As to the disposition of that magnetic matter, you can make a great variety out of that, and locate your mines in various parts of the state.

Prof. A. E. Dolbear inquired whether any investigations have been made as to the direction of earth-currents; and whether Professor Nipher knew of any device which would enable him to detect the direction of them in any place. He had made some observations on a line of his own, half a mile long, and had invariably found that in that line the current is in one direction; and its electro-motive force varies from about one-tenth of a volt up to three volts.

In regard to these lines, said President Rowland, quick flexures of that sort must be due to local causes. They cannot be due to any thing at the centre of the earth. With respect to using a line in determining earth-currents, I think it is unsatisfactory. I do not believe very much in it, myself. You can get a current in the line, but you are not certain it is in the earth.

A member remarked that in 1881, in Boone County, Missouri, he had a line in which a continuous current was evinced with an electro-motive force of from two to four volts. From 8 to 10 in the morning was the maximum, and 5 P.M. the minimum. The line being east and west, the direction of the current was from east to west.

President Rowland said: If you put the wire on the earth's surface from one point to another, you merely determine the difference of intensity between those points. It shows there is a current there when the wire is there, but not when the wire is not there.

A method of distributing weather forecasts by means of railways.

BY T. C. MENDENHALL OF COLUMBUS, OHIO.

THIS system has only been in operation in Ohio for about a year. To distribute forecasts, we place signals upon the sides of the baggage-cars, as distinct as possible from each other, so as to be easily recognized at considerable distances, and also to convey as much meaning as possible, so as to predict as many different conditions. We adopted a combination of form and color. The signals are three in number as to form, and two in number as to color. The red signals are confined to predictions as to temperature, — rise in temperature, stationary temperature, falling temperature. The other color is blue, and that is confined to predictions in regard to the general state of the weather. The question of form was a good deal considered, and three forms were adopted. We adopted the sun, moon, and star, because everybody was familiar with those words. We experimented with the triangle, and finally rejected it. The device for attaching to the car is due to Mr. Anderson, who has been in the service of the board of commissioners for the past year; and it is a really happy device. The signal is made as large as possible, and the disk can be seen a long distance. The red sun and blue moon mean higher temperature and general rain. The crescent means lower temperature; the full disk of blue means general rain; the star represents local rains. With regard to the proper working of the system, though it has been in operation but a short time, it has really done good work. We receive special telegrams every morning, and they are transmitted to the train-despatchers at five o'clock. We are as yet operating it only on one railroad. It happens, fortunately, that that road goes through an agricultural region of considerable importance. It is the road connecting the cities of Columbus and Cleveland. Two trains start out in the morning, at the middle point between those cities. The signals are put on the cars at five o'clock in the morning; and as they run through the morning hours, the farmers along the line can have an opportunity of seeing them, and predicting the weather for the day. The railway company circulated through the whole line little cards, having these signals displayed in colors, with their meaning in every combination. This helps us, because it enables everybody to understand what is meant. A recent communication from Gen. Hazen indicates a disposition on the part of the general government to take hold of the matter, and bring it into general operation as far as possible. Postal-cards have been sent to various persons along the line, with questions in regard to the practical working of the system, which are answered and sent in at the end of every week; and we find, that, on the average, 80 per cent of the predictions are verified.

Plan for a state weather service.

BY F. E. NIPHER OF ST. LOUIS, MO.

WHILE a good many are accommodated by the weather-signals which Professor Mendenhall has already inaugurated, many live a distance from the railroad, and cannot be interested in a scheme which makes it necessary to travel eight or ten miles to learn about the weather, because they might be interested in a different kind of weather by the time they got home. The information might be most easily circulated by telegraphing from picket-stations to the westward. There might be a line of stations on the railroad north and south; and stations might be found necessary in Nebraska, which would give immediate warning to the central office whenever it began to rain at the station; and a code might be arranged, so as to give the idea of the operator as to the probable violence or duration of the rain. Of course it would be necessary to make special study of the general laws for the progress of summer rains. Supposing the information is telegraphed to the central station, the predictions can easily be made out as soon as the picket-stations could be reached, and a clear idea obtained as to the probable direction of the storm, and the time at which it would reach the different portions of the state. That information could be transmitted by the railway companies. Finally, we should make more intimate connection between these and private telegraph-lines which can be constructed by the persons who are to be served with the weather-signals. This plan contemplates the erection of private telegraph-lines leading in from the country to the stations. Upon a twenty-mile line, which would be a frequent length in Missouri, ten farmers will have to pay for the erection of a couple of miles of wire, and the instruments, which can be put up for $30 a mile. Some person could be sent from the vicinity to the director of the service, and instructions given him in regard to the manner of operating the line and the management of the batteries. The cost of the line, therefore, to each farmer, would be, say, $75, which might be distributed over ten years. Mr. Nipher stated that in several localities the farmers will undertake it just as soon as the information can be furnished them. At the stations the lines could easily be made to terminate in the store of some merchant, who is anxious to secure the trade of the people on the line. This can be done at once in Missouri. The only thing necessary is for the state to appropriate a small amount of money to supply the persons and instruments for observations, rain-gauges, etc. The two things necessary to make it successful are information as to rainfall, and time of beginning and ending of rains.

NOTES AND NEWS.

— The next meeting of the American association for the advancement of science will be held in Philadelphia, probably during the first week in September, 1884. At the session in Minneapolis last Tuesday, the following persons were chosen as officers for the Philadelphia meeting: President: Dr. J. P. Lesley, of Philadelphia. Vice-presidents: Section A (mathematics and astronomy), Prof. H. T. Eddy, of Cincinnati; B (physics), Professor John Trowbridge, of Cambridge; C (chemistry), Prof. J. W. Langley, of Ann Arbor; D (mechanical science), Prof. R. H. Thurston, of Hoboken; E (geology and geography), Prof. N. H. Winchell, of Minneapolis; F (biology), Prof. E. D. Cope, of Philadelphia; G (histology and microscopy), Prof. T. G. Wormley, of Philadelphia; H (anthropology), Prof. E. S. Morse, of Salem; I (economic science and statistics), Hon. John Eaton, of Washington. Permanent secretary: Mr. F. W. Putnam, of Cambridge. General secretary: Dr. Alfred Springer, of Cincinnati. Assistant general secretary: Prof. E. S. Holden, of Madison. Secretaries of the sections: A, Mr. G. W. Hough, of Chicago; B, Mr. N. D. C. Hodges, of Salem; C, Prof. R. B. Warder, of Cincinnati; D, Prof. J. B. Webb, of Ithaca; E, Prof. E. A. Smith, of Tuscaloosa; F, Prof. C. E. Bessey, of Ames; G, Dr. Romyn Hitchcock, of New York; H, Mr. W. H. Holmes, of Washington; I, Mr. Charles W. Smiley, of Washington. Treasurer: Hon. William Lilly, of Mauch Chunk.

— A course of eighteen special lectures will be given next year to members of Johns Hopkins university on topics relating to instruction in the higher institutions of learning. They will be informal lectures, connected only by the general purpose of helping advanced students who are looking forward more or less definitely to the work of teachers to become familiar with the principles and methods followed by other persons, and with the results which have been obtained in different types of educational establishments. The following are announced: —

The present state of university and collegiate instruction in this country, by D. C. Gilman; Recent observations on educational foundations in Europe, by D. C. Gilman; Natural and ethnic history of arithmetic, by J. J. Sylvester; The educational value of grammar, by B. L. Gildersleeve; The future sphere of classical philology, by B. L Gildersleeve; Educational value of the study of chemistry, by Ira Remsen; What to teach in biology, by H. Newell Martin; One lecture by H. A. Rowland; The observational element in mathematics, by C. S. Peirce; The *a priori* element in physics, by C. S. Peirce; The *naïve* in education, by H. Wood; Modern methods in the study of history, by H. B. Adams; Methods of comparative philology as pursued to-day, by M. Bloomfield; The new impetus given to the study of Latin by the application of the historical method, and by the study of inscriptions, by Minton Warren; Hygiene in collegiate training, by E. M. Hartwell; Rhythm and education, by G. Stanley Hall; The educational value of specialization and original work, by G. Stanley Hall; The uses of libraries in education, by D. C. Gilman.

A course of nine lectures specially designed for college students will also be given, as follows: —

The choice of a profession, by D. C. Gilman; The light which biography throws on college life, by D. C. Gilman; Reading as an auxiliary to study, by W. Hand Browne; The right use of translations, by C. D. Morris; Historical fiction, by H. B. Adams; The English universities, by J. Rendel Harris; Recreation, by E. M. Hartwell; Mental hygiene, by G. Stanley Hall; Science work, by Ira Remsen.

— The Imperial meteorological observatory of Japan has established a telegraphic weather-service, and at present receives reports from twenty-two well-distributed stations. No forecasts are yet attempted, although it is the intention to make them as soon as sufficient experience will justify the step. Tri-daily maps and bulletins are, however, prepared. It is interesting to note that but one telegram is received each day from the several stations. This is sent by the aid of a cipher, which consists of a simple combination of figures, not of words, as is the case in the cipher used by the U. S. signal-service. The daily despatch is the equivalent of about eight words, and contains all the usual meteorological data for each of the three preceding observations.

— The Meteorological council publishes the results of rainfall observations at three hundred and thirty-six stations in Great Britain, made without interruption from 1866 to 1880, under the supervision of Mr. G. J. Symons. The monthly means are given for each year, for each period of five years, and for the whole fifteen years. No discussion of the observations is made, though it would seem that valuable conclusions could be derived from them.

— Mr. V. T. Chambers, an entomologist well known for his studies on the Tineina, died at his residence in Covington, Ky., at two o'clock on the morning of Aug. 7. During the afternoon of Aug 6 he had a stroke of paralysis, and died from its effects. He was fifty-two years old on that morning. He was a constant contributor to the *Canadian entomologist* and many other entomological journals. In the Bulletin of the U. S. geological survey there are several papers from his pen: viz., the Tineina of Colorado; notes on a collection of tineid moths made in Colorado in 1875 by A. S. Packard, jun.; on the distribution of Tineina in Colorado; new Entomostraca from Colorado; descriptions of new Tineina from Texas, etc.; Tineina and their food-plants; and an index to the described Tineina of the United States and Canada. He also contributed a number of papers to the *Journal* of the Cincinnati society of natural history, of which he was a member, and at one time president. The most important of these papers were: on the tongue (*lingua*) of some Hymenoptera; on Pronuba yuccasella Riley, and the habits of some Tineina; his annual address as president of the society on the metamorphoses of insects, as illustrated in the tineid genus Lithocolletis of Zeller; descriptions of some new Tineina, with notes on a few old species; illustrations of the neuration of the wings of American Tineina; and on the antennae and trophi of lepidopterous larvae. Many of these papers are illustrated by his own drawings. A lawyer by profession, he found time to do much excellent work in science, and formed a large collection, which has been for some years in the Museum of comparative zoölogy at Cambridge. He was also proficient as a microscopist and a botanist. He leaves a wife and three sons, and his loss will also be felt by all the entomologists of the country.

— Dr. John A. Warder, for many years one of the most prominent horticulturists and foresters in the west, died at his home at North Bend, O., on July 14, in the seventy-second year of his age. He has been identified with the west, and especially with Cincinnati, for nearly fifty years. He was president for many years of the Horticultural society, and has written many papers on botanical and kindred subjects. He was one of the founders of the American forestry association, always took an active interest in its proceedings, and contributed many papers to its meetings.

— Professor Simon Newcomb has taken passage for home in the Bothnia, which sails to-morrow from Liverpool to New York. He was to attend the meeting of the French association for the advancement of science at Rouen, just closed. Prof. E. C. Pickering, who has been spending the summer in Europe, will return in October.

— "At the end of May," says Dr. G. Hinrichs in his July Iowa weather bulletin, "this year's growing season, counted from April 1, was sixty degrees in the aggregate ahead of last year's. We had gained nothing more at the end of June; for last year's June was moderate, the same as this season's June. But during July we gained in the aggregate one hundred degrees over last year's July; so that, on the 1st of August of this year, we have received in the aggregate one hundred and sixty degrees of heat more than last year at this period. This fact, together with the fair sky and generally favorable distribution of rainfall, accounts for the greatly superior condition of our crops this year.

"The storm-record," he adds, "has been given in sufficient detail to help to dispel the exaggerated notions of danger from whirlwinds in Iowa. It will readily be seen, that if squalls extending simultaneously over a large storm-front, and progressing for hours like a huge wave, are heralded as 'tornadoes' at every place they reach, people at a distance will soon wonder that towns exist at all in the north-west, and our own people will be scared into expensive tornado insurance. In time our buildings will be substantial enough to withstand our summer squalls and winter blizzards successfully. As to genuine tornadoes, they are rare, and very limited in extent."

— For some months the electricians of Paris have held a monthly dinner. These dinners owed their origin to Count Hallez-d'Arros, and were attended by no organized society, but were re-unions of those interested in electrical science. Lately it has been thought better to give the gatherings more stability by some manner of permanent organization; and at the June meeting a *Société des électriciens* was formed.

— During the past year, original investigations in the following subjects, among others, have been carried on in the physical laboratory of Johns Hopkins university under the direction of Professor Rowland and Dr. Hastings: on the photography of the spectrum by means of the concave grating (the photographs of the spectrum, so far made, extend down to B, the original negatives being about $\frac{3}{4}$ the scale of Angström's map from B to b, equal to Angström's from b to G, and $1\frac{1}{2}$ Angström's from G to the extreme ultra-violet; they show 150 lines between the H lines, and give the 1474 and b_3 and b_4 widely double and the E line indistinctly double); on the determination of the B. A. unit of electrical resistance in absolute measure; the determination of the specific resistance of mercury; the variation of the specific heat of water with the temperature; the relative wave-lengths of the lines of the spectrum by means of the concave grating; the effect of difference of phase in the harmonics on the timbre of sound; and on the variation of the magnetic permeability of nickel by change of temperature.

— Professor Palmieri announces the existence in the lava of Vesuvius of a substance giving the spectrum line of 'helium,' — an element hitherto recognized only in the sun. He considers the late disaster at Ischia to be due to subsidence of land consequent on the unusual activity of Mount Vesuvius.

— There will shortly be published by Allen & Co. of London a book by A. H. Swinton, entitled 'The influence of the sun on natural phenomena.' One may judge of the book's value by the following quotation from the prospectus: "The multitude who read the morning's newspaper may find in it some reason for their successes and losses, further than blind fatality."

RECENT BOOKS AND PAMPHLETS.

SCIENCE.

FRIDAY, AUGUST 31, 1883.

SONNET.

The years through which aught that hath life, O Sun!
Hath watched or felt thy rising, what are they
To those vast aeons, when, from night to day,
From dawn to dark, thy circuit thou didst run,
With none to greet thee or regret thee; none
To bless thy glowing harbinger of cloud,
Rose-tinted; none to sigh, when, like a shroud,
The banner of Night proclaimed her victory won?

Yet through that reign of seeming death, so long
To our imperfect ken, the marvellous force
Which means to ends adjusts in Nature's plan
Was bringing to the birth that eye of man
Which now, O Sun, surveys thy farthest course,—
A speck amid the countless starry throng.

John Reade.

NOTES ON THE GEOLOGY OF THE TROAD.

A brief summary of the results derived from the observations made in connection with the Assos expedition.

The terranes of the Troadic peninsula comprise a variety of stratified and massive or eruptive rocks. The former, excepting the most recent deposits, which are not considered in this connection, may be divided into three groups, according to their mineralogical conditions and geological age.

The most ancient group is highly crystallized, and, in all probability, belongs to the mica-schist zone of the 'grundgebirge' or archean formation.

The youngest group, embracing the miocene and pliocene tertiary deposits, is, in part at least, well characterized by its fossils. The middle group is not defined, excepting by the widely separated limits of the other two groups. It embraces rocks which may be paleozoic or pre-paleozoic, as well as others which are probably of cretaceous and eocene age.

The crystalline schists have their greatest development in Mount Ida, of which they form almost the entire mass. They are of many varieties, all conformably interstratified, as if all belonged to the same great terrane.

True gneisses are not abundant, and occur chiefly upon the north side of Mount Ida, under such conditions that they appear to overlie the schistose rocks. In Hagi ouldòuren-dagh the mica is in large part replaced by hornblende, so that the gneiss has a somewhat dioritic aspect.

In the schistose rocks, chiefly amphibolites, hornblende is one of the most widely distributed and abundant minerals. It generally appears as actinolite, and not infrequently constitutes almost the whole of the rock in which it occurs. With amphibole, at times, are associated, besides plagioclase, more or less quartz, epidote, magnetite, titanite, and rutile. True mica-schists are of less common occurrence interstratified with the amphibolites.

Near the centre of Mount Ida, the oldest rocks crop out; and among them are talc-schists, which, by the gradual addition of olivine, pass into small lens-shaped masses composed almost exclusively of the latter mineral. According to the nomenclature of Brogger, this rock should be called olivine-schist. By alteration it gives rise to serpentine with the characteristic reticulated structure which ever marks the serpentine derived from olivine. Occasionally the fibrous serpentine forms veins of considerable size in the adjacent rocks.

The olivine-schist, where purest, has no schistose structure. The passage from talc-schist, in which no olivine occurs, to that composed almost completely of olivine, takes place sometimes within a short distance. The chief mass of the rock, however, is a middle stage between the two extremes, having a distinct schistose structure, and composed for the most part of olivine and talc, besides considerable quantities of pyroxene, as well as other minerals not yet determined. At various intervals throughout the zone of schistose rocks, occur rather coarsely crystalline white limestones.

The structure of Mount Ida is a comparatively simple anticlinal, with so short an axis extending east and west that the upper portion of the mountain is approximately a dome.

The highly crystalline stratified rocks are perhaps the chief topographical determinants of that region. Their position and distribution indicate, that, in the early stages of its development, the peninsula of the Troad was represented by several islands, which furnished much of the detritus for subsequent formations.

The rocks of the middle zone are for the most part semi-crystalline limestones, a very ferruginous quartzite, together with greenish, somewhat schistose rocks, and others which are macroscopically like argillites, but contain too large a proportion of quartz. The limestone is generally compact, gray or reddish colored, very like the cretaceous (according to Professor Neumayr) in the acropolis at Athens, and has often large quantities of silica so irregularly accumulated as to produce a very rough weathered surface like the cretaceous limestone west of Smyrna. This limestone is found chiefly about the base of Mount Ida, at Edremit, Qojikia-dagh, and Chaly-dagh, as well as between Qayalar and Ahmadja, and several kilometres south-west of Ilisfagy. At Qojikia-dagh it is peculiar in containing many small needle-shaped quartz crystals. The ferruginous quartzite was observed only upon the acute summit of Dikili-dagh.

The greenish, somewhat schistose rocks, with sandstones of the same color, near Ahmadja, as west of Smyrna, overlie the limestone. The cretaceous age of the limestone at the locality last named appears to be quite definitely determined by Strickland, Tchihatcheff, and Spratt; but the age of that near Ahmadja is yet uncertain. Only one fossil has been found in it. Concerning this, Professor Neumayr writes, "It is a Rhynconella which is so widely distributed that it cannot be used as a certain means of determining the age of the strata in which it occurs; but the limestone is probably cretaceous."

That these rocks are younger than those of the mica-schist zone is indicated, not only by the fact that they contain fossils, and are less crystalline than that group, but also by the fact that they are made up of sediments derived from the crystalline schists. On the other hand, that they are, at least in part, old rocks, is shown by the contact zone produced in them by the quartz diorite.

In 1881 Mr. Frank Calvert, American consul at Dardanelles, discovered undoubtedly eocene fossils (determined by Professor Neumayr) at several places in the Troadic peninsula outside of the region visited by the geologist of the expedition. The same rocks, in all probability, occur also in the southern Troad; but, until further investigations are made, their appearance must be left doubtful.

It seems probable, therefore, that in the intermediate zone there are a number of terranes of different age. It should be stated in this connection, that the rocks of the southern Troad, placed by Tchihatcheff provisionally in the lower tertiary, are, according to Professor Neumayr, of more recent origin.

The third or youngest group of stratified deposits, embracing those which are certainly not older than the miocene, may be divided into two portions. Geographically they are entirely distinct, and their stratigraphical relations are yet uncertain.

The rocks of the sarmatic stage (tufa) of the miocene, so well exposed at Eren-kieui, are now known to border the western coast from the Trojan plain to beyond the mouth of the Touzla, near the promontory of Baba-bournou.

At the site of ancient Hamaxitos, several kilometres south-west of Kinlahly, the 'mactra-kalk,' with its characteristic fossils, forms the acropolis. This limestone is undoubtedly of marine origin; and although it has a wide distribution north-eastward, toward the Caspian and the Vienna basin, yet it has not been recognized farther south-west than the coast of the Troad.

Beneath the limestone, as at Eren-kieui, is a great thickness of sand and clay beds which are underlaid by a conglomerate, and probably at the bottom of the series a stratum of red clay. The conglomerate is composed chiefly of fragments of andesite and liparite. Fossils have not been found in these beds near Hemaxitos; but at Eren-kieui, according to Calvert and Neumayr, organic remains are not infrequent, and of a mixed character, indicating that the strata belong, at least in great part, to the sarmatic stage. The marine beds which overlie the mactra limestone are largely developed south of the mouth of the Touzla, and contain great numbers of fossils, among which are many Ostrea and gastropods.

The second portion of the tertiary deposits occupies a large part of the interior of the Troad about the great plain of the Menderè, between Ezine and Bairamitch, as well as along the southern coast, west of Papazly. It has furnished but few fossils, and they are of such a character that its age cannot be determined with certainty. However, according to Professor Neumayr, who has kindly undertaken the determination of the fossils collected by the expedition, it must be upper miocene, miopliocene, or lower pliocene. That it is in great part a fresh, or at most a slightly brackish water deposit, cannot be doubted. As has already been shown in a preliminary report, where these deposits are described at some length, the basis of the series is a conglomerate in which fragments of the basalts, andesites, and liparites, have not been found. It is overlaid by a series of shales, upon which, between Demirdji-kieui and Narly, rests a puzzling rock, regarded by Tchihatcheff as limestone. It is usually pale-yellowish colored, soft, light, and porous, and generally shows no trace of effervescence in hydrochloric acid. In general appearance it closely resembles an impure siliceous limestone from which the greater portion of the carbonate of lime has been leached away. Having a thickness of about a hundred and thirty metres, it becomes the chief topographical determinant of that region, and gives rise to profound gorges and bold escarpments. Throughout the greater portion of the mass, it is uniformly fine-grained, but under the microscope has the structure of a tufa.

The upper beds of the series, consisting of thin fresh-water limestones, sandstones, shales, and a large proportion of stratified tufas, with conglomerates, have not been seen east of Demirdji-kiēui. The fossils collected were found in this portion of the series; and it is evident that the ejection of the andesites began before the deposition of those beds was completed.

Numerous oscillations of the land, as indicated by the varying character of the strata, must have occurred during the miocene and pliocene; and, in all probability, these were connected with the extrusion of the eruptive rocks so abundant in that region.

The massive rocks of the Troad belong in part to those of pre-tertiary origin, but the greater portion were extruded since the beginning of the tertiary period. The older group includes biotite-hornblende-granite, quartz-porphyry, quartz-diorite, augite-porphyrite, melaphyre, and serpentine, while the younger group embraces liparites, andesites, augite-andesites, basalts, and nepheline-basalt.

The biotite-hornblende-granite occurs in a stock-like mass, forming the serrated ridge of Chigri-dagh. It is distinctly younger than the highly crystalline stratified rocks which it penetrates, and is especially interesting from the fact, that, where it is altered, the titanite is changed to anatase. The alteration of titanite and ilmenite to anatase is doubtless a common and widely distributed occurrence; but, as the crystals of anatase are so small, they have generally been overlooked.

The quartz-porphyries are chiefly micrograntes. and are younger than the biotite-hornblende-granite through which they have been extruded. The dikes in which they occur are comparatively small, and do not exercise much influence upon the topographical features of the country.

The quartz-diorites form a number of comparatively small stöcke about the base of Mount Ida, and are evidently younger than the quartzose argillite of the middle zone of stratified rocks, which, in one case, has been metamorphosed into a cordierite and andalusite hornfels. It is to be especially noted that these eruptive rocks do not, as formerly supposed, enter into the structure of Mount Ida.

The augite-porphyrites (diabase-porphyrites) and melaphyres are, as far as yet known, limited to five outcrops, all lying in a line near the southern coast of the Troad, and, with the exception of that between Ahmadja and Qyalar, are not important. At the locality just named it is of especial interest from the fact that melaphyre was the first rock extruded in that isolated (completely surrounded by tertiary strata) volcanic centre, and was followed later by mica-andesite, hornblende-andesite, augite-andesite, basalt, and, late if not last, by a large outpouring of liparite.

The serpentine in the anterior part of the Troad about Qarâ-dagh has been derived from olivine-enstatite rocks of a truly eruptive nature. The almost entire absence of the characteristic reticulated structure in some of the serpentine from the Kemar valley leaves, perhaps, some doubt as to the original rock from which it has been derived. As previously stated, the serpentine about the summit of Mount Ida has been derived from olivine-schist which undoubtedly belongs to the stratified rocks.

Although the ancient eruptive rocks are apparently not nearly so abundant as those of more recent origin, yet they represent very nearly the same range in chemical and mineralogical composition. The granite and quartz porphyries have their modern equivalents in the liparites; the quartz-diorites, in the mica and hornblende andesites; the augite-porphyrites, in the augite-andesites; the melaphyre, in the basalt. However, no equivalents were found for the nepheline-basalts and the ancient olivine-enstatite rocks. On the other hand, the syenites, and their modern representatives the trachytes, which were once supposed to be abundant in the Troad, are now known to be at most only very sparingly represented.

The liparites occur in various types, with many varieties, and are limited to the southern part of the Troad. They appear also south of Molivo on the island of Mitylene, and at Sal Mosac south-west of Aivalÿ. They are generally in the stony condition, but frequently glassy upon the boundaries, and contain many fragments of the andesites which they have penetrated and overflowed. They always occur in dikes, as at Qozlou-dagh and the great plateau, which give rise to the peculiar drainage of the Touzla River. That some of the liparites were extruded before the deposition of the 'mactrakalk' is certain; but, from the fact that the exact age of the tertiary deposits in the southern part of the Troad has not been definitely determined, the time of the extrusion of the great mass of the liparites cannot be stated. However, it occurred most likely at the beginning or in the early part of the pliocene, when the land was raised above the sea, and the islands converted into a peninsula.

The andesites embrace typical mica-andesites and hornblende-andesites, as well as a great variety in which mica and hornblende occur in nearly equal proportion. These, with augite-andesite, occupy a great area between the Menderè and the southern coast; and, unlike the liparites, they seem to have reached the surface, at least in some cases, through volcanic vents. Not unfrequently they occur in dikes also, and have evidently overflowed a large area of late tertiary deposits.

Their extrusion along the western coast began before the deposition of the 'mactrakalk,' and along the southern coast during the formation of the fresh-water deposits of that region. Pyroxene is generally a prominent constituent of the andesites, and frequently both rhombic and monoclinic pyroxenes occur together. The former is generally the most abundant, and has in one case been proved to be hypersthene. It occurs not only in the mica-andesite at Assos and Smyrna, but also in the hornblende-andesite north-west of Qozlou-dagh, and the augite-andesite west of Sivriji-bournou. Among the great variety of andesites may be mentioned the oldest which flowed from the cràter at Assos. It is a mica-andesite, in the groundmass of which is a large proportion of apparently primary mica and hematite.

The basalts occur in dikes, and, although widely distributed, do not occupy large areas. Along the southern coast of the Troad it is of an andesitic type, and the olivine is occasionally altered to distinctly cleavable pleochroitic serpentine.

The same phenomenon is better developed in the typical nepheline-basalt which forms the prominent hill called Qaràlyly or Qapandjà-tepe, near the centre of the Troadic peninsula. The basalts and nepheline-basalt are evidently younger than the tertiary deposits with which they are associated; but the time of their extrusion with reference to that of the other eruptive rocks of the Troad cannot be definitely determined. J. S. Diller.

Greason, Cumberland County, Penn.,

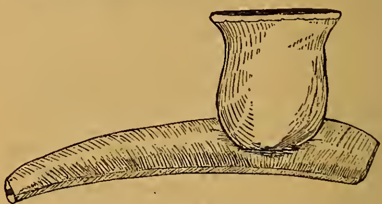
OCCURRENCE OF MOUND-BUILDERS' PIPES IN NEW JERSEY.

Until recently the one form of stone implement which is characteristic of the mounds of Ohio and westward, and that has not been duplicated in surface finds in New Jersey and elsewhere on our northern Atlantic sea-board, is the so-called mound-builders' pipes, such as were discovered in great numbers, and described in detail by Squier and Davis in the 'Ancient monuments of the Mississippi Valley,' and more recently by several authors. These pipes may be characterized as having a small bowl, usually in the shape of a bird, mammal, or human head, placed upon a short, flat, and slightly curved base, so perforated that it was used as the stem of the pipe. In other words, it was a complete smoking implement, and therefore unlike the ordinary pipes or pipe-bowls found in New Jersey and the New-England states, which, as a rule, required the addition of a stem of reed or hollow bone, to be used as the mouthpiece.



Within a few weeks, a pipe of the pattern I have described, assumed to be peculiar to the mound-builders, has been found in New Jersey. While the bowl is perfectly plain, except a slight scalloping of the rim, it will be seen at a glance, that the specimen is essentially of the same pattern as the 'animal pipes' found in Ohio, and recently also in Iowa.

Previous to 1882, I had been unable to find any pipes of this pattern, or traces of native copper implements of any kind; but since then copper spears, such as are found in Wisconsin, have been found in New Jersey, and now the pipe that I have described, and of which an illustration is given. Recently, also, specimens of flint arrow-heads have been collected, which in size, and delicacy of finish, are equal to the best examples from Oregon.

These specimens are now briefly referred to, as indicative of the fact, that in skill in working flint, and in the range of handiwork, whether in stone, bone, or clay, the difference between those people that erected the extensive earth-works of the Ohio valley and elsewhere, and the 'wild tribes' of the Atlantic seaboard, is practically nothing. I still hope to find unmistakable artificial mounds in New Jersey; basing my expectation upon the fact, that natural hillocks or knolls were frequently used as places of burial, and were chosen as desirable sites for the erection of wigwams.

CHARLES C. ABBOTT, M.D.

THE IGLOO OF THE INNUIT.[1]—III.

THE only instrument used in the construction of the igloo is the snow-knife. Where the Innuits have intercourse with white men, they bar-

MODERN SNOW-KNIFE.

ter for cheese-knives or long-bladed butcher-knives, remove the double handle from the tang, and put on a single one about three times as long, which can be readily grasped by both hands. The old knives were made of reindeer-horn or from the shin-bone of the reindeer.

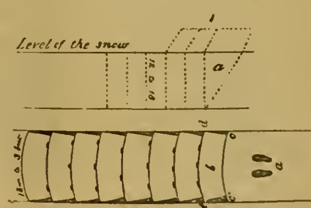
SNOW-KNIFE OF BONE.

Among the Esquimaux in and around King William's Land I found snow-knives made of copper stripped from Sir John Franklin's ships, the imprints of the queen's broad arrow still showing on many, the blades double-edged or dagger-shape, and the handles of musk-ox and reindeer horn rudely attached by sinew lashings.

The snow-knife of iron, while more convenient in many ways, is far more liable to break in the intense cold of the winter weather, such accidents with them being very common. I have seen igloos built when the thermometer registered −70° F. At such temperatures the snow becomes almost stone-like in its compactness. The snow-knife is often used as a substitute for the snow-tester whenever that instrument is broken or left behind, for the Esquimaux are a very careless and absent-minded people.

Before starting to cut the snow-blocks, the builder gets from the sledge a pair of gauntlets used for this purpose, only being of finer and softer reindeer-fur, so as to give the hands the most complete freedom of motion. These gloves extend half way up the fore-arm, and have a puckering-string around the top, which the builder's wife pulls tight, and ties so as to completely exclude the snow while he is at work in it.

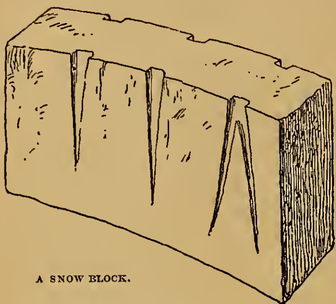
The igloo is built on the sloping drift of snow, the entrance being at the lowest point. The first trench from which the snow-blocks are cut is so disposed as to have its axis coincident with the diameter of the igloo, which runs directly up and down hill, or which makes the greatest angle with the horizontal. These snow-blocks are from a foot to a foot and a half wide, from a foot and a half to two or three feet long, and eight or ten inches thick. The first block cut from the trench is a thick triangular one, which is thrown away (see *a*, which is a vertical section through the axis of the trench). A ground plan of the blocks would show that they are partially curved, but in no manner to such an extent as would be needed to conform to the curvature of the igloo. This curvature is the result of their manner of cutting by a swinging motion of the whole body, held almost rigid, and rotating about the foot steps, *a*, in the figure. This motion of the whole body gives them considerable power; and the resulting curved blocks, if large, are in the best shape for the first part of the structure. In cutting the block *b*, first the right-hand edge, *cd*, is cut by three or four powerful downward strokes of the knife, and then the opposite edge, *c′d′*. The knife, with its blade held horizontally, is passed under the block in front of the toes of the builder's feet. About three or four inches in depth of the line *d′d* is cut; and,



with the knife in the right hand, two or three deep vertical thrusts are made along this line, which generally separate the snow-block from its bed, and it is caught with the left hand as it falls forward. I have tried to represent these gashes in the figure. They are plainly visible on the snow-block inside and out, and a good artist would represent them in his pictures of the huts. The blocks are carefully lifted out and placed beside the trench, as, under some circum-

[1] Continued from No. 29

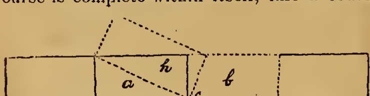
stances, they are extremely liable to break in handling. If the snow has been properly tested,



A SNOW BLOCK.

this should, however, seldom occur. The trench completed, and enough blocks secured to form the first or base course, the floor is laid out by a circular sweep of the knife, varying in diameter, of course, according to the number of intended occupants. Commencing at the left hand, this course is laid until the first block, *a*, is reached, which is cut in halves from its first lower corner, *c*, along the ascending diagonal; and the top half, *h*, is thrown away. The last block, *b*, has its contiguous corner cut off; so that the next block, shown in broken outline, ascends and forms the first block of the next course. The igloo is then formed of this spiral of snow-blocks, each course inclining inward slightly more than the one previous, until the last, which may be called the key-block, is perfectly horizontal, and firmly wedges in and binds the whole structure. This spiral form of the courses I have tried to show in the illustration of one of the half-completed igloos.

I know that the general idea is, that each course is complete within itself, like a course



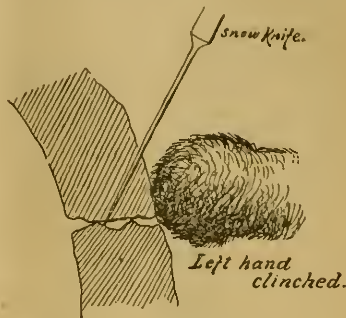
of bricks on a round tower in our method of building; but a moment's thought would show this to be almost impossible, as the first block in the course, after they had commenced to lean considerably, would have to be supported until it was flanked by others; and these, again, would be very unstable. In fact, one often wonders how a snow-block will hold in place against its own weight, leaning far inwards, almost horizontal, and supported only on two sides, and will imagine that the native workmanship must be very good to give such results. As the blocks approach the top, — where they are more nearly horizontal and more liable to tumble down, — their figure becomes trapezoidal in order to keep the vertical joints pointing to the centre and top; and, while supported on but two sides, these form a more or less acute angle, — more acute as it is needed and approaches the top, where the last few blocks are made triangular and meet at a point. The workman stands inside until it is completed. Despite all the care, the falling of

THE HALF-BUILT IGLOO.

blocks is a very common occurrence, and happens with nearly every building.

It will be remembered that the base course has been laid upon a sloping bank of snow, the lowest point being at the door, which has been formed by the trench running into the building. Therefore, when the builder is coming down with a course of blocks on the left side, they are peculiarly prone to tumble in. The fact that this side is used for starting up on the spiral course, as already explained, assists somewhat to overcome this; but it is mostly remedied by the builder, as each round is made, trimming down the up-hill part of the course to about half, until, by the time the blocks are leaning considerably, the course is level (leaving out the spiral inclination).

As each block is being fitted, it is held near its intended position by the left hand of the builder, who at one stroke cuts off the triangle on the right edge, giving a trapezoidal form. The left edge of the preceding block receives the same treatment, and the block is shoved into place. The snow-knife is rapidly passed backwards and forwards in the joints at the side and bottom, cutting off all inequalities, and making a fine powdery snow, which acts as a binding mortar. The last act is to give the block a sharp shoving blow with the open hand from the top, and another from the left side, which firmly sets it in place. The blocks all laid, the igloo is now complete, except the 'chinking' of the joints to render it air-tight, there being many large crevices. The chinking of an igloo is a very ingenious affair; the material being cut diagonally from the lower edge of the upper block on the horizontal joints, and from the left edge of the right block on the vertical ones, if the person be



VERTICAL CROSS-SECTION THROUGH WALL OF IGLOO.

right-handed. As the knife in the right hand thus trims the edges, the left fist, tightly clinched, follows the knife, and rams the cut portion tightly into the crevice, rendering it

THE FINISHING TOUCHES.

as perfectly air-tight as the body of the snow-block itself. An active Innuit will go completely around the igloo on a single joint in about a minute, and it seldom takes over ten to do all the chinking in a large hut. This part is generally assigned to the boys and women, especially the former, who are much lighter, as it is necessary to go on top to complete their work. A well-built igloo, however, will readily bear the weight of two large men on their hands and knees; and yet I have seen a small boy fall through one made of friable snow.

Meanwhile the boys and women have been busy throwing the loose snow from the trench-

THE SNOW-SHOVEL.

es, and piling it on the house, often following closely upon the work of block-laying, covering the whole to a depth of from six inches to half as many feet. The depth to which this is carried depends on the length of time they expect to use the hut, and on the temperature.

The common pictures of the huts, showing the block-work so conspicuously, are largely the work of the imagination of the artists, all that is seen being rounded heaps of rough granular snow. Such artistic license may, however, be allowable to show the essential features; and, so far as my criticism is concerned, I do not wish to be understood as saying that such uncovered igloos never occur.

I have spoken of the snow-walls, when chinked, as being perfectly air-tight. This is not strictly correct; the snow being more or less porous, and allowing a slow but ample current of air to pass through. In fact, at night the door is sealed, and the only means of ventilation is through the body of the snow.

In 1879, during a heavy north-east gale, I was in an igloo on the west bank of Back's River. The walls were of a granular snow, but were covered to a depth of three or four feet. Yet, with all this thickness, a candle-flame held near the wall on the windward side was deflected constantly at an angle of from thirty to thirty-five degrees from the vertical.

The banking is done with a snow-shovel made of half-inch boards, tapering off to a short handle for one hand: a bent piece of musk-ox horn fastened in at the centre furnishes a hold for the other. The cutting edge is protected by a sharpened shoe of reindeer-horn, neatly bound on with reindeer sinew, which is also used to sew the boards together. The Netschilluks use shovels of cedar, walnut, and mahogany from Franklin's ships.

(To be continued.)

MINNESOTA WEATHER.

Much has been said about the sanitary properties of the climate of Minnesota as a healing-place for the consumptive; and in this connection a great deal of erroneous information has been published, often to the serious injury of the invalid, who is misled by it. As might be expected, the newspaper is the principal agent in the dissemination of such literature. Here is an extract from the editorial page of the St. Paul and Minneapolis *Pioneer press*, the leading journal between Chicago and San Francisco: —

"Of the aid that may be given by a pure, rarefied, and dry atmosphere, thousands of people now living in Minnesota, who have been rescued from impending death, can bear substantial and grateful testimony."

Written in the haste of a newspaper office, by one who is practically pledged to the laudation of his state, as the western editor is, such a paragraph would scarcely deserve notice, were it not a summation in brief of some of the most popular errors afloat on this subject, and which one meets with everywhere in that land, from the drawing-room gossip to the medical journal. As such, it may profitably serve as text for analysis.

In the matter of pure air, Minnesota is not different from other northern states in which the face of nature has been moiled by the hand and habitation of man. On the prairies and in the pine-woods the atmosphere yet retains a large share of its pristine purity: in the cities it is the reverse. Especially is it vitiated in the large and rapidly growing cities of St. Paul and Minneapolis, whose systems of water-supply, drainage, garbage-removal, and sanitary inspection, cannot keep pace with their increase of population. This fault will be remedied in time, however, when the authorities shall have learned that the doubling or trebling of a city's people in a decade brings with it new responsibilities as well as new prosperity. It is an easy and pleasant thing to boast that one's town is gaining population at the rate of a thousand a month, and that the values of real estate are rising accordingly; but the real-estate owner is slow to appreciate the necessity of advancing the salaries of city officials, and the appropriations for city improvements, with corresponding alacrity. Minneapolis, although built upon the flat surface of the prairie, has admirable opportunities for drainage into the adjoining gorge of the Mississippi River; but its dilatoriness in this and other works of sanitary improvement has been severely punished by the scourge of typhoid-fever. The prevalence of this disease has caused Minneapolis at times to stand at the head of the column of death-rates of the cities of the United States. While there may be malaria in Minnesota, — and, indeed, the term is sometimes found in the reports of the physicians, — it is by no means the popular disease that it is in the south and east, where it is almost the fashion. A person may spend a year there without hearing the word mentioned; and that immunity alone should be enough to stimulate emigration in that direction.

Dryness of atmosphere is claimed for Minnesota; and if we consult only the amount of rainfall, whose annual value ranges from twenty to forty inches, there is apparent justice in this claim. But the manner as well as the amount of the pluvial precipitation must be considered. They have in that state a good deal of the lachrymose English weather, in which a drizzling dampness takes the place of the short, sharp, and decisive showers of equatorial lands. At the close of a rainy day the observer will go to his rain-gauge, and find its bottom scarcely covered. The effect of effort without accomplishment is always a depression of spirits in the looker-on; and this rule is never truer than when applied to a rainy day. Those who spent the month of October, 1881, in Minnesota, will remember it as a season of almost continual storm, during which, even when there was no absolute rainfall, there was an unwholesome mist floating in the air. Occasionally the sun shone, but not with sufficient power to make an impression. Farm-labor was almost suspended. The potatoes rotted in the ground, and the wheat grew in the stack. The streets of Venice were scarcely more liquid than the streets of St. Paul. Danger-signals were erected in the fashionable avenues to warn teamsters away from fathomless depths of mud. Hackney-coaches were stalled there, and their horses were detached, leaving the vehicles to be extracted by the processes of engineering. So impassable were the roads, that the fuel-supply was unequal to the demand, and invalids were obliged to go to bed to keep warm, and public schools were closed because their pupils were frozen out.

Still the rainfall of this month was less than four inches and a half. Many a single shower in the warm latitudes precipitates an equal amount of water. Indeed, there are records of rains in which as much water has fallen in one day as falls in Minnesota during the year; but, as a light rainfall does not necessarily mean a dry atmosphere, neither does an excessive precipitation invariably make a wet one. The water may flow away quickly, leaving no sign; and the next day the sun may shine as brightly as ever. Better, therefore, for the lungs, is an occasional drenching than a perpetual drizzle. While it must be admitted that the weather of the October just quoted, although not so bad as that of the September preceding, was yet exceptional in the extreme, still such exceptions could hardly occur in a very dry climate.

The student of physical geography would scarcely expect to find the climate of Minnesota a dry one. An average of such statistics as the writer has at hand indicates that rain or snow falls at least every third day in St. Paul. The state is almost directly under the influence of the Great Lakes, and is itself threaded with rivers, and dotted with lakes. Of the latter there are eight thousand worthy of the name, besides innumerable ponds. Two large river-systems receive their waters from the drainage of this region. The swamp-lands of the state play an important part in its area, as the maps of the land-office show. A large share of its forests are afloat upon ancient marshes. Cranberries and rheumatism abound. The Red River region is celebrated for its floods. At one time that stream was popularly said to be thirty miles wide; and the traveller down its valley was obliged to proceed by alternate stages of land and water, the steamboat being utilized when the railway-cars began to swim. Then it was that the facetious pilgrim from St. Paul to Winnipeg was, according to his habitual description of the journey, three days out of sight of land. It was a joke, to be sure; but such jokes are not heard in a dry climate.

The moisture of the atmosphere of Minnesota is the salvation of the state: it makes agriculture a possibility and a success. Given the same amount of rainfall in another latitude, and under more arid climatic conditions, and her wheat-fields would be blighted. As it is, her scanty rains, with the exception of a few showers in summer, fall slowly and gently; in times of drought the thirsty air freights itself with moisture from the abundant water-surface of the state; and these sources of humidity are re-enforced by the prolonged irrigation resulting from the melting of the winter snows and the thawing of the frozen ground in spring.

The beneficial effects of an unclouded sun in the treatment of consumption may, perhaps, be overrated. The dweller in a rainless atmosphere, dazzled by the perpetual brightness, and with lungs parched by the heat and dust and dryness of the air, might come at last to long for an occasional rainy day, as the traveller in the desert longs for the shadow of the palm. But, at any rate, our weather bureau could scarcely do better work than to give us a 'sunshine map,' upon which the statistics of hourly observations the year round, upon the state of the sky, should be graphically portrayed. Such frequent observations could be taken without inconvenience, as it would not be necessary for the observer to remain at a fixed station for that purpose. Such a map would show by depths of shading the relative amounts of sunshine and cloud at any place; and the invalid could select at a glance a residence which would have the desired proportion of these conditions. The complexion of Minnesota upon such a map would probably not vary widely from the average.

As has been seen, there is also a popular belief that the air of Minnesota is in a very rarefied condition. In the interests of meteorology, that superstition must be met and combated. The only cause of rarefaction of atmosphere worth considering here is elevation above the sea. Minnesota, as one might guess from its position in the Mississippi valley, is a low country. The mean elevation of the United States above sea-level is about twenty-five hundred feet. The average elevation of Minnesota is considerably less than half that number. Indeed, its 'height of land' falls much below twenty-five hundred feet. Therefore a large proportion of visitors to that state move into a heavier atmosphere than that which they have left; but unfortunately they do not know that fact, and, under the influence of their imaginations, they find their breath wonderfully shortened. The elevation of St. Paul above the sea is seven hundred or eight hundred feet; that of the plateau region of New York is from a thousand to two thousand feet. I once knew a lady to remove from the latter to the former place, thus going down hill and into a denser atmosphere. Arriving in St. Paul, she could with difficulty climb a flight of stairs, owing to the lightness of the air, as she expressed it. When informed of her mistake, she was indignant, and resented the information. People do not like to give up their errors, even if they are uncomfortable ones. Having come a thousand miles in search of novelty, it was strange and cruel if she could not be allowed to enjoy that novelty which is supposed to be characteristic of the west, — a rarefied atmosphere. With all its benefits, science works mankind an occasional mischief. The mountaineers of old suffered no inconvenience from their exalted position until the meteorologist came along, and explained to them that the air grew constantly thinner as they approached the clouds. Even to-day the unlearned inhabitants of our Rocky Mountain region make no complaints of a difficult respiration. It is only the scientific tourists who pant by the aneroid, and cough up a little blood when they cross the timber-line. Whether appreciated or not, however, it is certain that the air of the uplands is less substantial food for the lungs than that of the low countries; and it is the density of the atmosphere, and not the reverse, which is to the advantage of Minnesota as a home for the consumptive. There are many people who advise this unfortunate to seek out some elevated region in which to live, but there are very few who can give any reason for this counsel. A learned doctor tells us in one of the late magazines, that the harmful substance known as carbonic-acid gas is more abundant near the level of the sea. Certainly; since there is more air to the cubic measure at a low elevation, there is naturally more carbonic acid, which exists in the atmosphere, whether high or low, in a certain percentage of the whole; but there is at the same time more of the saving grace of oxygen, which the invalid is after. It is true that carbonic acid has a way of accumulating in low and unventilated recesses; but there are cellars, crevices, and deep and narrow valleys in the highlands as well as on the lower levels. As well recommend thin soup to the hungry man as to advise the sick man, whose one lung must do the duty of two, to breathe thin air. Should he climb the mountains to Leadville, he will be warned away by the inhabitants of that city, who will inform him, in the rude poetry of the mines, that a healthy man has to fan the air up into a corner in order to get enough for a breath.

The atmosphere is not necessarily dry at a great altitude, as some suppose, nor damp in the lowlands. There are lofty swamps and low deserts. The mountain peaks, according to the poet, milk the clouds; and in some parts of the world the mountaineer is more sure of his daily rain than of his daily bread. Mount Taylor, in New Mexico, is called the 'Mother of rain' by the imaginative Indians. On the other hand, the deserts of California, which are below the level of the sea, are so dry, that, in the language of the plains, the jack-rabbit has to pack his water with him when he goes upon a journey.

As to the thousands who have been rescued from death by the 'pure, rarefied, and dry atmosphere' of Minnesota, this is a matter of town talk, which impartial observation does not confirm, and which there is no census to deny. In this connection I would challenge the champion of the most celebrated sanitarium for consumptives to produce a list of the patients who have 'got better' under his notice, and I will match against him an equally honest observer from some undistinguished and unpretentious and confessedly unhealthy locality, whose proportional record of improvements will be equally favorable. Why, then, should the sick man become a wanderer, as he certainly will if he once starts in chase of the *ignis fatuus* of a climate cure?

Frank D. Y. Carpenter.

LETTERS TO THE EDITOR.

Prehensile feet of the crows.

In nos. 16, 18, and 20 of Science are communications by different writers on the intelligence of crows, suggested by one of mine in no. 13. I beg to add one more, concluding what I have to say on this subject.

All seem agreed as to the intelligence of these birds; but few, I find on inquiry, have seen them seize or carry objects in their claws. Yet no amount of negative testimony should invalidate my observation on the Italian bird, when taken in connection with the further evidence to be given. We all look at nature piecemeal; and it is certainly unreasonable to assume that one is in error because he claims to have seen through his pin-hole something which another has not observed through his.

I agree with the doubters, that crows ordinarily use their bills, and not their claws, in seizing and carrying their food. In confirmation of what I claim to have seen, I will adduce similar instances, noticed by others as well as myself, in the Corvidae. I cannot positively assert that the bird I saw was C. corone: it might have been C. cornix, possibly C. frugilegus, but, at any rate, a *crow*, for it had the flight, the proportions, the color, the voice, and the boldness of these birds.

As to crows not nesting among rocks, this is generally true of the American crow (C. Americanus); but the European C. corone, a larger and more solitary species, prefers the sides of steep rocks, as also does the hooded C. cornix. Both the American and European ravens often nest in inaccessible cliffs, and so do the rooks.

To begin with the largest. I have seen C. corax in Iceland holding and carrying in its claws fish-heads from the beaches, and, when disturbed, from one barren crag to another, — an object too large and too heavy to be conveniently carried in the bill, and too precious to be left behind where food is so scarce. I have seen C. carnivorus, in the winter wilderness of Lake Superior, carrying in the same way what looked like a squirrel or rabbit. It is well known that both these birds, when wounded, will strike savagely with their claws, like a bird of prey; which, being perching birds, according to our classifications they had no scientific right to do.

Of the fish-crow (C. ossifragus), Wilson (*Amer. ornith.*, v. 27) writes, "their favorite haunts being about the banks of the river, along which they usually sailed, dextrously snatching up *with their claws* [the italics are mine] dead fish or other garbage that floated on the surface;" and, on p. 28 (*op. cit.*), "These (a singular kind of lizard) the crow would frequently seize *with his claws*, as he flew along the surface, and retire to the summit of a dead tree to enjoy his repast." Audubon (*Orn. biog.*, ii. 269) says the same. Clark's Columbian crow is said to do the same thing, and its claws are sharp and raptorial. I have seen this species, along the shallows of the coast of North Carolina, seize and carry off in its *claws* living fish from the shoals over which it flew.

Buffon, Chenu, Wilson, and Nuttall allude to the custom of capturing crows by fastening one on its back, feet upward, on the ground: its cries bring its companions to the rescue, one of whom is sure to be seized and held by the *claws* of the prisoner.

For several summers I lived in the next house to a tame and speaking crow, which often came in front of the kitchen in quest of food. One day a half-eaten ear of boiled corn was thrown to him. While engaged in picking it, holding it by the claws, as is the habit with the crows, he was disturbed by the attacks of a barking terrier. Keeping him at bay for a time by vigorous pecks, he finally tried to carry the ear in his *bill* to a favorite perch in a low cedar. As he seized it, first at one end and then at another, the leverage of the free end was such that it gave his head and neck very uncomfortable twists. He finally perched upon the ear in defence of his food, and, clinching it tightly in his *claws*, flew with it, in my sight, to his perch a few feet distant.

Mr. E. A. Samuels (author of the 'Birds of New England') writes to me (Aug. 2, 1883), "I have known of its seizing with one foot — and hopping with the other — various small articles of food, in one case a small frog;" and also, "I have often seen the crow hold a frog or acorn firmly, with one foot on the ground or on a fence-rail, while he pecked away with his bill." Similar instances I remember to have read about, and one in the Bulletin of the Nuttall ornithological club, where it is described as holding a small bird, which it had killed in an aviary, in its claws, while it tore it in pieces with its bill, like a bird of prey.

The claws of the shrikes, weaker than those of the crows, and quite as insessorial, are used to seize and carry prey. A few winters ago I saw a shrike killed on the Boston public garden by the city forester's men, which had in its claws, during its flight, a still living English sparrow. That the crows in the above-mentioned instances, though perching birds, do use their claws as prehensile organs, I regard as evidence of their intelligence and reasoning power, which enable them, under exceptional circumstances, to use their perching feet for raptorial purposes. We must not measure animal intelligence by our imperfect and arbitrary zoölogical classifications. Since the writings of F. Cuvier, Flourens, and Fée, it seems impossible to deny the possession of a reasoning intelligence to animals below man.

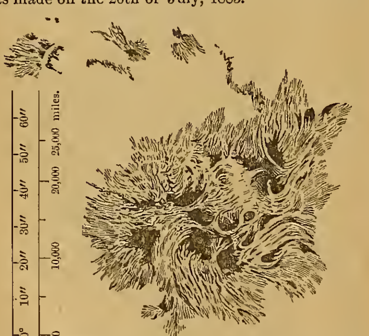
Leaving out of view the instance mentioned in no. 13, I think I have adduced sufficient evidence that the crows do *sometimes* — that is, when they find it necessary — seize and carry objects in their claws, like birds of prey. SAMUEL KNEELAND.

An interesting sun-spot.

The accompanying sketch represents the remarkable sun-spot of July (which was visible to the naked eye), and is of particular interest. I did not see it in its early or formative period, when this was taken; but from my knowledge of Mr. Very's experience and skill I have no doubt of the trustworthiness of the drawing in all its details. His remarks supply all the further information needed. S. P. LANGLEY.

Cambridge, Aug. 21, 1883.

I enclose a sketch of a large and unusually interesting sun-spot, as it appeared through the great equatorial of the Allegheny observatory, of 13 inches aperture, with the polarizing eye-piece. The drawing was made on the 26th of July, 1883.



The spot, while not so large as some, exhibited considerable activity and a remarkable assembly of odd forms, some of which appear so conflicting that it is difficult to imagine how they can exist side by side. The strong inrush from the following side gave one the idea of a viscid sheet or ribbon, rather than that of a bundle of filaments. It bore a striking resemblance to some of the forms which taffy assumes under the confectioner's manipulation. On the upper or northern side the filaments were more graceful, slender, and grass-like. The southern part was remarkable for the length and intensity of its curved filaments. (The longest could certainly be traced through more than 15,000 miles.) But perhaps the most curious portion was the centre, where a mass, possessed of photospheric brilliancy and fringed with curved and tangled threads, gave one the impression that a recently erupted facula, formed somehow in the very middle of the spot, was being torn to pieces by conflicting currents.

Numerous local whirls were evident, and the south-east half of the spot had a decidedly cyclonic appearance, the rotation being in an opposite direction to the hands of a watch. (It is to be remembered, that the drawing gives the appearance of a projection, and is therefore the reverse of a view by direct vision.) The north-west half of the spot did not show any such rotational tendency. F. W. VERY.

Allegheny, Aug. 20, 1883.

The right whale of the North Atlantic.

I am sufficiently impressed by the utter absurdity of occupying your valuable pages in discussing non-essentials; yet I am called upon by your critic to clear up two points remaining, both of which in any case hardly deserve serious notice. I will endeavor to close this correspondence by stating the facts.

Referring to Scoresby's pictures of the Greenland whale, I was led to attribute to the first or earlier one another authorship, from seeing in it so much error and exaggeration; and this because I had just read in Scoresby's book the following (Arct. reg., vol. i. p. 447. 1820): "I have confined my engravings, as well as my descriptions, to those animals that have come immediately under my own examination, or have been sketched by persons on whose accuracy and faithfulness I could fully depend; while drawings that I have met with, when the least doubtful, have been altogether rejected."

His second figure being so nearly correct, having evidently been carefully drawn from an entirely different and natural study of the animal, it was easy to assume, that, having first taken at second-hand an ill-considered sketch, he promptly replaced it by a better one. In this view it should not be assumed that we had any thing but the kindliest motives in thus speaking of this most eminent and valued man's work. In Scoresby's 'Arctic regions' (ed. 1820) the second figure of the Greenland whale appears. The caudal region, including the flukes, is entirely redrawn, showing the various elements that make up the beauty of those parts, as the carinae, etc. The other features, unfortunately, are not improved; yet more unfortunate is the fact that the earlier figure, with all its imperfections, has come down to us in most of the more important works.

With reference to the corrections of Scoresby's figures, we may point to an old work in the library of the American museum, which, by the way, is not noticed in Mr. Allen's bibliography; namely, "Histoire des pêches, des découvertes et des établissemens des Hollandois dans les mers du Nord, etc. Par Le C. Bernard DeReste. Tome premier. A Paris, 1801." This is an octavo volume, devoted almost entirely to cetaceans, and has large copperplate engravings, one of which contains a right whale labelled B. franche, and another the sperm whale.

The former figure is in some respects better than Scoresby's, as to form and proportions; but a most singular treatment has evidently been accorded it. The elements of the figure have been transposed, and the belly made to serve the purpose of back, and *vice versa*. It is evident that the figure was copied from a real model, as the baleen is shown correctly, though it projects in one place outside the mouth.

The remaining point relates to the authorship of the volume on whales in the 'Naturalists' library.' The portion of the titlepage of our edition relating to this point reads as follows: "Mammalia — whales, etc. By Robt. Hamilton, Esq., M.D., F.R.S.E., etc."

We now desire to ask our critic how much remains to justify the serious charges which he has caused to be distributed wide-cast over the scientific world, to more or less inevitable damage to institution and person. J. B. Holder.

If Dr. Holder is satisfied with the way he has met 'the serious charges,' I am quite willing to here rest the matter; failing, as I do, to see that any of them are materially vitiated by his defence, while, amid the obscurity of much irrelevant matter, all of the more important ones are virtually conceded.

In regard to the authorship of the volume on whales in the 'Naturalists' library,' not only have I, as I have said before, examined anonymous copies of the original edition, and found it given as anonymous in bibliographies, but have seen it attributed by contemporary British cetologists to Jardine. The discovery, however, of a copy by Dr. Holder, having Hamilton's name as author on the titlepage, of course settles the question. J. A. Allen.

Achenial hairs of Senecio.

Mr. Jos. F. James does not know of any explanation of the use of the threads which are projected from the hairs on the achenia of most species of Senecio, etc. Before calling on Science to help him, he might read up his text-books, say Gray's Structural botany, p. 306. Botanicus.

Kalmia or rhododendron.

In reply to Dr. Abbott, in Science for Aug. 17, I will call his attention to the fact that the woods of the kalmia and the rhododendron are quite distinct in appearance, and are not likely to be mistaken the one for the other. The kalmia wood is frequently found in commerce, in the form of handles for tools, such as chisels and the like. The wood is of a very light pink, with darker streaks through it resembling cells filled with woody fibre.

The rhododendron wood is destitute of such marking. As to size, I have seen plenty of the kalmia, four and five inches through the butt, in the mountains of Virginia; and have had in my possession sticks, large enough for any such purpose as the Doctor names, from eastern Pennsylvania. The rhododendron is an extremely rare plant in Chester and Delaware counties, Penn., but the kalmia is common. S. P. Sharples.

Boston, Aug. 22.

THE SOCIETY OF MECHANICAL ENGINEERS.

Transactions of the American society of mechanical engineers. Vol. iii. New York, 1882. 350 p. illustr. 8°.

This third volume of the transactions of the youngest of the three great societies of engineers in the United States is a well-printed large octavo of over three hundred pages. It contains a list of the officers and members of the society, its rules, the proceedings of the Philadelphia meeting of 1882, and the proceedings at a memorial session in remembrance of Dr. A. L. Holley, a distinguished engineer and a founder of the society. The proceedings at the latter meeting consisted of an introductory address by president R. H. Thurston, in eulogy of the deceased, and a formal tribute to his memory by Mr. J. C. Bayles, the orator appointed by a committee for the occasion. Many members, as well as the appointed orators, paid earnest and eloquent tribute to the great engineer.

Among the more generally interesting and important papers, are those of Professor Egleston, on the appointment of a government commission to test iron, steel, and other metals; G. W. Bond, on the Pratt & Whitney 'standard gauge system;' Professor Robinson, on the thermodynamics of the Worthington pumping-engine; an essay on the progress of engineering science from 1824 to 1882, by Mr. Fraley of the Franklin institute; the windmill as a prime motor, by Mr. Wolff; and a long paper on the several efficiencies of the steam-engine, by Professor R. H. Thurston.

Professor Egleston gives a history of a movement among the engineers and scientific and business men of the country, to secure the establishment of a permanent commission to determine, by direct investigation, the absolute and relative values of constructive materials in the United States. Under the lead of the Society of civil engineers, such a commission was demanded by a very large number of the leading men of the country, and was created by act of Congress in the year 1875. It consisted of Col. Laidley, Gen. Gilmore, Com. Beardslee, Chief-engineer Smith, Dr. A. L. Holley, and Professor Thurston, the latter acting as secretary. This commission, in the course of two years, working amidst many discouragements, did an enormous amount of work; the results of which are published in a report consisting of two large and fully illustrated volumes recently issued from the government press. The commission was not well sustained. Congress refused to continue its appropriations; and it ceased to exist, despite the protest of all the leading technical societies, polytechnic schools, the principal colleges, and such associations as that of the iron and steel makers. The effort is now making, to revive this commission, and to secure the continuance of its work. The publication of the enormous mass of information acquired by the board during the period of its short life is hoped to give good argument in favor of prompt and liberal action by another congress, in which, it is believed, there may be a sufficient number of intelligent and patriotic members to carry the measure through without regard to politics.

Mr. Bond describes the method adopted by Professor Rogers of Cambridge, and himself, to secure for Messrs. Pratt & Whitney of Hartford a standard system of exact measures for use in creating a basis for gauges to be used in the United States in general machine construction. The comparator built by the firm, under the advice of these gentlemen, is used. Its readings, with its 'B' microscope, are made from divisions measuring 0.000016 inches. The company has now a set of end measures running by sixteenths to four inches, and a complete plant for making them accurately to within the forty-thousandth of an inch, a magnitude which can be detected by an expert workman.

Professor Robinson gives the theory of the peculiar form of pumping-engine known as the Worthington engine. This is a Wolff form of compound engine in its general arrangement, built without fly-wheel and in pairs, and so constructed that each double engine has its valve-motion operated by the opposite machine. He shows that, theoretically, the 'tandem' type of this combination excels all the other possible adjustments of the engine, in its probable efficiency. The efficiency is not modified perceptibly by the ordinary slight variations of the exponent of the expansion curve. Numerical results of the use of the formulas are given in tabular form. The paper is illustrated by engravings of the several forms and parts of these engines.

Dr. Fraley describes the formation, the growth, and the work of the Franklin institute of the state of Pennsylvania. It was organized in 1824, and has been in active operation ever since. It established the first regular drawing-school in the United States, and has kept it in successful operation for fifty years. It has occasionally given exhibitions of domestic manufactures and products, has gathered together a great library, cabinets of materials, models, and machines, and has for many years regularly published a journal devoted to applied science and the arts.

Mr. Wolff gives the results of investigations of the efficiency and power of windmills, and presents a table, calculated in the course of his studies of the subject, of the relations between the pressure and the velocity of the wind at various temperatures, — the first in which the density and temperature of the atmosphere are taken into account.

Professor Thurston occupies nearly fifty pages in the discussion of the several efficiencies of the steam-engine, including the total commercial efficiency. Expressions are given by which to determine the best proportions of steam-boilers for given costs of boiler and fuel, storage, etc. The best area of heating surface per pound of fuel burned on the grate varies as the square root of the quotient of all annual expenses variable with the cost of fuel, reckoned per pound of coal and per square foot of grate, by the sum of all annual expenses per square foot of heating surface and per square foot of grate, the latter being reckoned only so far as they are dependent on the size of boiler. The efficiency of engine is found to be dependent upon both the ratio of expansion, and the method of variation of waste by internal cylinder condensation with the point of cut-off. Tables are given of the probable best points of cut-off in the various standard types of engines, at various pressures of steam; and also of the probable minimum weights of steam and of good coal required by such engines at various best ratios of expansion.

The 'efficiency of capital' is found to be dependent upon similar quantities, as well as upon the costs of fuel, attendance, operation, etc. The theory of the efficiencies of the ideal engine with non-conducting cylinder is given, and both algebraic and graphical methods of solving problems are presented and illustrated. The theory of the efficiencies of real engines is next treated, and the defects of the Rankine system are remedied. The 'general equation of all steam-engine efficiencies' is given, as deduced by Professor Thurston, and a series of problems falling under the general head are treated by the production of the necessary formulas and by a graphical construction involving the use of his newly discovered 'curve of efficiency.' One-half of the paper is devoted to the solution of various important problems arising in the practice of the engineer and previously unsolved. Tables follow giving the results as applicable to the common forms of steam-engine, and showing the enormous differences in economy and in the best ration of expansion, size of engine, etc., produced by the occurrence of cylinder condensation, a form of waste hitherto untreated by writers on thermodynamics and the theory of the steam-engine. He says, "By the use of this, or some more exact method, the art of proportioning the steam-engine can be elevated to the rank of a branch of the science of engineering; and that part of the science which has hitherto been in a most unsatisfactory condition, as viewed from the standpoint of the engineer engaged in its application, may be found to take a comparatively complete and useful form.''

GEOLOGY OF PHILADELPHIA.

The geology of Philadelphia: a lecture delivered before the Franklin institute, Jan. 12, 1883. By Professor Henry Carvill Lewis. Philadelphia, 1883. 21 p. 8°.

The author has distributed his pamphlet edition of this important paper, which deserves extended notice, and has placed him in the front rank of the young prosecutors of original research in the field of geology in this country. This memoir, and his previous lecture on the Ice age in Pennsylvania, have the rare merits that they are solid contributions to our knowledge from the first to the last pages; that they are almost exclusively due to the personal labors of the young geologist who brings them in their very complete form before the world; that they are closely and fairly reasoned out, and lucidly expressed. The great societies of the learned which require for membership the production of a work showing important, new, and original researches, have accepted many essays inferior in all these particulars to the subject of this review. To fully appreciate its merit, one must consider how very vague were the notions of geologists (including the large and growing class of Philadelphia geologists) as to our superficial deposits, before its appearance. The great influence of Louis Agassiz, and his theories of universal glaciation, had restricted the number of those who sought to define the action of glaciers in our continental geology, by extending the limits of this action over the tropics. The explanation of any thing obscure by the words 'glacial action' became almost as common as the explanation of any thing difficult in physiology used to be by the words 'lusus naturae.'

It required, therefore, peculiar independence of thought to break loose from these fictive (always the most insurmountable) fetters, and to see the phenomena with one's own eyes. Besides this, it required laborious journeys, patient note-taking, and attentive reading of what others had done, in order to do justice to the subject, and prepare a monograph upon it. All these Professor Lewis has accomplished; and, though much remains to be done, few presented so complete and neat a view of subject as he has.

It will already appear to be the writer's view, that his matter, and his manner of presenting it, have been found admirable, though as to the latter, his system, while supported by a clear style, will necessarily present some difficulties to the superficial reader. He could either have begun from the exterior and older boundaries of his superficial formations, and have proceeded inwards towards the present river Delaware; or he could have adopted his present plan of commencing in the middle with the red gravel, — inverting somewhat the order of the overlying sediments by considering the alluvium next (which is at the top of all), taking next the Trenton gravel (which underlies the latter), and completing the upper part of the column by treating of the Philadelphia brick clay (which belongs between the upland terrace material, first mentioned, and the Trenton gravel), — and then following the column downward through the red, yellow, and Bryn-Mawr gravels, finishing by a short sketch of the underlying rock formations; or he might have proceeded geographically from the newer deposits on the river, outwards to the Bryn-Mawr terrace.

The writer confesses, that, in view of the perfectly consistent theory which Professor Lewis has evolved, it would seem easier to follow the chronological order of the events which this theory comprehends, even though the geographical sequence were somewhat disturbed; but this criticism does not affect the real value of his results.

Those who read this essay as carefully as it deserves will be rewarded by obtaining a very probable history of this portion of our continent during post-tertiary time, with its submergences and elevations and the consequences thereof. It is perhaps to be regretted that Professor Lewis has not treated with the same care the subordinate part of his subject, to which he devotes a few concluding words; that is to say, the 'gneiss,' the 'auroral limestone,' and the 'triassic sandstone.' Thus, he confounds the views of two masters of our American geology in ascribing the gneiss of Philadelphia in the same breath to the Huronian and the Mont Alban.[1]

It is also somewhat vague to say 'the gneiss of the Rocky Mountains of Colorado;' since there are different gneisses belonging to different ages there, some of them probably Mont Alban, some Huronian, and some very likely Laurentian.

Again: it is conceded by most Philadelphia

[1] Compare Dr. T. Sterry Hunt's view, 2d geol. surv. of Penn., vol. E. p. 200.

geologists, that the section of gneiss along the left bank of the Schuylkill in the Park is not a fair representation of the stratigraphy of the measures. The structure here does not agree with that on the other side of the river for long distances within the limits of the Park, nor with that exposed by the cuts made for streets, etc., at short distances back from the river on this bank. Nor is it exact to say that the measures here dip 'at high angles;' since with the exception of a few hundred feet north of Lemon Hill, where one dip of 60° occurs, the dips for three miles are usually 30°, and never over 40°.

Under the caption of 'Primal sandstone,' it is the perpetuation of an error to call the 'sagging' of rocks standing at high angles '*creep*.' This term is employed by glacialists and mining engineers in two senses quite different from that which Professor Lewis intends to convey, and different from each other. Again: 'hydro-mica slates' is a contradiction in terms, though not infrequently used. If the rocks are *slates*, they cannot contain hydromicas, except as adventitious components. The last paragraph of this little pamphlet is very neat and well put; but we may be allowed to dissent from Professor Lewis in the statement that the marble of our doorsteps 'tells of an ocean inhabited by no fishes:' at least, mine does not tell me what were *not* in the ocean in which it was formed.

The blemishes in the main work are both few and superficial. Thus (p. 9), it is a little too hasty to infer, merely from the absence of shells or organic remains in a brick clay deposited on a gravel, that the water 'had a temperature too low to support life;' p. 11, the colors of the red and yellow gravels are not satisfactorily accounted for by the 'presence of a large body of water;' there is a slightly subjective trace in the assertion on the same page, that "there is no trace of glacial action in Pennsylvania south of the terminal moraine, *notwithstanding* all statements to the contrary hitherto made by other geologists," — which is in contrast with the modest style of other parts of the work; p. 14, 'Bryn Mawr age' is not a perfectly clear designation for the time or times when the gravels called by this name were being deposited, especially as there are crystalline rocks exposed at Bryn Mawr.

Notwithstanding these trivial faults (as the writer conceives them to be), the memoir will serve not only to teach our young students of geology to reason from these facts, but will live long, if not permanently, in our literature.

June 25, 1883. Persifor Frazer.

THE IROQUOIS BOOK OF RITES.

The Iroquois book of rites. Edited by Horatio Hale. Philadelphia, *Brinton*, 1883. (Brinton's Libr. Amer. lit., no ii.) 222 p. 8°.

Those who still hold in remembrance the valuable contributions to linguistics made by Mr. Horatio Hale while connected with the 'Wilkes exploring expedition' will be pleased to know that from his retirement in Canada he now sends forth this most interesting work. The reputation of the author, added to this fascinating title, will insure its favorable reception not only by ethnologists, but also the reading public. This aboriginal 'Iroquois Veda,' which furnishes the title, and which may be considered a remarkable discovery and indisputably of great ethnological value, is presented in its original Mohawk, with the English translation. An introduction of ten chapters precedes the Book of rites. These are devoted to the general history of the Iroquois, their league and its founders, condolence council, clans and classes, laws of the league, historical traditions, and their character, policy, and language. Portions of these chapters are deductions from the book which follows them.

The boundary-line between either folk-lore or myths, and actual history, is always so vague, that, even in the relation of facts, it is no easy task in their details to so discriminate as to keep truth clear from the brilliant coloring of tradition and conjecture. Especially is this the case when an author with inherited literary taste and vivid imagination enters a realm where the temptation to allow them full scope is as great as in the early history of the Iroquois. Accordingly, we find among these chapters, many of which indicate immense research and are of great value both ethnologically and philologically, those (such as the 'league and its founders') wherein the characters are portrayed in so exalted a manner that the sceptical reader will be disposed to assign the story of Hiawatha, as given in all its minute details, not to the realm of mythology even, but to that of classic historical romance. Much less will they be willing to accept it as sober Indian history five hundred years behind its present semi-civilized condition. The chapter on the 'Iroquois language' may be considered one of the most important, scientifically, of those in the introduction; and it is probably one of the best outlines of their formation and structure ever published in English, concerning any one of the Iroquois dialects. This fact quite throws the doubt on Mr. Hale's statement that no one except Father Cuoq would be competent to prepare a grammar of these dialects. With due respect for the great erudition of Father Cuoq, whose special studies have been in Algonquin, although a missionary to both tribes, we would say that the materials from which the reverend father prepared both his Lexique and the Iroquois portion of his Langues sauvages are through the courtesy of the Rev. Fathers Antoine and Burtin, of the order Oblat, now in the temporary possession of our Bureau of ethnology at Washington, where, already nearly translated, they will in time be published in connection with the other Iroquois dialects. We allude to the works of that greatest of all Mohawk scholars, the Rev. Father Marcoux. That the rules, the result of so much time and labor, can be clearly and distinctly presented to us in our own tongue, Mr. Hale has exemplified in the few which he presents in this chapter. The 'forms' and 'particles' which he has given are all from the Mohawk dialect, although he follows the example of all the Canadian authors, who dignify one dialect with the title which others contend belongs properly to a group. The examples he gives will many of them not apply to some of the other dialects, more especially to the Onondaga and Tuscarora.

In following too closely the rules of the French missionaries, great discrimination must naturally be exercised.

We do not agree, for example, with Mr. Hale, in the illustration given with his remarks upon the duplicative form, on p. 111.

The prefix of this form is *te;* the verb selected, *ikiaks,* — the same verb as given by Father Cuoq to illustrate this form.

I-kiăks, I cut, in the act of cutting; *te-kiaks*, I it cut in two, or divide; *hwisk* is the Mohawk numeral *five; hwisk té-kiăks*, I cut it into five pieces: hence *te*, the prefix, cannot be a synonyme of, or a literal translation of, the Latin *bi* in *bisecto* (I cut in two), but a sign that the act of cutting is or may be repeated as often as necessary.

Again, concerning gender (p. 106): the old French missionary idea of a 'noble' and 'ignoble' gender — the former of which included 'man and deities,' and the latter 'woman, evil spirits and objects' — is explained away very satisfactorily by Mr. Hale, until he admits with them the absence of any neuter form. This leads him into the error (p. 108) of following their form of conjugation.

The model containing the verbs 'to love' and 'to see' are as given originally by Father Marcoux, and presented to the public by Father Cuoq. Here the French form of conjugation is used, which lacks the neuter pronoun 'it,' but which is supplied with the indeterminate pronoun '*on*.' The neuter pronoun, however, does exist in these dialects as presented in five different chrestomathies already prepared.

The translation of the third person neuter (p. 108), *wat-kah-tos*, by 'she sees,' should be rendered by '*it* sees;' and the third person singular, translated as indeterminate 'one sees,' is, in fact, the third person feminine; and the same mistakes occur with the verb 'to love.'

These few exceptions are simply advanced to show how much study is yet to be given to these dialects, and that we cannot accept unreservedly the opinions of even the best acknowleged authority upon languages, which, we are learning, cannot be made amenable to the grammatical rules of any known tongue.

The author's opinions concerning clans are deserving of great attention; although many will be unwilling to agree with his conclusion, that, before the division of the Iroquois into tribes, there existed but the three presented in the Book of rites. It may be true that clans in some instances have been added, but we know of many more in our own day which have died out. The last male representative of the Rhut-kun-yah clan now occupies its chieftain's seat without a single constituent, upon the Tuscarora reservation, while among the same tribe the female remnants of the snipe clan have been passed over into that of the turtle. The examples of the added Onondaga and Oneida (p. 52) among the Iroquois of eastern Canada bear directly upon some remarks from a correspondent of Science in relation to the extra clans found among those Mohawks. This subject is referred to by our correspondent as 'an interesting field of inquiry.' Mr. Hale's remarks, while suggesting a clew, are not free from objections. The clans are not called by the above names. One is termed the 'calumet,' and has the pipe as its symbol, which it was the province of one chosen from this clan to present in solemn assemblies; and the chief of this clan also named the deputies, ambassadors, etc.: hence its title of '*Ro-te-sen-na-kéh-te*,' from which name Mr. Hale evidently christens it 'Onondaga,' whose council, not tribal name, is the same, signifying 'name-bearers.' The council name of the Cayuga tribe translates literally the 'great-pipe people' (p. 79): so might there not be as feasible a foundation for naming it the Cayuga clan? Moreover, would the same reasoning hold good concerning the rock clan, as the council name of the Oneida tribe differs on pp. 52 and 78? Before leaving this interesting subject, we would call attention to note 5 on p. 147: "It is deserving of notice, that the titles of clanship used in the language of ceremony are not derived from the ordinary names of the animals which give the clans their designations. *Okwaho* is 'wolf;' but a man of the wolf clan is called '*Tahionni*.'" The simple explanation is, that, in both the Seneca and Oneida, '*Tai-hyo-ni*' is the name of that animal. One might be tempted to theorize upon this; but so much is yet to be learned regarding this intermingling, retention, and coining of words, that for the present we have but to collate facts which can only be clearly explained or understood by a more full and complete comparison of the Iroquois dialects than has heretofore been obtainable.

The chapter entitled the 'Book of rites' explains its origin and character, the manner of its discovery by Mr. Hale, and the character of the Indians in whose possession it was found. That it is a genuine Indian production there can be no manner of doubt; and Mr. Hale's conclusions concerning its age are in all probability correct.

The Book of rites comprises the speeches, songs, and other ceremonies, which, from the earliest period of the confederacy, are supposed to have composed the proceedings of their council when a deceased chief was lamented, and his successor installed into office. The fundamental laws of the league, a list of their ancient towns, and the names of the chiefs who constituted their first council, all chanted in a kind of litany, are also comprised in the collection. These contents are said to have been preserved in the memory for many generations, and were written down by desire of the chiefs when their language was first reduced to writing. This manuscript, the original of which had been lost, Mr. Hale has, with the most competent Mohawk assistants, translated into English, and drawn from it most interesting conclusions regarding the character and policy of the Iroquois tribes, quite dissimilar from those generally accepted. The translation, notes, and glossary exhibit the work of a careful student. In the free translation rendered by Mr. Hale to the songs, he has given them a metre almost suggesting the peculiar melody, which, in the original Mohawk, was produced by intonations; for it must be remembered, that it is one orator who must untiringly continue to sing and chant, sometimes for twenty-four hours; and only by varying his key-note is he able to accomplish this feat.

A book which is as suggestive as this must bear good fruit. We have called the attention of our readers to many disputed points in the hope of awakening a spirit of inquiry upon subjects of such vital importance, many of which are here presented for the first time. We feel assured that the hopes of the author regarding it will be fully realized, and that students of history and of the science of man will here find new material of permanent interest and value.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The evidence for evolution in the history of the extinct Mammalia.[1]

BY E. D. COPE OF PHILADELPHIA.

The subject to which I wish to call your attention this morning requires neither preface nor apology, as it is one with the discussion of which you are perfectly familiar. My object in bringing it before the general session of the association was in view of the fact that you were all familiar with it in a general way, and that it probably interests the members of sections which do not pursue the special branch to which it refers, as well as those which do; also, since it has been brought before us in various public addresses for many years, during the meetings of this association, I thought it might be well to be introduced at this meeting of this association, in order that we might not omit to have all the sides of this interesting question presented.

The interests which are involved in it are large: they are chiefly, however, of a mental and metaphysical character; they do not refer so much to industrial and practical interests, nor do they involve questions of applied science. They involve, however, questions of opinion, questions of belief, questions which affect human happiness, I venture to say, even more than questions of applied science; certainly, which affect the happiness of the higher grades of men and women more than food or clothing, because they relate to the states of our mind, explaining as they do the reasons of our relations to our fellow-beings, and to all things by which we are surrounded, and the general system of the forces by which we are surrounded. So it has always appeared to me: hence I have selected the department of biology, and have taken a great interest in this aspect of it.

[1] A lecture given in general session, Aug. 20, 1883. Stenographically reported for Science.

The doctrine of evolution, as taught by the biologists of to-day, has several stages as grounds or parts of its presentation. First, the foundation principle is this: That the species of animals and of plants, the species of organic beings, as well as the various natural divisions into which these organic beings fall, have not always been as we see them to-day, but they have been produced by a process of change which has progressed from age to age through the influence of natural laws; that, therefore, the species which now exist are the descendants of other species which have existed heretofore, by the ordinary processes of reproduction; and that all the various structures of organic beings, which make them what they are, and which compel them to act as they now act, are the result of gradual or sudden modifications and changes during the periods of geologic time. That is the first phase or aspect which meets the naturalist or biologist.

Another phase of the question relates to the origin itself of that life which is supposed to inhabit or possess organic beings. There is an hypothesis of evolution which derives this life from no-life, which derives vitality from non-vitality. That is another branch of the subject, to which I cannot devote much attention to-day. There is still another department of the subject, which relates to the origin of mind, and which derives the mental organization of the higher animals, especially of man, from pre-existent types of mental organization. This gives us a genealogy of mind, a history of the production or creation of mind, as it is now presented in its more complex aspects as a function of the human brain. This aspect of the subject is, of course, interesting; and upon that I can touch with more confidence than upon the question of the origin of life.

Coming now to the question of the origin of structures, we have by this time accumulated a vast number of facts which have been collated by laborious and faithful workers, in many countries and during many years; so that we can speak with a good deal of confidence on this subject also. As to the phenomena which meet the student of zoölogy and botany at every turn, I would merely repeat, what every one knows, — and I beg pardon of my biological friends for telling them a few well-known truths, for there may be those present who are not in the biological section, — the phenomena which meet the student of biology come under two leading classes: the one is the remarkable fidelity of species in reproducing their like. 'Like produces like,' is the old theorem, and is true in a great many cases; just as coins are struck from the die, just as castings are turned out from a common mould. It is one of the most wonderful phenomena of nature, that such complex organisms, consisting of so many parts, should be repeated from age to age, and from generation to generation, with such surprising fidelity and precision. This fact is the first that strikes the student of these sciences. The general impression of the ordinary person would be, that these things must continue unchanged. When I began to study zoölogy and botany, I was remarkably surprised to find there was a science of which I had no conception, and that was this remarkable reproduction of types one after another in succession. After a man has had this idea thoroughly assimilated by his honest and conscientious studies, he will be again struck with another class of facts. He will find, not unfrequently, that this doctrine does not apply. He will find a series of facts which show that many individuals fail to coincide with their fellows precisely, the most remarkable variations and the most remarkable half-way attitudes and double-sided aspects occurring; and he will come to the conclusion, sooner or later, that like does not produce like with the same precision and fidelity with which he had supposed it did. So that we have these two classes of facts, — the one relating to, and expressing, the law of heredity; the other, which expresses the law of metamorphosis. I should not like to say which class of facts is the most numerously presented to the student. In the present fauna we find many groups of species and varieties before us; but how many species we have, how many genera we have, and families, we cannot definitely state. The more precise and exact a person is in his definition and in his analysis, the more definite his science becomes, and the more precise and scientific his work. It is a case of analysis and forms. What the scales are to the chemist and the physicist, the rule and measure are to the biologist. It is a question of dimension, it is a question of length and breadth and thickness, a question of curves, a question of crooked shapes or simple shapes, — rarely simple shapes, mostly crooked, generally bilateral. It requires that one should have a mechanical eye, and should have also something of an artistic eye, to appreciate these forms, to measure them, and to be able to compare and weigh them.

Now, when we come to arrange our shapes and our measurements, we find, as I said before, a certain number of identities, and a certain number of variations. This question of variation is so common and so remarkable, that it becomes perfectly evident to the specialist in each department, that like does not at all times produce like. It is perfectly clear, and I will venture the assertion that nearly all the biologists in this room will bear me witness, that variability is practically unlimited in its range, unlimited in the number of its examples, unlimited in the degree to which it extends. That is to say, the species vary by failing to retain certain characteristics, and generic and other characters are found to be absent or present in accordance with some law to be discussed farther on.

I believe that this is the simplest mode of stating and explaining the law of variation: that some forms acquire something which their parents do not possess; and that those which acquire something additional have to pass through more numerous stages than those which have not acquired so much had themselves passed through.

Of course we are met with the opposite side of the case, — this law of heredity. We are told that the facts there are not accounted for in that way; that we cannot pass from one class of facts to the other class of facts: what we find in one class is not applicable to the other. Here is a question of rational processes, of ordinary reason. If the rules of chemistry are true in America, I imagine they are true in Australia and Africa, although I have not been there to see. If the law of gravitation is effective here, I do not need to go to Australia or New Zealand to ascertain whether it is true there. So, if we find in a group of animals a law sufficient to account for their creation, it is not necessary to know that others of their relatives have gone through a similar process. I am willing to allow the ordinary practical law of induction, the practical law of inference, to carry me over these gaps, over these interruptions. And I state the case in that way, because this is just where some people differ from me, and that is just where I say the simple question of rationality comes in. I cannot believe that nature's laws are so dissimilar, so irregular, so inexact, that those which we can see and understand in one place are not true in another; and that the question of geological likelihood is similar to the question of geographical likelihood. If a given process is true in one of the geological periods, it is true in another; if it is true in one part of the world, it is true in another; because I find interruptions in the series here, it does not follow that there need be interruptions clear through from age to age. The assumption is on the side of that man who asserts that transitions have not taken place between forms which are now distinct.

We are told that we find no sort of evidence of that transition in past geological periods; we are assured that such changes have not taken place; we are even assured that no such sign of such transition from one species to another has ever been observed, — a most astonishing assertion to make *to* a biologist, or *by* a biologist; and such persons have even the temerity to cite special cases, as between the wolf and the dog. Many of our domestic dogs are nothing but wolves, which have been modified by the hand of man to a very slight extent indeed. Many dogs, in fact, nearly all dogs, are descendants of wild species of various countries, and are but slightly modified.

To take the question of the definition of species. Supposing we have several species well defined, say four or five. In the process of investigation we obtain a larger number of individuals, many of which betray characters which invalidate the definitions. It becomes necessary to unite the four or five species into one. And so, then, because our system requires that we shall have accurate definitions (the whole basis of the system is definitions: you know the very comprehension of the subject requires definitions), we throw them all together, because we cannot define all the various special forms as we did before, until we have but one species. And the critic of the view of evolution tells us, "I told you so! There is but one species, after all. There is no such thing as a connection between species: you never will find it." Now, how many discoveries of this kind will be necessary to convince the world that there are connections between species? How long are we to go on finding connecting links, and putting them together, as we have to do for the sake of the definition, and then be told that we have, nevertheless, no intermediate forms between species? The matter is too plain for further comment. We throw them together, simply because our definitions require it. If we knew all the known individuals which have lived, we should have no species, we should have no genera. That is all there is of it. It is simply a question of a universal accretion of material, and the collection of information. I do not believe that the well-defined groups will be found to run together, as we call it, in any one geological period, certainly in no one recent period. We recognize, however, that they diverge to a wonderful extent: one group has diverged at one period, and another one has become diversified in a different period; and so each one has its history, some beginning farther back than others, some reaching far back beyond the very beginning of the time when fossils could be preserved. I call attention to this view, because it is a very easy matter for us to use words for the purpose of confusing the mind; for, next to the power of language to express clear ideas, is its power of expressing no ideas at all. As we all know, we can *say* many things which we cannot *think*. It is a very easy thing to say twice two is equal to six, but it is impossible to think it.

I would cite what I mean by variations of species in one of its phases; I would just mention a genus of snakes, Ophibolus, which is found in the United States. If we take the species of this snake-genus as found in the Northern States, we have a good many species well defined. If we go to the Gulf States, and examine our material, we see we have certain other species well defined, and they are very nicely defined and distinguished. If, now, we go to the Pacific coast, to Arizona and New Mexico, we shall find another set of species well defined indeed. If we take all these different types of our specimens of different localities together, our species, as the Germans say, all tumble together: definitions disappear, and we have to recognize, out of the preliminary list of thirteen or fourteen, only four or five. That is simply a case of the kind of fact with which every biologist is perfectly familiar.

When we come to the history of the extinct forms of life, it is perfectly true, then, that we cannot observe the process of descent in actual operation, because, forsooth, fossils are necessarily dead. We cannot perceive any activities, because fossils have ceased to act. But if this doctrine be true, we should get the series, if there be such a thing; and we do, as a matter of fact, find longer or shorter series of structures, series of organisms proceeding from one thing into another form, which are exactly as they ought to be if this process of development by descent had taken place.

I am careful to say this; because it is literally true, as we all must admit, that the system must fall into some kind of order or other. You could not collect bottles, you could not collect old shoes, but you could make some kind of a serial order of them.

There are, no doubt, characters by which such and such shoes could be distinguished from other shoes, these bottles from other bottles; but it is also true, that we have, in recent forms of life in zoölogy and botany, irrefragable proofs of the metamorphoses, and transformations, and changes of the species, in accordance with the doctrine with which we commenced.

We now come to the second chapter of our subject. With the assumption, as I take it already satisfactorily proven, of species having changed over into others, in considering this matter of geological succession or biological succession, I bring you face to face with the nature and mode of the change; and hence we may get a glance, perhaps, at its laws.

I have on the board a sketch or table which represents the changes which took place in certain of the mammalia. I give you a summary of the kind of thing which we find in one of the branches of paleontology. I have here two figures, one representing a restoration, and the other an actual picture, of two extinct species that belong to the early eocene periods. One represents the ancestor of the horse line, Hyracotherium, which has four toes on his anterior feet, and three behind; and the other, a type of animal, Phenacodus, which antedated all the defined, or that a specific intermediate form of life will not be found. I think it is much safer to assert that such and such intermediate forms will be found. I have frequently had the pleasure of realizing anticipations of this kind. I have asserted that certain types would be found, and they have been found. You will see that I attend to the matter of time closely, because there have been a great many things discovered in the last ten or fifteen years in this department. In these forms I give the date of the discovery of the fauna in which they are embraced.

Here we have the White-River fauna discovered in 1856; then we skip a considerable period of time, and the next one was in 1869, when the cretaceous series was found. Six or seven cretaceous faunae have been found. Then we have the Bridger fauna in 1870, the Wasatch fauna in 1874. Next we have, in 1877, the Equus beds, and the fauna which they embrace, which also was found in 1878. The Permian fauna, which is one of the last, is 1879; and the last, the Puerco, which gives the oldest and ancestral types of the modern forms of mammalia, was only found in 1881. When I first commenced the study of this subject, about 1860, there were perhaps 250 species known. There are now something near 2,000, and we are augmenting them all the time. I have

Formation.	No. toes.	Feet.	Astragalus.	Carpus and tarsus.	Ulnoradius.	Superior molars.	Zygapophyses.	Brain.
Miocene . . Upper . . . . (Loup Fork.)	1-1 2-2 3-3 4-4 (5-5)	Digitigrade. (Plantigrade.)	Grooved. (Flat.)	Interlocking. (Opposite.)	Faceted.	4-tubercles, crested and cemented.	Doubly involute. Singly do.	Hemispheres larger, convoluted.
Middle . . . . (John Day.)	2-2 3-3 4-4	Digitigrade.	Grooved.	Interlocking.	Faceted. Smooth.	4-tubercles, and crested.	Singly involute. Doubly do.	Hemispheres larger, convoluted.
Lower . . . . (White River.)	3-3 4-3 4-4	Digitigrade. Plantigrade.	Grooved.	Interlocking.	Smooth. Faceted.	4 tubercles, and crested.	? Singly involute.	Hemispheres small; and larger.
Eocene . . Upper . . . . (Bridger.)	3-3 4-3 4-5 5-5	(Digitigrade.) Plantigrade.	Grooved. (Flat.)	Opposite. Interlocking.	Smooth.	4-tubercles. 3-tubercles, and crested.	Singly involute. Plane.	Hemispheres small.
Middle . . . . (Wasatch.)	4-3 4-5 5-5	Plantigrade. (Digitigrade.)	Flat. (Grooved)	Opposite. Interlocking.	Smooth.	4-tubercles. 3-tubercles, a few crested.	Plane. Singly involute.	Hemispheres small; mesencephalon sometimes exposed.
Lower . . . . (Puerco.)	5-5	Plantigrade.	Flat.	Opposite.	Smooth.	3-tubercles. (4-tubercles), none crested.	Plano.	Mesencephalon exposed; hemisphere small and smoother.

horse series, the elephant series, the hog, the rhinoceros, and all of the other series of hoofed animals. Each presents us with the primitive position in which they first come to our knowledge in the history of geological time.

I have also arranged here a series of some leading forms of the three principal epochs of the mesozoic times, and six of the leading ones of the tertiary time. I have added some da·s to show you the time when the faunae which are entombed in those beds were discovered, in the course of our studies; and you will easily see how unsafe it is to say that any given type of life has never existed, and assert that such and such a form is unknown; and it is still more unsafe, I think, to assert that any given form of life properly found many myself: if they were distributed through the days of the year, I think in some years I should have had several every day. But the accessions to knowledge which are constantly being made make it unsafe to indulge in any prophecies, that, because such and such things have not been found, therefore such and such things cannot be; for we find such and such things really have been and really are discovered.

The successive changes that we have in the mammalia have taken place in the feet, teeth, and brain, and the vertebral column. The parts which present us the greatest numbers of variations are those in which many parts are concerned, as in the limbs and feet. In the lower eocene (Puerco), the toes were

5–5. In the Loup-Fork fauna, some possess toes but 1–1. Prior to this period no such reduction was known, though in the Loup-Fork fauna a very few species were 5–5. Through this entire series we have transitions steady and constant, from 5–5, to 4–5, to 4–4, to 4–3, to 3–3, to 2–2, to 1–1. In the Puerco period there was not a single mammal of any kind which had a good ankle-joint; which had an ankle-joint constructed as ankle-joints ought to be, with tongue and groove. The model ankle-joint is a tongue-and-groove arrangement. In this period they were all perfectly flat. As time passes on we get them more and more grooved, until in the Loup-Fork fauna and the White-River fauna they are all grooved. In the sole of the foot, in the Puerco fauna, they are all flat; but in the Loup-Fork fauna the sole of the foot is in the air, and the toes only are applied to the ground, with the exception of the line of monkeys, in which the feet have not become erect on the toes, and the elephant, in which the feet are nearly flat also, and the line of bears, where they are also flat. As regards the ungulation between the small bones of the palm and of the sole, there is not a single instance in which the bones of the toes are locked in the lower eocene, as they are in the later and latest tertiary.

When we come to the limbs, the species of the Puerco fauna have short legs. They have gradually lengthened out, and in the late periods they are nearly all relatively long.

Coming to the vertebrae as a part of the osseous system, I will mention the zygapophyses, or antero-posterior direct processes, of which the posterior looks down, and the anterior looks up. They move on each other, and the vertebral column bends from side to side. In the lower forms of mammals they are always flat, and in the hoofed mammals of the Puerco period they are all flat. In the Wasatch period we get a single group in which the articulation, instead of being perfectly flat, comes to be rounded; in the later periods we get them very much rounded; and finally, in the latest forms, we get the double curve and the locking process in the vertebral column, which, as in the limb, secures the greatest strength with the greatest mobility. In the first stages of the growth of the spinal cord, it is a notochord, or a cylinder of cartilage or softer material. In later stages the bony deposit is made in its sheath until it is perfectly segmented.

Now, all the Permian land-animals, reptiles, and batrachians retain this notochord with the beginnings of osseous vertebrae, in a greater or less degree of complexity. There are some in South Africa, I believe, in which the ossification has come clear through the notochord; but they are few. This characteristic of the Permian appears almost alone, — perhaps absolutely alone as regards land-animals. There is something to be said as to the condition of that column from a mechanical standpoint, and it is this: that the cord exists, its osseous elements disposed about it; and in the batrachians related to the salamanders, and the frogs, these osseous elements are arranged under the sheath in the skin of the cord; and they are in the form of regular concave segments, very much like such segments as you will take from the skin of an orange, — parts of spheres, and having greater or less dimensions according to the group or species. Now, the point of divergence of these segments is on the side of the column. They are placed on the side of the column where the segments separate, — the upper segments rising and the lower segments coming downward. To the upper segments are attached the arches and their articulations, and the lower segments are like the segments of a sphere. If you take a flexible cylinder, and cover it with a more or less inflexible skin or sheath, and bend that cylinder sidewise, you of course will find that the fractures of that part of the surface will take place along the line of the shortest curve, which is on the side; and, as a matter of fact, you have breaks of very much the character of the segments of the Permian batrachia. It may not be so symmetrical as in the actual animal, for organic growth is symmetrical so far as not interfered with; for, when we have two forces, the one of growth and the other of change or alteration, and they contend, you will find in the organic being a quite symmetrical result. That is the universal rule. In the cylinder bending in this way, of course the shortest line of curve is right at the centre of the side of that cylinder, and the longest curve is of course at the summit and base, and the shortest curve will be the point of fracture. And that is exactly what I presume has happened in the case of the construction of the segments of the sheath of the vertebral column in the lateral motion of the animal swimming, always on one side, and which, at least, has been the actual cause of the disposition of the osseous material in its form. I have gone beyond the state of the discussion in calling attention to one of the forces which have probably produced this kind of result. That is the state of the vertebral column of many of the vertebrata of the Permian period.

I go back to the mammalia, and call attention to the teeth. The ordinary tooth of the higher type of the mammalia, whether hoofed or not, with some exceptions, is complex with crests or cusps. In cutting the complex grinding surfaces we find they have been derived by the infolding extensions of four original cusps or tubercles. They have been flattened, have been rendered oblique, have run together, have folded up, have become spiked, have descended deeply or have lifted themselves, so that we have teeth of all sorts and kinds, oftentimes very elegant, and sometimes very effective in mechanism. In many primary ungulates, the primitive condition of four conical tubercles is found. In passing to older periods we find the mammalia of the Puerco period, which never have more than three tubercles, with the exception of three or four species. In the succeeding periods, however, they get the fourth tubercle on the posterior side. Finally, you get a complicated series of grinding or cutting apparatus, as the case may be.

Last, but not least, we take the series of the brain. No doubt the generalization is true, that the primitive forms of mammalia had small brains with smooth hemispheres; later ones had larger brains with complex hemispheres. In general, the carnivora have retained a more simple form of brain, while herbivorous animals have retained a most complicated type of brain. The lowest forms of mammalia display the additional peculiarity of having the middle brain exposed; and the hemispheres or large lobes of the brain, which are supposed to be the seat of the mental phenomena, are so reduced in size at the back end that you see the middle brain distinctly, though it is smaller than in reptiles and fishes. It is beyond the possibility of controversy, that these series have existed, and that they have originated in simplicity, and have resulted in complication; and the further deduction must be drawn, that the process of succession has always been towards greater effectiveness of mechanical work. There are cases of degradation, as in the growing deficiency in dentition in man. There is no doubt that a large number of people are now losing their wisdom-teeth in both jaws.

We are now brought to the question of the relations which mind bears to these principles. The question as to the nature of mind is not so complex as it might seem. There is a great deal of it, to be sure; but on examination it resolves itself into a few ultimate forms. An analysis reduces it to a few principal types or departments, — the departments of the intelligence and of emotions (with their modified smaller forms, likes and dislikes), and the will, if such there be. Those three groups, proposed by Kant, are well known, and adopted by many metaphysicians; and they stand the scrutiny of modern science perfectly well in both men and the lower animals. But the question of the material of the mind, the original raw stuff out of which mind was made, is one which is claiming attention now from biologists, as it always has done from physiologists proper and physicians. This is sensibility, mere simple sensibility, unmodified sensibility or consciousness. Sensibility, in connection with memory, is sufficient for the accomplishment of wonderful results. It is only necessary to impress the sensibility with the stimuli which this world affords, whether from the outside or the inside, to have the record made, and to have the record kept. Among wonderful things this is perhaps the most wonderful: that any given form of matter should be able to retain a record of events, a record which is made during a state of sensibility for the most part, a greater or less degree of sensibility, which is retained in a state of insensibility, and is finally returned to the sensibility by some curious process of adhesion, and the results of impresses which are found on the material tissue concerned.

And these simple elements of mind are found in animals. No zoölogist who has perception or honesty, nor any farmer or breeder, nor any person who has charge of animals in any way, can deny sensibility to all the lower animals at times. The great stumbling-block in the way of the thinker in all this field is the great evanescence of this sensibility: the great ease with which we dissipate it, the readiness with which we can deprive a fellow-being of his sense, is a stumbling-block in more ways than one. While it is a question of the greatest difficulty, nevertheless, like other departments of nature, doubtless it will ultimately be explained by the researches of physiologists. I only need to call attention to the fact as an important factor in evolution.

Of course, if these structures are suggested, affecting the mechanical apparatus, the question arises, whether they were made ready to hand, whether the animal, as soon as he got it, undertook to use it, and whether he undertook to use the organism under the dire stimuli of necessity, or amended through ages these modifications in his own structure. We are told by some of our friends, that law implies a lawgiver, that evolution implies an evolver: the only question is, Where is the lawgiver? where is the evolver? where are they located? I may say, it is distinctly proven in some directions, that the constant applications of force or motion in the form of strains, in the form of impacts and blows, upon any given part of the animal organism, do not fail to produce results in change of structure. I believe the changes in the ungulates to which I have called your attention are the result of strains and impacts, precisely as I have shown you the manner of the fracture of the vertebral column of the primitive vertebrates of the Permian period. This would require long discussion to render clear: nevertheless, I venture to make the assertion that this series of structures is the result of definite and distinct organic forces, directed to special ends. We have yet to get at the conflicting forces which have produced the results we see. Mechanical evolution will give us a good deal to do for some time to come. Of course, if motion has had an effect in modifying structure, it behooves us to investigate these forces which give origin to motion in animals. First in order come the sensibilities of the animal, which we have traced to simple consciousness; stimuli, upon notice of which he immediately begins to move. The primary stimulus of all kinds of motion is necessarily touch. If a stone falls upon the tail of some animal which has a tail, he immediately gets out of that vicinity. If a jelly-fish with a stinging apparatus runs across an eel which has no scales, the eel promptly removes. External applications of unpleasant bodies will always cause an animal to change his location. Then he is constantly assaulted by the dire enemy of beasts, hunger, an instinct which is evidently universal, to judge from the actions of animals. This seems to have fashioned, in large part, all forms of life, from the least to the greatest, from the most unorganized to the most complex. Each exercised itself for the purpose of filling its stomach with protoplasm. Then come the stimuli, which should be included under the class of touch, changes of temperature. No animals like to be cold or too hot; and when the temperature is disagreeable, the tendency is to go away from that locality. Among primary instincts must be included that of reproduction. After that comes the sensation of resistance, or, carried to a high degree, of anger: when an animal's interests are interfered with, its movements restricted, it prompts to the most energetic displays. So, you see, it is a matter of necessity that mental phenomena lie at the back of evolution, provided always that the connecting link of the argument — that motion has ever affected structure — be true. That is a point which, of course, admits of much discussion. I have placed myself on the affirmative side of that question; and, if I live long enough, I expect to see it absolutely demonstrated.

Of course the development of mind becomes possible under such circumstances. It is not like a man lifting himself up by his boots; which it would be if he had no such thing as memory. But with that memory which accumulates, which formulates first habits, and then structures, especially in the soft, delicate nervous tissue, the development of the mind as well as the machinery of the mind becomes perfectly possible. We develop our intellect through the accumulation of exact facts; through the collation of pure truth, no matter whether it be a humble kind of truth, — as the knowledge of the changes of the seasons, which induces some animals to lay up the winter's store, — whether it be knowledge of the fact that the sting of the bee is very unpleasant, or knowledge of the fact (of which the ox, no doubt, is thoroughly aware) that the teeth of the wolf are not pleasant to come in contact with; or whether it be the complex knowledge of man. When the cerebral matter has become larger and more complex, it receives and retains a much greater number of impressions, and the animal becomes a more highly educated being.

As regards the department of emotions or passions, it is also much stimulated by the environment. Animals which live in a state of constant strife, naturally have their antagonistic passions much developed; while amiable, sympathetic sentiments are better and more largely produced by peace-loving animals. Thus it is that the various departments of the mind have the beautiful results which we now find in the human species.

There are some departments of the mind which some of our friends decline to admit having had such an origin. The moral faculty, for instance, is excepted by many from this series. But the reasons why they object to its production in this way are, to my mind, not valid. The development of the moral faculty, which is essentially the sense of justice, appears to them not to fall within the scope of a theory of descent or of evolution. It consists of two parts. First is the sentiment of benevolence, or of sympathy with mankind, which gives us the desire to treat them as they should be treated. It is not sufficient for justice that it is unmixed mercy, or benevolence, which is sometimes very injurious, and very often misplaced. It requires, in the second place, the criticism of the judgment, of the mature intellect, of the rational faculty, to enable the possessor to dispose of his sentiments in the proper manner. The combination of rational discrimination and true judgment, with benevolence, constitutes the sense of justice, which has been derived, no doubt, as a summary of the development of those two departments of the mind, — the emotions and the intellect.

It is said, that a sense of justice could not be derived from the sense of no justice; that it could not have been derived from the state of things which we find in the animals, because no animal is known to exhibit real justice: and that objection is valid as far as it goes. I suspect that no animal has been observed to show a true sense of justice. That they show sympathy and kindness, there is no question; but when it comes to real justice, they do not display it. But do all men display justice? Do all men *understand* justice? I am very sure not. There are a good many men in civilized communities, and there are many tribes, who do not know what justice is. It does not exist as a part of every mental constitution. I never lived among the Bushmen, and do not know exactly what their mental constitution is; but in a general way the justice of savages is restricted to the very smallest possible circle, — that of their tribe or of their own family. There is a class of people who do not understand justice. I do not refer to people who know what right is, and do not do it; but to the primitive state of moral character, in which, as in children, a sense of justice is unknown. I call attention to the fact, because some of our friends have been very much afraid that the demonstration of the law of evolution, physical and metaphysical, would result in danger to society. I suspect not. The mode in which I understand this question appears to me to be beneficial to society, rather than injurious; and I therefore take the liberty of appending this part of the subject to its more material aspect.

To refer to another topic, and that is to the origin of life, the physical basis of life. The word 'life' is so complex that it is necessary to define it, and so to define it away that really the word 'life' does not retain its usual definition. Many phenomena of life are chemical, physical, mechanical. We have to remove all these from consideration, because they come within the ordinary laws of mechanical forces; but we have a few things left which are of a different character. One is the law of growth, which is displayed in the processes of embryonic succession; secondly, the wonderful phenomena of sensibility. Those two things we have not yet reduced to any identity with the ordinary laws of force. In the phenomena of embryology the phenomena of evolution are repeated, only concentrated in the early stages through which animals have to pass. So whatever explains the general phenomena of evolution explains the phenomena of embryology.

What is the nature of physical sensibility? In this planet, it is found residing only in one form of matter, which has a slightly varied chemical constitution, namely, protoplasm; so-called from a physical standpoint. Now, this world, as you all know, has passed through many changes of temperature. Its early periods, it is probable, were so very hot that protoplasm had a very poor chance. The earth has passed through a great many changes of temperature, many of which would not permit the existence of protoplasm. Again, can we assume for a moment that this little speck in the great universe is the only seat of life? I suppose scarcely any scientific man will venture to do so. If, therefore, life exists in other parts of this great universe, does it necessarily occupy bodies of protoplasm in those different, remote spheres? It would be a great assumption. It is altogether improbable. The certainty is, that in those planets which are in proximity to the sun's heat there could be no protoplasm. Protoplasm in the remote planets would be a hard mineral, and near the sun it would be dissipated into its component gases. So that, if life be found in other parts of this universe, it must reside in some different kind of material. It is extremely probable that the physical conditions that reside in protoplasm might be found in other kinds of matter. It is in its chemical inertness, and in its physical constitution, that its adaptation to life resides; and the physical constitution necessary for the sustentation of life may be well supposed to exist in matter in other parts of the universe. I only say the door is open, and not closed: any one who asserts that life cannot exist in any other material basis than protoplasm is assuming more than the world of science will permit him to assume. And that it is confined to this single planet, and not in the great systems of the universe, — that assumption will not for a moment be allowed. Therefore the subject is one which allows us a free field for future investigation: it is by no means closed in the most important laws which it presents to the rational thinker. I hope, therefore, that, if the evidence in favor of this hypothesis of the creation of living forms be regarded as true, that no one will find in it any ground for any very serious modification of existing ideas on the great questions of right and wrong which have long since been known by men as a result of ordinary experience, and without any scientific demonstration whatsoever.

A classification of the natural sciences.[1]

BY T. STERRY HUNT, LL.D., F.R.S., OF MONTREAL.

To frame a rational classification of the natural sciences, and to define their mutual relations, have often been attempted. The present writer, in an essay read before the National academy of sciences in April, 1881, and since published in the Philosophical magazine, with the title of 'The domain of physiology,' suggested the basis of such a scheme, and now, at the request of some of his readers, ventures, for the first time, to embody in a concise and tabulated form the views then and there enunciated, in the hope that other students may find it not unworthy of their notice.

The study of material nature constitutes what the older scholars correctly and comprehensively termed physics (the words 'physical' and 'natural' being synonymous), and presents itself in a twofold aspect, — first, as descriptive: and, second, as philosophical, — a distinction embodied in the terms 'natural history' and 'natural philosophy,' or, more concisely, in the words 'physiography' and 'physiology.' The latter word has been employed, in this general sense, to designate the philosophical study of nature from the time of Aristotle, and will so be used in the present classification.

The world of nature is divided into the inorganic or mineralogical, and the organic or biological, kingdoms; the division of the latter into vegetable and animal being a subordinate one. The natural history, or physiography, of the inorganic kingdom, takes cognizance of the sensible characters of chemical species, and gives us descriptive and systematic mineralogy, which have hitherto been restricted to native species, but, in their wider sense, include all artificial species as well. The study of native mineral species, their aggregations, and their arrangement as constituents of our planet, is the object of geognosy and physical geography. The physiography of other worlds gives rise to descriptive astronomy.

The natural philosophy of the inorganic kingdom, or mineral physiology, is concerned, in the first place, with what is generally called dynamics or physics; including the phenomena of ordinary motion, sound, temperature, radiant energy, electricity, and magnetism. Dynamics, in the abstract, regards matter in general, without relation to species; chemism generates therefrom mineralogical or so-called chemical species, which, theoretically, may be supposed to be formed from a single elemental substance, or *materia prima*, by the chemical process. Dynamics and chemistry build up our inorganic world, giving rise to geogeny, and, as applied to other worlds, to theoretical astronomy.

Proceeding next to the organic kingdom, its physiographical study leads us first to organography, and then to descriptive and systematic botany and zoölogy, two great subdivisions of natural history. Coming, then, to consider the physiological aspect of organic nature, we find, besides the dynamical and chemical activities manifested in the mineral, other and higher ones which characterize the organic kingdom. On this higher plane of existence, are found portions of matter which have become individualized, exhibit irritability, the power of growth by assimilation, and of reproduction, and which establish relations with the external world by the development of organs, all of which characters are foreign to the mineral kingdom. These new activities are often designated as vital; but since this word is generally made to include at the same time other manifestations which are simply dynamical or chemical, I have elsewhere proposed for the activities characteristic of the organism the term biotics (βιοτικός, pertaining to life). The physiology of matter in the abstract is dynamical, that of mineral species is both dynamical and chemical, while that of organized forms is at once dynamical, chemical, and biotical. All of these, I may remark, I regard as successive manifestations of an energy inherent in matter.

The study of the biotical activities of matter leads to organogeny and morphology, while the relations of organisms to one another and to the inorganic kingdom give us physiological botany and zoölogy. We thus arrive at a comprehensive and simple scheme of the natural sciences, which I have endeavored to set forth in the subjoined table.

[1] Abstract of paper read in general session, Aug. 17, 1883.

Natural Sciences;	Inorganic Nature;	Organic Nature.
Descriptive. General Physiography, or Natural History.	Mineral Physiography. Descriptive and Systematic Mineralogy; Geognosy; Geography; Descriptive Astronomy.	Biophysiography. Organography; Descriptive and Systematic Botany and Zoölogy.
Philosophical. General Physiology, or Natural Philosophy.	Mineral Physiology. *Dynamics* or *Physics*; *Chemistry.* Geogeny; Theoretical Astronomy.	Biophysiology. *Biotics.* Organogeny; Morphology; Physiological Botany and Zoölogy.

Orbit of the great comet of 1882.

BY EDGAR FRISBIE OF WASHINGTON, D.C.

This is a partial record of observations at Washington. Mr. Winlock is preparing a description of all the physical phenomena of the comet which were there observed. The first Washington observation of the comet was at two o'clock on a September afternoon, and a comparison was then made with the position of the sun. Good observations were obtained on the meridian for three days. The calculations from these served to fix the place of the comet with fair approximate accuracy for three months, which was a somewhat remarkable success. Afterward a difficulty occurred in obtaining accurate observations; because there were several different points of light presented in an ill-defined nucleus, and it was uncertain whether the observations always referred to the same luminous point. These observations were made in October and November. The following ephemeris was calculated: —

Sept.	17.2282	ϕ	89° 13′ 42.70″
Ω	346° 1′ 7.91″	log. a	1.9331366
π Ω	69 36 12.79	log. q	7.8904739
i	141 59 52.16	period	793.689

The author compared the foregoing with the observations of other astronomers. The most prominent variation was in respect to the period, which others gave as 659, 997, 852, and 654 years. A contrivance was exhibited, showing the respective positions of the earth and comet, and their directions of motion, by means of pasteboard planes attached at an angle.

The rotation of domes.

BY G. W. HOUGH OF CHICAGO, ILL.

Observatory domes are in general very heavy. As they grow old, owing to the settling of walls and other changes, they are apt to become almost unmanageable. The dome at Chicago is very weighty, every thing about the observatory being built in a very substantial manner. When Dr. Hough first tried to move the dome, he found its two sides working with unequal friction; and this was afterward remedied to some extent, but by no means fully. About two months ago a gas-engine was placed in position to revolve the dome. It was a great satisfaction to see the dome go round continuously, without hitches. The cost of moving the dome by such means is a mere trifle, aside from the first cost of the engine. The use of water-power where that was easily accessible must, however, be preferred in many instances where a sufficient head is supplied by street mains.

Dr. C. A. Young said, in discussing the foregoing, that when he came to Princeton he found a very heavy dome there. One man, using thirty pounds pressure on a two-foot crank, was very tired after giving the dome one turn. A gas-engine has since been put in below, and the power is communicated by a belt. A revolution can be made in four minutes, and the shutter raised in two. In general, the dome is placed and the shutter opened within five minutes. Dr. Young expressed a hope that the Brush storage batteries would furnish electrical illumination and power for the work of observatories, as the electricity might be stored even from a gas-engine operating a dynamo during hours of the day when there was no other use for its power. At present the direct action of a gas-engine on a dynamo, with no intervention between the dynamo and the light, was too irregular to serve the purpose.

Descriptive-geometrical treatment of surfaces of the second degree.

BY J. BURKITT WEBB OF ITHACA, N.Y.

For the purpose of greater conciseness the speaker confined his remarks to the general ellipsoid, remarking that the usual treatment of problems upon this surface — as, for instance, such problems as finding the shade and shadow, or drawing tangent planes — is lacking in generality; the body being taken in such special position, or referred to such special axes, as reduce the general problem to a specially simple one.

The speaker then drew the projections of three conjugate diameters of a general ellipsoid upon the board, stating that this was the best method of defining that body. He then proceeded to find the projections of the enveloping cylinders, and the shadow of the body; which he showed could as easily be done for the general ellipsoid, in a perfectly general position, as for special cases. In fact, it appeared that problems on this body gained nothing in simplicity by special methods and devices which detract from the generality of the treatment.

List of other papers.

The following additional papers were read in this section, some of them by title only: Tidal observations on soundings distant from shore, by *J. M. Batchelder*. Investigation of light variations of Sawyer's variable, by *S. C. Chandler*. Standard time-pointer and a time longitude dial; System of algebraic geometry, by *Samuel Emerson*. The calculus of direction and position, by *E. W. Hyde*. Observations on the transit of Venus made at Columbia college; Description of the new observatory at Columbia college, by *J. K. Rees*. The light variations of T. Monocerotis, by *E. F. Sawyer*. Method of observing eclipses of Jupiter's satellites, by *D. P. Todd*. Conic sections in descriptive geometry, by *J. B. Webb*. Descriptive geometry applied to the general ellipsoid, by *C. M. Woodward*. Some observations on Uranus, by *C. A. Young*.

PROCEEDINGS OF SECTION B.—PHYSICS.

PAPERS READ BEFORE SECTION B.

[*Continued.*]

The tornado at Racine, May 18, 1883.

BY P. R. HOY OF RACINE, WIS.

A CURIOUS mistake preceded the reading of this paper. There was some confusion between the abstracts of this and another paper on a tornado, which were submitted to the sectional committee; and the other paper was entered on the daily programme, but was withdrawn.

Mr. Hoy's paper began by stating that the early part of the day was pleasant, but about 6.45 in the evening two clouds of ominous appearance joined, from opposite quarters of the heavens, and at once the cyclone began. Its general direction was to the north of east. There was no rain at Racine with the storm, but there was noticed a very strong odor of ozone while the cyclone was at its height. At the start it was barely two rods wide, but when it reached Racine it had expanded to twenty rods. Its motion was rotary and oscillatory, and all *débris* was thrown to the centre of the track. When the cyclone crossed the lake it formed huge water-spouts, one central, and seven to eight accessory, whirling about the main trunk.

Prof. H. A. Rowland proceeded to discuss the paper as follows: Most observers of tornadoes just perceive that there is a whirling motion of the air, and it knocks down objects, and that is the principal thing they see. But that is very ordinary observation. Of course, a column of air in such swift rotation will tear houses down, spurt water up, and do every thing of that sort. The particular point which I observed in this paper was the description of the formation of the tornado. The phenomenon which is to be explained is the formation of the tornado, and very few have observed this. This description was very short; merely, that, over in the west or south-west, the clouds formed. Of course, to an observer from the west, one would appear north, and the other south. The point I wish to bring out is, that there was lightning passing between the two clouds. In Mr. Finley's description of six hundred tornadoes, I do not see any similar account. Many observers have seen lightning play around these clouds, but not passing between the two clouds. Mr. Finley applied to me to know whether there was any thing in the electrical theory of a tornado. Of course, any theory of the destruction being caused by electricity, houses being attracted, etc.,—all that is mere nonsense. We know that the attraction of electricity is only a mere fraction of an ounce to the square inch. Before the force becomes sufficient to raise a great weight, a spark passes, and a discharge of electricity takes place. But in this case (these two clouds passing from north to south, and boiling up, having flashes of lightning playing round them), I thought there might be something in the electrical theory, as far as formation was concerned; and I calculated for the signal-service and Mr. Finley what amount of energy there was in two clouds approaching each other in this way. The rotation of the earth will cause them to come together, not in a straight line, but a little aside from each other, forming a spiral motion. The direction of the rotation of the tornado is a necessary consequence of the earth's rotation: so that it might be possible to have these electrified clouds approach each other by mutual attraction, and form a tornado at the point where they meet. I calculated the energy, and found there was sufficient for a rather small tornado in the case I took. I would not be willing to say that is the theory of all tornadoes. I say that it is only possible. There is a great deal more energy in a mass of air heated up to a considerable temperature, and rising, by force of gravitation,—a great many times more. If it were not for the electrical phenomena observed in the case, I should say there was very little probability of the electrical theory. I believe Mr. Finley will direct the signal-service observers to watch the direction of the wind. If it flows in from all directions at the point where the tornado is formed, we should determine it to be due to the rise of hot air at that point. When the ground is very hot and the air very sultry, we have two causes; and it is only by observation that we can find out its true manner. I do not lay very much stress upon the electrical theory. But it is an interesting point, to me, to notice that flashes of lightning have been observed between these two clouds, showing that they were differently electrified, and that there was some plausibility for the theory which I sent to the signal-service.

Prof. F. E. Nipher continued this discussion the next day, as follows: One matter connected with the effects of this tornado contained a point, it seems to me, of sufficient interest to call the attention of observers to the matter, in case any one should have an opportunity to observe the effect of a tornado upon water. Mr. Ferrel, I think, in his description of a tornado, states that we have a rising of the water, forming a sort of cone in the centre of the tornado; the effect being, of course, ascribed to the diminution of pressure which is known to be there. In the cyclone proper, where we have a large area, we have a storm-wave as the principal element in the case, and there is an upheaval of the water in the area of low pressure. In the tornado it seems to me very questionable whether that occurs. I base that upon this observation: A smaller wind-whirl which was observed by myself in northern Missouri, which was rather violent though not destructive, — a column of dust several hundred feet high being raised, — passed out upon a pond of water five or six feet deep, and a depression was formed in the water, extending to the bottom of the pond, — an immense cup. The water was revolving rapidly; and it was thrown into rotation with a centrifugal effect, — the same effect as when a vessel is whirled. It seems to me that this is an element which has not been considered as it should be. If the whirl is small, and you have not only a diminution of pressure in the centre, but of the whole body of the water, the friction producing a rotation of the water, if the result is sufficiently small you might get a depression instead of an elevation. I call attention to this, so that those who may be fortunate enough to see a tornado on the water may not take it for granted that it is all known.

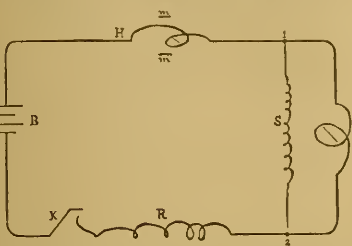
As to the remarks of Professor Rowland in regard to the possible electrical origin of a tornado, I know that he was very careful to say that he did not think any of the destructive effects could be ascribed to the action of electricity. I gathered the idea that he thought a tornado might originate in that way, — that two electrified clouds will attract each other, and come together; and he calculates the energy of the attraction which bodies can have for each other in air. It seems to me that the simple observation that was made by Mr. Hoy, together with another fact which we know, — that when the discharge passes between electrified bodies they are almost wholly discharged, — would show that when that happens the cause for that motion has disappeared. When these two clouds approach, a spark passes, and the whole thing is gone. So long as there is no spark passing, we know very well that the attraction is very much less than the maximum attraction of $\frac{1}{100}$ of an ounce on the square inch. I think, perhaps, that is a matter Professor Rowland did not consider. It does not seem to me at all likely that any such origin can be ascribed to the tornado. When it is developed, you may have a rarefied column which may be very highly rarefied, connecting the earth with the upper regions, which is precisely the reason that the lightning which was observed in the case of the Racine tornado was not accompanied by thunder.

Prof. J. T. Lovewell said it occurred to him, from his observation, that a good deal of care is necessary in order that the observer may know exactly what he sees. It was my fortune, said he, to witness a small whirl at a distance of three or four miles. I saw the funnel-shaped cloud descend toward the earth, and it looked to me as though there were a column of water. Many people who saw it spoke of it as a waterspout. It might have been water, for aught that we could have said from our point of sight. I immediately drove to the spot, and it appeared that not a drop of rain had fallen in that track. The whirl had been sufficient to overturn a few stacks of grain and hay, and a man was thrown about with his team in the road. I think, if it had struck a body of water, I should be slow to believe that it lifted any solid column of water into the air one hundred feet. It would have made a grand scattering of the water, and a great deal of it would have been thrown up into the air. I believe that a good deal of that which is commonly ascribed to columns of water rising up, and pouring down the sides in cataracts, is optical illusion. I should be slow to take the testimony of a person seeing them, unless he had his mind disabused of the common notions about these waterspouts. So far as their electrical origin is concerned, I quite agree with Professor Nipher that it is not by any means proven that electricity has any thing to do with them, except that it is a necessary adjunct, of course, to all such disturbances.

A method for the calibration of a galvanometer.

BY B. F. THOMAS OF COLUMBIA, MO.

A BATTERY of any sort is joined in circuit with a sensitive galvanoscope H, a galvanometer G, and any variable resistance R. When the circuit is closed at K, the current is so adjusted by varying R, as to give the highest desirable deflection of the galvanometer needle. The needle of H will be forced against the stops. By means of magnets m and m, the needle of H is brought back to zero. If these magnets and the galvanoscope be undisturbed, the original current strength will be indicated when the needle stands at zero, whatever changes may have been made in the circuit. If now the shunt S be connected at 1, 2, and the resistance of the shunt is made equal to that of the galvanometer (positively determined), and the needle of H brought back to zero (by increasing R, as insertion of the shunts lowers the total resistance of the circuit, and therefore increases the current strength, deflecting H), a new deflection of the galvanometer needle will be produced, the deflection being that due to a current of one-half the strength of the original current. By giving to S values equal to ∞, 3, 2, 1, ½, ⅓, ¼, etc., times the resistance of G, and bringing the needle of H to zero each time, deflection of G will result, due to currents whose strengths are as 1, ¾, ⅔, ½, ⅓, ¼, ⅕, etc. The curve is then plotted with deflections and current strengths as co-ordinates. Any desired number of points in the



curve may be obtained by giving S the proper values. The calibration may be checked by making a new adjustment for the united current, so that the deflection of G shall be about two-thirds the first deflection, and proceeding as above. Plotting the new values obtained, the curves will coincide if the work is correct. If it be found desirable, the battery may be exchanged for another during the determination.

The utilization of the sun's rays for warming and ventilating apartments.

BY E. S. MORSE OF SALEM, MASS.

MR. MORSE drew attention to this device a year ago, before the National academy of sciences. At that time he was able to offer only crude computations as to the operations of the heater, derived from its use at the museum of Salem, Mass.

The device consists mainly of a slaty surface painted black, standing vertically upon a wall, outside the building, with flues to conduct warmed air to the inside. The slates are inserted in a groove, much as one might place glass in a frame. One made within the last year was three feet wide and eight long. It was placed where it received the sun's rays as directly as practicable. Its service was to warm a room used for a library. During an entire winter the room was thus made comfortable, except on a few of the coldest days. The current of air passing through it, when the sun's rays impinged directly upon it, was raised about 30°; it discharged 3,206 feet of warmed air in an hour. This was in the morning. At 11.45 the air of the apartment was raised 29°, with 3,326 cubic feet of air discharged; at 12.45, 29° and 4,119 feet; at 1.55, 24° and 3,062 feet; at 2.45, 20° and 1,299 feet. The room measured 20×14, and was ten feet high.

The apparatus works to most advantage in a room that is ventilated by an open chimney. But some very good results have been obtained in closed rooms. One was cited, where the air in a public building was raised by such means to nearly 40° above the outside temperature. In general, a difference of 30° to 35° can thus be secured during four or five working hours of the day.

Professor Mendenhall stated that he had seen the working of the apparatus, and it proved very satisfactory. Professor Rogers gave similar testimony.

New form of selenium cell, with some remarkable electrical discoveries made by its use.

BY C. E. FRITTS OF NEW YORK.

PROFESSOR MENDENHALL stated that in the absence of the author he was able to give only a brief summary of the paper. In the ordinary method of making selenium cells, they are constructed of a great many portions put side by side; the resistances are necessarily very high in these cells, and the light is allowed to strike in the direction of a right angle to the direction of the passage of the current. Mr. Fritts seems to have devised a different mode of operating these cells by using a very large surface, and in that way has succeeded in diminishing the resistance very greatly, which is very desirable. He has resistance as low as nine or ten ohms in the dark. The radical point of difference is, that in this case the light is allowed to strike upon the cell in the same direction as the current. He states that he has discovered many remarkable properties by means of his investigations with the instrument. When a cell of this kind breaks down, it can easily be remedied and repaired: in fact, there is no danger or difficulty of their breaking down permanently.

A method of determining the centre of gravity of a mass.

BY B. F. THOMAS OF COLUMBIA, MO.

A BAR, *L L*, is balanced on a knife-edge, *F*, so as to form a very sensitive balance. The body, *B*, of mass, *M*, is placed with a marked point in contact with a fine point, *d*; and another body of mass, *W*, is placed

at *A*, so as to nearly balance *B*. A small body of mass, *p*, is placed at *S*, to complete equilibrium. *B* is then rotated 180° horizontally, bringing its marked spot in contact with a second fixed point, *E*. Equilibrium is restored by placing *p* at *R*. The equations of moments in the two positions are, respectively, —

$$W \times AF + p \times SF = M\,(Fd + dc);$$

(*c* being centre of gravity); and

$$W \times AF + p \times RF = M\,(Fe - dc);\ (ec = dc).$$

Subtracting the first equation from the second, —

$$p \times RS = M\,(de - 2\,cd);$$

$$\therefore cd = \frac{de}{2} - \frac{p \times RS}{2\,M};$$

cd is therefore the distance from the marked spot to a vertical plane containing the centre of gravity. Taking a second marked spot in the plane thus found, the operation is repeated, with the plane horizontal. This gives a second plane through the centre of gravity. A third operation, with the intersection of the two planes in the line *de*, locates the centre of gravity.

The kinetic theory of the specific heat of solids.

BY H. T. EDDY OF CINCINNATI, OHIO.

THIS paper was based upon the well-known views of its author respecting the use to be made of the different degrees of freedom of motion among the atoms of solid bodies, in deducing a theory that will explain their diverse powers of conducting heat, and of transmitting or causing the transmission of radiant energy. The theory is based upon the conception that all bodies are constituted of equal ultimate atoms, whose combination, in different degrees of freedom, in different molecules, gives rise to the characteristic differences of elementary substances. This paper shows that the same hypothesis would cause solids, which are kept in equilibrium by radiation, to be also in thermal equilibrium when brought into contact; the equilibrium depending upon collisions of the molecules.

A kinetic theory of melting and boiling.

BY H. T. EDDY OF CINCINNATI, OHIO.

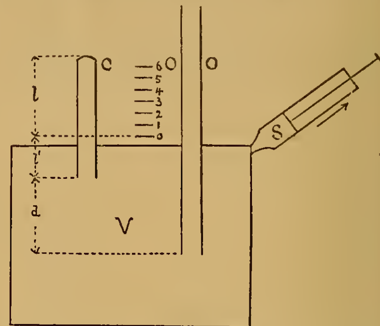
IN a solid in which the molecules are evidently held at nearly fixed mean distances by cohesive and elastic forces, there are two kinds of partially constrained freedom of motion possible for each molecule as a whole: first, a motion of its centre in a small orbit of more or less irregular shape about a mean position; and, second, a more or less irregular pendular motion of oscillation about a mean directional position. Both of these motions can be treated as vibratory motions; and the laws of force under which the motions occur, though somewhat unlike, have a general resemblance.

Two forms of apparatus for Boyle's law.

BY B. F. THOMAS OF COLUMBIA, MO.

THESE pieces are intended to enable one to adjust with accuracy and ease the mass of air to be experimented upon.

V is an iron cistern into which the open or pressure tube O, the closed tube C, and the reversible air-syringe S are screwed air-tight, and the cistern nearly filled with mercury. The syringe being connected for exhausting, and operated, air is withdrawn from C, until the mercury sinks to the bottom of the open tube, when air escapes from it, and rises through the mercury. No more air can be withdrawn from C. The mass of air remaining in C will evidently depend on the difference in depth of immersion of C and O. Let d = this difference, and let it be required to find such a value of d as will permit just enough air to remain in C to fill it from the zero of the scale, when at atmospheric pressure H. Let L = length of C from top to zero, and let l' = the length from zero to the open end of C. If now the mass of air which

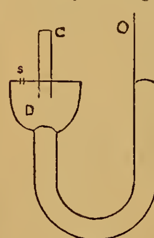


will fill the length l at H be expanded to fill the length l', the pressure H' at the bottom of C by Boyle's law is $H' = \frac{Hl}{l+l'}$.

The pressure at the open end of $O = H$. The difference in pressure at the ends of C and O is that due to a column (d) of mercury. Hence $H' = H - d$. Equating, $H - d = \frac{Hl}{l+l'}$. $\therefore d = \frac{Hl'}{l+l'}$.

On reversing the syringe, and forcing air in, the mercury will be found to rise and stand at zero in both tubes together. The demonstration is continued by forcing in more air.

A second form consists of two glass tubes connected by a strong rubber tube, and mounted on a stand with scales. The closed tube C is sealed into the screw-cover of an iron cistern D. Mercury being poured in, it will expel the air in D, and rise in an open screw-hole S in the cover. The hole being sealed by insertion of the screw, and O lowered, the air in C expands, filling C and D. On raising O, the mercury rises, and cuts off communication between C and D, preventing the return of some of the air. By making D of proper volume, the desired mass of air will remain in C. Let the volume of C above the zero = V. Let the entire volume of $C = V'$, and the volume of D above the open end of $C = V''$. Following the above steps it will be seen that a volume V' at H becomes a volume $V' + V''$ at H'; also that a volume V at H becomes a volume V' at H'. Hence the proportions $V : V' :: V' : V' + V''$, $\therefore V'' = (V' - V)\frac{V'}{V}$. The use of the rubber tube is not new: the method of adjusting the air-mass is be-



lieved to be. This form is convenient because it answers for demonstrating the law at pressures above and below one atmosphere. Of course, for the latter, the air in D must be removed through S as at first.

Natural snow-balls or snow-rollers.

BY SAMUEL HART OF HARTFORD, CONN.

The author carefully described the production and appearance of snow-balls or snow-rollers, the result of natural causes, of which a fine example was presented in Connecticut and southern Massachusetts last February. Snow had fallen, and had been covered with a frozen surface by a light subsequent rain. Upon this surface fresh snow fell, and this under the influence of wind was collected in masses of differing shapes. Some were spherical, from one to nine inches in diameter; most were rollers shaped like muffs, cylindrical, with a conical depression at each end reaching nearly to the middle. The largest observed by the author was 18 inches long, and 12 inches in diameter; but some were reported much larger. The path of formation showed that the roller had started with a small pellet, and, gaining both in length and diameter, had rolled up a long isosceles triangle of snow from its vertex. These paths were observed of a length of 25 to 30 feet, and others were reported as of 60 feet. The paths of the round balls were of nearly the same width throughout. None of these masses could be lifted without breakage. Such rollers were seen over an area of 40 miles in length: the author believed that they must have been millions in number.

Remarks on the tracings of self-registering instruments, and the value of the signal-service indications for Iowa, in June and July, 1883.

BY GUSTAVUS HINRICHS OF IOWA CITY, IO.

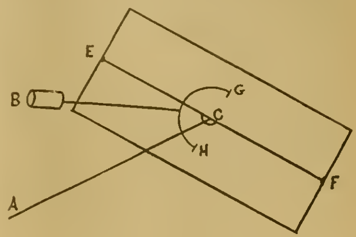
This paper was mainly a severe criticism on the work of the signal-service bureau. The author claimed that the predictions of the weather for Iowa in June had been quite untrustworthy, only 50 per cent proving correct. His views as to the value of this service were vigorously combated in a discussion which followed the reading of his paper.

A new heliostat.

BY B. F. THOMAS OF COLUMBIA, MO.

The instrument is intended to throw the reflected ray horizontally in the meridian.

A polar axis A C, driven by clockwork, is provided with a declination-arm E F, with arc, pivoted at C, and pivoted to the longer axis of the mirror at E and F. A 'horizontal axis' B G H, with the shaft portion B supported (by proper bearings in the standard not represented) in the same vertical plane with the polar axis, is pivoted to the mirror in its shorter axis at G and H, the points E C F G H being always in one plane, and G and H so adjusted that a line through them will pass through C perpendicular to E C F. Moreover, the axis of the shaft portion B, extended, is perpendicular to and bisects G C H at C. In order that the reflected ray be thrown horizontally in the meridian by our mirror, two conditions must be met: viz., 1°. The longer axis of the mirror must make and maintain the proper angle between itself and a line from C to the sun; or, what is



the same thing, the angle A C E must equal latitude plus one-half the sun's altitude at noon. 2°. The shorter axis must move in a vertical plane, perpendicular to the meridian; or, in other words, the prime vertical. These conditions are rigidly met by the above combination.

The static telephone.

BY PROF. A. E. DOLBEAR OF COLLEGE HILL, MASS.

In the static telephone, a ring of hard rubber is used, within which are two parallel metal-plates separated by a body of air (a non-conductor), one plate connected with the line carrying the current. The electrifying of one plate then causes attraction or repulsion of the free plate, and thus a sound in the receiver. This does away with magnetism. This system therefore requires a very large electro-motive power, and uses an induction coil of 2,000 ohms. A ground or return circuit is not present here. The equivalent is the body itself. There is no passage of electricity from plate to plate: the action is purely inductive through space. The insulation is accomplished by the intervening air-space, and by a coating of varnish, — an excellent di-electric. There is a device to discharge the induction plate in connection with this instrument, which keeps it constantly up to its full possibilities. When this instrument is fully charged, and the electrical conditions are perfect, the receiver may be entirely disconnected from the transmitter, and sounds and conversation can still be heard, even across a room.

He also called attention to the fact, that instruments that have been in use work much better than new ones, as each plate acts as a condenser.

In the discussion which followed, Dr. Dolbear was asked if the state of the atmosphere, in any way, affects the operation of the instrument. I have used these instruments, said he, on an actual line between Boston and New York, in a night when it rained over the whole length of the line, and the whole line was as badly insulated as it well could be. I have also used it on the same line under the most favorable conditions for insulation, and could not really perceive much difference. It seemed to be as loud at one time as at another.

Pres. H. A. Rowland. — Of course this is on an entirely different principle from our telephone. What interested me considerably was the fact, that one could hear better when the plates were charged. The explanation theoretically is very simple, and it is the same as that the Thompson electrometer is more sensitive when the jar is charged than when it is not charged; the reason being, that the attraction is proportionate to the square of the difference of the potentials, rather than the simple difference of the potentials. Therefore a small difference in the quantity, when it is large, produces a greater effect than when it is small. So the explanation is exactly the same as that the Thompson electrometer is more sensitive when you have the jar charged than when you do not. So, the higher the charge one would get, the more sensitive the instrument would be. I was especially interested in it, because it was on such an entirely different principle from the Bell instrument. I don't wish to say any thing about patent laws or decisions on this subject, for they have nothing to do with this; but, scientifically, this is an entirely different instrument from the Bell instrument, and I am especially interested on that account.

Prof. T. C. Mendenhall. — I profess not to have quite understood the statement made by Professor Dolbear. I should like to hear your own (the president's) opinion with regard to that charge which remains in spite of the fact that the two poles of the condenser are connected by conductors. I may have misunderstood the statement; but if that is correct, I should like to know whether that can be explained or not.

President Rowland. — Well, I suppose we all know how retentive an electroscope is of a charge. I suppose the idea is very similar in this case. I do not suppose the plates have a difference of potential. If you should leave them for a moment, I should suppose they would soon have a little return charge. If the two plates of the condenser were together, they would have the same potential. I understood it as merely a return charge. I do not know how Professor Dolbear understands it.

Professor Dolbear. — The instrument itself is a most delicate electrometer when tested in this way; and when it is charged and really in good working order, the gentlest tap upon the instrument serves to show that it is in good working order, for one can apply the instrument to his ear and hear himself talk. This is the case, even when the two plates of the condenser are connected with each other through the induction coil; and so, although they may have been there for hours, or even for days, — the difference between an instrument that has not been used and one that has been charged is very appreciable.

President Rowland. — I suppose in that case it would be simply from the charge of the varnished surface?

Professor Dolbear. — Yes: I think they retain their charge for a much longer time if the surface is varnished. I do think there is a difference between the behavior of this and the charged cable. If a cable be charged for half an hour by battery, it will require half an hour to run out again, but it will be at that time quite discharged. But that is not the case with this instrument.

President Rowland. — I should suppose it was the charge in the varnished surface.

Prof. W. A. Anthony. — Professor Dolbear did not say any thing about one advantage that this telephone has over the other, that struck me when I read the descriptions of it earlier, — that, in consequence of using this electricity at such a high potential, the ordinary telegraph-lines or other instruments would have very little effect upon it: therefore the telephone is very free from induction.

Professor Dolbear. — My experience has been in accordance with that theory. Electro-motive force from induction from telegraph-lines is ordinarily tolerably small, although there may be at times considerable strength of current. But, the electro-motive force being so strong in my circuit, it follows that the action of such induced currents is very slight, and does not interfere with work.

Prof. C. A. Young. — I would like to inquire whether you have tried any experiments in putting the end of the wire to the ear to illustrate the sensitiveness of the ear?

Professor Dolbear. — Yes: I have heard simply by putting the end of an insulated wire to my ear, and listening. I consider the instrument as simply the enlarged terminal of a wire, and that you are actually listening at the end of a wire.

Mr. E. Gray. — I have made a good many experiments in another line, which I may state briefly, which may throw some light upon this, and yet I think it is very well understood. You remember, some of you, reading of such experiments made in 1874, relating to the reproducing of music on a plate by simply rapping with the finger or with some animal tissue. Now, I made this experiment, which seems to prove to my mind that the operation is as Professor Dolbear has explained it. I set my revolving disc, which was a simple disc of zinc, revolving at a steady rate, giving it a pressure with the fingers. Then I had fifty cells of battery set up, as much as I could bear, passing through them, and had some one close the circuit with a Morse key. At the same time the key was closed, my finger would be jerked forward in the direction of the rotation of the disc; and it would remain in that forward condition, showing an increase of friction, until the key would be opened, and then it would drop back; showing that from some cause there was an increase of friction, either due to molecular disturbance, or, what is probably the case, to attraction between the finger and the plate. It is necessary, to produce this experiment, that the cuticle be perfectly dry. You must rub it a long time, and have it perfectly polished; and then the cuticle becomes a dielectric, and the body is charged with one kind of electricity, and the wire or the plate with another. Later I got some fairly good results in articulation by using a small diaphragm with all the conditions as nearly right as possible; and, having a current of sufficient electro-motive force, I could actually understand words produced on the end of my finger.

President ROWLAND. — What is the difference between that and Edison's motorphone?

Mr. GRAY. — In Edison's motorphone, when the current was thrown on, there was a decrease of friction; there was chemical action taking place on the surface. In this case there is none, and there is an increase of friction when the current is on: perhaps 'current' is a bad word to use.

President ROWLAND. — The principle is the same.

Mr. GRAY. — One is a chemical action, which causes the friction to be less at the moment of charge. In this case, however, this is purely static contact, and increases the friction in the same manner that the plates are thrown together when they are charged in this telephone. And the motion, of course, or sound, is produced by a letting-go of the finger from the plate, and not by actual vibration, in the same sense that it takes place between the two plates in this receiver of Professor Dolbear.

President ROWLAND. — You attribute it to attraction?

Mr. GRAY. — Yes: my experiments seem to prove that; I presume, because there was adhesion, there was an increase of friction during the time of the charge and the letting-go, when the circuit was open. There was really no circuit except when the charge was taken off.

Sec. F. E. NIPHER. — In regard to the case of which Professor Dolbear spoke, when it might be supposed that electricity does actually pass from the line into the ground, it seems to me that that fact, so far as it did exist, would be prejudicial to the action of the instruments; that what we want to bring about is not a current, but as great a difference of potential as possible, between the plates.

PROCEEDINGS OF SECTION C. — CHEMISTRY.

Report of the committee on indexing the literature of chemical elements.

THE undersigned, a committee appointed at the Montreal meeting of the American association for the advancement of science, "to devise and inaugurate a plan for the proper indexing of the literature of the chemical elements," respectfully submit the following report.

The members have conferred with each other orally and by correspondence. Several plans have been suggested, and their merits discussed. Three methods of collecting material for the indexes may be named: —

1°. Revising the Catalogue of scientific papers published by the Royal Society (8 vols. 4to).

2°. Indexing special journals by different individuals, and collating the matter.

3°. The independent plan, whereby each chemist indexes all the journals available to him with reference to a given element, in which he is presumably especially interested.

Each of these schemes is open to objections, and has its difficulties. The first would necessitate an enormous amount of clerical labor, for which volunteers would scarcely be secured; besides, data previous to 1800 could not be obtained from this catalogue.

The second involves, also, securing a large number of self-sacrificing volunteers; and both plans would require a vast amount of editorial work on the part of this committee.

The third plan seems, to a majority of the committee, the only feasible one at present. On the independent plan, seven indexes have already been compiled. The best arrangement of material has also been considered; and here again a threefold problem occurs: —

1. Chronologically.
2. Alphabetically, by authors.
3. Topically.

The committee do not venture to dictate to independent workers, but recommend the chronological arrangement, with the understanding that a topical index accompany each monograph.

The best channel of publication has also been considered by the committee. All the indexes hitherto published have been printed in the annals of the New-York academy of sciences; and the academy has generously offered, through its officers, to continue its good work. The Smithsonian institution further agrees to distribute, free of expense, all circulars and documents in furtherance of this undertaking; an offer which is of greatest importance, and for which this committee expresses sincere thanks.

Since the appointment of the committee, Mr. Webb's index to the literature of electrolysis has been published in the annals of the New-York academy of sciences; and several chemists have expressed a willingness to co-operate in the proposed undertaking. Prof. R. B. Warder of Cincinnati has promised an index to the literature of the velocity of chemical reactions; and Dr. Henry Leffmann of Philadelphia proposes to index the important element arsenic.

Your committee present to the association this brief report of progress, and respectfully desire to be continued.

H. C. BOLTON, *Chairman;* IRA REMSEN; F. W. CLARKE; A. R. LEEDS; A. A. JULIEN.

PAPERS READ BEFORE SECTION C.

On γ-dichlordibrompropionic and γ-dichlorbromacrylic acids.

BY C. F. MABERY AND H. H. NICHOLSON.

When dry chlorine is passed through β-dibromacrylic acid, the reaction is easily accomplished, and the product may be purified without difficulty by crystallization from carbonic disulphide. This acid is very sparingly soluble in water, more soluble in hot than in cold carbonic disulphide and chloroform. It melts at 100°. Its salts were carefully studied, but the silver salt was found so unstable that it could not be prepared in a state of purity. Since β-dibromacrylic acid has, without doubt, the form

$$\begin{array}{l} CBr_2 \\ \| \\ CH \\ | \\ COOH \end{array}$$

, the chlorine addition product would have the form

$$\begin{array}{l} CBr_2Cl \\ | \\ CHCl \\ | \\ COOH \end{array}$$

. This acid is entirely decomposed when heated with an excess of any alkaline hydrate. If, however, the reaction is allowed to progress in the cold, keeping the hydrate in slight excess, the elements of hydrobromic acid are easily removed, with the formation of the corresponding dichlordibromacrylic acid. In order to distinguish this from two other products which have already been obtained, it will be called the γ-acid. It is prepared by the action of baric hydrate upon γ-dichlordibrompropionic acid, and the reaction proceeds so rapidly that it is difficult to keep the solution alkaline. Upon acidifying the baric hydrate solution with hydrochloric acid, γ-dichlorbromacrylic acid is precipitated partly as a crystalline solid, and is easily purified by crystallization from hot water. It is sparingly soluble in cold, readily in hot water, and in alcohol, ether, carbonic disulphide, and chloroform. It crystallizes in pearly-white scales, which melt at 78° to 80°. For further identification, the acid was analyzed, and its salts submitted to careful study.

The sub-aqueous dissociation of certain salts.

BY JOHN W. LANGLEY AND CHARLES K. McGEE OF ANN ARBOR, MICH.

The question as to whether salts are dissociated into their components when simply dissolved in water has been attacked by different chemists in various ways. The method described in this paper seems to have furnished some remarkable results, which may help in pointing the way to the final answer of this important problem.

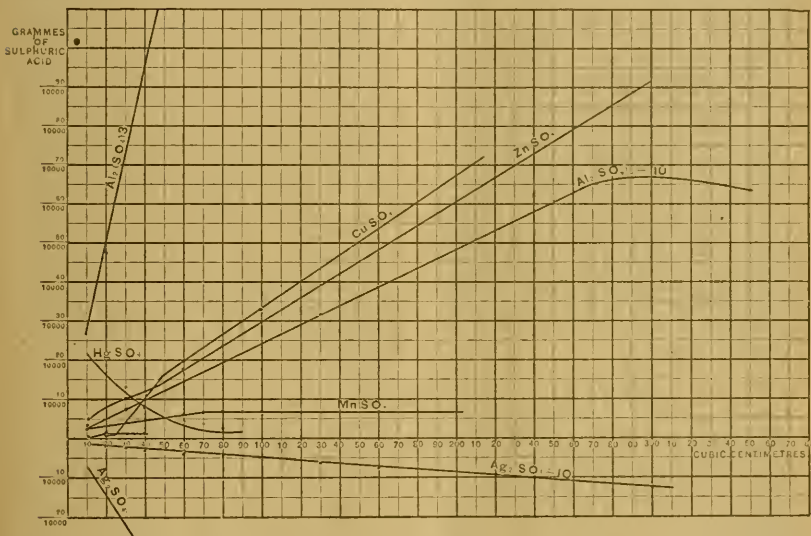
Sainte Claire Deville has called attention to apparent chemical changes which a salt may undergo by the mere fact of solution, and that such changes may increase in extent with the mere addition of water. He concludes that there is no absolute distinction between solution and chemical union; that the difference is rather of degree than of kind. From this point of view, a salt in dissolving has its particles separated much as if it were vaporized by heat, and the heat units necessary to perform this sort of vaporization are taken from surrounding bodies. As the heat absorbed increases with the degree of dilution, it will eventually become sufficient to dissociate into its elements a salt dissolved in a suitably large quantity of a neutral solvent, such as water.

Assuming that salts tend to dissociate by solution, and are decomposed when sufficiently diluted, we should expect them to break into simpler molecules first, and, of course, along the lines of least resistance. We may take three views of the possible condition of a salt dissolved in a small quantity of water — as, for instance, one molecule of sodic sulphate in two molecules of water: 1. That it is attached to the water by a sort of physical adhesion, which may be represented by $[Na_2\ SO_4\ ,\ 2H_2\ O]$. 2. That the water and salt are united in a new group which acts as a compound molecule so long as the amount of the solvent is small; this might be $[2\ (Na\ OH)\ ,\ H_2\ SO_4]$, the comma indicating a molecular as distinguished from an atomic union. 3. That we have in these cases a certain quantity of different kinds of matter held momentarily in equilibrium, but ready to form definite combinations when the external forces change. The last view would be expressed by $[Na_2\ H_2\ SO_6]$, and does not require that Na be combined with H, S, or SO_4.

The heat of combination between $H_2\ SO_4$ and 2Na OH is less than that in the formation of sodium hydrate starting with metallic sodium and water, or of sulphuric acid starting with SO_3 and water. Therefore, in the group $Na_2\ H_2\ SO_6$, the line of least resistance probably passes through where the comma is placed in the arrangement $[2\ (Na\ OH)\ ,\ H_2\ SO_4]$. Then the first stage of dissociation will be the appearance of free sodium hydrate and free sulphuric acid. The change will be partial for finite ratios between quantities of the salt and the water, and should gradually increase with augmented dilution to a point where free acid can be shown quantitatively.

For the present occasion, advantage was taken of the circumstance that in some neutral salts the bases have less power to turn litmus blue than the acids have to turn it red; and also, that in certain other salts the converse is true. Thus the power of the hydrates of zinc, iron, and copper, to turn litmus blue, is quite feeble; while the power of the mineral acids to redden litmus is very great. On the other hand, the hydrates of the alkaline metals are singularly powerful in turning litmus blue. Now, if the power of the base to produce the blue is not the exact quantitative counterpart of the acid to produce red, the difference of color-producing power must increase in proportion as the solution becomes more dilute, if the theory of dissociation is well founded.

The method of experiment may be briefly stated. A series of test tubes was prepared, holding respectively one, two, three, four, etc., portions of sulphuric acid; and each was then diluted with litmus solution to an equal amount. The tubes thus filled presented a series from neutral purple to decided red. This formed a scale of colors for reference. Saturated solutions were prepared of the sulphates of Zn, Cu, Pb, Ag, Ca, Na, Hg, Mn, Al, and Fe, and Zn Cl_2. To each of these solutions, enough litmus solution was added, in a series for each salt, to exactly correspond in amount with the sulphuric-acid tubes. As each tube of a dissolved salt was prepared, and also as it was successively diluted with increasing amounts of litmus, it was compared with the tubes in the color-scale, by looking across the two tubes, until its corresponding tint was found. A complete record of these correspondences was made; and it furnished the means for constructing a diagram, in which the results are plotted in curves.



The following were the chief results: Ca So_4 and Na_2 So_4 each continued to act as a neutral salt, without effect on the litmus throughout the range of dilutions. Ag_2SO_4 was the only salt which changed the solution to a blue. The results with Fe_2 $(SO_4)_3$ and Fe SO_4 were unsatisfactory because of a dirty precipitate, but both made the litmus red. Zn Cl_2 presented a similar difficulty. There is a doubt about the result with Hg SO_4, and some obscurity about the greatly diluted solutions of Al_2 $(SO_4)_3$ and Cu So_4.

On account of instability of color, probably caused by oxidation, a fresh color-scale had to be prepared every day, and the mixtures were made under a film of paraffine.

These experiments seem to indicate that: 1°. Sulphates of the alkali metals, except silver, are strictly neutral under all degrees of dilution. 2°. Sulphates of the R. SO_4 type, where R is a dyad metal, show an amount of dissociation proportioned to the degree of dilution. 3°. Aluminic sulphate, and other double triads, are not neutral when concentrated. When diluted they soon become strongly acid. When the dilution exceeds a certain limit, they lose acid at a decreasing rate.

Suggestions for computing the speed of chemical reactions.

BY R. B. WARDER OF CINCINNATI, O.

THIS paper urges a thorough discussion of data upon the subject indicated in its title, for the following reasons: 1°. To discover and investigate the causes of certain discrepancies between published observations and current theories. 2°. To obtain more definite information as to the nature of certain reactions and the conditions determining their speed. 3°. To afford numerical data for a fuller study of relations between the speed of reactions and other physical constants. 4°. To suggest fruitful lines for further research in chemical dynamics.

As instances of the need of such discussion, the determinations by Professor Menschutkin, of the speed and limits of the etherification of the several alcohols and acids, give numbers for the initial speed of reaction in one hour which are not proportional to speeds during the first minute. Prof. L. Meyer in his *Dynamik der atomen* passes very lightly over both the theory and the observations of speed during a reaction.

The prevalent theory of the action of mass is expressed, $\frac{du}{dt} = kuv$ . . . in which the differential expresses the rate of change in any substance, u and v represent the masses taking part in the change, and k is a constant. Some observations by Ostwald and others indicate that some modifications of this theory are needed. Determinations of the speed of reaction require special care, both to measure time in relation to mass, and to control temperature and other conditions. The chemical section of the Ohio mechanics' institute has recently undertaken some work of the sort, and invites co-operation.

The following provisional system is suggested: for volume, one cc.; for mass, the chemical equivalent expressed in mg.; and for time, one hour. The unit of speed would be the transformation of unit of each active body per unit of volume and time. Possibly the comparison of the constants of speed or of chemical affinity with those of heat, electricity, etc., could be better made from the unit of one second or 1,000 seconds. At least two observations of time and two of mass are required, and preferably several, to determine the limits of error. Determinations which do not accord with the hypothesis that diminished speed and diminished product vary in the same ratio, need special investigation. In reciprocal reactions, some of the ratios may be combined with constants of speed already determined. By bringing all the facts into systematic order, these data can be made of use for comparison in other physical-science fields. The paper concludes with an extended bibliography of the subject, which will be very serviceable to workers in this branch of research.

Twelve months of lysimeter record at the New-York agricultural experiment station.

BY E. L. STURTEVANT OF GENEVA, N.Y.

THE lysimeters were described. They are boxes of peculiar construction, containing selected samples of soils in layers. The relative percolation of rainfall through these different soils, and the evaporation, are determined by observations of the instrument. The results are summarized as follows: Sod land allowed 11.68 of the rainfall to percolate; soil of which the surface was simply bared allowed 25.88 per cent percolation; the cultivated soil passed 37.93 per cent. The evaporation from the first of these was, of course, 88.32 per cent; from the second, 74.12; from the third, 62.07; the sum of percolation and evaporation being held to account for the entire rain-fall.

The composition of American wheat and corn.

BY CLIFFORD RICHARDSON OF WASHINGTON, D.C.

THIS paper gave an account of results obtained by the author in his work as first assistant chemist of the U. S. department of agriculture. More than 200 analyses of wheat, and 100 of corn, have been made during the last ten years under his supervision. It appears that while our wheats are of somewhat lighter weight, they contain less water, about the same ash, more oil, less fibre, and less albumen, than the foreign wheats. Among our wheats, only those from Colorado, Dakota, and Minnesota equal the European in albuminoids and in size of grain. The wheats of the Atlantic states are poor in nitrogen. Corn, compared with wheat, contains twice as much oil, less starch, more water and fibre, and less of albuminoids. The following table gives a condensed statement of the wheat analyses: —

Average percentage of nitrogen, albumen, etc., in wheats of the world.

COUNTRIES.	No. of analyses.	Per cent of nitrogen.	Per cent of albumen.	Highest albumen.	Lowest albumen.	Weight of 100 kernels.	Highest weight.	Lowest weight.	Authority.

The sotol, a Mexican forage plant.

BY CLIFFORD RICHARDSON OF WASHINGTON, D.C.

This plant, Dasylinion texanum, grows wild and extensively on the borders of the Rio Grande and elsewhere in Texas, and in Mexico, on a rocky and gravelly soil. The plains covered with it look like a vast cabbage-field. Sheep feeding on it go without water for many weeks. Only the bulb is eaten. It is split open by the shepherd, who carries a knife for the purpose. Mexicans eat the bulb after roasting or baking it in pits. Also a liquor is obtained from it, by fermenting and distilling after roasting, called 'sotol mescal,' and possessed of highly intoxicating powers.

The plant is described in Watson's Revision of the North-American Liliaceae. About 18 per cent of sugar can be obtained from the outer husks; in the interior, more than 10.5 per cent exists: and in the whole head of the plant there is probably more than 15.5 per cent of sugars. No starch seems to be present.

A proximate analysis of the soft interior of the head gave 17 per cent sugars: 65 per cent of this soft substance in the head, when fresh, is water.

As a food-plant in dry districts, the sotol is of great value; as a fibre-producing plant, it will not be of any importance, owing to the shortness of the cells.

American butters and their adulterations.

BY H. W. WILEY OF WASHINGTON, D.C.

A series of elaborate experiments and analyses of various samples of butter, oleomargarine, tallow, and lard, have been made by Professor Wiley, chemist of the U.S. department of agriculture. The paper contained a description of Professor Wiley's method. He takes a weighed quantity of the butter, puts it in a sand-bath, and dries for two hours at 100°. The curd or caseine is determined by ignition: five grains are used for the purpose. Dry combustion in a tube is difficult and unsatisfactory: he therefore uses the moist-combustion method, with permanganate and nesslerizing. The amount of salt he considers important. It is usually determined by ignition, and weighing the residue; but he found that so much chlorine was thereby lost, that the result was not trustworthy. He washes the butter by shaking it in a separating funnel with hot water, and then determines the chlorine with standard silver nitrate and potassium bichromate as an indicator.

Professor Wiley has devised several novelties for these analyses. One of the neatest is for ascertaining the melting-point. The butter is packed in a U-shaped tube, of which one leg is longer than the other. The tube is placed upright in a vessel containing sufficient mercury to overflow the top of the tube. This vessel is placed in another containing water, and heat is applied beneath. The water, heated, in turn heats the mercury surrounding the tube, until the contents of the tube are melted. As soon as the melting takes place, the melted material leaves the tube, and floats on the surface of the mercury. Another method consisted in laying platinum wires upon the sample of butter, etc., heating the wires, and noting the heat required to cause them to disappear by sinking into the sample. These methods determined not only the melting-point of samples of butter, oleomargarine, tallow, and lard, but also of the fatty acids. But the variations in the melting-point of genuine butter are so wide, that no certain conclusion can be arrived at by comparison with melting-point of oleomargarine, etc., to test the question of genuineness. Thus it was found that first-rate butter from an Alderney cow at one time, owing to special feeding, had a higher melting-point than oleomargarine; while a few weeks later, with different food, the same cow supplied milk from which was made butter with a lower melting-point than oleomargarine.

In regard to other tests, concerning which full details were given in the paper, it may be briefly stated, that, as a general rule, the amount of caseine present in pure butter is much greater than in oleomargarine. The specific gravity of genuine butter is lower. The saturation co-efficient for the insoluble acids in the genuine butter is low, in the imitations it is high. Professor Wiley seems to place more reliance on tests for saturation co-efficient than on other methods. The soluble fatty acids in pure butter range from three to five per cent; while in oleomargarine, tallow, etc., they are either absent, or show a mere trace. The author also called attention to polarization tests. The genuine butter gives a uniform field in polarized light: oleomargarine gives a field with mottled and crystalline structure. He had made no analysis of butter known or suspected to be adulterated by mixture. He considered it unwise to decide the question of genuineness from any one of the constituents or conditions of a sample; believing that all the different tests should be brought to bear. He presented elaborate tables of analyses of different kinds of butter, etc; specifying for each the place of purchase, name sold by, price, color, percentage of water, of caseine, of salt, specific gravity at 40°, melting and solidifying points, percentage of soluble and of insoluble acids, and the melting and solidifying points and the saturation equivalent of the insoluble acids.

The discussion respecting the analysis of butter which was brought about by this paper revolved around the question of the value of the data presented for the practical work of the determination of actual proportion of adulteration. Mr. Noyes held that the variations in pure butters in specific gravity, in melting-point, in saturation co-efficient, and in caseine, as determined by Professor Wiley, would be of little value except in cases where the adulteration was very great. Mr. Springer held that the principal constituent to be taken into account in the determination of adulteration was the amount of caseine, and that although there were some difficulties in the way of its accurate determination, they might be removed, and he should then have more faith in this than in the comparison of other data. He suggested that the accurate determination of caseine might be effected by some rapid-fermentation process by which caseine could be broken up into other organic products that could be separated by albumen. He held to this point as to caseine, because it cannot conveniently be added in the manufacture of oleomargarine; while the acids upon which the saturation co-efficient depends could readily be added as sodium compounds.

On account of the difficulty of getting accurate results in determining nitrogen, it was thought best to use the wet-combustion method with permanganate, because a small quantity of material might be used, and there would be fewer chances for loss that otherwise occurs in nitrogen determinations that are effected by the combustion of butters.

Dr. Wheeler called the attention of the section to the use of what is known as 'cotton-seed-oil stock,' in the manufacture of oleomargarine. This, doubtless, contains considerable nitrogen, and, of course, would reduce the value of the caseine-test for adulteration. A sample was shown, supposed to contain cotton-seed-oil.

The sense of the discussion was, that it was very desirable that Professor Wiley should continue his experiments, as they are of great value; but there is yet a great deal of work to be done in the investigation.

List of other papers.

The following additional papers were read in this section:— The formation and constitution of chlordibromacrylic acid, by *C. F. Mabery* and *Rachel Lloyd*. Orthiodtoluolsulfonic acid, by *C. F. Mabery* and *G. M. Palmer*. Estimation of carbon and nitrogen in organic compounds, by *C. Leo Mees*. New forms of burettes, by *W. H. Seaman*.

PROCEEDINGS OF SECTION D.—MECHANICAL SCIENCE.

PAPERS READ BEFORE SECTION D.

A comparison of terra-cotta lumber with other materials.

BY T. R. BAKER OF MILLERSVILLE, PENN.

The material called 'terra-cotta lumber' is made out of clay and sawdust. The investigation which formed the subject of this paper was to ascertain certain qualities of this artificial product. The paper also described the apparatus used for the tests. The results indicated that the material was 875 times as permeable to air as pine, and 135 times as brick. Air was forced by pressure of a column of water. Other tests showed that the material was four times as hard as pine, but not so hard as brick. Its grip on nails driven into it was about half that of pine. The author was careful to disclaim any intention of advertising the merits of the material, but he evidently regarded it as serviceable for the purposes for which it is intended. Specimens were exhibited.

Improvements in shaping-machines.

BY J. BURKITT WEBB OF ITHACA, N.Y.

In the ordinary shaping-machine there are two defects, one of which is found also in the planer. The ram of a shaping-machine is a bar sliding in bearings, and carrying at one end the cutting-tool. If we represent by a the variable horizontal distance from the tool to the first bearing (or nearest end of the long bearing), and by b the variable horizontal distance from the tool to the second or farthest bearing (back end of long bearing), and by c the length of stroke, we shall have,—

Maximum value of a = (minimum value of a) + c.
Maximum value of b = (minimum value of b) + c.

In other words, the length of the ram is variable, and the spring of the ram from the work is variable, the tool springing away from its work more at the end of its stroke. This springing takes place mostly in the joint between the ram and its bearings, and cannot be wholly avoided without a change of construction. To remedy the defect, the author proposes a reversed construction of the sliding parts; the two bearings (preferable to a long bearing) to be formed on the ram, so as to make the distances a and b constant, and the long slide being part of the bed of the machine.

The second defect, which is also common to the planer, is in having a 'drop-block' which fits but indifferently between the jaws and against the bottom of its seat. From the necessity of the usual construction, the tool attached to this block will have more or less spring. The remedy is to dispense with the drop-block, and introduce an automatic motion to lift the tool on the return stroke, as has been done, the author has understood, on some large machines.

Regularity of flow in double-cylinder rotary pumps.

BY J. BURKITT WEBB OF ITHACA, N.Y.

The speaker introduced his subject by exhibiting a number of models of these pumps from the cabinets of Cornell university, which has recently purchased copies (243 in number) of the celebrated models of the Reuleaux collection in Berlin. Class I. of this collection is devoted to these pumps. The speaker then produced and demonstrated a formula for the flow of these pumps, and showed that the regularity of flow depended upon other principles opposite to those which have been given for determining this point. The formula given for the flow was:—

$\pi[R'^2 + R''^2 - (r'^2 + r''^2)]$ = Flow for one revolution, when R' and R'' (generally equal to each other) are the extreme radii of the two revolving wheels; and r' and r'' are the radii (often, perhaps generally, variable) from the point of contact between the wheels to their centres. It was shown that the regularity of flow depends upon $r'^2 + r''^2$ = constant. R' and R'' may be called the 'piston radii,' and r' and r'' the 'valve radii.' These pumps are called by Reuleaux 'Kapsel räderwerke,' or 'chamber-crank trains,' according to Kennedy.

List of other papers.

The following additional papers were read in this section, some of them by title only: — A method of testing long plane surfaces, applicable to the alignment of planer-beds, lathe-beds, heavy shafting, etc., by *W. A. Rogers*. The commercial and dynamic efficiencies of the steam-engine; Centrifugal action in turbines, by *R. H. Thurston*. Velocity of the piston of a crank engine, by *C. M. Woodward*.

PROCEEDINGS OF SECTION E. — GEOLOGY AND GEOGRAPHY.

ADDRESS OF C. H. HITCHCOCK OF HANOVER, N.H., VICE-PRESIDENT OF SECTION E, AUG. 15, 1883

THE EARLY HISTORY OF THE NORTH-AMERICAN CONTINENT.

There is a special appropriateness in the association of geography with geology, as indicated in the assignment of sciences to section E; for the latter gives us an account of the origin of every topographical feature of the earth's surface, whether island, continent, mountain, plateau, valley, or oceanic depression. If we would properly understand the significance of the earth's contours, we must unravel the mysteries of geology: so a knowledge of topography is essential to the complete comprehension of the geological features of any country. If a geologist were taken by a balloon to an unexplored part of the earth, he would instantly recognize, from their topographical outlines, volcanic and granitic cones, limestone hills, elevated plateaus of basalt or horizontal sandstones, and special types of orographic structure. Hence the modern geologist first draws the contours of his district before applying the colors of geological age. The existing relief features of the earth have been produced one by one in successive periods; and it is the task of the geologist to discover what were the characteristic physical developments of the several ages. He can delineate a connected historical sketch of the beginning, growth, and completion of a continent. Such histories are rare, because attention has but recently been turned into this direction. One of the first American geologists to frame such an outline is Prof. J. D. Dana, to whom we owe the enunciation of this fundamental truth, — that the first formed land has always remained above water, and has been a nucleus about which zones of sediment have accumulated. We can now recognize this primitive continent, with all its successive stages of growth, upon every geological map.

Time would fail us to present the entire physical history of our continent; and we will therefore confine our attention chiefly to its earlier chapters, noting those points which are under discussion. As we are endeavoring to *advance* science, we must touch upon debatable topics, and hope by friendly discussions to become wiser.

We must assume the correctness of the commonly received opinions concerning the earliest history of our planet, — that it passed through the condition of a nebula, and then of a burning sun, the period of igneous fluidity. By subsequent refrigeration it has become either partially or wholly solid. Not until a crust had formed, and the earth had cooled enough to allow water to remain permanently, was it possible to talk of dry land and ocean. With these premises allowed, it seems to us evident that the material of the earth must be disposed in concentric zones, arranged according to density, the heaviest being at the centre. If the various elements were free to move, as is the case in all natural or artificial igneous fluids, we must expect to find the heavier metals situated beneath the others; and, following the analogy of extra-terrestrial bodies, the central nucleus may be principally iron, like the heavier meteors. Zones corresponding to stony meteors, lavas, the trap family, and granites would naturally succeed in order, the last named being at the surface. This outer zone is also characterized by the presence of much silica and oxygen. The primeval ocean came from the vapors surrounding the igneous sphere, condensed to liquidity as soon as water could remain upon the solid crust without immediate vaporization.

This original crust may have been essentially a plain, and consequently entirely covered by water; for if the land were now levelled off, the ocean would submerge every acre of the continents. As refrigeration progressed, ridges and valleys would form in accordance with that fundamental principle that the outer envelope must conform to the shrunken nucleus; and this contraction gives rise to that tangential force or lateral pressure which has acted through all time. Whether these earliest ridges rose above the ocean would depend upon the amount of elevation. Some authors argue that these ridges follow the course of great circles. If there are causes adequate to produce such results, — or any other world-wide arrangement, — they must have commenced to operate at the very beginning of contraction. Most authors maintain that the very thick strata of the older rocks have been formed just like modern sediments, having been broken off the ledges, and transported into oceanic basins in horizontal attitude. If so, there must have been great mountainous elevations, deep oceanic depressions, and extensive aqueous action; since the thickness of the crystalline schists is greater than that of the strata in the fossiliferous ages. The amount of distortion, crumpling, and faulting of the crystalline rocks is also greater. These same authors hold that the original strata were in all respects like modern sands, gravels, and clays, and that their present crystalline structure is due to metamorphism. No one has yet discovered any uncrystalline pre-Cambrian beds; nor have the original foundation rocks been pointed out, since the oldest known layers are stratified, and cannot therefore have constituted part of the original unstratified crust.

Professor Dana thinks the primitive land originated because of a difference in the rate of conduction of heat during the process of refrigeration. Cooling would be fastest where the heat was conducted most rapidly. The first areas to cool would be the first to solidify. The first solidified crust was heavier than the adjacent liquid: so it sank until it found a fluid as dense as itself. Then the liquid above this crust would in turn become solid, and sink; and this process is supposed to have continued until a permanent shell had become fixed in the earth's circumference, which constantly increased in breadth and thickness, becoming continents. Meanwhile the other portions remained liquid; and their surfaces must have stood at the same level with the first-formed crust till that congealed, and became depressed because of the diminution of volume in solidification. These depressions became the ocean's beds. From this beginning down to the present time the processes of growth have consisted in the thickening of the continents and the settling-down of the oceanic depressions, while the chief force employed has been the lateral pressure derived from contraction. LeConte and Pratt express the process thus far described by the term 'unequal radial contraction.' The total gravity of the particles of matter along each radius is supposed to be the same; and hence, if the heat is conducted most rapidly over the shorter radii composed of denser minerals, the ocean-basins would cool first. These two views thus demand a different arrangement of the lighter and denser materials; the one necessitating that the continents, and the other the depressions, were first to congeal. Both, however, make the gratuitous and unproved assumption, that the surface was not uniform in composition; the differences being probably like that between granite and trap. The principle stated above — that, where all the particles are free to move in a liquid, the lighter elements must rise to the surface, and the heavier minerals sink down in proportion to their specific gravity — is at variance with this assumption. Fortunately it is not essential to a right theory of continental growth. There is no reason, therefore, to doubt that the original crust had essentially a uniform thickness over the whole earth. Contraction would originate ridges and valleys in the normal way, most likely of similar dimensions. There must soon burst forth ejections of igneous matter, owing to tidal attraction; and these would show themselves along the weakest lines. At the outset it is difficult to assign reasons why either the elevations or depressions would be the weaker; and hence we should look for a multitude of locations of igneous overflow, both over the future continents and oceans. There may be no better reason for the eventual enlargement of certain of these volcanoes than that circumstances only very slightly favored them; but, this favor being continued, they would exist and enlarge at the expense of the others, affording us another illustration of the 'survival of the fittest.'

It seems to us there is now afforded an opportunity for reviving in a modified form the view of Poulett Scrope in regard to the origination of the earlier crystalline deposits. Suppose we say, that, besides the original unstratified igneous granitic material, the oldest stratified crystalline rocks are derived from volcanic ejections; being the continued enlargement in size, and reduction in number, of the early indeterminate vents. The several ejections would increase in size till they became islands, either gneissic or granitic; and, if an archipelago is allowed us, we can easily show how continents would accumulate, using only the universally acting forces of lateral pressure and sedimentary accumulation.

Of other theories relating to the origin of the earlier crystalline beds I may mention two. The first is that advocated by Lyell, who termed these rocks *hypogene*. After the solid granitic crust had been formed by refrigeration, "the hot waters of the ocean held in solution the ingredients of gneiss, mica-schist, hornblende-schist, clay slate, and marble, — rocks which were precipitated one after the other in a crystalline form" (Lyell's Principles of geology, 10th ed., i. 142). In such a menstruum, life could not have existed. A very similiar view was advocated by Dr. T. Sterry Hunt in his presidential address before this association in 1871.

The second is the view more commonly entertained, — that, after the solidification of the crust, sedimentation accumulated stratified systems from the granitic foundations, as ordinary sand, gravel, and clay, which were subsequently acted upon by thermal and aqueous influences termed *metamorphic*, and thus converted into crystalline schists. The wide-spread and powerful action of metamorphism is conceded; but it is a more appropriate adjunct to volcanic than sedimentary accumulation.

A few of the considerations favoring our theory will now be presented.

1. Considering the igneous origin of the earth, volcanic energies would naturally continue their action as soon as there was a crust to be broken through, and immense piles of melted rock would ooze from the numerous fissures. Up to Laurentian times all admit the universality of igneous outflow, while but few have ventured to speak of any thing like volcanic action, except as it has been manifested in the formation of dikes in these early periods. There has been a tendency to class the ancient granites and porphyries with rocks of sedimentary origin, and consequently to restrict the action of igneous agencies to phenomena of slight importance. Several English writers, and, in our country, Dr. Selwyn of Canada, have been calling our attention to the existence of a volcanic group in later Huronian or early Cambrian times. These are the rocks so largely developed about Lake Superior, New England, and the Province of Quebec, consisting of stratified schists, diorites, diabases, amygdaloids, and felsites, identical in composition with true eruptive masses of the same name. Investigation shows that

oftentimes these schists are disposed like the lavas ejected from one series of volcanic vents. Suppose, for example, that Etna or Vesuvius should become extinct. In the course of ages the rains would obliterate the craters, and reduce the lavas to a rounded dome of greater or less regularity. We should recognize the volcanic origin of the mountain in the absence of craters from the lithological similarity of the rocks to those known to have been melted and ejected from vents, while the disposal of the material in a conical attitude shows us that it might once have been covered by craters. So we find in our eastern country many domes of diabasic or protogenic schists, whose volcanic origin may be predicated, both from their lithological character and physical aspect.

Now, this volcanic group of Huronian times indicates the existence of a greater degree of igneous activity than has been described for the paleozoic ages, even those of Great Britain ; and consequently this is an indication pointing significantly towards the predominance of thermal influences in the still earlier periods. In the Laurentian age the fires should have been yet more vigorous, because the time of universal igneous fluidity was less remote.

2. A careful study of the crystalline rocks of the Atlantic slope indicates the presence of scattered ovoidal areas of Laurentian gneisses. Those best known have been described in the Geology of New Hampshire. Instead of a few large synclinal troughs filled to great depths with sediments, the oldest group is disposed in no less than twenty-two areas of small size, scattered like the islands in an archipelago. In a chapter upon the physical history of the state, I have proposed the theory that the earliest land within its limits consisted of this series of islands, not packed as closely together as now, in an area of perhaps three thousand five hundred square miles, but as much more widely separated as would be determined by smoothing out the various anticlinals and synclinals that were formed later. By reference to our maps in Maine, Massachusetts, New Jersey, Pennsylvania, Virginia, North Carolina, and Georgia, many similar ovoidal Laurentian areas may be specified, usually larger than those of New Hampshire. This may be due partly to a less thorough knowledge of the exact areas occupied by this older gneiss, and partly to the existence of a greater number of volcanic vents, giving rise to a more widely spread and thicker mass of ejected material. Over the Atlantic slope and Canadian highlands these primeval islands have, in later periods, been cemented together by a subsequent deposition of material; but in Missouri, Arkansas, and Texas, we recognize, even now, these early islands.

3. The lithology of the Laurentian and other crystalline rocks is very like that of igneous ejections. It is proper at this point to recall the proper restriction of the term Laurentian. As originally defined by Logan, it included every formation that antedated the Huronian. In the Report upon the geology of Canada for 1877–78, Selwyn proposes to restrict the Laurentian outcrops to "all those clearly lower, unconformable, granitoid, or syenitic gneisses in which we never find interstratified bands of calcareous, argillaceous, arenaceous, and conglomeratic rocks." The Hastings and Grenville series, and all the schists containing the eozoon, are excluded from the Laurentian by this definition, as well as the Bethlehem, Lake Winnipiseogee, and Montalban groups of the Atlantic slope. The Laurentian is azoic, the other groups eozoic; and, unless newer distinctions are to be made hereafter, it looks as if we might claim these various azoic Laurentian islands as the first-formed dry land, as they certainly are the nuclei of the existing continents.

There are no minerals in these Laurentian islands that do not occur in eruptive granite; and the schistose structure is often so faint that the field geologist need not be blamed if he acknowledges his inability to detect it. Likewise we discover the same fluidal inclusions and the vacuoles that pertain to granite. If we follow Sorby and Clifton Ward in saying that granite has been formed beneath a pressure equivalent to a weight of forty thousand feet of strata, the same must be said of the early gneisses. With this general assertion of the identity of gneiss and eruptive granite, we must be satisfied at present, without entering into detail.

4. The analogy of the origin of oceanic islands at the present day suggests the igneous derivation of the Laurentian areas. Most of the high islands of the Pacific are composed of lava, with the volcanoes frequently in action. Hawaii, of the Hawaiian group, may illustrate their position and shape. Its area above the water-line is 4,210 □ miles, and its cubical contents above the sea-level are about the same with those of New Hampshire. It rises from a plateau over 16,000 feet deep, thus forming a cone 30,000 feet high, whose cubical contents must be twenty times greater than the portion making dry land. The length of the entire series of islands, all of similar character, is 350 miles, and the area of the base of the lava must be about 100,000 □ miles. These cones have been built up by the accumulation of lava ejected from the interior of the earth, and they are entirely isolated, the nearest land being 1,000 miles distant. The ground-plan of this volcanic mass is that of two elliptical areas, either of which is like some of our Laurentian islands, and is certainly as large as any of these ancient lands south of the St. Lawrence. The land area of the Hawaiian Islands is less than that of Massachusetts, but their base must be equal to the whole of New England and New York combined. Surely it cannot be avowed that volcanic areas are too small to be compared with the space occupied by our oldest formation.

The so-called lowlands are likewise of volcanic origin; since coral polyps have built up reefs upon the igneous area after the disappearance of the fire, and the Hawaiian areas are encircled by reefs. After the volcanoes have become cold, loose material would be worked in between them, coral reefs would grow, and, in various ways, the land area would be enlarged, and finally an archipelago may become a large island. It needs only time and a repetition of these constructive agencies to make a continent out of a series of archipelagos.

There are two points requiring explanation in this connection, — first, the supposed deeply seated localities where granite is produced; and, second, the origin of foliation in the schists.

We should naturally expect that the earlier igneous rocks would have been derived from reservoirs quite near the surface, because of the thinness of the crust. With this notion agrees the presence of cavities containing liquid, and of hydrated minerals, which are more common in the older eruptive rocks, and have led to the aqueo-igneous theories of the origin of granite. Water would be scarce at great depths, and hence these rocks ought to originate near the surface where moisture was abundant. It seems to us that this consideration should more than balance the arguments usually cited in favor of the origin of granite at enormous depths, as it is difficult to see how both can be true.

Mr. H. C. Sorby has led the way in studies of the mineral constituents of eruptive rocks. He measures the included cavities in the component minerals, and calculates how much the contained substances must have contracted in cooling, allowing for an increase in the temperature of the point of vaporization under pressure. By assuming the temperature to be correctly determined, he ascertains the amount of pressure indicated by mathematical formulae, and finds it to be the equivalent of a thickness of 40,000 feet of overlying rock in Cornish granites, and of 60,000 feet in Scotch granites. Later writers seem to have regarded this pressure as certainly produced in the way thus suggested, and that its appearance at the surface has been due to an enormous erosion which has denuded the overlying blanket. This conclusion is not necessary; for, 1°, an enormous pressure would result from the tangential force of contraction, which would be entirely adequate to have produced the cavities. 2°. The necessity of an erosion of 40,000 feet over all the granites in every part of the world cannot be maintained. In North America, for example, it would necessitate the supposition that nearly eight miles' thickness of rock had been removed from one-fourth of the surface since the Laurentian, for the blanket removed would have equalled in dimensions the crystalline areas. The mere statement of the amount of denudation required refutes the theory. 3°. By reference to existing volcanoes, it is plain that a column of lava will often be adequate to exert the needed pressure. Teneriffe rises 12,000 feet above the ocean, and its cone descends 18,000 feet more to the submarine plateau. When the crater is full of melted lava, there must be a pressure of 30,000 feet at the base of the cone: hence the lava from the reservoir supplying Teneriffe might exhibit the vacuities produced by a pressure of 30,000 feet without any weight above the peak.

When molten lava pours down the side of a crater, the included vapors and liquids must disappear because of the removal of the pressure; but, after a substantial crust has formed, the peculiar markings imprinted at the great depth would remain: hence we can understand how it is that the vacuities are to be seen both in granites and lavas that have been subjected to great pressure. At the Boston meeting of this association I endeavored to show that there are mountain masses of granite in New England possessing all the physical characteristics of volcanic cones. The material must have been liquid, hot, ejected from a vent, and flowed over a plateau, building up a cone, and indurating the underlying floor. It was claimed that such phenomena could be explained only by supposing the granite to have been erupted just like lava. This granite contained the usual vacuities indicative of great pressure just as they are also found in the lava of Monte Somma or the trachyte of Ponza.

When one examines the interior structure of modern lava-flows, he is surprised to find beds nearly as well defined as the foliation of schists. Around vents like Vesuvius or Etna the lava accumulates naturally in quaquaversal sheets, no one eruption being very extensive. When steam and hot water are copiously supplied from the caldron, there may be flows of hot mud and tufa. The closing phases of eruptions are usually showers of ashes falling upon the cone or beyond. If the vent is beneath the ocean-level, the lava is minutely subdivided and the deposit will be like sand or gravel. Between the igneous flows the ordinary aqueous agencies will wear off excrescences, and scatter the fragments down the slope. These various agencies will produce a concentric stratiform arrangement in the whole mass. Where the eruption is massive, a similar set of layers will be formed.

This mass of volcanic material will be very susceptible to metamorphic influences when placed under the proper conditions of heat and pressure. As the result, new minerals will be formed, arranged in foliated beds or schists. Thus briefly stated may be the origin of foliation. So long ago as 1825, Poulett Scrope advocated essentially this doctrine for the arrangement of the crystalline particles in the crystalline schists, having found an analogous structure in certain volcanic accumulations.

Sufficient has now been said in advocacy of our doctrine that the first land consisted of volcanic islands. This was the Laurentian or azoic accumulation. Cartographers have not yet distinguished the several crystalline deposits, so that it will not be practicable at present to point out the supposed volcanic areas of the Hastings, Grenville, Montalban, Huronian, and other eozoic periods. Sedimentation would also act so that in this age many beds must be referred to an aqueous derivation. By the close of the eozoic the continent was outlined; or at least the framework of the future superstructure was put into position. The broader patches about to be mentioned had their origin in the earlier numerous islands cemented by detrital accumulations.

The more important areas developed in the eozoic must have been Greenland, Canada east of Lake Winnipeg, the Atlantic district, the Rocky Mountains, the Sierra Nevadas, and numerous buttes over the Cordilleras. The three great depressions of Hudson's Bay, the Mississippi valley, and the Salt-Lake and Nevada basins commenced to sink very early, and the future growth of the continent consisted largely in filling them up with marine sediments. An inspection of a map drawn upon a correct scale will dissipate the fancied resemblance to the letter V, in the Canadian dominion, so often insisted upon. Neither has the development of the land been in bands parallel to the north-west and south-east arms of this supposed angle. A better conception would find three great basins, excluding the unknown regions of Mexico and Alaska, in each of which operations were conducted independently. The best known is that of the interior of the United States, or the Mississippi hydrographic basin. This depression was nearly encircled by a crystalline border of high land. Beginning at Alabama, we follow it to New England, thence by a slight gap to the Adirondack promontory, thence across the Lakes to the Dakota promontory. In Minnesota and Dakota the schists are more or less covered by cretaceous clays and tertiary sands; but they evidently constitute the floor for the surface strata occasionally piercing through the later deposit, as in the Black Hills. Thus we may connect the Dakota and Rocky Mountain crystallines. From Wyoming southerly the granites are again conspicuous into New Mexico. Thus the circuit is not complete: it is like a horseshoe, with the lower Mississippi valley in the gap; yet this may have been filled in the Cambrian age, since Laurentian islands are found in Texas, Arkansas, and Missouri. We might give reasons for believing in the recent origin of the depression between New Mexico and Alabama.

The map will show, around the borders of this Mediterranean Sea, the primordial sea-beach, whether examined in Virginia, New York, Michigan, Colorado, or Texas. Could we dissect the land, we should find an immense platter of Cambrian sediments coextensive with the crystalline highlands surrounding and underlying it. In Cambro-Silurian times the story is repeated. Marine limestones formed other dishes, each limited in size by the upturned edges of the platter underneath. The rest of the history is given in our text-books. Our Mediterranean Sea was not closed till the end of the cretaceous, when the salt-water was expelled, never to return.

In the west a similar ovoidal, crystalline border can be traced, holding paleozoic sediments. Beginning at the Rocky Mountain chain in Wyoming, we follow it southerly to Mexico. Across Arizona are many gneissic outlines, but not sufficiently numerous to close the gap. In California we reach a country entirely gneissic beneath the sands of the desert, which connects with the Sierra Nevadas, and is traceable along the Nevada line nearly to Oregon. There the course is changed, the rocks trend north-easterly, show themselves conspicuously in the Blue Mountains of eastern Oregon, the Salmon River Mountains of Idaho, and western spurs of the Rockies again in Montana, which are continuous to our starting-point in Wyoming. Our crystallines do not pass north of the parallel of 49° into Columbia. We have therefore found a complete crystalline border for the depressions of our western territories, and, within this ovoidal line, all the members of the paleozoic, mesozoic, and cenozoic groups, but not arranged with the simplicity of their distribution in the east.

Less is known of the arctic basin than of the others; but the scattered sketches afforded by voyagers indicate the presence of the more important members of the geological column. Where these basins adjoin, there is a much wider area of ancient land.

In conclusion, I will simply recapitulate the more important phases of the growth of our continent.

We start with the earth in the condition of igneous fluidity.

It cools so as to become incrusted and covered by an ocean.

Numerous volcanoes discharge melted rock, building up ovoidal piles of granite, which change gradually into crystalline schists. When these hills are high enough to overlook the water, they constitute the beginnings of dry land.

At the commencement of paleozoic time the continent is composed of three immense basins, located near Hudson's Bay, the Mississippi hydrographic area, and the great Nevada series of land-locked valleys.

The later history of the development of the continent presents the details of the filling-up of these depressions, the expulsion of the Mediterranean seas, and the description of the varied forms of life that successively peopled the land and water.

The history opens with igneous agency in the ascendant. Aqueous and organic forces became conspicuous later on, and ice has put on the finishing touches to the terrestrial contours. The completed structure we must acknowledge to be 'very good.'

NOTES AND NEWS.

Our leading article of June 29 was based in part upon a mistake, which we desire to correct. Foreign periodicals received by mail in single numbers have not been dutiable within the last five years. Nevertheless, the writer of the article, who subscribes to three foreign scientific journals, and receives them by mail, had been forced to pay duty on each number for the past nine or ten months; and the same has been the case with others of our acquaintance. Our post-office regulations are so frequently changed that one can rarely tell whether he is the victim of a blunder or a whim.

—M. Pasteur, who has just obtained a grant of fifty thousand francs from the French Chambers to send a scientific mission to Egypt to investigate whether the cholera be not due to the development of a microscopic animal in the human body, states, in a letter to *Voltaire*, the reasons which induced him to recommend the board of health to send out the mission in question. He says, "I urged the sending-out of this mission on account of the great progress that science has made since the last cholera epidemic respecting transmissible diseases. Every one of these diseases that have been the subject of a thorough investigation has led biologists to the conclusion that they were caused by the development, in the body of man or the animals, of a microscopic animal, causing therein disturbances frequently fatal. All the symptoms of the disease, all the causes of death, are directly under the influence of the physiological properties of the microbes. What is needed at present to meet the requirements of science, is to ascertain the primary cause of the scourge. Now, the present state of our knowledge indicates that we should direct all our attention to the possible existence in the blood, or in such or such an organ, of an infinitesimally small being whose nature and properties would in all likelihood account for all the peculiarities of cholera, both as regards its morbid symptoms and the mode of its propagation. The existence of that microbe once ascertained would speedily settle the question as to the measures to be taken to check the spread of the disease, and might possibly suggest new therapeutic means to cure it." The mission consists of four young *savants*, doctors, and biologists, — Drs. Roux, Thuillier, Straus, and Nocard. M. Pasteur hopes, that, by scrupulously attending to the hygienic precautions he has written down for them, the great danger they are incurring may be minimized.

— The September *Century* has several papers to which our readers' attention may be called. One of the illustrated articles relates Lieut. Schwatka's personal adventures in the hunt for the musk-ox. Ernest Ingersoll gives an excellent account of Mr. Agassiz' private laboratory at Newport, and of the methods he has so successfully introduced for carrying delicate sea-animals through their earlier stages. An admirable portrait, engraved by Velten, from a photograph of Notman's, will interest many. It has more spirit than one formerly published in the *Harvard register*. Under the title, 'The tragedies of the nests,' John Burroughs writes of the difficulties birds encounter in rearing their young. The attempts toward the unification in railway time in this country are briefly discussed by W. F. Allen.

A writer on ornamental forms in nature gives several striking illustrations of the effects producible, with due study, by 'the naturalistic school' of decorators. With eyes capable of seeing the stream, moth, vine, and skunk-cabbage 'in nature' as they appear to our writer, we may doubt the possibility of their evolutionary limit in art being ever reached. Like the Spanish-Moorish designer, he 'evidently did not care three straws for what all the botanists and florists on earth might think of his work,' so long as it teach us to regard nature from the standpoint of art, and tend in some measure to straighten the devious paths of the modern conventionalizer.

— The *Tribune* of Minneapolis, for Aug 16, printed Dr. Dawson's address before the American association in full, as well as long abstracts of several of the sectional addresses. Subsequent issues gave very fair reports of the papers read.

— The first number of Kobelt's *Iconographie der schalentragenden europaischen Meeres conchylien* has appeared. It is in quarto, with colored plates, and this number is devoted to species of Muricidae. The descriptions are in Latin, with German text.

— The Washington, of the Italian navy, under command of Capt. Magnaghi, is engaged in its annual cruise for the study of the western Mediterranean.

— One of the Akkas (African pygmies) taken to Italy in 1873 by Miani has just died of consumption at Verona.

— The newspapers of yesterdav announce that Mr. J. A. Ryder has succeeded in rearing the American oyster from the egg. His experiments were made in natural enclosures, and so conducted as to preclude any doubt that the spat obtained has been derived from any source except that of the spawn artificially fertilized and introduced into the enclosure. The greatest obstacle to the cultivation of the oyster is now removed.

SCIENCE.

FRIDAY, SEPTEMBER 7, 1883.

FRANCIS MAITLAND BALFOUR.

About a year ago came the sad news of the sudden death of Professor Balfour of Cambridge. If the loss was felt less severely in this country than in England, it was only because he had fewer personal friends here; and to fully understand his worth one must have known and talked with him. It is true that it required no unusual insight to read the fine qualities of the man in his writings; but none save those who knew him could appreciate his remarkable personal attractiveness. Not the least part of the wonderful work of his short life was that which he accomplished as a teacher: here as everywhere, his personal influence had a large share; and a sketch of Balfour's scientific work would be incomplete without a recognition of the bearing which his noble character had upon it.

The meeting of leading biologists in October last, to found the Memorial studentship, was remarkable in many ways: rarely have been heard such words of admiration and love for one man as were then expressed for Balfour. Many spoke at length of the debt Cambridge owed him. It may be said that he divided with Foster the honor of giving the great impetus to the biological movement in the English universities. What Huxley had done for Foster, the latter did for Balfour, giving him the first hearty encouragement and support; together they raised biology from the third to the level of the first rank of studies at Cambridge, equalling that held by mathematics. Oxford soon followed this important movement, trying to secure Balfour for the professorship left vacant by the death of Rolleston. His connection with natural science at Cambridge was described in warm language by Foster, his teacher, and by Sedgwick, one of his pupils: he advanced morphology there by his brilliant success in teaching and in research.

In teaching he combined manly force with a delicate regard for the feelings of his pupils. From the writer's personal impressions of him as a lecturer, he did not aim at eloquence, but to be understood in every step; rarely looking at his hearers, he spoke rapidly and with intense earnestness, crowding a vast deal into the hour. The main qualities of his character shone forth in his lectures, — energy, which he infused into his hearers; truthfulness, which soon gave implicit confidence in his statements; modesty and sympathy, which inspired effort and free exchange of thought.

Balfour's love of truth came constantly into play in his laboratory instruction. While looking over a student's shoulder, he would sometimes say with a laugh, "You must interpret that specimen with the eye of faith;" but this was very far from being a serious injunction, for he exacted of his students the greatest caution in the progress of their microscopic work. However tempting a certain interpretation of a specimen might be, Balfour never accepted it until it rested on the clearest evidence. An instance of this sort is recalled by the writer, which related to the much disputed origin of a well-known embryonic structure. A number of sections had been prepared, seeming to confirm the view which Balfour himself had advocated some time before; it required considerable self-control not to attach a somewhat forced meaning to them: this was, however, forbidden; and it was not until several days afterwards that fresh sections established the fact beyond question.

To Foster, Balfour repaid his student-debt by extending, in turn, continued encouragement to others. He did not fear, as many great teachers have, that joint labor with his juniors would derogate from his reputation: his joint articles are numerous; he was zealous to recognize research done by his pupils, seeming to be prouder of this than of his own work. Nothing could be more stimulating to the young men about him, still distrustful of their powers, than this generous co-operation. Is it surprising, then, that the voluntary attendance upon his lectures increased in seven years from ten to ninety, and that at the time of his death twenty students were engaged in difficult research in his laboratory? Only those who are familiar by experience with the few incentives among younger students to the study of biology can appreciate what these numbers mean.

We need not attempt to give a full list of Balfour's writings. They began in 1873, his twenty-first year, with a few short papers appearing over Foster's name and his own in the *Quarterly journal of microscopical science:* they terminated nine years later, with his fine work upon Peripatus, published posthumously in the same journal, and of which a full abstract will be found farther on. His extensive intermediate works, the Elasmobranch fishes and Comparative embryology, are universally known.

From the first he devoted himself to embryology. While this, as among the youngest of the biological sciences, admits of rapid work, it is far from admitting rapid generalization. No other branch of morphology requires more painstaking; the very materials one has to study are minute and indefinite; and two minds will often place different constructions upon the same specimen. There is abundant opportunity for scientific guesswork, with the feeling of security that disproval will be difficult. Balfour understood the real value of guessing at truth, but he always made it very clear to the reader when he was so doing; his hypotheses were accompanied by definite statements, in which the reasons *pro* and *con* were set forth in all impartiality to each. Herein lies a chief charm and merit of his work, its brilliant suggestiveness, side by side but never in confusion with well-established facts. Every chapter contains half a dozen invitations to other investigators to prove or disprove certain provisional statements. Vast as is the information contained in his Comparative embryology, Balfour himself appreciated, that, as far as mere facts went, the first volume would be somewhat out of date before the second was in press. Not so, however, with his masterly discussions of these facts, which are found on every page, and the value of which, to embryologists, cannot be estimated. Moreover, to his authorship is largely due the rapidly spreading interest in embryology in England and America, — a branch of science, it will be remembered, which had previously been mostly in German hands.

One frequently heard from him his own very modest opinion of his work; this was not at all inconsistent with striking independence and originality of thought, and adherence to his convictions. His modesty added more to the recognition of his genius than any assertions of his own could have done. Many were pressing forward to assert his claims, and honors were fast showered upon him in England and abroad. He was admired and beloved by all who knew him. In scientific discussion he had the rare quality, which Richard Cobden is said to have possessed, of remaining on the pleasantest personal terms with his opponents.

His energy in all matters was great, and his power of writing was unusually rapid; but, advised by kind friends, he rarely overtaxed his strength, which was limited. He spent most of his evenings with his friends, throwing off from his mind the labors of the day, and talking vivaciously upon the topics of the times. When the first volume of Comparative embryology was being written, he generally worked but five hours daily, giving much time to physical exercise, bicycling, or tennis, into which he entered with all the enthusiasm of his nature. He was courageous, but not reckless; and nothing in his previous life would lead us to suppose that the mountain climb which proved fatal was undertaken in a foolhardy spirit.

Balfour in a few years accomplished the work of a lifetime. His influence was and is twofold, — first, upon those with whom he came in personal contact, especially his scientific associates and students (an influence which cannot fail to endure, well expressed by Professor Kitchen Parker: "I feel that his presence is still with me; I cannot lose the sense of his presence"); and, secondly, the influence of his scientific work, which for genius, breadth, and truth, can never be surpassed. May the splendid memorial which has been raised for him perpetuate his noble example as a teacher and man of science! Henry F. Osborn.

THE INTELLIGENCE OF BIRDS.

Having met with many instances wherein birds have shown considerable ingenuity in overcoming the ill results of accidents to their nests, such as often arise during violent storms, it occurred to me, at the outset of the bird-nesting season of the present year, to endeavor to test their intellectual powers generally, by a series of simple experiments, hoping thereby to be able to determine to what extent birds exercise their reasoning faculties.

My experiments, and the inferences I drew, are as follows: —

Noting the material being gathered for the nest, partially constructed, of a chipping-sparrow (Spizella socialis), I placed a small quantity of the same in a conspicuous position near the nest. It was seen by the sparrows, and examined, but none was removed. I placed a portion of it upon the margin of the unfinished nest: it was promptly removed by the male bird, who used only such materials as were brought to him by his mate. The following day the task of lining the nest with hair was commenced. I placed a quantity of this material on a branch near by, but it was passed unnoticed. I next placed a few hairs on the margin of the nest: they were promptly removed. On replacing many of these in the nest, the entire lining was thrown out. I replaced it, and the nest was abandoned.

A week later, finding another nest with three eggs, I added a few white cat-hairs to the lining: these were removed. Others of dark colors were added: they, also, were removed. I replaced both dark and white hairs: the eggs were broken, and the nest abandoned.

Four eggs found in a third nest were removed without touching the nest, a wooden spoon whittled for the purpose being used. In three days the female commenced laying again: four days later three eggs had been laid. Replaced the four I had removed: they were promptly thrown from the nest. I then removed the nest, and, substituting another, carefully replaced the eggs without handling them. After what appeared to be a serious consultation, the new nest was accepted.

These birds suffered no further annoyance, and reared their brood without mishap.

Why should not these have utilized the material for their nest which I offered, rather than gather similar stuff from distant points? They could not have been frightened by any odor attached to the material through handling, as I was careful not to touch a particle of it, using a pair of wooden tweezers in every case. Neither did they see me carrying any thing to or from their nests. As these, in all cases, were nearly or quite completed, the birds had necessarily become thoroughly familiar with the surroundings, and doubtless recognized the fact that these offered twigs and the hair had suddenly appeared in, to them, some unexplained manner, and the mystery surrounding it made them suspicious. Suspicion, I suggest, is a complicated mental effort. Again: the sparrows were sorely perplexed when a nest not of their building, but of the same character, was substituted for their own. Here, these birds exhibited fear; but finally the maternal instinct overcame the timidity of the female, and she resolved to brave the danger or solve the mystery, and cared for her eggs as usual. The male bird kept aloof for several days, I think; but of this I am not positive. These sparrows were moved by conflicting emotions, — evidence, I think, of an advanced degree of intelligence.

Another series of experiments were as follows: finding a nest of the summer warbler (Dendroeca aestiva) in a low alder, the foliage of which was about one-third grown, I girdled the supporting growths a few inches below the nest. The leaf-buds withered, and the nest, which under ordinary circumstances would have been quite concealed from view by the full-grown leaves, was now exposed. The nest was abandoned.

The next girdling experiment was made on the nest of a white-eyed vireo (Vireo noveboracencis) found attached to a low limb of a small beech. The leaves quickly shrivelled, and the nest, although just finished, was abandoned.

A second experiment of the same sort was tried, with identical result.

A nest of the summer warbler was found in a low shrub, containing young birds, and the supporting branches girdled. The leaves withered and fell, exposing the nest to full view. The parent birds remained, and successfully reared their brood.

In these cases we have evidence of mental operations of a more complicated character than any exhibited by the sparrows. It is evident, that in every case, these birds, in selecting the position for their nests, knew that the growth of the foliage would afford a desirable, if not necessary, protection to them. Finding that the growth of the foliage had been checked, that the little shelter at first afforded was daily growing less, they foresaw that the nests, under these circumstances, would be too much exposed to be safe from molestation, and they were abandoned, even after a full complement of eggs had been laid. Can we explain this by any other means than by using that very suggestive term 'foresight'? But mark: when the same circumstance occurred after the young had appeared, the claims of the brood upon the parents were too strong to be overcome, and the danger of occupying an exposed nest was readily braved.

Experiments of another character were as follows: I placed a series of short pieces of woollen yarn, fastened together at one end, near the tree containing a partially constructed nest of a Baltimore oriole (Icterus Baltimore). These yarns were red, yellow, purple, green, and gray. An equal number of strands of each color were thus offered to the orioles as building-materials. I purposely placed the red and yellow strands on the outside of the tassel-shaped mass, so that these would be first taken, if the color was not objectionable. To my complete surprise, the gray strands only were taken, until the nest was nearly finished, when a few of the purple and blue yarns were used. Not a red, yellow, or green strand was disturbed. Here we have an instance of the exercise of choice, on the part of a bird, which is full of interest. The woollen threads being otherwise identical, it was the color only that influenced the choice of the birds: they realized that the red or yellow yarns would render the nest conspicuous, although well protected by the foliage of the branch to which it was attached. Why the green threads were not taken I cannot imagine. As a result of this experiment, I anticipated that the orioles would reserve the brightly colored yarns for the lining of the nest, and the gray and green for the exterior. This was a result obtained two years ago, when I tried a similar experiment; but the use of red yarn as a lining may have been merely accidental.

Out of mere curiosity, for I could not anticipate what might be the result, I made a few transfers of the eggs of one species into the nest of another bird. The results were not, however, particularly suggestive. I placed the eggs of a cat-bird (Mimus carolinensis) in the nest of a song-thrush (Turdus mustelinus), and *vice versa*. The eggs of the former are dark green; of the latter, light blue. No act indicative of recognition of the change was observed. I placed eggs of the song-sparrow (Melospiza melodia) in the nest of a pee-wee (Sayornis fuscus), and *vice versa*. The fly-catchers rejected the eggs of the sparrow; but the latter accepted the situation, although disturbed by it. Many other changes were made, with similar results; and I concluded, that, unless the eggs were greatly different in size and color, about one-half would be accepted; but, when a single egg was placed in the nest of another bird, it was destroyed in nearly every case. This I found to be true, even when I tested such birds as are subjected to the annoyance of the cowpen bird's egg being deposited in their nests. I was surprised at this result, and am led to believe that large numbers of the eggs of this bird are destroyed. It is well known that our summer warbler frequently outwits the cowpen bird by building a new nest directly above the old, — a two-story nest, in fact, — and leaves the egg that has been left to her care to rot in the basement, while she rears her young on the floor above. It will be seen that from these experiments no very positive results were obtained. I did note, however, that, where the change was accepted, it was not because it passed unnoticed, but was submitted to, notwithstanding the evidences of much misgiving on the part of the birds. In one case, the nest was practically deserted for twenty-four hours, and the eggs were chilled in consequence. The birds sat upon them for five days, when, as they did not hatch, the nest was abandoned. In previous years I have made these changes occasionally with success, but was not able to determine that the young were recognized as not the offspring of the parent birds. In such cases the young were tended with the usual care up to the time for leaving the nest. This may possibly be indicative of stupidity. It appeared so to me at the time; but I am now disposed to see in it an indication that the maternal instincts here, as in other cases I have mentioned, overcame all other feelings, and that the fact was accepted by the birds with as good grace as they could command.

The co-operation of birds, when constructing their nests, is a subject that demands a good deal of close attention, and is one surely worthy of more systematic observation than has as yet been given it. The many ways in which birds assist each other in nest-building offer, perhaps, the clearest evidence that they have a very intelligent notion of what they are doing, or propose to do. I feel warranted at the outset in making the somewhat startling assertion, that the choice of location for a nest is made only after protracted joint examination of suitable sites, and is the choice of both birds. I doubt if it ever happens that one of a pair of birds 'gives in' to its mate. Certainly such a thing as madame giving up to her lord is unknown in the bird-world. My impression is, that the female birds of every species are exacting, obstinate, and tyrannical. I have seen marked instances of this among house-wrens, pee-wees, and even known a cooing turtle-dove to exhibit unmistakable evidences of a quick temper. These may seem to be trivial matters, and not within the range of the scientific study of animal intelligence; but it is an error to look upon such proofs of individuality in this light: they are among the most convincing evidences of a high degree of intelligence. If a hundred or more nests of the same species of birds are carefully compared, it will be found that there is a considerable range of variation in their construction, and a varying degree of merit in the skill shown by the builders. Is not this evidence of different degrees of mental strength occurring among birds of the same species?

But to return to the subject of co-operation in nest-building. I have found, that where very long, fibrous materials are used, as in the case of the globular nests of the marsh-wrens, the birds work together in weaving the long grasses that form the exterior. I have seen one of these birds adjusting one end of a long blade of rush-grass, while its mate held the other end, until the former had completed its task to its satisfaction. It was evident that the weight of the ribbon-like growth that the bird was using, quite a metre in length, was too heavy to be moved to and fro, and at the same time prevented from slipping from the unfinished nest. Only by assistance could such materials be utilized, and only by intelligent joint labor could these little birds build such large and complete globular nests. Many birds, too, have been known to jointly carry away a long string or piece of muslin too heavy or cumbersome for either one to move. Again: materials are often brought by one of a pair of birds to a nest which the other considers unsuitable, and fierce quarrels often arise from this circumstance. In such cases we have instances of a difference of opinion among birds, which is a marked indication of mental activity.

Charles C. Abbott, M.D.

THE IGLOO OF THE INNUIT.[1]—IV.

The interior of an igloo can be best understood by reference to the diagrams. The one, fig. 1, is a vertical section through the entrance; and the other, fig. 2, a ground-plan. Directly opposite the entrance is raised a platform of solid snow, eighteen inches to two feet in height, which takes up about two-thirds of the floor; and on this are spread the reindeer-skins which make the bed. Sometimes, if the party be large and but one igloo built, there are two of these snow-beds, separated by a narrow aisle running from the entrance; the persons then sleeping at right angles to the positions shown in the illustration. But such large igloos are rare, unless of a permanent or semi-permanent character. On an extension of the platform forward, on the woman's side, is placed the stone lamp; and here the food is cooked, and the native skin clothes are dried. The height of this platform or snow-bed is nearly always above the top of the low door; for the Innuits are instinctively masters of the simple laws of pneumatics, and try to keep the snow-bed as high as possible to reach the upper or warmer strata of air, especially to keep higher than the cold air, which can come in through the open door. The height varies with the permanency of the abode, the temperature, and with the tribe. If very cold, or if intending to occupy the igloo for some time, the beds are made higher than they would be otherwise. The Netschilluks and Kinnepetoo always make much higher beds than the Iwilliks or Iglooliks. There is also much variation in the flatness of the dome; those of the former tribes, especially the Netschilluks, being very flat. This, with their high beds, makes the space between them very small; but in compensation their igloos are the warmest and most comfortable in the whole arctic region. These Netschilluks (in and around King William's Land) nearly always have to jump out in front of their beds to get standing-room to dress in, although all Innuits are adepts in the art of putting on the most intricate clothing in the smallest space conceivable.

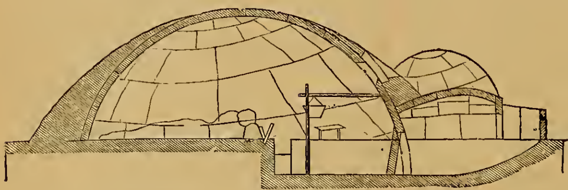

Fig. 1.

The Kinnepetoo Innuits (around Chesterfield Inlet, especially north of it) use few or no lamps to warm their snow-huts, and, despite the high beds and low roofs, they are cold, cheerless, and uncomfortable beyond measure. These Innuits are essentially reindeer killers and eaters, and lay in an insignificant stock of seal-oil to burn in their lamps. Walrus-killing is unknown to them. For light they use a piece of rendered reindeer suet, laid beside a piece of lighted moss, all being on a large flat stone. The light of the stone lamp in all igloos where it is used is sufficient for all purposes of sewing and repairing. It is certainly equal to the light from three or four kerosene-lamps, and, with the white snow-walls, gives ample illumination.

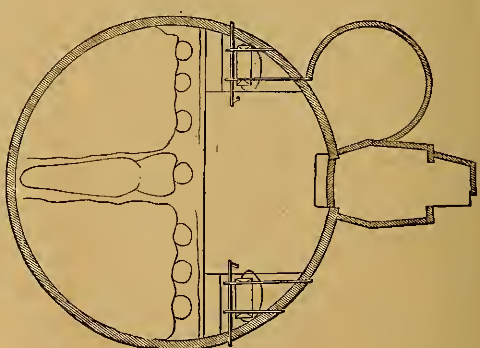

Fig. 2.

The Oo-quee-sik Salik Innuits (around the mouth of Back's River), who are salmon-eaters, are another tribe that dispense with warming the snow-houses for want of oil; and this with their very poor stock of clothing, they being

[1] Continued from No. 30.

almost constantly in rags, makes them a most forlorn, uncomfortable-looking, and dejected lot of human beings. The powers of these two tribes to withstand the cold seem almost phenomenal.

The flatness of the domes, however, is not wholly a tribal peculiarity, but is also a function of the season of the year. In the wintertime, when the snow is hard and compact, the roof can be made much flatter than in the spring, when the warm, sunny days bring on a thaw, and threaten to tumble it in. At such times it is made very peaked, to gain strength for its weakest points, the inclining blocks.

The Iwilliks and Iglooliks (among the estuaries of North Hudson's Bay) have ample supplies of whale, seal, and walrus oil, and, despite their higher roofs, have very comfortable houses in the way of warmth, while they exceed all others in roominess, and ease and comfort in dressing and undressing.

The heated air, of course, rises to the top; and, should it grow too warm inside, this heat soon cuts its way through the joints of the top blocks, and enough fresh air enters to quickly reduce the temperature below freezing again, especially if it be very cold on the outside. Sometimes this ascending heat makes so much impression on the edges of the top blocks that they commence to thaw and drip in an annoying manner. This is always remedied by taking a handful or a small block of snow from the floor, where the temperature is very low, and applying it to the dripping spot, where it freezes immediately, and, like a sponge, absorbs the drippings. These little pests have to be watched closely, however: for when they are saturated with water, and thawed from their frozen fastenings, they will come down like a slushy ball of lead; and it seems as if they would defy all the laws of gravity to get down a person's back, or hit a sleeper in the face. I once had a large one fall in a pint cup full of hot reindeer-soup just as I had it near my nose, blowing it to hurry up the meal and get away from a delayed camp.

Small store-igloos are built outside to hold the bulky material, and often connect with the main igloo or its entrance, if their contents are needed from time to time.

Where several families, generally related, build a family igloo, it is done by making a large central one, without bed-platforms or other impediments to roominess; and around this are built the smaller family igloos, — two, three, or even a half-dozen, — connecting with the central one by high groined arches that will generally allow of passing from one to the other without stooping; and conversation can be readily carried on between them, these smaller igloos being more like radiating alcoves than separate structures. Then the entrance to the main part is made very long (fifteen or twenty feet), and its outer end is changed from time to time to face *away* from the wind, if it be at all strong. The usual entrance is so low that one always has to enter on his hands and knees; but in these family igloos the greater part one can accomplish by stooping considerably. There is always a crowd of hungry dogs ready to take advantage of a person's entering to crowd in close behind, so as to steal a stray piece of blubber from the lamp-platform or floor. At all other times two or three of their heads can be seen closing the entrance, waiting a good opportunity for a dash. The matron of the house, sitting *à la Turc* on the edge of the bed, keeps a good stout club convenient, and whacks them over the nose whenever they make an unusually impudent intrusion. At night-times, and during cold, windy weather, the more belligerent of these camels of the cold monopolize the entrance for sleeping-apartments; but they generally manage to get into some sort of fight, breaking in the door, and the master then arises and vacates these canine compartments with the butt-end of a whip or a sledge-slat, and they remain quiet for the rest of the night.

The temperature inside ranges from freezing (above which, of course, it cannot ascend) to about ten to twenty degrees below. Late in the winter, when all have inured themselves to the cold, the same tribe will keep their houses much colder with the same apparent comfort. At these temperatures one feels very warm after coming in from the outside. The outer clothes are taken off, and even baths are indulged in; the little children, *stark naked*, playing on the reindeer-skins of the bed with the little puppies and toy harness. Those tribes that do not use oil-lamps are, of course, much colder in their houses, having only the warmth of the body and a few lights, with occasionally some cooking from the lamps; yet I do not think it ever gets below zero. Even in these igloos I have known a Kinnepetoo to take a reindeer-skin that had been soaked to rid it of hair, and that was apparently frozen as solid as boiler plate iron, and, putting it under his coat against the bare skin, hold it there not only until it was thawed out, but also until it was dry, and fit to be used for a drumhead for their superstitious rites. Juggernaut could show no greater devotees among his followers. Such are the iron Innuits of the unwarmed igloos of the Arctic.

A recently constructed igloo is more comfortable than one long used, the alternating heat and cold of the day and night soon converting the latter into a translucent mass of ice, that becomes uncomfortably chilly on a cold night; besides, the steam from the cooking and the moisture from the breath congeal upon the roof, and, in the course of ten or twelve days, become so thick as to form a base for a constant liliputian snow-storm, which is disagreeable beyond measure. One of the most conspicuous comforts of arctic travelling is the constant changing of igloos.

(*To be continued.*)

BALFOUR'S LAST RESEARCHES ON PERIPATUS.

At the time of his death, the late lamented Prof. F. M. Balfour was engaged upon an investigation of the anatomy and development of Peripatus, the lowest known form of Tracheata (insects). Unfortunately, he left his work far from complete; but two friends, Mr. Sedgwick and Professor Moseley, both thoroughly competent, have undertaken and completed the grateful task of editing what could be gathered from Balfour's material. We have, however, hardly more than a descriptive account of the anatomy and development of the animal. We miss the fruitful thought with which Balfour enriched his writings before committing them to the press.

The article is published in the April number of the *Quarterly journal of microscopical science*, and is accompanied by numerous beautiful plates. A portion of these were drawn by Miss Balfour. Their excellence graces this quiet expression of a sister's close relation to a gifted brother.

Balfour's investigations were directed especially upon Peripatus capensis. The memoir opens with a careful description of the external characters of the species. The account of the legs is the first satisfactory one published. The number of legs is variable, but usually there are seventeen pairs. Each leg has the form of a cone, with a pair of claws at the apex: it bears a succession of rings of papillae, but towards the tip the papillae in part fuse together to form three ventrally placed pads. The foot is distinct, being separated by a constriction from the upper part of the limb, and has several pads upon its ventral surface, and bears the two conical recurved claws. On the middle of the ventral line of junction of the leg with the body lies the opening of the segmental organs. The disposition of this opening on the fourth and fifth legs is slightly different. The last leg has a papilla with a slit-like gland opening at its apex. The gland itself is large, and runs far forward, and is probably a modified crural gland.

Part II. is a monograph of the internal anatomy. In the *alimentary canal*, a nearly straight tube slightly longer than the body, five parts may be distinguished. 1. The buccal cavity. Its opening is surrounded by a tumid lip, covered by a soft skin raised into papilliform ridges. Attached to the median dorsal wall of the cavity is a muscular protuberance (tongue), covered by the oral epithelium, and furnished with organs of special sense, like those in the skin, and with chitinous teeth. On each side of the tongue is placed the jaw, with recurved chitinous teeth. The jaws are, no doubt, modified limbs: their structure and action are minutely described. The salivary glands open into the buccal cavity by a short common duct, are variable in length, but stretch usually two-thirds the length of the body. They consist of two parts: the first runs backward as a wide, straight tube; the second runs forward and upward, is small in diameter, and apparently branching in the figures, though the fact is not mentioned in the text. The anterior end of the first part serves as a duct, and is lined by a cubical-celled epithelium; while the rest of the same part is

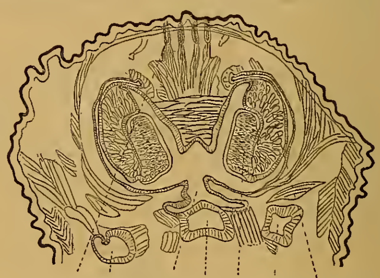

FIG. 1. Horizontal section through the head: *tr p*, tracheal pit; *sal*, salivary gland; *M*, mouth; *s d*, common salivary duct; *J*, jaw; *o j*, outer jaw, or muscular portion; between the two jaws lies the section of the tongue.

glandular, and lined by very elongated epithelial cells with their nuclei at their bases. 2. The pharynx is a highly muscular tube, with a triangular lumen, which extends from the mouth to about half way between the first and second pair of legs. (It appears to me that the author is in error when he states that such a structure is not characteristic of insects.) 3. The oesophagus, on the dorsal wall of which occurs the junction of the two sympathetic nerves. 4. The stomach, by far the largest part of the alimentary tract, has its walls irregularly, not segmentally, folded. The walls themselves are composed principally by the internal epithelium, the cells of which are elongated, fibre-like, with their nuclei about one-fourth of the way from the base; and around their bases are short cells irregularly scattered, and having round nuclei. 5. The short rectum is chiefly remarkable because the circular muscular layer is *outside* the internal layer formed of isolated longitudinal bands.

The *nervous system* is particularly interesting; for it consists of two ventral cords united by numerous transverse bands, and having an enlargement corresponding to each leg. The cords are united in front, above the oesophagus, to form the cephalic ganglia, and are also united behind over the anus. The arrangement of the commissure and nerves of the ventral cords is minutely described. The supra-oesophageal ganglia give origin to the immense antennary nerves, and a few small epidermal nerves; laterally, one-third of the way back, the optic nerves, and two pairs of smaller nerves near the optic; still farther back, a large median nerve from the dorsal surface;

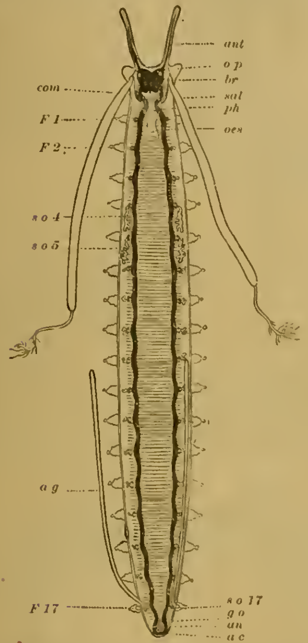

Fig. 2. General anatomy; the digestive tract is supposed to be excised; the nervous system is represented in black: *ant*, antenna; *o p*, oral papilla; *br*, brain; *sal*, salivary gland; *ph*, pharynx; *oes*, oesophagus; *com*, commissures; *F 1*, *F 2*, *F 17*, feet; *s o 4*, *s o 5*, *s o 17*, segmental organs; *a g*, accessory gland; *g o*, genital opening; *an*, anus; *a c*, anal commissure.

from the ventral surface, the sympathetic nerves, which follow the grooves of the pharynx, and unite upon the dorsal wall of the oesophagus. The ganglion-cells are confined, for the most part, to the surface in the supra-oesophageal ganglia, and to the ventral layer in the longitudinal cords. On the under side of each lobe of the brain is a conical protuberance of ganglion-cells, which Grube regards as an organ of hearing; but Balfour questions that interpretation.

The *skin* resembles that of other insects. The cuticle is thin, and forms a separate conical cap over each cell. The surface of the cuticle is dotted over with minute spinous tubercles. Scattered over the skin are organs of special sense, which I think resemble the olfactory organs of insects; but Balfour regards them as tactile. Each is a broad, conical, cuticular spine supported by large specialized sensory cells.

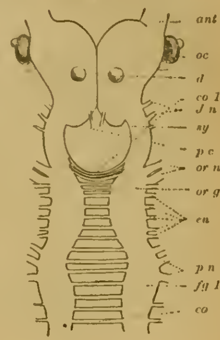

Fig. 3. Anterior portion of nervous system: *ant*, antennal nerve; *oc*, eye; *d*, ventral appendages; *co 1*, first commissure; *J n*, nerves of the jaw; *sy*, sympathetic nerves; *p c*, posterior lobe of brain; *or n*, nerves of the oral papillae; *or g*, ganglion of oral nerves; *en*, lateral nerves of ventral chords; *p n*, pedal nerves; *fg 1*, enlargement corresponding to pedal nerves; *co*, commissure.

The *tracheae* arise from openings between the ridges of the skin. Each aperture leads into a pit formed by the invaginated skin; and from the bottom thereof springs a bunch of fine tracheal tubes, which display large adherent nuclei on their walls, and transverse lines indicating the presence of a spiral fibre. The openings form two rows (subdorsal) on the back, and two rows on either side of the median ventral line; they are also found on the feet, around the bases of the feet, and on the head.

The *muscles* of the jaws are alone striated: all others are unstriated. The muscles of the body form an external double layer of circular fibres, an inner layer of longitudinal muscles forming five bands (one

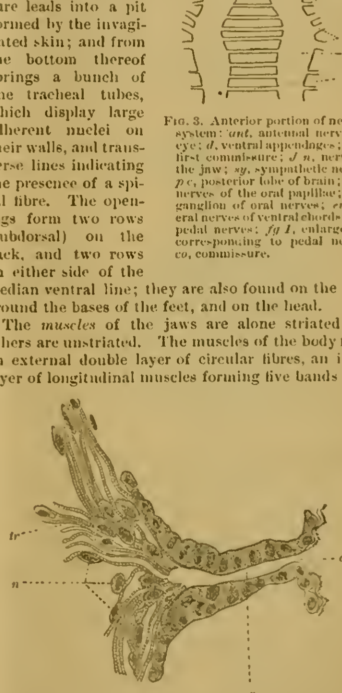

Fig. 4. Section of tracheal orifice: *o*, external orifice; *p*, pit; *tr*, tracheae; *n*, tracheal nuclei.

being median and ventral), and vertical septa of transverse fibres (one septum on each side of the alimentary canal): so that the body-cavity is divided into three regions, — a median, containing the alimentary tract, slime-glands, etc.; and two lateral, containing the nervous system, salivary glands, segmental organs, etc.

The *vascular system* is imperfectly known. Balfour describes a dorsal tube without apparent muscular walls as the probable representative of the heart, and mentions a less distinct ventral vessel. (Cf. note.)

The *segmental organs*, which were first recognized by Balfour,[1] conform to the structures designated by the same name in annelids. They consist of: 1°. a vesicular portion opening to the exterior; 2°. a coiled portion, which is again subdivided into several sections; 3°. a terminal section ending by a somewhat enlarged opening into the lateral compartment of the body-cavity. The first two pairs, corresponding to the fourth and fifth legs, differ somewhat from the rest, which are all similarly constructed. They are lined by an epithelium, which varies in character in the different parts of the organs: in the first portion, the cells are large, flattened, and have large protuberant nuclei; the second portion has a columnar epithelium in its outer part, in which, further, two regions may

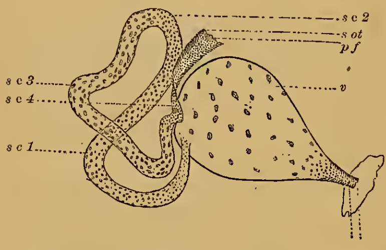

FIG. 5. Part of segmental organ: *o s*, external opening of the segmental organ; *d*, terminal portion of duct; *v*, vesicle; *s c*, *1*, *2*, *3*, *4*, successive portions of segmental canal: *p f*, internal opening; *s ot*, terminal portion.

be distinguished histologically; a third region within this outer part has large, flat, granular cells, with disk-like nucleolated nuclei; while a fourth region, the innermost of the middle portion again, has a lining of small columnar cells. The inner portion has a thick columnar epithelium crowded with oval nuclei, and opens with reflected lips into the body-cavity.

The *generative organs* are briefly described by the editors, who do not, however, deal with their histology. The male organs consist of a pair of testes, a pair of prostates, and vasa deferentia and accessory glandular tubules. The female organs consist of a median unpaired ovary and a pair of oviducts, which are dilated for a great part of their course to perform a uterine function, and which open behind into a common vestibule communicating directly with the exterior. In all the legs except the first there are glandular bodies. The large accessory gland opening in the last leg of the male is probably a modification of one of the series for which the name 'crural glands' is proposed.

Part III., also entirely written by the editors, treats of the development. This contains illustrations, serving to accompany the notice published in the Royal society's proceedings (SCIENCE, i. 453); certain requisite explanations are added; then follow descriptions and figures of older embryos than had been previously described by Balfour. Special attention is called to the following more important facts: —

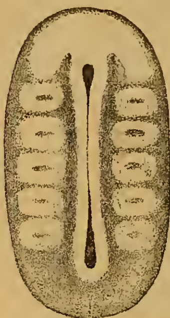

FIG. 6. Embryo, 'stage C,' with five somites: *a*, anal (?) end. The lips of the blastopore have united in the middle.

"1. The greater part of the mesoblast is developed from the walls of the archenteron.

"2. The embryonic mouth and anus are derived from the respective ends of the original blastopore, the middle part of the blastopore closing up.

"3. The embryonic mouth almost certainly becomes the adult mouth; i.e., the aperture leading from the buccal cavity into the pharynx, the two being in the same position. The embryonic anus is in front of the position of the adult anus, but in all probability shifts back, and persists as the adult anus.

"4. The anterior pair of mesoblastic somites give rise to the swellings of the pre-oral lobes and to the mesoblast of the head.[1]

"There is no need for us to enlarge upon the importance of these facts. Their close bearing upon some

FIG. 7. Section through the open blastopore of the embryo drawn in fig. 6: *bl*, blastopore; *mes*, mesoderm; *ec*, ectoderm; *ent*, entoderm.

of the most important problems of morphology will be apparent to all."

The paper terminates with a few appropriate and telling quotations from Balfour's 'Comparative embryology.' The memoir displays the best qualities

[1] Balfour: *Quart. journ. microsc. sc.*, xix. 1879.

[1] "We have seen nothing in any of our sections which we can identify as of so-called mesenchymatous origin."

of Balfour's work, and can only enhance the respect which all biologists feel for him.

[NOTE. — Since writing this notice, I have learned of the paper since published by Gaffron upon Peripatus (*Schneider's Zoologische beiträge*, I. 33). The original I have not seen, but only a notice in the *Biologisches centralblatt*, iii. 319. From the latter it appears that Gaffron has independently observed many of the facts discovered by Balfour, and in some respects has added to them. The following is the abstract of his description of the heart. "As in the tracheate arthropods, it lies in a special pericardial sinus, completely embedded in a cellular mass, most developed laterally. Its walls are perforated by fissures, corresponding to the body-segments, and which must be sought in the upper half of the tube. Along the dorsal median line runs a round cord, which is held (probably wrongly) to be a nerve. The pericardial sinus and the body-cavity communicate through numerous oval openings in the septum."]

CHARLES SEDGWICK MINOT.

LETTERS TO THE EDITOR.

Prairie warbler in New Hampshire.

Several seasons ago the prairie warbler (Dendroeca discolor Bd.), was found nesting at Northfield in New Hampshire, in June I believe, though I cannot give the exact date. Two of the nests, however, and an egg, are preserved, and place the identity beyond question.

The locality was a high, bush-grown pasture in the vicinity of a town; and the nests were pitched about head-high from the ground, in the crotch of a thorn-bush. The birds made no demonstrations at the approach to their haunts, but retired noiselessly, seeking to screen themselves from view. One nest contained three eggs, a second four. They are substantially the same, finely and firmly wrought, cup-shaped structures, with a well-turned rim. In the latter instance, the external depth is 2½ inches, the internal 1¼; outer diameter 2¾, inner 1½. The nest is composed essentially of bark strippings, Andromeda chiefly, fine grass, and blasted vegetable fibre intermingled, and lined with hairs and the reddish filaments of Polytrichum. The exterior is covered with much cobweb silk and some soft compositaceous substance, which serves to compact the whole and secure it in position.

The egg is pointed at one end, dull white, rather finely and sparsely specked with lilac and marble markings, aggregating in a circle about the crown, measures .68 × .50 inches, resembling occasional specimens of the chestnut-sided warbler.

So far as I am aware, there is no previous authentic record of this warbler breeding north of Massachusetts in New England. F. H. HERRICK.

Kalmia.

In your issue for Aug. 17, Dr. Abbott doubts if Kalmia grows sufficiently large to be used for making spoons. The abundant thickets of Kalmia latifolia, beautiful but troublesome, are among the clearest recollections of my youth in southern New Hampshire. This shrub is there familiarly known as 'spoonhunt;' and its stems, near the ground, are not infrequently three or four inches in diameter.

CHAS. H. CHANDLER.

Letters in a surface film.

Can any one suggest an explanation of the phenomenon described below?

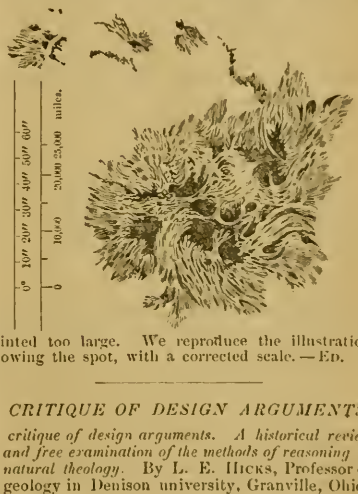
In a box four feet square, and sunk five feet below the surface of the ground, was a water-meter connected with pipes for supplying a factory. Over the face or dial of this meter was a cast-iron cover, on the outside of which the maker's name was inscribed in raised letters. During the spring thaws, the box was half full of surface-water, submerging the top of the meter some eight or ten inches. After a time a greasy film collected on the water, and in this film appeared a counterpart of the raised letters. That it was not a reflection or other optical illusion, was proved by carefully introducing a shovel under these filmy letters, when they were raised and taken outside of the box, being still visible.

In the course of a few hours, fresh letters would appear on the surface. A. P. H.

Boston, Aug. 28, 1883.

An interesting sun-spot.

Owing to a misunderstanding, the scale given with the sketch of a sun-spot, in the letter from S. P. Langley and F. W. Very (SCIENCE, ii. 266), was



printed too large. We reproduce the illustration showing the spot, with a corrected scale. — ED.

A CRITIQUE OF DESIGN ARGUMENTS.

A critique of design arguments. A historical review and free examination of the methods of reasoning in natural theology. By L. E. HICKS, Professor of geology in Denison university, Granville, Ohio. New York, *Charles Scribner's Sons*, 1883. 11 + 417 p. 8°.

THAT men can talk about the most serious problems without passion, is certainly shown by our author, whose candor and excellent aims have already been recognized on all hands. For the rest, we must regard the book with mixed feelings. When we undertook to read it, we did not go forth to see a reed shaken by the wind, nor did we find such; we did not venture to look for a prophet, nor did we find one: but we were prepared for just a little more definiteness of philosophic thought, for just a little more acquaintance with the history of the subject, and, in general, for just a little more strength. But we must not be too exacting. This is the work of a student of a special science. He comes with suggestions that have been a good while in maturing; he expresses himself in clear language, with great and generally successful effort at fairness; and he shows no small ingenuity. His book will do good both to theological and to scientific students if they read it. And it can do no harm to philosophy. Such discussion is, in fact, so timely that one cannot wish that the book had been kept any longer out of print; but one must wish that the author had begun to study the history of thought a good deal earlier. Achilles at the trench will always be a sublime figure; but the lack of armor is not just that feature in the situation of Achilles which it is safest for other people, at other trenches, to imitate.

The argument from design, says the author, is in fact twofold. In one form it is teleological. Certain events or things are judged to be intended for certain purposes. This argument has less signifiance for the men of to-day than it had for former generations. The advance of science throws it somewhat into the shade. But the advance of science itself tends to bring into clearer light the other design argument. This is the argument from the *order of nature*. Order, it maintains, implies intelligence, is itself a mark or sign of mind. The more order we discover, the more intelligence is indicated in the world. This does not necessarily mean that we infer intelligence as the *cause* of order; but it means that we regard order, however it may actually be connected with intelligence, as a *mark* of intelligence. This argument needs a name; and Mr. Hicks proposes to call it the eutaxiological argument, to distinguish it from the teleological.

The teleological argument alone is not satisfactory. To prove that any thing implies intelligence as the cause whereby it was adjusted to an end, you must know what the end or purpose of this thing is. And to do this, you must know that there are ends or purposes for things at all; but to assume that you know this is to beg the question. Teleologically, therefore, intelligence as the cause of things cannot be proven; but only particular adjustments, made by an intelligence already known to be the cause of things, can be teleologically discovered. Teleologically you could at best show, that, if there is intelligence in connection with the world as a whole, then this intelligence works for certain special aims. But teleologically it would be impossible, without aid from some other source, to make certain that any mind at all is associated with the world as a whole. It is impossible 'to prove the *existence* of intelligence by means of the definite *direction* given to intelligence,' because the existence of intelligence 'must be *assumed* in order to ascertain its direction.'

On the other hand, maintains our author, the eutaxiological argument escapes the analogous objection. Teleology has to assume the existence of purpose, in order to use it as a proof of intelligence. But eutaxiology has not to assume the existence of order. Order is the first and last word of natural science; and from first to last science continues to deepen the meaning, and to widen the application, of the word 'order.' The difficulty of the eutaxiologist begins not at this point, but later. Are we sure that order is a sign of intelligence? An orderly arrangement of things is a mark of intelligence in many cases. "Suppose we find smooth stones or shells on the beach, arranged at regular intervals in a straight line, or in three straight lines to form a triangle: we should say that an intelligent being had done this." To be sure, in this case we should suppose that some man had done it; but that would not affect the matter, for, "if we saw such figures upon the moon or upon any of the planets, we should at once conclude that they were inhabited by intelligent beings." Thus in these cases, reasons Mr. Hicks, order is inductively connected by us with intelligence. "We see intelligence producing orderly results; and we project the inference thence derived over those cases of orderly phenomena of which we do not know the cause." But what is done in special cases of order observed in forms or in groupings of objects, ought fairly to be done in regard to the whole of nature; and that especially because every case of orderly connection that we find, and that suggests intelligence, is found not alone, but itself in connection with other cases, so that we could not finally stop with our examination of one case of order before we should know its connections with the whole of the rest of the universe. The more, then, we know of nature, the more orderly and connected does it seem, and the more reason we have to apply our induction to the world as a whole.

All this, of course, implies no definite view about the way in which intelligence is connected with the order of the universe. Whether it be that arbitrary collocations of matter are the immediate sources of the order, or whether the order follows from the fundamental properties of matter, the result is the same. And for a like reason eutaxiology has nothing to say of divine attributes over and above intelligence. Eutaxiology does not even by itself prove the existence of God. It simply proves that intelligence exists in the universe. It leaves to other proofs the discussion of other divine attributes. Eutaxiology having proved intelligence, teleology can then be used to prove that this intelligence is somehow associated with will and power, and works (through evolution or otherwise) for definite aims; and other proofs may be used for other purposes. In conclusion, why may not the various theistic arguments agree to divide labor, and combine the outcome, so that each one shall undertake to prove just that divine attribute to whose defence it is especially fitted? Thus confusion might be avoided, and the cause of natural theology advanced. Mr. Hicks even goes so far as to suggest, in a very generous outburst (p. 389), that possibly that despised creature, the ontological proof, might find some kind of mission in the midst of his desired association of theistic arguments. The ontological proof, having very long been able to say, —

> "I lie so composedly now in my bed,
> That any beholder might fancy me dead,"—

must regard the kindness of Mr. Hicks with very mixed emotions. He thinks that it might be 'just the thing to supplement' the others. But during its natural life the ontological proof used to think that the others might possibly be of use to supplement itself.

Such, then, is our author's own line of argument. Between the introduction and the final exposition of this argument, he inserts a discussion of the history of design arguments. This is a mere collection of notes, with more or less ingenious reflections that suggested themselves to the mind of the collector here and there in the course of his work. The 'Natural theology of the Greeks and Romans' is treated in some thirty pages, which are devoted to Socrates, Cicero, and Galen. How, one may ask, would it look for one to head a chapter with the title 'The astronomy of modern times,' and then to treat the subject by briefly expounding some statements of Galileo, Lord Brougham, and Dr. Whewell? Thirty pages might well be the limit allowed by the plan of our author; but such a space is not too limited for a really connected historical sketch, with some attention to the perspective in which every man's thought ought to be viewed. The author's account of Spinoza is similarly imperfect, because no effort has been made to see what the man, with his odd, crabbed method, really had in mind. We are told, what we all knew before, that Spinoza's method is unsuccessful; but, for the rest, we learn more in this chapter about Mr. Lewes than about Spinoza. 'Reimarus, Kant, Hume, and Reid' are somewhat embarrassed to find themselves side by side in one chapter; and poor Kant especially is made to speak as he did in 1763, instead of being allowed to present himself as he does in the 'Critique of pure reason,' nearly twenty years later. Although this error is in just this discussion not so serious as the corresponding error would be in expounding other parts of Kant's doctrine, yet the method is unhistorical; and the result is, that, in summing up, Mr. Hicks hopelessly confuses Kant's pre-critical and critical periods. In short, our author shows himself in general no historian of thought. Throughout the whole sketch, there is a lack of a sense of the development of thought. Each man's notions stand beside his neighbor's, as if the philosophers were all speakers in a debating-club. And Mr. Hicks, as intelligent listener, adds his applause and his comments in brackets, and is not afraid to express himself with even boyish freedom of speech. But he is always good-humored, and his criticisms often hit the mark very well. Yet it is to be hoped that nobody will undertake to judge the history of natural theology on the basis of this account.

Now as to the result. What shall we say of eutaxiology? We have no hesitation in declaring the argument, as our author presents it, an altogether defective one. For, as he presents the eutaxiological argument, it is an inductive argument, and solely inductive. If we saw a triangular arrangement of objects on the moon, we should conclude that some intelligence had done this. We should extend the known association of intelligence and order, as we find it about us, to cases of order more remote from our direct observation. We should conclude that order is a sign of intelligence, even where we have no other evidence of the presence of intelligence. So reasons Mr. Hicks. But is this sound? And, first, is the author's suggestion about the supposed geometrical figure seen on some planet a correct one? Should we, if we saw such a figure on some planet, at once conclude that intelligence had caused it, or was in any way associated with it? Surely not everybody would feel the force of such an induction.

Most scientific astronomers, observing such a regular figure for the first time, would at once look for some ordinary physical explanation of its presence, even as they now try to explain the shapes of the planets; and, failing to find such an explanation, they would be content to call the triangle a mystery. Only some man whose position as a public lecturer on astronomy demanded that he should have a new sensation ready for each new lecture-season would be apt to insist on the existence of some set of geometrically disposed planetary giants. More sober people would be content with an *ignoramus*. But how much less satisfactory becomes such an induction when applied to the whole of nature! At best would not such an argument be like the inductive reasoning of a man, who, having already learned the modern doctrine of the relation of the colors of flowers to the habits of insects, should for the first time, and without any previous knowledge of marine zoölogy, find a colored shell by the sea-shore, and who should then at once expect to find some race of insects in some analogous relation to the inhabitant of this shell? Or, again, if one extended even to the rainbow, or to the sunset, an explanation derived from the case of colored flowers, and their relations to insects, would not the argument possibly be no more absurd than the induction upon which Mr. Hicks lays so much stress? Men and beavers and other creatures make orderly groupings of things. Hence order implies intelligence, and that wherever we find order. Is this argument any better than the old teleology?. Mr. Hicks is deceived, it would seem, by the vast wealth of facts to which his argument appeals. He neglects the difficulty of bringing such various facts within the control of an induction that has for its narrow basis such intelligent activity as we see about us among men and animals. As induction, pure and simple, eutaxiology seems to us simply worthless.

But is the order argument in any form therefore worthless? Certainly not. Mr. Hicks does fine service in bringing before the public, just at this moment, a thought that is by no means new, and that is profoundly suggestive. 'What does the order in the world imply?' This is a great question, not of inductive science, which is concerned solely with discovering the actual order itself, but of general philosophy. And Mr. Hicks is, we doubt not at all, quite right in saying that order implies intelligence. But how, and what intelligence? Such questions he leaves wholly unanswered. The critical philosophy of Kant would, strictly speaking, affirm that order in the world implies only the intelligence of the thinking subject to whom the world appears. The world is orderly, because only as orderly could it become known to an intelligent being. Not the world in itself, but the world for thinking beings, is to be viewed as orderly. This view would make short work of our author's 'induction,' but it would not satisfy him. He would then need to know and build beyond Kant. In short, Mr. Hicks has very ingeniously set his reader down at the beginning of a great philosophic problem. It would argue a lack of intelligence in the reader if he did not seek to bring his thoughts into a better order than that in which Mr. Hicks will have left them; and the author's service lies in making it impossible for an inquiring mind to rest content with what is here offered to him. This, however, at least, he has very well suggested, though he has not proved his suggestion: viz., that the postulate of natural science is the rationality of the world. Whether we find order, or only seek it in nature, we are always *a priori* sure that the world is actually full of connections that admit of expression in rational terms, of explanation to an intelligent mind. And so we assume a fundamental likeness of nature and intelligence that suggests to us very strongly some kind of real unity or identity of nature and intelligence. But whether this suggestion has any ground, whether this identity of nature and mind is to be accepted at all, or is to be accepted in Kant's sense only, or in Berkeley's sense, or in Hegel's sense, or in some other sense, this is a matter for philosophy to discuss. We thank Mr. Hicks for having shown afresh the necessity for such discussion. His eutaxiology is not so original as he thinks; but his offering on the altar of philosophy deserves the reward due to every gift that a special student of natural science finds time to offer in the true spirit of calm investigation.

MAYNARD'S MANUAL OF TAXIDERMY.

Manual of taxidermy: a complete guide in collecting and preserving birds and mammals. By C. J. MAYNARD. Boston, *S. E. Cassino & Co.*, 1883. 16 + 111 p., illustr. 12°.

A REALLY *complete* guide in collecting and preserving the objects named in the title of this work, which can safely be relied upon for information under all circumstances and in all climates, has long been sorely needed by the host of amateurs, taxidermists, travellers, and even professional naturalists interested in vertebrate zoölogy. Notwithstanding the presence of the neat little volume before us, and its promising title, a complete guide is still as much a desideratum as ever. Like all other books which have appeared in English on this subject, this volume is small and thin, and, we are compelled to add, wretchedly illustrated. Of the one hundred and one pages of subject-matter, sixteen are frittered away in an effort to inform the reader where birds of the various families from Turdidae to Alcidae are to be found. How much better to have devoted this space to adequate instructions for mounting dried skins, which important branch of the subject is summarily disposed of on a single page, instead of to such cheap information as that 'the chimney-swift inhabits chimneys,' that kingfishers are found 'in the vicinity of streams,' and the like. With the exception of the above, all the information and advice contained in the chapter on collecting is valuable, and bears the stamp which experience places upon its work.

The chapters on 'skinning birds' and 'making skins' would be very satisfactory but for one thing. While the author strongly condemns dry arsenic as a dangerous poison, and says not a word about arsenical soap, the only preservative he recommends as fit for use is one compounded only by himself. After extolling its virtues to the extent of two pages, but carefully withholding all information as to its composition, he coolly informs the reader that its price is 'twenty-five cents per single pound.' We are told that tannic acid, alum, salt, or black pepper (!) may be used to temporarily preserve skins until the other can be procured. The 'dermal preservative,' which, strange to say, is not a poison, is recommended, or rather exclusively directed, in no fewer than fourteen places throughout the work, for mammals, birds, reptiles, and fishes, as a non-poisonous astringent, absorbent, deodorizer, and insecticide; and, if the reader is at all credulous, he will be led to exclaim, There is but one preservative, and C. J. Maynard is its maker! If this little book is honestly intended to meet the wants of amateur collectors wherever it may find them, and not to increase the sale of a nostrum of doubtful value, nor to advertise the author's business, the author has taken a queer way to show it. It will not be surprising if his readers resent such unfair treatment.

While there is much that is practical, valuable, and new in the chapter on mounting birds, and in those detailing the treatment of mammals, reptiles, and fishes, they are all deplorably incomplete; and we vainly regret that the author did not go as deeply into the subject, and with as good diagrams and illustrations, as he might have done. The information given is valuable as far as it goes; but there are only one-quarter as many facts stated, and directions given, as the unskilled operator needs to know.

As an example of the doubtful value of such highly condensed instructions, we may take those for skinning small mammals. The author says, ". . . peel down on either side [of the body] until the knee-bones are exposed, then cut the joint, and draw out the leg, *at least as far as the heel.*" Not a word is said about skinning the foot, and removing the flesh under the metacarpal and metatarsal bones: hence we suppose it is left to decompose, which it will generally do right speedily, and at the expense of the hair and epidermis above. We should like to see the author remove and prepare the skin of any monkey according to his own directions.

We are honestly sorry we cannot freely recommend this manual — nor any other in our language, for that matter — as being well calculated to meet the wants of those for whom it is intended. An epitome of the subject is no longer wanted, but a handbook which shall be really complete is needed very much.

ELEMENTARY TREATISE ON THE MICROSCOPE.

Traité élémentaire du microscope. Par Eugène Trutat, Conservateur du musée d'histoire naturelle de Toulouse. Paris, *Gauthier-Villars*, 1883. 322 p., 165 ill.

Few are aware of the magnitude to which microscopical work has grown. The modern methods of research in the physical and biological sciences have involved more and more an appeal to the microscope. As a result of this growth, we find whole volumes devoted to a description of the microscope and its application to the various departments of study.

Microscopy has been taught in our schools only a very few years. This is partly due to the fact that formerly the instruments were both expensive and imperfect. There was also an almost total lack of literature upon the subject. At the present time, however, there are plenty of good works on microscopical technology, and the microscope as applied to the study of medicine in all its branches, including biological research.

In a work like this before us, it is necessary to present a large amount of material of such an elementary character that it is of value only to the novice. It is decidedly a French work, written by a true Frenchman. Neither an instrument nor an accessory is mentioned, unless either invented or manufactured by a Frenchman. The stands of Verick are given great prominence, as are also those of Hartnack. When we consider how beautiful and useful are the instruments of our own country, to say nothing of the fine productions of English houses, we are forced to call the work 'an elementary treatise on the French microscope.' For convenience, elegance of design, and varied adaptability, the French microscope will not compare with those of our own country, while we far excel in the superior quality of our objectives.

The microscopist will be much interested in reading the chapter on the projection microscope. Electricity will soon furnish us with proper illumination.

More information is given under the head of mineralogical research than in any work brought to our notice. Among the accessories mentioned is the camera lucida of Oberhauser. It is a form little used in America, and yet it is one of the most convenient and perfect of its kind.

The new pattern of Malassez's *Compte-globules*, by Verick, is minutely described. The results obtained by this instrument promise to be very accurate: we have practically tested its merits, and can give testimony to its precision. The method for photographing from the microscope is not so simple as that employed here by the use of dry plates; and, if the frontispiece be taken as a sample, it is not more satisfactory. The author shows perfect familiarity with the instruments and accessories, together with their applications as made and used in his own country. C. H. STOWELL.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

PROCEEDINGS OF SECTION E.—GEOLOGY AND GEOGRAPHY.

Reports of committees on geological subjects.

To the call for a report of the *Committee to memorialize the legislature of New York for a new survey of Niagara Falls*, Prof. James Hall responded, that several surveys had been made, or were in progress, in connection with legislation by the State of New York for preserving the scenery. These would supersede the need of any work of the kind by the association. The committee was discharged.

To the call for a report of the *Committee on state geological surveys*, Prof. N. H. Winchell responded, that the committee had never been called together, and there was no probability of its action. The committee was discharged.

To the call for a report of the *Committee on the international congress of geologists*, Dr. T. Sterry Hunt (by request of the chairman, Professor Hall) responded as follows:—

The committee held a meeting in the month of November last. Two important questions came up,—of geological nomenclature, and topography. It was suggested by Professor Hall, that the only action which could be taken in support of the system of uniform mapping and colors, and signs and symbols, would be to prepare maps of the United States as a whole, and perhaps also maps of portions of the United States, and to color them by different systems; the system adopted being that of Major Powell of the U. S. geological survey, and one or two others. Major Powell has been good enough to say that he would endeavor to prepare such maps, and aid in every way the carrying-out of the scheme. I have no doubt that the matter will be so well managed that the whole question of geological topography will be settled.

As to the question of geological nomenclature, we had much difficulty in getting reports of the previous meetings; and we have named several persons, some of whom have already handed in, or have in process of preparation, their abstracts of geological nomenclature; and I have every reason to hope that in the course of a few weeks we shall have the whole of that matter in shape to transmit to the Berlin congress a full and proper representation of the views of American geologists with regard to our geological nomenclature. There is one thing very much to be regretted,—the possibility that the meeting of the American association and the British association will come in collision with the meeting of the Berlin congress. Nothing definite has been arranged, so far as I can learn by letters. I have met with no response, but I was told that the time of the Berlin congress had not been fixed. In the committee which was held to consider arrangements for the meeting of the British association, it was suggested that we put ourselves in communication with the local authorities of the Berlin congress, and endeavor to get them to fix the time of their meeting so late in September as will allow members of the American and British associations to leave this continent after the meeting of our associations so as to be present at the Berlin congress.

The committee was continued.

The *Committee to confer with the United-States geologist in regard to co-operation between government and state geological surveys* was called on for a report. Prof. James Hall of Albany responded in-formally: The condition of the state survey is likely to be materially influenced by the law of the general government extending the U. S. geological survey over the states. Proper deference to the head of the U. S. survey required that some action should be taken by which we could confer with Major Powell, to understand our relations to the survey. To prevent any jealousy or uncertainty with regard to what might be the relation of the state survey and the general survey, I suggested the appointment of this committee. I had no intention myself of taking any active part in the matter; and I think there are gentlemen on the committee, much younger than myself, who will do all the work. I believe several members of the committee have had very pleasant interviews with Major Powell, as I have myself, since these meetings commenced; but I had forgotten that I was to make a report. I think it is desirable that there should be very frank intercourse between the gentlemen who are conducting the state surveys and the head of the general government survey, so that we may know what is to be the result of their various surveys which are so very important to geological science. Workers at a distance from each other cannot, without some means of inter-communication, — which, I think, may be established with the head of the general survey, — bring the results of their labors to a fair comparison with those which are done a thousand miles away.

Major Powell expressed the hope that the committee would be continued. Several members of the committee had conferred with him with reference to the surveys, but they had not conferred as a committee. Practical relations have been established between the general survey of the United States and several of the state surveys. He thought it was probable that such arrangements could be established as would make it satisfactory to all.

The committee was continued.

PAPERS READ BEFORE SECTION E.

(*PAPERS ON GLACIAL PHENOMENA.*)

The life history of the Niagara river.

BY JULIUS POHLMAN OF BUFFALO, N.Y.

A series of observations whose points were given in detail had convinced the author that the formation of the gorge of Niagara had been a matter of tens of thousands, rather than of hundreds of thousands, of years. The beginning of the history might be stated as in the pre-glacial epoch. A lake then occupied the valley of the Tonawanda; its outlet was the line of the ancient Niagara River from the falls to the whirlpool; thence, by way of the St. Davids valley, into the Ontario valley. All these valleys were closed during the glacial period. The subsidence of Lakes Erie and Ontario was that of one body or region, until they were separated by the Lewiston escarpment; after that the drainage of Lake Erie found its path through drift deposits and old existing valleys to Lake Ontario. The latter lake subsided slowly, and no waterfall was formed at its entrance. The river excavated its gorge to the whirlpool, not by means of a retreating fall, but as a rapid in an old shallow valley. At the third pool, this path met the ancient river-valley: it was along that valley only, that the falls receded to their present site. The retreat of the fall was not the means of excavation, for at least seven miles usually ascribed to it; the portion which would offer the most resistance, between the falls and the whirlpool, being already excavated.

From that point to Lewiston, the progress was very rapid in cutting the gorge; a shallow valley had partly removed the hard limestone, and the softer underlying shale rock was a barrier much more easily penetrated. We have no exact data of the retrocession of the falls within periods of modern observation. A comparison of Professor Hall's map of the falls in 1841, and that of the United-States lake survey in 1875, shows wide discrepancies. After all reasonable allowance for inaccuracies, we must admit that parts of the Horse-shoe fall have receded in thirty-four years at least one hundred feet, and on the American side the recession is from twenty to forty feet. These facts all tend toward a shortening of the history of the present river.

In the discussion that followed, Professor Hall expressed a doubt as to the dependence that could be placed on differences between surveys made by different persons, using differing methods. That there had been retrocession within the period of our observation, he did not doubt; but it could scarcely be so rapid as was indicated by the estimates of Dr. Pohlman. Other speakers discussed the paper, which was of special interest, because it fired the first gun of the glacialists in the geological section, and it roused their opponents.

Glacial cañons.

BY W. J. McGEE OF SALT LAKE CITY, UTAH.

This paper was read, in the absence of its author, by Mr. Warren Upham. It considered the action of a glacier as being, to a certain extent, capable of representation by mathematical formulae. It was admitted, however, that some of the quantities in the equations must remain very indefinite. The paper was almost wholly theoretical, and arrived at the following conclusions: The temporary occupancy of a typical water-cut cañon by glacier-ice will, 1°. increase its width; 2°. change the V to a U cross profile; 3°. cut off the terminal portions of tributary cañons, and thus relatively elevate their embouchures; 4°. intensify certain irregularities of gradient in the cañon bottom; 5°. excavate rock basins; 6°. develop cirques; and, in general, transform each cañon into an equally typical glacial cañon. It follows that these features do not necessarily imply extensive glacial excavation, or indicate that glaciers are superlatively energetic engines of erosion.

Owing to the custom of abstaining from discussion on a paper in the absence of its author, the dissentient opinion of many who were present was not fully elicited. The general expression was to the effect, that the theory had been framed without sufficient observation of the facts, and that, if the author had taken the trouble to see and examine various cañons, he would have come to a widely different set of conclusions.

The ancient glaciation of North America: its extent, character, and teachings.

BY J. S. NEWBERRY OF NEW YORK.

WHILE the glacial area on our continent has not been fully explored, there is abundant proof for the following propositions: 1°. Glaciers covered most of the elevated portions of the mountain belts in the far west as far south as the 36th parallel, and in the eastern half of the continent to the 40th parallel of latitude. 2°. The ancient glaciers, which occupied the area above described, were not produced by local causes, but were evidences of a general climatic condition. 3°. They could not have been the effect of a warm climate and an abundant precipitation of moisture, but were results of a general depression of temperature.

The traces of glaciation are similar in kind, and apparently in date, over the whole area: they are therefore effects of general, not of local, causes. East of the Mississippi, the evidence is even more widespread and impressive than in the far west. The area bearing marks of ice action, and strewn with drift, extends from New England westward, parallel with the Canadian highlands, in a belt five hundred miles wide and over two thousand miles long. Its northern extension has not been traced beyond Winnipeg; but there are reasons for believing that it reached to the Arctic ocean, and that the great lakes are pre-glacial river-valleys, scooped out and modified by ice. Fully half the continent north of the 36th parallel was glaciated. So far as we now know, the glaciation was synchronous.

The iceberg theory was opposed by Dr. Newberry, on the following grounds: It postulated a water-line with irregularities of level that are irreconcilable. The direction of the scratches, and the lines of deviation of the bowlders, require that the northern portion of the continent should have been all submerged, leaving no land for the origin and starting-point of icebergs. If the icebergs could have been formed and floated, an incomprehensible tangle of ocean-currents would be required to account for their movements. The evidence of sea-covering, in the form of marine shells, is totally absent from the great drift area of the interior, while they are found abundantly in the Champlain and bowlder clays of the coast. Finally, the inscription left by the eroding agency is characteristic and *sui generis.*

The record of the ice period on our continent is far more extensive and impressive than it has been represented. The phenomena were due to an extraneous and cosmical cause, not to any thing local or even telluric. The question here passes from the geologist, and must be addressed to the astronomer. Professor Newberry briefly recapitulated some of the theories which have been suggested by Croll, Newcomb, and others, to account for the glacial epoch.

Result of explorations of the glacial boundary between New Jersey and Illinois.

BY G. F. WRIGHT OF OBERLIN, OHIO.

AFTER citing reasons for desiring a careful *résumé* of the subject, — the observations being scattered in the works of different explorers, — the author proceeded to name those who had determined, for different regions, the southern boundary of the glacial area. Starting at the eastern coast, President Edward Hitchcock was the first to intimate that the backbone of Cape Cod was a part of the terminal moraine if the theory of Professor Agassiz were true. Clarence King made a similar assertion as to accumulations near Wood's Holl and on the Elizabeth islands. Professor Charles H. Hitchcock declared that the backbone of Long Island was the foot of a terminal moraine. Warren Upham went over this field, from the end of Cape Cod to Brooklyn, to verify the hypothesis. Professors Cook and Smock traced the moraine across the state of New Jersey. Professor Lesley commissioned Professor Carvill Lewis and the author of the paper to continue the exploration across Pennsylvania. In Ohio, Professor Newberry has approximately outlined the boundary; but in Ohio, Indiana, and Illinois, the survey was carried on by a number of different persons before the most distinctive glacial features were fully understood.

The chief indications on which reliance can be placed to determine glacial action are striated rocks, striated stones, bowlders, and till. Rocks near the margin are often so deeply embedded in till, that their markings are not apparent. The softer rocks do not always retain their striae: this has often been the case in Ohio. In certain situations, stones might be striated by a landslide, or the grounding of an iceberg; but the area over which striated stones are found is too vast for such explanation of their presence. The bowlders are of granite and metamorphosed rocks from northern Canada and the shores of Lake Superior: their presence is relied upon only when they are on such high lines as to preclude the likelihood of their having been transported by the agency of rivers. Till is spread over the whole area: it is defined as an unstratified deposit, containing striated stones of various sizes, — fragments of rock foreign to the locality. Its composition varies, through mixture with underlying material. It covers and gives fertility to northern Ohio, Indiana, and Illinois. Till has been characterized by Professor Newberry as the grist of the glacier.

Briefly told, the boundary-line of the glaciated area, so far as now accurately known, is as follows: Beginning on the island of Nantucket, it runs through Martha's Vineyard, No Man's Land, Long Island from east to west, across Staten Island, entering New Jersey at North Amboy, and after bending northward and making a right angle near Dover, crosses the Delaware at Belvidere. Thence it runs north-westerly through Northampton, Monroe, Luzerne, Columbia, Lycoming. Tioga, and Potter counties in Pennsylvania, and Cattaraugus county, New York, reaching its most northerly part about five miles north of Salamanca. From here it runs through Warren, Venango, Butler, Lawrence, and Beaver counties, to the Ohio line, crossing Beaver creek at Chaintown about fifteen miles above the Ohio river.

The boundary enters Ohio in the northern part of Columbiana county, and proceeds nearly west to the middle of Stark; then turns more to the south, touching the corner of Tuscarawas, and dividing Holmes into two nearly north-and-south sections. Near the north-east corner of Knox, the line makes a right angle, and runs south through Knox, Licking, the north-west corner of Perry, Fairfield, Ross, Highland, Adams, and Brown counties. Then it follows the line of the Ohio river across Clermont, and enters Kentucky near the boundary between Pendleton and Campbell counties, and, after crossing the northern part of Kenton and Boone counties, recrosses the Ohio, entering Indiana a little below Aurora.

In Indiana the line still continues to bear in a southerly direction through Ohio and Jefferson counties, grazing the edge of Kentucky again opposite Madison, and reaching its southernmost point near Charleston in Clarke county, Ind. From here it bears again to the north, through Scott and Jackson counties, to the line between Bartholomew and Brown, and follows this to the north-east corner of Brown. There again it turns to the south-west, touching the north-east corner of Monroe, where it again bears north for ten miles, to near Martinsville in Morgan county. Here again the line turns west and south, passing diagonally through Owen and Green counties, and in Knox as far as Harrison township, ten miles south-east of Vincennes. Beyond this point, the author did not propose at present to trace the line.

The signs of glaciation cease where there is no barrier to account for their cessation, and where no barrier ever could have existed such as must be supposed if the so-called glacial phenomena are the product of floating ice. Of the correctness of this inference, the different elevations at which the signs of glacial action cease are sufficient proof. For instance, the line is near sea-level in New Jersey; in Pennsylvania it rises over Mount Kittatinny to a height of 1,200 feet, then descends 800 feet into a valley, and, again rising, reaches the summits of mountains 2,000 feet above sea-level. Crossing the valley of the Susquehanna at an elevation of only 500 feet, the line mounts the Alleghanies diagonally, and runs over them at a height of 2,500 feet.

The paper proceeds to describe certain marked features of glaciated areas. South of New England, the terminal line is characterized by a series of glacial hills, 100 to 300 feet high. These are also observable in New Jersey, near Plainfield and Menlo Park.

Among the most interesting results of the author's survey in Ohio, was the demonstration of the existence of an ice-dam across the river at Cincinnati. The line bounding two glacial accumulations crosses the Ohio river into Kentucky, near the boundary between Campbell and Pendleton counties, about twenty-five miles above Cincinnati, and recrosses it near Aurora, Ind., about twenty-five miles below Cincinnati, thus filling the channel for about fifty miles of its course. The Ohio, it should be said, occupies, throughout nearly its whole extent, a narrow valley of erosion, not often more than a mile wide, and from 300 to 500 feet deep. Emptying into the main channel there are subordinate channels all along, of smaller dimensions, but of nearly equal depth. The proofs that the ice bodily crossed the river at the point indicated are, that till and granitic bowlders are found in the Kentucky hills south of the river to a certain distance, and not beyond it.

To the question, Why is the boundary of the glacial area so crooked? the author replied at some length; assigning as a principal cause, aside from differences of level, the probability that unequal amounts of snow fell over different regions of the north. The effect of such differences of accumulating snowfall, in determining the extension of the glacial outline, is illustrated by supposing that two loads of sand are placed in one pile, and one load in an adjoining pile; when the sand will flow downward to unequal distances upon a level.

A little reflection will show that the glacial theory will not make extravagant suppositions as to the amount of ice required. The ice was indeed 600 feet deep over New England, and, very likely, of an equal depth over the area to the west; but it is not necessary to suppose a great increase of this depth to the north. All that is necessary is to suppose great accumulations of ice to the north of the granitic hills of Canada, starting a movement past them to the south. This movement may have been kept up toward the margin by fresh accumulations of snow upon the spreading glacier. An accumulation of snow over the glacier in any part of it would spend its effective force in giving impetus to the movement of the front along the lines of least resistance.

The discussion which followed the reading of this paper took a wide range, as the paper itself contained many points of interest. The opponents of the glacial theory, or of the younger theories which have sprung from its loins, based their criticisms chiefly upon doubts of the evidences of glaciation. The questions raised, as to the distinctive characteristics of glacial and subaqueous deposits, gave tone to the paper of the next speaker, which was delivered orally, and was, at least in part, extemporaneous.

The terminal moraine weat of Ohio.

BY T. C. CHAMBERLIN OF BELOIT, WIS.

This paper was introduced by a statement of the author's views on some points that had been alluded to in the discussion of Professor Wright's paper. Dr. Chamberlin had himself observed the features of the drift-bearing area west of the Rocky Mountains. Certain of the drift clays are unquestionably glacial: others have quite as certainly had a wholly different origin. He specified with great particularity the means for discrimination between the clays, but admitted that there were instances where the different types seem to blend insensibly into each other.

West of the Scioto valley, the border of the drift-bearing area is not marked by what is regarded as a moraine. There is, however, an extension of what Professor Wright has characterized as the 'glacial fringe,' consisting of bowlders. In Dakota county, Minn., this fringe is very wide. At Crystal lake there is a well-marked moraine, and possibly there is another a little to the westward. Farther to the west, there is no accumulated morainic drift. West of the Missouri, there is no evidence of glacial ploughing.

A line of drift-hills known as the Potash Kettle range, in eastern Wisconsin, had been regarded as an old beach-line. Dr. Chamberlin has ascertained that the range is a glacial moraine. He described it as an interlobate moraine, formed jointly by glacial lobes occupying the valleys of Lake Michigan and Green Bay, respectively. This was correlated with moraines to the westward in Wisconsin.

Furthermore, there was a system of moraines, — a belt or group, including the glacier lobes at Lake Michigan, in the Chippewa valley, at the western extension of Lake Superior, and in the valley of the Minnesota River, and Red River of the North. These moraines were more pronounced, with a few exceptions, than those on the outer edge. Investigations were being carried eastward with a view of showing their correlation with other moraines in that direction. The hypothesis of their exact correlation, of course, would imply that they were contemporaneous; but there are doubts upon that point.

The author claimed, that there were evidences that the lake-basins were caused in part by depressions during the ice age, caused by the exceptional accumulation of ice in the basins. He deprecated the notion that subsidence must always take as long a period as elevation, or that the reverse is true. He applied this to the case which he alleged of the depression during the presence of ice in the lake-basins, and the elevation since.

In discussing this paper, Professor Lesley said it was time to cry halt as to this theory of depression by weight of ice. It was made to do duty for a great variety of emergencies. In point of fact, ice was much lighter, very much lighter, than any rock. Professor Lesley pointed out instances where this theory had been advanced to account for depressions which now contained a greater weight than the ice could have made with any reasonable hypothesis of its thickness.

Professor Chamberlin explained the theory further, and claimed that in instances which he cited the depression was greatest at the weakest part of the strata.

Prof. E. S. Morse referred to some English experiments to determine the question whether the moon's attraction deformed the earth's outline. It was found (according to newspaper report), that the weight of the incoming tide deformed the surface to such an extent that the effect of the moon's attraction could not be separately calculated. Major Powell called attention to the theory, that, if the earth were divided into conical sections radiating from its centre, there would be found an equal pressure in each. Every sediment, every erosion of the surface, must be balanced by corresponding depression or rise elsewhere. Finally, the case of Lake Saltonstall was cited by Mr. Hovey. It is evidently situated in a valley that was ploughed out by the foot of a glacier; certainly not in a hollow caused by pressure. Professor Cox clung to another theory entirely, as to the great lakes. He believed them to be prolongations of a sea-coast which had at one time extended to them through the valley of the St. Lawrence.

The Minnesota valley in the ice age.

BY WARREN UPHAM OF MINNEAPOLIS, MINN.

The paper was based upon the author's observations for three years as assistant on the geological and natural-history survey of Minnesota, under the direction of Professor Winchell. To the question: During what ages was the glacial, rock-walled channel of the valley of the Minnesota River formed? — the paper offered an answer. Deposits of cretaceous clay were found in water-worn hollows at several enumerated localities; and, in other places, cretaceous sandstone and shale occasionally containing lignite. It thus appears, that, before the cretaceous age, a deep channel had been cut by some river in the lower magnesian sandstone, and the Potsdam formation. The slopes, the drainage, perhaps even the channel, of that river, were not widely different from those of the present; but that channel was probably eroded during the later paleozoic and earlier mesozoic ages, before the cretaceous subsidence.

In the first epoch of glaciation, when the ice covered its greatest area, a thick drift-sheet, mostly unmodified, probably covered all this region, including the preglacial valley, with an unbroken, though undulating, expanse of till. During the ensuing interglacial epoch, the drainage cut a channel, whose position was largely determined by the slopes of the erosion which had preceded the glacial epoch. The preglacial, and also the interglacial river, lay far below the present stream. The till of the later epoch blocked the course of the river only in part of its extent, and the obstacle was soon channelled anew.

During the recession of the last ice-sheet, the valley was filled with modified drift. After the ice was melted in the Minnesota basin, this avenue of drainage was, for a long period, the outlet of Lake Agassiz. The volume of water that it carried was very large, being supplied by the melting ice-fields of Northwestern Minnesota, and from the region of Lake Winnipeg and the Saskatchewan. While streams poured into this river from the melting ice-sheet, its modified drift continually increased in depth; but, when the great glacier had sufficiently retreated, the water from Lake Agassiz not only ceased to contain drift, but became a powerful eroding agent. The deposited drift was mostly swept away, and the channel was again excavated, perhaps to a greater depth than the present river, possibly to the bottom of the gravel and sand, at a point in the valley which is 150 feet below the river there, and 135 feet below low water in the Mississippi at St. Paul.

When the ice-barrier which had made Lake Agassiz disappeared, that lake was drained northward toward Hudson bay. Thenceforward, the rivers of the Minnesota and Mississippi valleys carried only a fraction of the former volume of water from this source. They have since become extensively filled with alluvial gravel, sand, clay, and silt, brought in by the tributaries of those rivers. The changes produced by this post-glacial sedimentation have been ably discussed by Gen. G. K. Warren, and were briefly summarized in the paper of Mr. Upham.

Lake Superior seems to have been held by an ice-barrier at a level of about 500 feet from its present height. The locality of its overflow was stated, and various results detailed. Lake Michigan, until the ice-sheet receded from its northern border, discharged southward by the Illinois river, which, like the former outlet of Lake Superior, was eventually obstructed by alluvium, so that now it has a very slight current for two hundred miles.

The paper closed with a proposition to call the ancient river of the glacial age, the river Warren, in honor of Gen. G. K. Warren.

The discussion which followed was, in part, a conflict between the glacialists and their opponents, and, in part, a debate upon the general question of naming geological features after distinguished investigators.

Changes in the currents of the ice of the last glacial epoch in eastern Minnesota.

BY WARREN UPHAM OF MINNEAPOLIS, MINN.

Without a map, or a thorough familiarity with the region referred to, this paper would not convey very definite ideas. Through some inadvertency the map intended to be used was not on hand when the paper was read. The author's observations had led him to conclusions of a very definite character. He conceived, that, when the ice of the last glacial epoch attained its maximum extent, there were two ice-currents. One moved south-westerly from Lake Superior, across the north-east part of Minnesota, spreading a reddish till with bowlders and pebbles, and limited by a line from Lake St. Croix south-west across the Mississippi, and thence bending north-west by Lake Minnetonka, and through Wright and Stearns counties. The other portion of the ice-sheet was pushed from the region of Lake Winnipeg, south and south-east. The two met along a line from Stearns county, south-east by Lake Minnetonka to Crystal Lake, Dakota county. Afterward, when the ice had partly melted and retreated, a second and inner terminal moraine was formed. Owing to climatic changes (the rationale of which was carefully and very explicitly set forth in the paper), the current from the north-west pushed back that from the east, and covered the reddish till, already deposited, with a blue till from the west and north-west, also abundant in its peculiar bowlders and other evidences of its source.

The kame rivers of Maine.

BY G. H. STONE OF COLORADO SPRINGS, COL.

In the absence of its author, this paper was read by Mr. Upham. After defining and describing the characteristics of kames, and stating that they are very numerous in Maine, where he had observed them, the author proceeded to discuss a single question in relation to these geological features. Most glacialists are agreed that the kame gravels of the drift region were chiefly deposited by glacial streams. The question is, whether these streams were sub-glacial or super-glacial. In exploration during the past five years, the author had found evidences of both kinds of streams; but he nowhere found stratified or even water-classified material enclosed in this formation, except within a few miles of the coast.

The essayist sought to answer the question by considering the processes of melting which take place in a glacier. Strict analogy with existing glaciers — even with those of Greenland — should not be supposed. In modern glaciers, nearly all the water of their lower extremities is sub-glacial. The ice is so broken by crevasses that melting waters soon find their way to the bottom. But a different state of affairs may have prevailed in the continental glacier. Several of these kame rivers are a hundred or more miles in length. Granting all reasonable development of sub-glacial streams, these kames can scarcely be thus accounted for. Superficial water flowing along the surface would gradually deepen its channel: when the melting had so far proceeded that the bottoms of these streams reached the moraine stuff in the lower part of the ice, the kame gravel would begin to gather on the bottoms of their channels. During the final melting, when the condition was such that few if any additional crevasses would be formed, there would be no time to extend the previously formed sub-glaclal channels. The sudden floods would pass over the lowest part of the ice as they would over ground. A great and rapid northward extension of the superficial streams would result.

In discussing this paper, Mr. Upham stated that erosion does not appear in kames. They are not unfrequently a hundred feet in height: one on the borders of the Merrimac river was instanced. They appear to be gravel deposits laid down before the glacier was fully melted.

Relation of the glacial dam at Cincinnati to the terrace in the upper Ohio and its tributaries.

BY I. C. WHITE OF MORGANTOWN, W. VA.

This paper, in the absence of its author, was read by Professor Winchell.

In a paper read before the Boston society of natural history, March 7, 1883, Rev. G. F. Wright showed that the southern rim of the great northern ice-sheet covered the Ohio river near the site of New Richmond, a few miles above Cincinnati; and presented the hypothesis, that one effect of this invasion of the Ohio valley by the glacial ice was to form an immense dam of ice and morainic *débris*, which effectually closed the old channel way, and set back the water of the Ohio and its tributaries, until, rising to the level of the Licking River divide, it probably found an outlet through Kentucky, around the glacial dam. The writer of the essay, after reviewing the evidence, regards Mr. Wright's hypothesis as proved beyond a reasonable doubt. He also claimed, that during the period of the continuance of the dam, the principal tributaries of the Ohio had their valleys filled with sediment carried down and dumped into them by the mountain torrents and other streams which drained the area south from the glaciated region; that subsequently, when the barrier disappeared, the rivers recut their channels through the silt deposits, probably by spasmodic lowering of the dam, in such a manner as to leave the deposits in a series of more or less regular terraces, which in favored localities subsequent erosion has failed to obliterate, though from steep slopes it has removed their every trace. The elevation of this dam at Cincinnati, as determined from the upper limit of the fifth Monongahela River terrace, would be somewhere about 625 feet above low water there in the present Ohio.

In discussing this paper, Professor Lesley said that there were two separate glacial formations to be considered, and the two could not be correlated. The ice-dam could not thus be explained. Professor Wright had discussed the subject with clearness, claiming that the dam was glacial; but at best there were only a few places in the west where the height of the ice could be measured.

The eroding power of ice.

BY J. S. NEWBERRY OF NEW YORK.

THE object of this essay was to enter a protest against the theories of certain geologists who claim that glacial ice has not played an important part in the erosion of valleys. They have undertaken to deny that ice has any great excavating power. Examples of utterances of this school, the speaker said, were to be found in Prof. J. D. Whitney's Climatic changes; in papers by Prof. J. W. Spencer, on the Old outlet of Lake Erie; by Mr. W. M. Davis, on the Classification of lake basins, and the erosive action of ice; and remarks on the same subject by Prof. J. P. Lesley.

The most important heresies which had been advanced in regard to this subject were, first, the denial that there was ever a glacial period; second, if there was an ice period, it was a warm and not a cold one; third, that the phenomena usually ascribed to glacial action in the record of an ice period were generally due to icebergs; fourth, that ice has little or no eroding power, and that glaciers have never been an important geological agent. Professor Newberry proceeded, in controversion of these theories, to give the results of his extended studies of geological action in the Alps and in many different regions of the United States and Canada. These observations lead to the conclusions, 1°. That the glacial period was a reality, and that its record constitutes one of the most important and interesting chapters of geological history; 2°. That this was a cold period; 3°. That ice has a great, though unmeasured and perhaps immeasurable, eroding power; and that, in regions which they have occupied, glaciers have been always important, and often preponderating, agents in effecting geological changes.

No cautious geologist would assert or concede that *all* lake-basins had been excavated by ice, but to deny its influence in their formation would be a far greater error. The basins of our great lakes, and of many of our smaller ones, bear the traces of ice that has moved in the line, at least approximately, of their major axes. The broad, boat-shaped basins indicate the work of this same agency. The islands of Lake Erie are carved from the solid rock: their surfaces and sides, and the channels between them, are all glaciated. The plastic ice has inwrapped those islands, fitting into every irregularity, and carving, with the sand it carried, every surface. The marks of glaciation are to be seen on mountain belts from Canada to Mexico. Even at the present day glaciers are transporting enormous loads. In midsummer the Aar glacier brings down 280 tons per day; the Justedal glacier of Norway wears down, it is estimated, 69,000 cubic meters of solid rock annually. These measurements of the eroding power of two small glaciers should show the fallacy of a denial of the excavating power of ice. Dr. Newberry concluded by citing authorities on the subject.

This paper elicited the most acrimonious discussion of the meeting. Professor Lesley took exception to certain phrases in the paper which seemed to cast a reflection upon the methods of his coadjutors, — men who were conscientiously engaged in scientific investigation, and had seen reason for breaking away from the trammels of opinion formulated by Agassiz and Ramsey. For himself, he did not believe in the theory of erosive glacial processes, and he asserted that there was no good reason for believing that the basins of the great lakes were so produced. He claimed that the basin of Ontario was a Silurian valley; the basins of Erie, Michigan, and Huron, were Devonian valleys. Ice had no more eroding effect than a piece of sandpaper has upon a rough board. He believed in the eroding of water, and represented his idea of the relative power of ice and water, as follows: Ice, 1; rain-water, 10; acidulated water, 100; ice set with stones, 1,000; water set with stones, 10,000.

Professor Newberry disclaimed any intention of attacking the young men of science who were laboring in this field. He re-affirmed the positions taken in his paper. On the other hand, Professor T. Sterry Hunt declared his substantial agreement with the views of Professor Lesley. On account of the length of this debate, the five-minute rule for discussions was adopted and subsequently enforced.

Informal remarks on moraines and terraces.

BY J. W. DAWSON OF MONTREAL, AND J. W. POWELL OF WASHINGTON.

At the opening of the morning and afternoon sessions of the geological section in its last day's work, Dr. Dawson and Major Powell made respectively some informal remarks of interest. Dr. Dawson objected to the loose significance with which the term 'moraine' had been used, and especially to the definition of it as 'detrital matter heaped up by the forcible mechanical action of ice.' He pointed out that such a definition would include work which certainly was not performed by land glaciers.

Dr. Dawson described the glacial deposits exposed along the line of the Canadian Pacific railway, from the Laurentian areas west and north of Lake Superior to the Rocky Mountains, noticing the lacustrine deposit of the Red-river valley, containing only a very few, small, ice-borne stones; the second prairie level covered with Laurentian drift from the north-east, and with an interrupted ridge of scrub material extending along the middle of it, northward from Turtle mountain. He referred to the great Missouri coteau, at an elevation of 2,500 feet, and made up of local mud, and sand, with Laurentian bowlders piled up against the higher prairie steppe; the drift on the surface of this steppe being partly Laurentian and Silurian from the east, and partly from the Rocky Mountains. He finally stated, that huge Laurentian and Huronian bowlders were placed at an elevation of more than 4,000 feet on the foot-hills of the Rocky Mountains, more than 700 miles from their original site. He did not intend to offer any explanation, as investigations into the matter were still being carried on by his son; but he wished to say briefly, that it appeared to him perfectly plain that we could not account for such phenomena as had been described, without taking into account great changes of level, or, without doubt, great submergence and remergence.

Major Powell called attention to the fact, that wholly different agencies, each acting in its own way, produced a class of geological features that went under the general name of 'terraces.' We have sea-beach terraces, lake-shore terraces, and yet another class of terraces exceedingly common in the Rocky and the Cascade mountains. The last-named class of terraces is due to a different cause from the others. Some of this class in the east have been relegated erroneously to the class of beach terraces: those which are said to dam the Ohio, and others found in the Alleghanies, have been formed by a process which can be briefly sketched.

We have a valley. It runs irregularly between bluffs and mountains. We have a force in the river which simply tends down stream; it is itself irregular, its energy depending upon its transient volume and local depth. If the region is upheaved, the river no longer keeps its old course. It seeks the line of least resistance, and may form a new flood-plain below. Then the river, for a while at least, excavates laterally instead of vertically. No longer occupying its old place in the valley, it gradually cuts a new path. But the old terrace may remain. In some places there are more than twenty systems of terraces: In a locality near Pittsburgh, there are fifty-three such systems. These the speaker regarded as chiefly due to changes in the level of the regions, — to elevations and depressions. Further explanation by the speaker was cut short under the five-minute rule.

(*OTHER GEOLOGICAL PAPERS.*)

The earth's orographic framework; its seismology and geology.

The 'continental type,' or the normal orography and geology of continents.

BY RICHARD OWEN OF NEW HARMONY, IND.

These papers were read successively, as being closely related. They refer to a well-known theory of their author, which traces the frame-work of the earth in its mountain chains. He finds such a framework running from east to west in numerous parallel ranges near the equator, and instances those of Sumatra and of South America. This he calls the 'strong girdle' of the earth: it is of mesozoic age, terminating its heights in the cenozoic age. Remotely parallel are the arctic and antarctic belts. Great braces come down to meet this girdle, having at least four ramifications in Asia, starting from the great plateau, and in America forming the great 'backbone' of the continent. The five equidistant continental trends of mountain chains often mark paleozoic belts. But the later as well as the older results tell of strong interior forces that have produced the mountains, and the central belt gives marked evidence that an intense reaction from within aided in its construction.

The similarity of the five great continents has often been the occasion of remark. They seem to have a general plan of construction, that may have been connected with their appearance as land above the ocean. The similarity extends even to their present geographical area. If we cut cross-sections from W. S. W. to E. S. E. through the geographical centre of each continent, we shall find in each case a seismic belt near one rim of the continent, and often near both rims. Thus the continent is usually basin-shaped, and comparatively low in its central area with its chief river drainage, and low near the ocean borders; rising in an eastern and western main range, with usually several parallel subordinate ridges. These eastern and western mountains converge southerly, thus assuming a somewhat irregular form, evolving usually on the west some table-land. The eastern river is usually paleozoic, with perhaps some mesozoic on the flanks and cenozoic on the ocean border. The western elevation is more commonly mesozoic in its main range, and cenozoic in the flanks or subordinate ridges. A section running north and south through the three northern continents would successively expose Cambrian, paleozoic, mesozoic, and cenozoic cuts, which would generally increase in area as we go south.

The papers of Professor Owen elicited, for the greater part, unfavorable comment. It was urged against them, that their generalizations were too broad, and that they were based rather upon closet study than actual observation. As to at least one of the continents, we know as yet far too little of its geology, especially in the interior, to frame a theory of its history and constitution.

The pre-Cambrian rocks of the Alps.

BY T. STERRY HUNT OF MONTREAL, CAN.

THE writer began by reviewing the history of Alpine geology, and noticed first that speculative period when the crystalline rocks of the Alps, including gneisses, hornblendic and micaceous schists, euphotides, serpentines, etc., were looked upon as altered sedimentary strata of carboniferous or more recent times. He then traced the steps by which these views have been discarded, and more and more of these rocks shown to belong to eozoic or pre-Cambrian ages. In this connection the labors of von Hauer, Gerlach, Heim, Favre, Renevier, Lory, Gastaldi, and others, were analyzed; and reference was made to the great progress since the writer in 1872 published a review of Favre on the geology of the Alps.

The sections by Neri, Gerlach, and Gastaldi in the western, and those of von Hauer in the eastern Alps, were described; and it was shown that all these agree in establishing in the crystalline rocks four great divisions in ascending order: 1°. The older granitoid gneiss with crystalline limestones, graphite, etc., referred by Gastaldi to the Laurentian. 2°. The so-called *pietre verdi*, or greenstone group, consisting chiefly of dioritic, chloritic, steatitic, and epidotic rocks, with euphotides and serpentines, including also talcose gneisses, limestones, and dolomites, and regarded by Gastaldi as Huronian. 3°. The so-called recent gneisses of von Hauer and Gastaldi, interstratified with and passing into granulites and micaceous and hornblendic schists, also with serpentines and crystalline limestones. 4°. The series of argillites and soft glossy schists with quartzites and detrital sandstones, including also beds of serpentine with talc, gypsum, karstenite, dolomite, and much crystalline limestone. This fourth series, well seen at the Mont Cenis tunnel, is still claimed by Lory and some others as altered trias; but the present writer's view, put forth in 1872, that it is, like the preceding groups, of eozoic age, was subsequently accepted by Favre and by Gastaldi, and is now established by many observations. To this horizon belong the crystalline limestones of the Apnan Alps, including the marbles of Carrara.

The writer next recalls the fact that he, in 1870, insisted upon the existence of a younger series of gneisses in North America, alike in the Atlantic states, in Ontario, and to the north-west of Lake Superior. These, in his address before the American association for the advancement of science, in 1871, he further described under the name of the White-Mountain series, and subsequently, in the same year, called them Montalban. These rocks were then declared to be younger than the Huronian, and to overlie it; though, in the absence of this latter, it was pointed out that in Ontario and in Newfoundland the Montalban reposes unconformably upon the Laurentian. When these newer gneisses and mica-schists were first described, in 1870, there was included with them an overlying group of argillites, quartzites, and crystalline limestones; and for the whole the name of Terranovan was suggested, provisionally. But in defining, in the following year, the White-Mountain series, this upper group was omitted, and was subsequently referred to the Taconian series,—the lower Taconic of Emmons, and the so-called altered primal and auroral of H. D. Rogers, in eastern Pennsylvania.

The writer next describes his own observations in the Alps and the Apennines in 1881. He affirms the correctness of Gastaldi in referring the groups one and two to Laurentian and Huronian, finds the third, or the younger gneiss and mica-schist group of the Alps, indistinguishable from the Montalban, and regards the fourth as the representative of the American Taconian. It was maintained by Gastaldi, that these pre-Cambrian groups of the Alps underlie directly the newer rocks of northern and central Italy, forming the skeleton of the Apennines, reappearing in Calabria, and, moreover, protruding in various localities in Liguria, Tuscany, and elsewhere. The serpentines, euphotides, and other resisting rocks thus exposed, have been regarded as eruptive masses of triassic and eocene time. The writer, however, holds with Gastaldi, that they are indigenous rocks of pre-Cambrian age, exposed by geological accidents.

The uncrystalline rocks of the mainland of Italy are chiefly cenozoic or mesozoic, and the only paleozoic strata known are carboniferous, the organic forms in the limestone of Chaberton having been shown to be triassic. Triassic, liassic, cretaceous, eocene, and miocene strata are found in different localities, resting on the various pre-Cambrian groups. In the island of Sardinia, however, all these are overlaid by a great body of uncrystalline lower paleozoic rocks, in which the late studies of Bornemann and Meneghini have made known the existence of a lower Cambrian fauna, including Paradoxides, Conocephalites, and Archeocyathus, succeeded by an abundant fauna of upper Cambrian or Ordovian age.

The existence of the younger or Montalban gneiss in Sweden and in the Harz and the Erzgebirge was noticed, and to it were referred the Hercynian gneisses and mica-schists of Gümbel. The presence both in Sweden and in Saxony of conglomerates, as described by Hummel and by Sauer, wherein pebbles of the older gneiss are enclosed in beds of the younger series, was discussed, and the direct unconformable superposition of the latter upon the older gneiss, in the absence of the Huronian, was considered; evidences of the same relations being adduced from the Alps. The gneisses of the St. Gothard, as seen on the Italian slope, were also referred to the newer series; and the important studies of Stapff in this connection were discussed. It was declared that the views put forth by the author in 1870–71, on the relations and succession of the crystalline stratified rocks in North America, and then extended by him to Europe, have been fully confirmed by the labors of a great many European geologists, as already shown. Those of Hicks, Hughes, Bonney, Callaway, Lapworth, and others, in the pre-Cambrian rocks of the British islands, were cited in support of these conclusions. It was said, that, whatever may have been the conditions under which these vast series of crystalline stratified rocks were deposited, there is evidence, in the similarity of their mineralogical and geognostical relations, of a remarkable uniformity over widely separated regions of the earth's surface, as well as of long intervals of time, marked by great foldings and disturbance, and by vast and wide-spread erosion of the successive series of rocks.

In conclusion, the writer took occasion to call attention to the important labors of the present school of Italian geologists, and their great zeal, skill, and disinterested service, as shown in the memoirs of the R. accademia dei lincei, and in the work of the Royal geological commission, including the special studies, maps, and memoirs prepared by it for the International geological congress of Bologna in 1881. The new Geological society of Italy, founded at the same date, gives promise of a brilliant future, and has already published many important memoirs.

The serpentine of Staten Island, New York.

BY T. STERRY HUNT OF MONTREAL, CAN.

THE serpentine of Staten Island appears as a north-and-south range of bold hills rising out of a plain of mesozoic rocks, which on the west side are triassic sandstones like those of the adjacent mainland, including a belt of intrusive diorite, and on the east the overlying, nearly horizontal, cretaceous marls, which are traced south and west into New Jersey. The only rocks besides these mentioned, seen on the island, are small areas of a coarse-grained granite, having the character of a veinstone or endogenous mass, and others of an actinolite rock; both exposed among the sands on the north-east shore of the island.

Mather, who described this locality more than forty years since, looked upon the serpentine as an eruptive rock, related in origin to the parallel belt of diabase which is included in the triassic sandstone to the west. Dr. Britton, of the School of mines, Columbia college, who in 1880 published, in the transactions of the New-York academy of sciences, a careful geological description and map of the island, regarded the serpentine belt as a protruding portion of the eozoic series, including serpentine, which is seen at Hoboken, on Manhattan Island, and in Westchester County, New York, — a conclusion which the writer regards as unquestionably correct.

The appearance of isolated hills and ridges of serpentine is common in other regions, and is by the writer explained by the consideration that this very insoluble magnesian silicate resists the atmospheric agencies which dissolve limestones, and convert gneisses to clay; the removal of which rocks leaves exposed the included beds and lenticular masses of serpentine. Similar appearances are seen in many parts of Italy, where ridges and bosses of serpentine are found protruding in the midst of eocene strata, and have hitherto by most European geologists been regarded as eruptive masses of tertiary age. The problem is there often complicated by the fact that subsequent movements of the earth's crust have involved alike the older crystalline strata (of which the serpentines form an integral part) and the unconformably overlying eocene beds; faulting and folding the latter, and even giving rise to inversions by which the newer rocks, overturned, are made to dip towards and beneath the ancient crystalline masses. This the writer illustrated by reference to localities recently examined by him in Liguria and in Tuscany, where this relation of the serpentines had already been pointed out by Gastaldi. The structure in question was declared to be analogous to that presented by similar foldings and overturns to be seen along the western base of the Atlantic belt throughout the Appalachian valley.

The speaker further alluded to the fact, that, although the sub-aërial decay of serpentine was far less rapid than that of most other rocks, it had not escaped this process; and described the decayed layer on portions of the Staten Island serpentine hills, including a chromiferous limonite segregated from the decayed serpentine. This was a slow pre-glacial process, and in the subsequent erosion of the serpentine ridges the decayed layer has been in parts entirely removed. The details of this decay, and its relations to the limonite, and to glaciation in this locality, have been described by the writer in an essay on the decay of rocks, to appear in the *American journal of science* for September, 1883. He gratefully acknowledged his personal obligations to Dr. Britton for the many facts contained in his memoir and map, as well as for personal guidance during a late visit to Staten Island.

The equivalent of the New-York water-lime group developed in Iowa.

BY A. S. TIFFANY OF DAVENPORT, IO.

THE author stated, that the upper Silurian rocks of Iowa had hitherto been classed wholly as of the Niagara limestone. There has, however, been some dispute as to the magnesian buff-colored limestone of the Le Claire and Anamosa quarries. Such disputes must, of course, be settled by the fossils; but he had been for more than twelve years seeking organic remains in that formation, without success until February of last year, when he found them in considerable quantities. Specimens of the fossils were exhibited. Mr. Tiffany considered that they gave conclusive evidence of belonging to a group higher in the scale than the fossils of the Niagara limestone, that their affinities were with those of the water-lime group of the lower Helderberg, and that the identity of many species had been determined.

Clay pebbles from Princetown, Minn.

BY N. H. WINCHELL OF MINNEAPOLIS, MINN.

THIS paper was accompanied by an exhibition of specimens. The pebbles were of various shapes and sizes, several of them somewhat cylindrical. Outside, they are composed of fine sand and gravel; inside, they consist wholly of a fine sedimentary clay, such as is deposited by standing water, and contain no interior pebbles. Professor Winchell had compared these with pebbles found in till-deposits, and with various others, without finding any thing exactly similar.

Professor Newberry examined the pebbles, and admitted that they were not exactly like any that he had seen, but he thought they bore a general resemblance to pebbles found throughout the range of geological strata wherever there is a bed of sandstone capped by clay. Professor Claypole claimed to have seen similar specimens in Pennsylvania deposits.

The 'earthquake' at New Madrid, Mo., in 1811, probably not an earthquake.

BY JAMES MACFARLANE OF TOWANDA, PENN.

AFTER dwelling upon the fact, that the locality of the alleged earthquake was not the seat of any apparent volcanic action, the author proceeded to state his view that the event in question was due to a different cause. He claimed that the locality was underlaid by cavernous limestones of the St. Louis group. He believed that what took place was a subsidence, due to the solution of underlying strata. He alluded to the descriptions afforded by Humboldt and Lyell, the latter having visited the locality, and given it a careful examination. The inhabitants described it as a convulsion, taking place at intervals during several months, creating new lakes and islands, changing the face of the country. The graveyard was precipitated into the Mississippi river; forest-trees were tilted in all directions; vast volumes of sand and water were discharged on high.

The author claimed that the long continuance of such phenomena, which lasted for several months, was an evidence that they proceeded from mere subsidence, and not from earthquake shock. In respect to the geology of the region, he stated that New Madrid and its vicinity rested on tertiary or quaternary strata. Underlying sub-carboniferous formations are represented near the borders of the depression. The sinking of a shaft brought to light coal, or coal-shales; also there were coaly shales found in the crevices and sink-holes thirty-five years after the so-called earthquake.

This paper elicited strong expressions of dissent from several members. Professor Cox declared that there were no sub-carboniferous rocks in that locality, no caverns, no soluble limestones underlying the surface. The shocks were sudden. There was great destruction of life. No mere subsidence can account for what actually happened. A question as to the truthfulness of the reports from that region brought out very contradictory opinions in the discussion. Professor Cox, who had personally examined the scene of the occurrences, declared that he had found evidences of great disturbance. Professor Nipher suggested that the position of the trees, whether upright or not, which were alleged to be at the bottom of Reelfoot Lake (a lake formed at the time of the earthquake), would help to determine whether a subsidence, or an earthquake, had taken place. Some doubt was expressed as to whether any submerged trees were there. To these doubts and queries, Professor Cox was able to give a definite answer: he had seen the trees still upright beneath the water.

Comparative strength of Minnesota and New-England granites.

BY N. H. WINCHELL OF MINNEAPOLIS, MINN.

HAVING had recent occasion to test the qualities of the building-stones of Minnesota, the author subjected them to the usual tests of crushing, using for this purpose specimens of two-inch cube. The specimens included sandstones, limestones, granites, and trap-rocks, and numbered about 100. Great care was taken in preparing them accurately. They were sent to Gen. Gillmore at Staten Island, and there subjected to the tests, which were applied by crushing the samples, one in the direction of the schistose structure and one across it. The following were the results with twenty samples of Minnesota granites:

Kind of stone.	Location of quarry.	Position.	Strength in pounds. Of sample.	Per cubic inch.
Dark trap-rock, massive melaphyr . . .	Taylor's Falls, Chisago county	On bed .	105,000	26,250
		On edge,	105,000	26,250
Dark trap-rock, from a dyke .	Fischer's creek, n'r Duluth, St. Louis county,	On bed .	105,000	26,250
		On edge,	105,000	26,250
Gray gabbro, massive, fine,	Rice's Point, Duluth, St. Louis county,	On bed .	109,000	27,250
		On edge,	105,000	26,250
Red, fine sienite	Beaver Bay, Lake county,	On bed .	106,000	25,000
		On edge,	103,000	25,750
Red quartzose sienite . . .	Watab, Benton county . . .	On bed .	103,000	25,750
		On edge,	103,000[1]	25,750
Red quartzose sienite . . .	East St. Cloud, Sherburne county . . .	On bed .	112,000	28,000
		On edge,	105,000	26,250
Red quartzite .	Pipestone City, Pipestone county . . .	On bed .	111,000	27,750
		On edge,	108,000	27,000
Massive gray quartzose sienite . . .	East St. Cloud, Sherburne county . . .	On bed .	105,000	26,250
		On edge,	103,000	25,750
Fine-grained gray sienite .	East St. Cloud, Sherburne county . . .	On bed .	112,000	28,000
		On edge,	105,000	26,250
Fine-grained gray sienite,[2]	Sauk Rapids .	On bed .	86,000	21,500
		On edge,	100,000	25,000
Average of	twenty samples,	. . . .	104,800	26,675

Allowing for eleven per cent difference between processes of crushing between steel-plates and between wooden cushions, this gives an average for Minnesota granites of 23,318 pounds.

[1] Estimated. [2] Probably imperfect sample.

The following are the records of tests of New-England granites: —

Kind of stone.	Location of quarry.	Position.	Strength in pounds. Of sample.	Per cubic inch.
Blue . . .	Staten Island, N.Y. .	On bed .	89,250	22,315
	Fox Island, Me. . .	– –	59,500	14,875
	Dix Island, Me. . .	– –	60,000	15,000
Dark . . .	Quincy, Mass. . . .	– –	71,000	17,750
Light . . .	Quincy, Mass. . . .	– –	59,000	14,750
Flagging . .	Hudson River, N.Y.	– –	53,700	13,425
	Cape Ann, Mass. . .	On bed .	59,750	14,937
Porter's rock,	Mystic River, Conn.	On bed .	72,500	18,125
Gray . . .	Stony Creek, Conn. .	On bed .	60,000	15,000
Gray . . .	Fall River, Mass. . .	On bed .	63,750	15,937
Bluish-gray .	Keene, N.H. . . .	On bed .	41,000	10,250
Bluish-gray .	Keene, N.H. . . .	On bed .	51,500	12,875
	Millstone Pt., Conn.	– –	64,750	16,187
	Greenwich, Conn. .	– –	45,200	11,300
Niantic river,	New London, Conn.	– –	50,000	12,500
Niantic river,	New London, Conn.	On edge,	56,700	14.175
	Vinalhaven, Me. . .	– –	52,600	13,150
	Vinalhaven, Me. . .	– –	67,000	16,750
	Westerly, R.I. . .	On bed .	58,750	14,689
	Westerly, R.I. . .	On edge,	59,750	14,937
Average of	twenty granites . . .	. . . . .	59,785	14,940

After discussing several supposable causes of error, and showing that they could not have applied to the present case, the author proceeds to suggest causes why the Minnesota granites may be stronger than those of New England. He thinks those of the west may have been less changed by decay. The lateness of the glaciation to which they were exposed may have left them comparatively fresh through the recent removal of a considerable thickness. On this point we shall be more certain when the glacial moraines have been fully traced from east to west, and the western analogues are determined.

The singing beach of Manchester, Mass.

BY A. A. JULIEN OF NEW YORK AND H. C. BOLTON OF HARTFORD, CONN.

SANDS were taken from the so-called 'singing beach' on the coast of Massachusetts, near Manchester-on-the-Sea, and subjected to microscopical examination. In this beach, the felspathic rocks are intersected by numerous dykes of igneous rocks, among which porphyritic diorite is noticeable. The phenomenon which gives rise to the name of the beach is confined to the portion of sand lying between the water-line and the loose sand above the reach of ordinary high tide. Portions emit the sound; but closely contiguous areas fail to do so, or answer feebly. The sounding sand is near the surface; at the depth of one or two feet it ceases, perhaps because of moisture. The sound is produced by pressure, and may be likened to a subdued crushing; it is of low intensity and pitch, is not metallic nor crackling. It occurs when the sand is pressed by ordinary walking, increases with sudden pressure of the foot upon the sand, and is perceptible upon mere stirring by the hand, or even plunging one finger and removing it suddenly. It can be intensified by dragging wood over the beach.

The authors review and cite very fully the literature of the subject, giving in full a description of the singing sands of the Island of Kaui, one of the Hawaiian group. That gives a sound as of distant thunder, when any thing of weight is dragged over it. Dampness prevents the sound. That sand is calcareous. Hugh Miller cites similar instances at Jebel Nakous in Arabia Petrea, and Reg Rawan near Cabul. Those are silicious sands. The sounds were a sort of humming.

In Churchill county, Nevada, a similar phenomenon is described with regard to a sand-hill, as like the sound of telegraph-wires when wind blows them.

The authors also review and characterize the various sands of different mineral origin.

To explain the sonorous peculiarity of the sand, several theories are considered. That of equality, or of the unequal size of the grains, is rejected. Cellular structure has been supposed, but is not found in the present instance. Effervescence of air between moistened surfaces does not apply to this case. Sonorous mineral, such as clinkstone, is not present. There is no evidence of electrical phenomena being concerned. The hypothesis adopted is that the sand, instead of being, as ordinarily, composed of rounded particles, is made up of grains with flat and angular surfaces. In the present instance, the plane surface of felspar is apparent in many of the grains. Probably a certain proportion of quartz and felspar grains is adapted to give the sound, while less or more of either component would fail of the result.

Dr. Bolton has himself examined a sand of similar quality, on the island of Eigg in the Hebrides, and has described its properties. That is largely calcareous. Its constitution is a mixture of large and small grains, the larger ones being rounded quartz. Many small, angular fragments of quartz are also contained, and many dark granules of chert, the last being about three or four per cent of the whole, and having a cellular structure.

It is concluded, that the sound is produced either by the intermixture of grains having cleavage planes, or of grains with minute cavities. The paper ends with a table of the physical structure of the sands of many localities.

(*PALEONTOLOGICAL PAPERS.*)

Preliminary note on the microscopic shell-structure of the paleozoic Brachiopoda.

BY JAMES HALL OF ALBANY, N.Y.

IN the earlier studies of the Brachiopoda, the numerous species were referred to few generic terms, determined from their perforated apex and external form, and later from the study of the interior as these became known. The author said, that from time to time, as these characters had become known to him from the study of large collections, he had found it necessary to propose the separation of eighteen new generic forms from those previously known in this class of fossils. Other authors had also proposed new generic terms, until the list had become many times greater than it was twenty-five years ago.

While the interior structure of the hinge, and the muscular and vascular markings, were now pretty well known for most of the generic forms in use, comparatively little attention had been given to the minute structure of the shell. Little more had been done than to show that some forms possessed a punctate and others a fibrous texture.

The study of this structure had been commenced by him many years ago, but he had been thwarted in his efforts to procure the required cutting and polishing of specimens of the shells for microscopic study. He had now been able to obtain such thin slices of the shell as were required for this purpose, and had already several hundred slides prepared for the microscope.

A few of these only were shown, exhibiting the shell structure of as many genera. A considerable number of photographs had been made, illustrating, in a very satisfactory manner, the minute structure of each one, enlarged to twenty diameters. The photographs exhibited were illustrations of several species of Orthis, Leptaena, Strophomena, Strophodonta, Chonetes, etc.

The study of this shell-structure has shown very satisfactorily, what was partially known before, that the genus Orthis, as now defined and constituted, includes very heterogenous material. External form, hinge characters, and interior muscular impressions, have been the chief guide; and yet forms have been included under this genus, showing widely different muscular markings. On further microscopic study, it has been found that these differences in form of muscular imprints are accompanied by important differences in the shell structure.

These differences may be noted in the illustrations presented, where the shell of Orthis biforata, O. borealis, O. tricenaria, O. occidentalis, O. flabella, are non-punctate and coarsely fibrous. Orthis (?) strophomenoides is, like Streptorhynchus, fibrous. Orthis subquadrata has, like O. occidentalis, a few large punctae.

In the second group, Orthis testudinaria, O. Vanuxemi, O. perveta, O. penelope, O. elegantula, O. clytie, and O. hybrida, have one or more rows of punctae to each ray, the rows well defined, and the intermediate shell finely fibrous.

The third group, consisting of Orthis multicostata of the lower Helderberg, O. jowensis of the Hamilton group, O. tulliensis of the Tully limestone, O. impressa of the Chemung group, are highly punctate with a fine fibrous texture of the shell substance.

The punctae usually come out along the summits of the radiating striae or plications of the shell. In some species the minute tubes perforating the shell, and producing these punctae, bifurcate and diverge before coming to the external surface of the shell.

This difference in shell structure, in forms known as Orthis, will require a separation of the species into groups based upon the shell structure, and character of muscular impressions. Already we see that the shells of compact fibrous texture have a form of muscular impression quite unlike those with the punctate structure; and we shall probably find that all the interior modifications of the muscular system are accompanied by differences in the microscopic structure.

This method of determining the shell structure, in cases where the specimens may be imperfect, and thereby enabling the determination of obscure or fragmentary material, and its geological relations, will be of much importance to the geologist.

The structure of the shell in Strophomena is closely fibrous, with distant large punctae. In Strophodonta, the punctae are more numerous. In Chonetes, the punctae are large, and arranged parallel to the radii, having a pustulose aspect.

In many other forms, the punctate texture of the shell is characteristic, and of importance in the determination of the generic forms.

The physiological significance of this peculiar shell structure will be considered upon some future occasion, illustrated by more numerous examples.

Rhizocarps in the paleozoic period.

BY J. W. DAWSON OF MONTREAL, CAN.

THE author referred to a previous memoir, entitled 'Spore-cases in coal,' published in 1871. This described fossil remains in a shale from the Erian formation at Kettle Point, Lake Huron, supposed to be on the horizon of the Marcellus shale of New York. The remains are minute brownish discs scarcely more than one-hundredth of an inch in diameter. They were recognized as probably spore-cases or macrospores of some acrogenous plant. The shale also contains vast numbers of granules, which may be escaped spores or microspores. In 1882 Dr. Dawson's attention was called to the discovery of similar bodies in vast numbers in the Erian and lower carboniferous shales of Ohio. The discoverer, Professor Orton, regarded these bodies as spore-cases, and as the chief source of the bituminous matter in those shales. Professor Williams found similar bodies in the Hamilton shales of New York; and Prof. J. M. Clarke, in the Genesee shale and in the corniferous limestone. The last named are of larger size than the others.

No certain clew had been thus far afforded to the affinities of these widely distributed bodies. But last March, specimens were found in the Erian formation of Brazil, by Mr. Orville Derby, which threw new light on the subject, containing as they did, along with the Sporangites, abundant fronds of Spirophyton. The Sporangites of Brazil resemble in every respect the involucres or spore-sacs of modern rhizocarps, and especially the sporocarps of the genus Salvinia.

Dr. Dawson describes with technical exactness two leading types which he has named provisionally Sporangites braziliensis and S. bilobatus. The paper offers the suggestion that these plants, now so insignificant, culminated in the paleozoic age, and, occupying the submerged flats of that period with abundant vegetation, produced a great quantity of the bituminous matter found in resulting beds. A rich rhizocarpean vegetation in the early paleozoic and eozoic ages may have preceded the great development of acrogens in the later paleozoic.

In the discussion which followed. Dr. Dawson disclaimed any intention to assert that the Sporangites were the sole source of the bituminous matter.

Rensselaeria and a fossil fish from the Hamilton group of Pennsylvania.

BY E. W. CLAYPOLE OF NEW BLOOMFIELD, PENN.

THE Hamilton sandstone of Pennsylvania is found in ridges just before we come to the Blue Mountains. The sand tapers off from a centre in these ridges both ways. At places it is eight hundred feet in thickness, some of it quite hard and flinty. Perhaps this sand was left by rivers; but, at all events, where it is missing it must have been cut away by erosion. The author believed that an ancient river had occupied nearly the place of the present Susquehanna, but running in an opposite direction, — to the north, — and probably debouching where the city of Harrisburg now stands. That locality had previously been below the sea: it was raised so as to become dry land through which this river runs. That land and that river again sank slowly. Then the sunken land received sand from the river. Afterward this region became the bed of a sea. It is a fan-shaped deposit, thickening toward the centre of the fan.

The author exhibited a model of a fish whose remains were discovered in this sandstone. He also showed specimens of alleged Rensselaeria found in the Hamilton sandstone. The latter were shown to Prof. James Hall, during the reading of the paper. Mr. Claypole thought them identical with the Rensselaeria of the Oriskany sandstone, there being a difference of a thousand feet between the two horizons; and he believed this the first instance of such discovery. The strata were tilted on edge in the locality where the fossils were found. Mr. Claypole made a diagram of the geological structure of the region. The fossils were in the middle of the sandstone, which is six hundred to eight hundred feet thick. A Spirifer very much like S. formosa is found there in great quantities.

Professor Hall, after a brief examination, said that anybody was excusable for supposing the fossils to be Rensselaeria. The differences between them and the Oriskany fossil were slight though well marked. Professor Hall described some of these differences, and Mr. Claypole acknowledged that a certain V-shaped groove was wanting in his specimens. Professor Hall thought that possibly the fossils should be referrred to Amphigenia, which had many similarities to Rensselaeria. Professor Newberry thought the fish fossil new.

A large crustacean from the Catskill group of Pennsylvania.

BY E. W. CLAYPOLE OF NEW BLOOMFIELD, PENN.

OF this fossil the author exhibited a cast. It showed no evidence of fish structure. Its apparent affinities were with the king crab, yet it was not a true Limulus nor even a limuloid. A cast in gutta-percha was also shown, which better exhibited the markings. There was a resemblance in the fine surface-marks to Eurypterus. But the eurypterids, with a single exception, were all found in strata vertically distant six thousand feet.

Professor Hall said that the eurypterids were widely distributed. They were found in the coal-measures, in the Waverly sandstone, and perhaps — though that was not quite certain — in the Portage group.

Animal remains from the loess and glacial clays.

BY WILLIAM McADAMS OF ALTON, ILL.

THE drift clays proper at Alton, Ill., had a maximum thickness of about one hundred feet, and the bluff clays were nearly of the same thickness. These clays were remarkably rich in animal remains, such as teeth and bones, attached to calcareous nodules or claystones. Remains of thirteen different species, now perhaps all extinct, had been found. The rodents were well represented in the bones of seven species, including three or more beavers and some gophers. Nearly seventy teeth were found in the quaternary deposits, a majority of them in a single quarry.

A new vertebrate from the St. Louis limestone.

BY WILLIAM McADAMS OF ALTON, ILL.

ONE of the groups of subcarboniferous limestone is quarried extensively near Alton and St. Louis. It lies beneath the coal, and in some places the coal rests directly upon it. A number of vertebrate remains have been found in one of the quarries near Alton. Specimens were shown by the author of the paper. In the judgment of Professor Newberry, the fossils shown were the bones of some large fish. One appeared to be the mandible or dental bone of the lower jaw. Without pronouncing a final opinion, he would say that it bore a general resemblance to a group of fossil fishes in which the teeth were inserted in sockets; but the animal itself was large and hitherto unknown.

List of other papers.

The following additional papers were read in this section, some of them by title only: Thermal belts, by *J. W. Chickering*. The Hamilton sandstone of middle Pennsylvania, by *E. W. Claypole*. Evidences from southern New England against the iceberg theory of the drift, by *J. D. Dana* [this paper will appear in full in SCIENCE]. Topaz and associated minerals from Stoneham, Oxford county, Me.; Colored tourmalines and lepidolite crystals from a new American locality; A note on the finding of two American beryls; Andalusite from a new American locality; On a white garnet from near Hull, Canada, — by *G. F. Kunz*. The genesis and classification of mineral veins, by *J. S. Newberry*.

PROCEEDINGS OF SECTION F.—BIOLOGY.

ADDRESS OF W. J. BEAL OF LANSING, MICH., VICE-PRESIDENT OF THE SECTION, AUG. 15, 1883.

AGRICULTURE: ITS NEEDS AND OPPORTUNITIES.

Instead of presenting a summary of the progress made in biology during the past year, I have chosen, rather, to speak of the 'Needs and opportunities of agriculture,'—a subject which has heretofore scarcely been mentioned at the meetings of this association. Within the past few years the progress of agriculture, which I use in its broadest sense, has been greater than ever before. This may be attributed to a variety of causes; such as the general thrift and intelligence of our people, and the advancement of science.

Many agricultural schools have been established, experiment-stations organized, the rural press has been much improved in quality and quantity, clubs and societies are flourishing, and thousands of granges have helped to stimulate thought and investigation. Though there is much chance for improvement, the U. S. department of agriculture in several of its sections has done excellent work. It is true, and it is strange that it should be true, that, until within a comparatively recent period, but very little of the best thought, even of civilized nations, has been devoted to subjects intended to advance agriculture.

Columella, eighteen hundred years ago, keenly felt the want of more thought in agriculture when he said, "Husbandry alone, which, without doubt, is next to, and, as it were, near akin to, wisdom, is in want of both masters and scholars. Of agriculture, I have never known any that professed themselves either teachers or students." Many of our states have freely appropriated money to conduct surveys in geology, mining, with a little attention given to zoölogy and botany, not neglecting to provide liberally for coast-surveys.

The nation, considering its age, has also been very generous with money in support of surveys of various kinds, including, also, anthropology, construction of lighthouses, improving rivers and harbors, investigating the supplies of fish, and even astronomy has been generously supported. It is true that some of this work performed by the government has been very poorly done, and has been enormously expensive; but the methods of work are improving.

This munificence of the United States in support of science is encouraging, and, as far as it goes, speaks well for the country and our law-makers. Doubtless, in many cases, the close connection with politics is one great hindrance to successfully conducting investigations in science for the government. The chances of losing positions are often too great to make them desirable, especially to persons who dislike political contests. Frequent changes are fatal to good, long-continued work.

Notwithstanding the large sums of money expended by our national and state governments in support of science, but a small sum, considering its importance, has been appropriated in the interest of agriculture. Even private gifts have gone to endow literary colleges, schools of physical or natural science, astronomical observatories, public libraries, and not to endow something which is directly intended to encourage agriculture. The men like Lawrence, Sheffield, Smithson, Peabody, Washburn, Swift, Stevens, are numerous, but not numerous enough. All honor to the noble names of those who have so generously contributed to the advancement of science.

To illustrate the hesitancy of men to bequeath money for the promotion of agriculture, I take the following from an address given by President T. C. Abbot:—

"I met a very pleasant and intelligent gentleman, who, from his large wealth, was about to give some sixty or seventy thousand dollars for the advancement of higher education. He had been for some years, and was still, the president of a state agricultural society. He was a farmer. Did he then endow some chair of agriculture, or agricultural chemistry, of veterinary science, of horticulture? Did he fit out an experiment-station to analyze fertilizers, to study the value of cattle-foods? Did he establish an agricultural library? None of these. He found the science that was the most advanced of any, the one that government supports at a great expense from the public treasury. This farmer gave his thousands to endow another workshop of astronomy."

Yet, even in respect to private endowment, there are approaching signs of better days for agriculture. A few far-seeing men have observed the needs of this interest, and have set a noble example by giving of their wealth bounteously. Cornell, Bussey, Purdue, Valentine, Storrs, in this country, are names which will long be honored for liberal gifts in the interest of agriculture. They showed great sagacity, and not a little originality, by placing endowments in a new field, where gifts are few, and the opportunities for good are boundless. It is hoped that these illustrious examples will stimulate others to make similar bequests.

Where agriculture thrives, there we always find a prosperous people. She needs more trained minds to work in her interest. With better thought would come great and needed improvements in the agricultural department of the nation. It lacks means, strength, and stability.

The matter of plans, and the naming of a competent director of the geological survey, was referred to the National academy of sciences, whose suggestions the government authorities sought and adopted.

The same body, or the standing committee of this association, or the members of the Society for the promotion of agricultural science, would be amply competent to name a good man for commissioner of agriculture. Such a plan would throw the position more out of politics, and it would be more likely to run smoothly on, like the work of the Smithsonian institution.

Greater permanency would tend to make the department more efficient, and help it to co-operate with the agricultural departments of the several states and the agricultural colleges and experiment-stations.

The leading object of these remarks is to call the attention of those who are working for the advancement of pure science to the great needs of agriculture, the grand opportunities for making discoveries, and the lasting gratitude which such workers are likely to receive from the people. Of course, we grant that all science is valuable, that much of pure science has a practical bearing, that no one can foretell what practical results may be reached by investigations in pure science; still there is a tendency among scientific men to ignore economic science.

I will illustrate my meaning. The U. S. signal-service is generally supposed to have been established in the interest of science, with the avowed intention, also, of benefiting navigation. The benefits in these respects are certainly worth all they cost, but these are not all the benefits which the service should recognize.

I note the following as given by Dr. R. C. Kedzie some months ago, to illustrate the tardiness of science and the government to promptly grant assistance to the interests of agriculture.

"No industry, except navigation, is so completely at the mercy of the weather as agriculture, in its widest sense. In the magnitude of the interests thus threatened, agriculture outweighs all others in importance. Indeed, without the sustaining influence of agriculture, commerce itself would vanish like the dew of morning. Timely warnings of impending meteorological dangers might be given by the signal-service, which would be of incalculable worth to agriculture."

He illustrates the subject by referring to the protracted rainy weather during the wheat-harvest of 1882, in Michigan, where the loss was very great. "The approach of a protracted storm was known for days before the damage was done. If specific warning had been given our farmers at that time, most of the wheat might have been safely housed, and the farmers of Michigan saved from a loss of more than $1,000,000. The damage inflicted in this way is not isolated and exceptional."

At length the growers of cotton and tobacco in the south, and of cranberries in New Jersey, have been recognized by the government, and warnings of approaching frosts have been promptly given. "The general government, through the signal-service, should hold the shield of its protection over land as over sea, over corn-field as over tobacco-plant, over hay-field as over cranberry-marsh, over wheat-field as over cotton-plantation, over orchards and vineyards, and the cattle upon a thousand hills and prairie leas. Why not extend this work into wider fields by doing for the *producer* what it has so well done for the *carrier?*"

The opinion seems to be too prevalent that few experiments in agriculture are worth attempting, unless it be those conducted by a chemist. This is by no means the case, though it is true that none but a chemist is capable of making those of a certain nature. A physicist will still find in the soil much to interest him, and there is, no doubt, a chance to make discoveries valuable to agriculture.

With regard to the great importance of investigations and united action concerning the control of various plagues of our domestic animals, we should suppose no one would give a dissenting voice. Some valuable investigations have been made concerning the cause and nature of these diseases, among the most interesting of which, it seems to me, are the experiments made by Dr. Salmon in using an attenuated virus for inoculating animals, and inoculating again and again with a stronger virus those not affected by the attenuated virus. If the subject of animal plagues and the means of controlling them were fully discussed at meetings of this association, it would tend to allay prejudice, enlighten the minds of our citizens, and stimulate our law-makers to action. That there is need of a more general knowledge of this subject, I quote from a recent article by Professor Law in the proceedings of the Society for the promotion of agricultural science. "The present agitation on behalf of legislation for the extinction of this lung plague in America began actively in 1878, and, notwithstanding that the subject has been continually before federal and state legislators for four years, but little real progress has been made. Among the drawbacks that may be specially named is the ignorance of legislators, of executives, and even of electors, on this subject."

In learning how to economically feed domestic animals, there is a great opportunity for investigation. There is much of interest and value to be learned in reference to the causes of fluctuation in weight of animals which are carefully fed and watered in a uniform manner.

Concerning the great need of continued and increasing efforts to investigate our injurious and beneficial insects, I need say but little; for the subject has been kept before the people, and the people are always interested to know something about an insect as soon as it injures their crops, or causes them trouble in any way. There is especially much need of more experiments to find better remedies for injurious insects. Attention to this portion of the subject cannot fail to meet with some degree of success. Success here is sure to win the gratitude of every one engaged in agriculture. Success in finding good, cheap, and safe remedies for injurious insects will tend to make science popular, and make endowments for research much easier and more frequent than ever before.

I need hardly add, that he who finds or breeds a race of honey-bees which is hardier, more industrious, longer-lived, quieter, possessed of longer tongues, and, last but not least, possessed of blunter stings, with less inclination to use them, — he who can succeed in any or all of these objects is entitled to rank with the man who shall cause two blades of grass to grow where only one grew before.

The U. S. commission on fish and fisheries is an example of good scientific work, with prospects of early returns in the form of an increase in knowledge and a large increase in the supply of fish. A somewhat similar work, conducted by Prof. S. A. Forbes of Illinois, is in progress, where the object of the survey is to inquire into the food of birds and the food of fishes.

Some valuable scientific work of an economic nature has been done in connection with the tenth census, conspicuous among which is that performed by Prof. C. S. Sargent, in the study of forestry.

Botanical explorers in every land have repeatedly and liberally contributed plants of economic importance to the horticulturist, — a few new fruits, but more especially flowers and foliage-plants. An occasional contribution has been made to agriculture in the form of plants which promised to be of value for seeds or forage, or for some other purpose.

I have often been surprised that more attempts had not been made to secure the introduction of some new foreign grasses, and test them to ascertain their value for meadows and pastures. To be sure, grasses from western Europe have been tried; but we need others.

More than twelve years ago this idea appeared in my address on grasses, as given before the Northwestern dairymen's association, where the advice was given to get other grasses from Japan, China, central Asia, and the dryer portions of South America. The cereals and pasture-grasses, the world over, are of more value to man and his domestic animals than all other plants taken together; yet the list of pasture-grasses now generally sown in any state can be counted on the fingers of one hand. In Great Britain, where much attention has been given to the subject, twenty-five or thirty species are much cultivated. It is hard to give all the reasons why so few grasses are employed in this country; but the fact remains, that few are cultivated. The grass family is a large one, containing from thirty-one hundred to four thousand or more species. They are widely distributed in nearly all parts of the habitable globe, in every soil, in society with others, and alone. This does not convey an adequate idea of their value in unwooded regions, because the number of individuals of several of them is exceedingly large.

I have recently found the following in the *American agriculturist* for 1858, a statement probably made by Dr. Thurber. "A dozen sorts, probably, cover nineteen-twentieths of all the cultivated meadow-land from Maine to Texas. It can hardly be supposed that so limited a number meets, in the best manner possible, all the wants of so great a variety of soil and climate. This is one of the pressing wants of our agriculture. Experimental farms are needed where the value of new grasses and kindred questions can be determined. A single new grass, that would add but an extra yield of a hundred pounds to the acre, would add millions of dollars annually to the productive wealth of the nation."

Still farther back, in 1853, the late I. A. Lapham of Wisconsin expressed similar views; and still longer ago, in 1843, forty years ago, in a prize-essay, J. J. Thomas said, "The great deficiency in the number and variety of our cultivated grasses has been long felt by intelligent cultivators." In this subject, but very slow progress has been made in forty years.

In the extensive unwooded regions west of the Mississippi, the native grasses afford much pasture; but many of them start very late in spring, and stop growing early in autumn. They do not completely occupy the ground: they are easily stamped out by the hoofs of cattle and sheep. Some of the tame grasses will thrive better, and afford much more pasture.

In Science, vol. i. p. 186, of this year, Prof. N. S. Shaler refers to this subject. He says, "It seems possible to improve this pasture by the introduction of other forage-plants indigenous to regions having something like the same climate. The regions likely to furnish plants calculated to flourish in a region of low rainfall include a large part of the earth's surface. Those that would succeed in Dakota are not likely to do well in Texas or Arizona. For the northern region, the uplands of northern Asia or Patagonia are the most promising fields of search; while for the middle and southern fields, the valley of the La Plata, southern Africa, Australia, and the Algerian district, may be looked to for suitable species." He recommends three experiment-stations, — one in Nebraska, one in Texas, and one in Arizona.

In this connection, when we remember that exotic plants often thrive better than natives, we see what a vast field lies ready for experimenting with the grasses.

Grasses look much alike to all who have not closely studied them; so that farmers — in fact, none except botanists are likely to attempt experiments. This is a strong reason why the state and national governments should assist agriculture in an undertaking which seems so fruitful of good results within a short time, at so trifling an expense. Expeditions are sent at great expense to explore polar seas, with a view to slightly extending our knowledge of a barren portion of the earth's surface. Large sums are employed to fit up in magnificent style, and send to the remotest parts of the earth, expeditions to spend a few minutes in observing an eclipse or a transit of Venus. Would the sending of competent persons around the earth in search of better grasses be an undertaking less praiseworthy?

The men who control the Northern Pacific railway were enterprising enough to see that a complete economic survey of the adjacent territory would help the sale of their lands. Among other things, the grasses will be carefully examined.

For the past ten years the writer has been testing, in a small way, some hundred and fifty species of grasses. These, with few exceptions, are natives of the eastern United States and western Europe. I am fully convinced that further experiments, carefully made on a larger scale in several portions of our country, will be quite sure to result in great gain to agriculture.

Grasses suitable for the western prairies, to take the place of those which will be rapidly stamped out by close feeding, are sure to be found even without the aid of the government; but greater time will be required.

Prof. E. M. Shelton of Kansas agricultural college has probably done more than any one else in the west to test grasses and clovers, and diffuse information in regard to the results, which are most gratifying. At nearly all gatherings of farmers in the west, this question of new grasses is a prominent topic of discussion.

Wherever irrigation has been well tried, especially on land which is light and well drained, the results have been quite surprising, converting a dry, hungry meadow into a little oasis. Such a meadow is the triumph of agricultural art.

One of the most remarkable results of irrigation, as viewed by a scientific man, is this: the list of grasses will not remain the same, or maintain the same proportion. The bad grasses will nearly all die out, or improve in quality; while the best ones will rapidly increase. And again: experiments in England have shown that irrigation causes many herbaceous plants, distinct from grasses, such as plantain and buttercups, to give place to good grasses. Docks are not diminished by irrigation. The best grasses are a sign of good land in fine condition. Such grasses are hearty feeders, and are most sensitive to good treatment. In a well-managed meadow, irrigation in four years increased the value threefold.

Solon Robinson long ago expressed the view, that, if the streams of Connecticut were properly utilized in irrigating the soil, they would be more productive in value than by turning all the water-wheels of the state. More experiments in irrigation are much needed in this country.

Baron J. B. Lawes, a most renowned experimenter in agriculture, possessed an old pasture having been in permanent grass over a century. No fresh seed of any kind was sown during this period. For some seven years or more, he experimented by applying to this old pasture, on different plats, twelve different kinds of manures. The results were very interesting and gratifying. "The manures, which much increased the produce of hay, at the same time very much increased its proportion of graminaceous herbage. The total miscellaneous herbage (chiefly weeds) was the most numerous in kind, and nearly in the greatest proportion, on the *unmanured* land, — viz., sixteen per cent, — while on the manured plat it decreased to two per cent. Every description of manure diminished the number of species and the frequency of occurrence of the miscellaneous or weedy herbage. A few weeds were increased by the manures, such as Rumex and Achillaea."

"The plants of a meadow," in the words of the *Agricultural gazette*, "live in harmony on the unmanured open park, having nothing to fight for in a state of nature; but toss them a bone, ground fine, or any other choice bit, and their harmonious companionship terminates at once. Every act of improved cultivation occasions instant war. A grass likes the best that can be got. It will swallow soda, but not when it can get potash. As a general principle, all manures tend to drive out the weeds by increasing the better herbage." A repetition of like experiments in this country could not fail to give valuable results.

In Europe some success has been reached in selecting and cultivating different varieties of Lolium perenne, Dactylis glomerata, and Trifolium pratense.

The field is a promising one for any careful and enthusiastic student. For three years past, I have been studying hundreds of plants of red clover at all seasons and stages of growth. I have plants growing, the seeds of which came from marked plants which varied much from each other. Plants in the fields of red clover vary amazingly in many respects, which influences their value for forage-crops. I believe our fields of red clover to-day contain nearly or quite as great a variety of plants as would a field of Indian corn, if we were to mix in a little seed of all the varieties cultivated in any one state.

Some of our grasses in cultivation are quite variable, notably the fescues, orchard-grass, and perennial rye-grass. It was some time ago observed that alfalfa of California, and lucerne of Europe, were quite different in their capacity to endure dry weather, though they belong to the same species. Different treatment in widely separated countries for many years has wrought a great change.

The subject of changing seed, planting old seed, mixing seed, raising it one year or more in a remote country, and then returning to the starting-point, deserves the attention of careful experimenters.

The late Charles Darwin experimented on the effects of cross and self fertilization of plants, and found that in most cases plants from crossed stock were earlier, hardier, germinated better, and yielded more seeds, than those from seed of self-fertilized plants, while crossing with foreign stock of the same variety is a far greater improvement. The idea is to cross the flowers of a plant with pollen from other plants of the same variety, the seeds of which were raised pure for five or more years in a remote locality, fifty miles or more away.

Mr. Darwin said, "It is a common practice with horticulturists to obtain seeds from another place, having a very different soil, so as to avoid raising plants for a long succession of generations under the same conditions; but, with all the species which freely intercross by the aid of insects or the wind, it would be an incomparably better plan to obtain seeds of the required variety, which had been raised for some generations under as different conditions as possible, and sow them in alternate rows with seeds matured in the old garden. The two stocks would then intercross, with a thorough blending of their whole organizations, and with no loss of purity to the variety; and this would yield far more favorable results than a mere exchange of seeds."

In a word, with plants which may be easily crossed, get some foreign seed of the same sort to mix with your own seeds to raise seeds for ensuing crops.

In 1877 I began some experiments of this kind with Indian corn and with beans, and have since made others. The advantage shown by crossing of corn over that not crossed was as 151 exceeds 100, and in the case of black wax-beans it was as 236 exceeds 100. Since then similar experiments have several times resulted in showing a large increase in favor of crossing with foreign stock.

In a review of Darwin's book, the *Gardener's chronicle* of England said in 1877, "It is certain that these practical results will be a long time filtering into the minds of those who will eventually profit most by them." The results of my experiments have been widely printed in the agricultural papers of the day, and have been given at numerous farmers' institutes and granges, beginning in the winter of 1877, nearly six years ago; and yet I cannot learn that any other person in this country has attempted similar experiments. I will make one exception, in case of Prof. W. A. Henry of Wisconsin university, who tried the experiment in connection with myself. The results, so far, fully accord with the prophetic statement above quoted from the *Gardener's chronicle*.

In originating new varieties and races, see what has already been done, largely in our own country, in a haphazard way, with strawberries, raspberries, blackberries, gooseberries, and grapes, to say nothing of improvements in ornamental plants.

I need hardly add, that some of the best results, considering the time and means employed, have been obtained by persons who have crossed and hybridized according to some well-devised plan.

Our varieties of fruits in cultivation have become so numerous, that to describe them by the fruit and foliage alone often baffles the skill of the most expert pomologist. In the proceedings of the American pomological society for 1877, 1879, and 1881, I have shown that much help can be obtained by noticing the peculiarities of the flowers of apples and pears. The same is no doubt true, to some extent, with grapes, peaches, gooseberries, and other fruits.

Here is a promising field, full of interest to the botanist, — a field where he may accomplish much to aid the horticulturist, and something to advance science. A new variety of any cultivated fruit can no longer be considered as well described, unless some account be made of the flowers.

It has often been shown that many kinds of insects are beneficial to plants by aiding the fertilization of the flowers. The subject has still about it much that is new. Even Mr. Darwin said he did not suppose that he fully understood all the contrivances for fertilization in any one flower.

If it be true, as my experiments during the past six years help to indicate, that bumble-bees aid in fertilizing red clover, then farmers should try to encourage these interesting insects, even though they be disagreeable companions. Bumble-bees prefer to raise their colonies in old nests of meadow-mice. I mentioned in my last report, that it had been suggested that we should not keep many cats, nor allow hawks, foxes, or dogs to catch these mice; for they make nests which are quite necessary for the bumble-bees, which help fertilize our red clover, and thereby largely increase the yield of seed.

Perhaps it may not be altogether visionary to predict that men will yet engage in raising bumble-bee queens, and sell them to farmers at a fair profit, for starting colonies to improve the yield of clover-seed. We may yet have conventions and societies where the leading object shall be to discuss the merits of different sorts of bumble-bees.

A few years ago experiment-stations in Europe began testing seeds which were offered for sale in the markets. Adulterations were discovered most ingenious in character, harmful in effect, and remarkable in amount.

The more the subject was investigated, the worse it seemed to be. Something of the same sort has been undertaken in this country, showing that even in Michigan some worthless seeds are put on the market. In 1877 and later I tested large numbers of vegetable-seeds purchased of fifteen of our large dealers and growers. Not one of these is free from selling seeds that are worthless. The remedy is not easy. On account of its effect on their advertising, publishers are unwilling to print for their readers the results of these experiments. Only a few people can acquire the information after experiments are made.

In making tests of seeds, we still lack information in regard to the surest and best mode of testing each sort. Here is a good work for some accurate and ingenious scientist to invent new apparatus, learn the proper amount of heat, air, and moisture, for producing the best results, find out whether seeds will thrive best with a constant temperature, or a variable temperature; and learn the best modes of preserving seeds alive from one year to another.

I need hardly mention to intelligent students, that there is an extensive field, a very attractive one, in the study of fungi. The agriculturist who deals with plants, not only wants to know the kinds, but the requirements which are favorable or unfavorable to their development. In the study of effectual remedies against fungi, something has been done; but there is still much demand for more knowledge. Successful experiments in regard to fungi are not likely to be made except by botanists.

I have only glanced at a few points where the biologist can find interesting work which will give threefold returns by advancing science, helping to elevate agriculture, and benefiting our country. There are many experiment-stations in Europe, and some in this country. We hope their number may soon increase, and that liberal and permanent endowments will not be lacking. This association, and all other societies working in the interest of science, can render a great service by doing what they can to encourage experiments in all departments of agriculture. Men can be encouraged to prepare papers, and committees can make reports pertaining to the subject. There is a need of thorough state surveys, solely with a view to the interests of agriculture and kindred subjects. More knowledge of our soils, water, building-materials, plants, timber, injurious fungi, insects, and birds, would return to a state, fivefold the cost of acquiring such information. In brief, then, as one of the humble workers in the interests of agriculture, I most cordially invite you to turn your attention to some of the problems which vex the husbandman.

PAPERS READ BEFORE SECTION F.

On the use of vaseline to prevent the loss of alcohol from specimen jars.

BY B. G. WILDER AND S. H. GAGE OF ITHACA, N.Y.

In the absence of the authors of the paper, an abstract of it was read by the secretary of the section, Professor Forbes. Vaseline, when used for the purpose indicated, proves to be an agent unaffected by temperature, and by most chemical substances. It is sparingly soluble in cold alcohol, but wholly soluble in hot alcohol, solidifying on cooling. It can be fitly applied in sealing specimen-jars, and meets many requirements when so used.

A new plan of museum-case.

BY E. S. MORSE OF SALEM, MASS.

The author described, and exhibited by means of drawings, a new plan of museum-case. He said his observations in the museums of Paris proved the great inferiority of the cases there to those in the United States. He gave, in addition to a detailed plan of a case, some suggestions as to the best method of arranging articles within. Mr. Morse has had the subject of arrangements for museum exhibitions under consideration for several years, and the present plan includes contrivances which he has previously suggested as separate devices.

(*BOTANICAL PAPERS.*)

A supposed poisonous seaweed in the lakes of Minnesota.

BY J. C. ARTHUR OF CHARLES CITY, IO.

In the summer of last year many cattle and hogs died in the vicinity of Waterville, Minn. Residents in the locality believed that the animals were poisoned by drinking the water of adjoining lakes. There are two lakes of considerable size in the neighborhood: they are free from marsh, and have wooded borders; through them runs a somewhat sluggish river.

At the time of the occurrence, the lakes showed a quantity of dark-green scum on the surface, as well as disseminated through the water. The surface-layers of the scum were in places several inches thick. The scum proved to be a water-weed, having some characteristics like those of the nostoc, but is known to botanists as Rivularia fluitans, and has been described by Cohn, a European naturalist. The plant is spoken of by the author of this paper as a seaweed: he supposed it did not occur in this country elsewhere than in Minnesota, and it is not frequent in Europe.

Last year Mr. Arthur visited the locality of the occurrence, and he repeated his visit this summer; but in each instance too late in the season to examine the scum *in situ*. It appears to be composed of innumerable small round bulbs of a transparent gelatinous substance, which are filled with a dark-green material. After they first begin to be seen on the water, the bulbs increase in number with marvellous rapidity. In about two weeks they begin to decay, and their entire disappearance quickly ensues. These phenomena take place usually in June. As no actual experiments have been made upon animals, the deadly qualities ascribed to the so-called seaweed are as yet a matter of conjecture, though the reported facts tend strongly to strengthen the belief that the plant is poisonous.

Relations of certain forms of algae to disagreeable tastes and odors.

BY W. G. FARLOW OF CAMBRIDGE, MASS.

Although large masses of any decaying vegetation may render water unfit for drinking, the only group of plants to be feared, as far as their effect on the taste and odor is concerned, is the members of the nostoc family, which form floating scums of a bluish-green color. When exposed to a bright sun, especially in shallow water, they are transformed into fetid, repulsive-looking masses of slime, which give to the water the so-called pig-pen odor. The water-supplies of several eastern cities have been thus contaminated, and principally by species of Coelosphaerium, Clathrocystis, and Anabaena. In Minnesota is the representative of a fourth genus, Rivularia, which was first found last year at Waterville by Professor Arthur, and which has been found to be very abundant this year in Lake Minnetonka; and in all probability it occurs in most of the other lakes of this region. The singular fact is, that while unknown elsewhere in this country, the species was found several years ago by Cohn in Silesia, who named it Rivularia fluitans; and it was detected also by Gobi near the Gulf of Riga. It appears also to be very closely related to, if not identical with, an alga abundant in certain parts of England, referred by Harvey and more recently by Philips to Echinella articulata, Ag. This is another illustration of the very wide distribution of the species of the nostoc family, of which we have other recent illustrations in the Nostochopsis lobatus of Wood, first described from the northern states, but which has since been found to be identical with Mazea Rivulariaides subsequently discovered in Brazil, and with Hormactis Quoyi found only at Falmouth, Mass., and the Marianne islands in the Pacific.

There is a strong probability, that in the future Minneapolis may be troubled by the decay of the different nostocs floating in the lakes near the city, where they are very abundant. As far as avoiding trouble from these plants is concerned, undoubtedly river-water is to be preferred to lake-water; but before many years the Mississippi near Minneapolis will be contaminated by sewage, and the water will probably then be obtained from the lakes. If the shallower lakes near the city are used, there can be little doubt that in summer Minneapolis will have the same trouble as that experienced in Boston. Even at greater expense, the water should be brought from large and deep lakes, especially those across which the winds sweep so as to keep the surface-water roughened.

The spread of epidemic diseases in plants.

BY W. G. FARLOW OF CAMBRIDGE, MASS.

In the case of animals it can be said, that, excepting the diseases attributed to bacteria, they are subject to but few diseases caused by fungi. In the case of plants, however, the greater part of the diseases to which they are subject are caused by parasitic fungi; excepting, of course, the injuries caused by insects, which need hardly be considered in speaking of epidemic diseases. Most of the violent epidemic diseases of plants are caused by fungi of the orders Uredineae, rusts, and Peronosporeae, rots. Fortunately the species of these orders attack only a single species of host, or at most several species closely related botanically; so that, for instance, a rot which would attack the potato would not probably attack the grape, although it might be expected to attack the tomato, which is botanically closely allied to the potato. As might be expected, the most violent epidemics occur during, or just after, unusually wet periods. An epidemic disease spreads either by the dispersion of its spores through the air, or by the transportation of the host-plant on which it is growing; the latter being probably the means by which diseases are carried across large bodies of water, as the Atlantic.

With the introduction of food-plants from Europe to this country come, of course, many of their parasitic diseases. It should be noted, however, that the most violent plant-epidemics of recent times have advanced not from east to west, but from west to east. The best-known case is that of the potato-rot in 1845, and since then the very accurately recorded case of the grape-mildew, Peronospora viticola, has arisen. In the first case, the disease is supposed to have reached Europe from the west coast of South America, by way of the United States. In the latter case, the grape-mould, which is a native of North America, can, as I showed by experiments in 1876, be transferred to the European vine; and it was prophesied that the disease would extend to Europe, and do more harm than with us. The prophesy was very soon fulfilled, as you all know. In the two diseases just mentioned, it is a characteristic of the spores, that in germinating, instead of giving off a filament, they discharge a number of motile zoöspores, each of which is capable of propagating the disease. We have several other species of Peronospora, which produce zoöspores, some of which have apparently crossed from America to Europe; and there are others which, although common in this country, have not yet appeared in Europe, although, following the grape-mould, they may be expected to appear there hereafter. Among these may be mentioned Peronospora Halstedii, which grows on composites, and may later be found in Europe on the Jerusalem artichoke. Professor Trelease has recently found a Peronospora on Sicyos in Wisconsin, which resembles the grape-mould in general appearance. The germination of the spores has not yet been observed, but judging by analogy one would expect them to produce zoöspores. It would not be surprising if the Peronospora on Sicyos should also be found hereafter causing a disease of squashes or melons; and its progress eastward might be expected as in the cases previously cited.

The speaker then referred to a modification of the spores sometimes observed in Peronospora. Mr. Earle of Cobden, Ill., collected species on Geranium and Viola, where, instead of the usual branching spore-stalks, the spores were borne on the mycelium close to the breathing-pores; the spores themselves being very much larger than in the common form. A similar monstrosity has been noted by Cornu in the grape-mould. The specimens were collected by Mr. Earle in April, and the speaker suggested that this form of spores might perhaps be an adaptation to the cold and wet weather of spring. The conditions which produce the monstrous forms are worth considering by collectors.

Of the diseases caused by Uredineae which have advanced from west to east, the hollyhock-disease, Puccinia malvacearum, is the best-known instance. Its original home was probably Chili; but it spread through Europe about ten years ago, not, however, by way of this country, as was probably the case with the potato-rot. The diseases produced by fungi of other orders, as Ascomycetes, do not spread with the same rapidity as the rusts and rots. This is shown by the black knot, which is so destructive in this country to plums and some kinds of cherries. It is a native of this country, and is found on most of our wild species of Prunus, especially the choke-cherry, a shrub which has been introduced into many places in Europe. As yet, however, the black knot has not made its appearance in Europe.

The speaker then said that he had just found the grape-mildew growing on the Virginia creeper (Ampelopsis quinquefolia) near Minneapolis. As this plant is closely related to the vine, the occurrence of the mildew might have been expected. In attempting to prevent the spread of the disease to countries where it is now unknown, the discovery is of importance. It is evident, that, to prevent the spread of the disease, the importation of Ampelopsis as well as of grape-vines must be prohibited.

Parallelism of structure of maize and sorghum kernels.

BY E. L. STURTEVANT OF GENEVA, N.Y.

If kernels of flint, pop, sweet, and Tuscarora maize be split parallel to the germ, each race will be seen to present a definite arrangement of structure. Thus, the flint corn presents a germ surrounded by starchy matter, and this in turn by a corneous envelope; in the pop-corn proper, the germ is enclosed in the corneous matter, the starchy matter being absent except as the pop variety intrenches upon the flints; the sweet corn has a similar structure to the pop, but the corneous matter is translucent and wrinkled.

By means of blackboard diagrams, the relative arrangements were exhibited of the 'chit' or germ, the corneous matter, and the starch, in the kernels of the above-named varieties of maize and in sorghum.

These different arrangements are constant, and do not pass into each other. The proportion of these elements is also, in general, constant throughout the development of the kernels. The parallelism which is apparent may be accounted for on the familiar axiom that similar forces acting under like circumstances produce similar results.

Agricultural botany.

BY E. L. STURTEVANT OF GENEVA, N.Y.

If kitchen-garden plants be closely studied, in many varieties it will be found that selection has differentiated the various natural species in accordance with desired uses. It will be noticed, that, while there is a striking uniformity within varieties in those portions of the plant which have not been selected for improvement, there is a great variation between those portions which have secured attention on account of their uses. Thus, in forty-five varieties of onions growing side by side, the foliage is all similar; yet the bulbs vary in size, color, shape, and habit of formation. The effect of selection concentrated upon visible forms has been to produce and fix changes from the natural plant to such an extent as in cases to mask the original plant, so that historical data must supplement morphological data in order to connect the genetic record. It is clearly evident, that conscious selection is a powerful agency for the changing of form, and by long exercise can overcome the type affixed by nature to a species. In the domesticated plant, the power of intelligence to eliminate, modify, and direct the action of natural laws under a given purpose introduced a new factor to influence plant-growth; and forms designed for uses mask genetic resemblances in those portions of the plant where change means value to man. If these views are correctly stated, then it is seen that an agricultural botany, as an annex to natural botany, is imperatively required for the purpose of furthering classification of domesticated plants; and such an annex must vary in its methods as widely from the methods of the natural botany as cultivated plants vary from feral plants, the key to the motive being in one case the use, while in the other it is the floral organs.

The present condition of the box huckleberry, Vaccinium brachycerum, in Perry county, Pennsylvania.

BY E. W. CLAYPOLE OF NEW BLOOMFIELD, PENN.

This was an interesting account of a plant that may become extinct. The discovery of this plant took place over hundred years ago, in Virginia, and it subsequently disappeared until 1846, when it was again discovered by Prof. Spencer F. Baird in Pennsylvania. This peculiar plant exists in Perry county, Penn., and in New Castle county, Md., and in no other known locality in the world. It exists in limited quantities there. Its geographical limits are sharply defined, and never extend, but rather recede, indicating a probability of its extinction.

Relation of root and leaf areas; corn.

BY D. P. PENHALLOW OF MONTREAL, CAN.

In the absence of the author of the paper, the secretary of the section briefly stated the contents. The paper sets forth the importance of the relations between the aërial and subterranean surfaces of plants, especially in respect to area. The experiments of the author were mainly upon the growth and development of maize, of which he has tabulated careful measurements showing the proportions of areas above and beneath the soil.

Influence of position on seed.

BY E. L. STURTEVANT OF GENEVA, N.Y.

The 'position' referred to in the title of this paper is that of the individual seeds grown on a spike. The object of experiment was to ascertain the differences of germinating force between seeds from the middle and from the ends of the spike. In trials carried forward at the New-York agricultural experiment-station last winter, it was found, that, for an average of 91 per cent of butt kernels, 88 per cent of central kernels, and 98 per cent of tip kernels, of flint corn, germinated. Other experiments gave the following results: In the butts planted, 79 per cent germinated; of the centres, 84 per cent germinated; and of the tips, 86 per cent germinated. For flint-corn, the tip-kernels have the stronger vegetative power.

Periodicity of Sabbacia angularis.

BY MARY E. MURTFELDT OF ST. LOUIS, MO.

The attention of the authoress was first drawn to this plant in Missouri. It is a matter of popular belief there, that the plant flowers only once in seven years. Mindful of the story in the Greek Reader, of the *scholasticus* who bought a turtle to ascertain whether it would live a hundred years, Miss Murtfeldt obtained some seed of the Sabbacia, and planted it at once. Seven years have expired since the planting, and now the plant is for the first time in flower. In a brief discussion on this paper, Professor Mason showed reasons for doubting in general the popular notions about periodicity in the flowering of certain plants.

An abnormal orchid, Habenaria hyperborea.

BY W. R. DUDLEY OF ITHACA, N.Y.

The peculiarities of this orchid, as observed by the author of this paper, consist of the spur characteristic of its generic relations, the smaller size of the plant, the narrowness of the side petals, and the broad spatula-form of the lips of the flower. These changes are apparently in a direction from an irregular to a regular form of flower. The peculiar cases observed, of which mounted specimens were exhibited to the section, may be due to arrested development; but, the author suggested, they possibly indicate a tendency to revert to older and simpler forms. The habitat of this orchid is not invariably in swamps, but also in dry beech-woods, where they are found to bloom much later than in damp regions.

In the discussion of the paper, Prof. E. D. Cope inquired as to the likelihood of a reversion to a variety of non-spurred orchids, an idea which met with a favorable response from the author.

Origin of the flora of the central New-York lake region.

BY W. R. DUDLEY OF ITHACA, N.Y.

The region referred to contains a series of lakes, and is bounded on the west by the Genesee river and on the east by Oneida lake. It is of a low, sandy character, the shores of the lakes having but a slight elevation; but towards the north the country gradually rises to a level of 2,000 feet above the sea. The whole region may be regarded as a series of old eroded valleys, filled with drift deposits, and having occasional lake-basins; its entire characteristics being such as would naturally give rise to a peculiar flora.

Professor Dudley described seven species among a large and varied flora peculiarly localized in this lake-country, the natural or ordinary habitat of which is variously situated to the south-west, west, and north-west. The conclusion he sought to establish was that the waters of the great lakes had formerly flowed through these valleys, and carried with them these several varieties of a widely scattered flora.

The remarks which followed the reading of the essay favored this theory, and pointed especially to the abrupt eastern limit of the species in question.

Development of a dandelion flower.

BY J. M. COULTER OF CRAWFORDSVILLE, IND.

By means of crayon illustrations, the author of this paper displayed the changes which the different parts of a dandelion-flower undergo in the process of growth to full maturity. The main object was to demonstrate the place, and method of origin, of the ovule.

(*ZOÖLOGICAL PAPERS.*)

Mya arenaria: its changes in pliocene and prehistoric times.

BY E. S. MORSE OF SALEM, MASS.

At a previous meeting of the association, the author showed that the species of shells found in the Indian shell-heaps along the coast of New England differed in their proportionate diameters from the same species living to-day. He pointed out, moreover, that species belonging to similar genera, in the shell-heaps of Japan, had changed in precisely similar ways. It was important to find out, if possible, the cause of these changes. A comparison between the shells of two common species, found north and south of Cape Cod, gave indications that temperature was the inducing cause. The two species selected were Mya arenaria and Venus mercenaria; the former extremely variable, the latter very constant, in its characters. Specimens of these species had been collected in great numbers, both recent and ancient. The following are the indices, of Mya arenaria: —

Recent.		Ancient.	
South of Cape Cod, 61.42.	North of Cape Cod, 61.67.	South of Cape Cod, 62.	North of Cape Cod, 62.78.

of Venus mercenaria: —

Recent.		Ancient.	
South of Cape Cod, 81.01.	North of Cape Cod, 81.10.	South of Cape Cod, 81.51.	North of Cape Cod, 81.81.

Since the waters south of Cape Cod are much warmer than those north of Cape Cod, it was reasonable to suppose that these changes were due to temperature, and that the higher index of the ancient specimens found in the Indian deposits might indicate a colder climate. This supposition receives some support in the fact that a measurement of specimens found in the glacial clays about Portland, Me., and on the Kennebec river in the same state, gave the high index of 66, and a number of Norwich and Red Crag fossils of Mya, which he had the opportunity of measuring at the British museum, had an index of 64; recent Mya from South End, Eng., having the low index of 58.30.

It was interesting to observe, that measurements of Mya in Japan gave, for the southern form, an index of 61.10, and, of a more northern form, 62.50.

In the discussion which followed, Mr. Morse stated that he had made similar observations with regard to other shell-fish.

Some recent discoveries in reference to Phylloxera.

BY C. V. RILEY OF WASHINGTON, D.C.

Every new fact in the life-history of the insects of this genus has an exceptional interest, because of its bearing on the destructive grape-vine Phylloxera. The genus is most largely represented in this country by a number of gall-making species on our different hickories, and the full annual life-cycle of none of them has hitherto been traced. The galls are produced, for the most part, in early spring; the winged females issue therefrom in early summer; and thenceforth, for the remainder of the year, the whereabouts of the insect has been a mystery. The author has for several years endeavored to solve this mystery and at last the stem-mother (the founder of the gall), the winged agamic females (issue of the stem-mother), the eggs (of two sizes) from these winged females, the sexed individuals from these eggs, and the single impregnated egg from the true female, have been traced in several species. There is some evidence, though not yet absolutely conclusive, that this impregnated egg hatches exceptionally the same season; also, of a summer root-inhabiting life. In Phylloxera spinosa, which forms a large roseate somewhat spinose gall on Carya alba, and which has been most closely studied, the impregnated egg is laid in all sorts of crevices upon the twigs and bark and in the old galls, in which last case they fall to the ground.

Up to this time they have remained unhatched, and will in all probability not hatch till next spring, thus corresponding to the 'winter egg' of the grape Phylloxera.

Psephenus Lecontei; the external anatomy of the larva.

BY D. S. KELLICOTT OF BUFFALO, N.Y.

THE species referred to is found in large numbers at the rapids above the falls of Niagara, and is scattered throughout the north-eastern part of North America. The author proposed to supplement the accounts given of it by earlier observers with a record of his own observations, which differed in some respects from those of Dr. LeConte. Several details of anatomical structure were brought to the attention of the members, and illustrated with wood-cuts prepared for the purpose and with specimens mounted in balsam for observation under the microscope.

The Psyllidae of the United States.

BY C. V. RILEY OF WASHINGTON, D.C.

THE Psyllidae, or flea-lice, are rather small homopterous insects, that have remarkable jumping powers. Some of them injure cultivated plants. This is notably true of the Psylla pyri, which blights the buds of pear-trees; and Phyllopleeta tripunctata, which crumples the tips of the blackberry. The family has received little attention in the United States, and scarcely any thing has been known of the life-history and development of the species. The paper enumerates 17 described species, four of these being synonymes, and one of them (Psylla pyri) introduced from Europe. They fall into four subfamilies, and represent four genera already characterized, and three new genera, — Brachylivia, Pachypsylla, and Phyllopleeta. The new species characterized are Calophya vitreipennis, from Arizona; C. nigripennis, on Rhus copallina; C. flavida, on Rhus glabra; Pachypsylla celtidis-cucurbita, forming galls on Celtis texana; P. c.-pubescens, P. c.-asteriscus, P. c.-umbilicus, and P. c.-vesiculum — all forming galls on leaves of Celtis occidentalis; Blastophysa (nov. gen.) c.-gemma, forming galls on the twigs of the same tree; Ceropsylla (nov. gen.) xyderoxyli, a remarkable form developing in pits on the leaves of Xyderoxylon masticodendron; Trioza sanguinosa, on Pinus australis; T. sonchi, on Sonchus arvensis; and Rhinopsylla Schwarzii, from the cypress-swamps of Florida. The paper records discoveries as to the entomography of the species, and especially those affecting Rhus and Celtis; the latter forming a group peculiar to North America, and the most perfect gall-makers in the family.

The most interesting portion of Professor Riley's paper, to those who are not entomologists, was that where he dwelt on the life-histories and habits of the insects he described. The eggs are attached to leaves by a pedicel, and are somewhat pointed at one end, and often terminate in a filament. The young are broad and flattened, with a fringed margin. They are generally pale, and more or less covered with a flocculent secretion. Those on sumach are dark, and without such flocculence. Those making galls on hackberry have stout spines at the end of the body, by the aid of which they are able to work out of their galls.

Note on Phytoptidae.

BY HERBERT OSBORN OF AMES, IO.

THE Phytoptidae comprise a group of very minute mites, species of which produce galls of various forms on the leaves or twigs of various trees. Recent investigation in Europe has placed the group in a different light from that in which it previously was considered. Their study is rendered difficult by their extreme minuteness, and the care necessary to discover the different stages. One of the most common species produces the little wart-like swellings which occur so abundantly on soft maple leaves. A species on ash leaves produces a swelling which is nearly uniform on the upper and under surfaces of the leaf; while another species on the same tree produces a leafy growth at the end of the twigs, the growth sometimes being inhabited also by cecidomyian larvae. On the elm occurs a large deformed leafy growth, which also contains Phytopti: while still another form of gall occurs on box elder, consisting of a depression on the under surface of the leaf, this depression being filled with a woolly growth, and containing Phytopti.

Notes on the potato-beetle and the Hessian fly for 1883.

BY E. W. CLAYPOLE OF NEW BLOOMFIELD, PENN.

THE author found that only one brood of the potato-beetle appeared last year. This seemed an unusual fact, but no second brood had appeared on the potatoes under his observation. In the present year, no beetles appeared during the early stage of the growth of the plant. This fact had been also noticed in New York and New Jersey. He attributed the cessation in the early part of this year to the same unknown cause which had checked the late brood of last year, and asked the opinions of members in determining the cause. Professor Riley thought the disappearance of the beetle could be attributed to the drought. But Professor Claypole said that in 1881, which was an unusually hot and dry season, the beetles were more numerous than he had ever seen them, and gave him more trouble than ever before or since.

In regard to the Hessian fly, Professor Claypole was of opinion that the insect injured the later wheat much more than the early crop, because the crops that gain full strength are best able to resist the attack. Wheat sown before Sept. 10 escaped the ravages of the fly. The winter wheat being chiefly attacked, the observations on the insect had been directed especially to that crop. Contrary to the opinion of many farmers, Professor Claypole believes there are two broods, one in the autumn, and one in the spring. The insect, it is thought, often killed the stalk in the fall, and then probably died with it.

Professor Riley thought that this class of observations could apply only to certain localities, and that in the southern states the conditions might be entirely changed. Professor Forbes thought there were three distinct broods per year in Illinois. As late as July he had found eggs of a brood already abroad.

The structure of the skull in Diclonius mirabilis, a Laramie dinosaurian.

BY E. D. COPE OF PHILADELPHIA, PENN.

A BLACKBOARD sketch of this dinosaur, as reconstructed by Professor Cope, attracted much attention. The animal existed in the mesozoic age, and is estimated to have been 38 feet long. The skull, which is about four feet in length, is in profile a good deal like that of a goose, but, seen from above, is somewhat like that of a spoonbill. Skulls of this type of reptiles are rarely found, and this one throws much light on the question of the classification of the order. The arrangement of the teeth is very peculiar; and the number is very great, amounting to nearly 2,000. The general form of the animal is that of a gigantic kangaroo. The food evidently consisted of very soft aquatic vegetation.

The trituberculate type of superior molar, and the origin of the quadrituberculate.

BY E. D. COPE OF PHILADELPHIA, PENN.

IN the lower eocene, Professor Cope finds all the mammalian molar-teeth to be trituberculate. He has now a complete series of molar-teeth from different mammals in successive horizons, showing all the steps of transition from trituberculate molars of somewhat triangular form and very simple structure, up to the regular quadrituberculate tooth, which is defined as of nearly square section and having four tubercles. Man has quadrituberculate molars: all the monkeys are similarly equipped. Some of the lemurs have trituberculate teeth. Among lower types, such as marsupials and hedgehogs, about half have the tri- and half the quadri-tuberculate development. The insectivora are similarly divided, about half having the old eocene molars and half the modern form. The various steps of development were illustrated by blackboard-drawings.

Two primitive types of Ungulata.

BY E. D. COPE OF PHILADELPHIA, PENN.

THE author announced the discovery of a new mammalian fauna of the eocene, having the following characteristics: 1°. All the fingers and toes are retained; they are plantigrade, each limb having five digital extremities. 2°. The limbs are shorter than usual. 3°. They invariably have a flat astragalus. To the second specification there is one exception, a swimming animal whose hind-limbs were long. One of the discoveries is of a hoof-type animal with carnivorous jaws. It existed in the eocene, and appears to have been of short duration.

In the discussion on this paper, Dr. Dawson stated that some of the plants he had traced in the eocene were well adapted, by the circumstances under which they grew, for supplying food to the creatures described. Professor Cope received this announcement with expressions of pleasure. Thus the new mammal of the old eocene not only bridged the interval between ungulates and carnivores, but also the wider gulf between Dr. Dawson and Professor Cope.

Pharyngeal respiration in the soft-shelled turtle, Aspidonectes spinifer.

BY S. H. GAGE OF ITHACA, N.Y.

DURING the last twenty-five years, respiration in the Chelonia has been investigated with considerable thoroughness, both in this country and in Europe; and at present the chelonian form of respiration is considered to be comparable with that of the mammal, rather than with that of the frog as formerly supposed. While, however, the mechanism of respiration has been very fully investigated, there has been, so far as the author is aware, but one investigator who has considered the organs of respiration in the different groups of turtles. The author showed reasons for believing that a true aquatic respiration, and a true aërial respiration, co-existed in the soft-shelled turtle. It is hoped, that, during the coming year, investigations may be completed which shall determine the exact proportion of the pharyngeal respiration, and the structure of this unusual respiratory organ.

The application of nitrous oxide and air to produce anaesthesia; with clinics on animals in an experimental air-chamber.

BY E. P. HOWLAND OF WASHINGTON, D.C.

THE paper opened with the conclusion of the author that a mixture of nitrous oxide and oxygen, administered in a closed air-chamber, would eventually take the place of ether and chloroform as an anaesthetic for all surgical operations. As ordinarily administered, nitrous oxide cannot be used for prolonged operations, because the blood does not separate oxygen from the gas. Nitrous oxide is expelled from the lungs without change: if it is supplied to them without air or oxygen, death ensues from asphyxia. The author claimed to have administered nitrous oxide for dental and surgical operations in over 30,000 cases. He has found that where unmixed nitrous oxide is used, in the average of cases insensibility is produced in fifty seconds, and recovery from unconsciousness takes place in two minutes. With animals experimented upon, in the average of cases, death ensued within two and a half minutes, where air or oxygen was excluded.

If, at the ordinary pressure of the atmosphere, enough air is mixed with nitrous oxide to support respiration, the mixture fails in producing anaesthesia. But the increase of pressure which can be effected by administration in an air-tight chamber changes the result materially. In such a chamber, with suitable air-pressure, equal parts of air and nitrous oxide breathed from a gas-bag, or a mixture of 85 parts oxide and 15 parts oxygen, can be breathed for an indefinite time without danger or injury, producing perfect anaesthesia while thoroughly oxygenating the blood. The effect of the pressure of air in the chamber is simply to concentrate the mixture in the gas-bag into smaller space; and, when thus concentrated, the oxide does the work of producing insensibility, while the air or oxygen of the mixture keeps up the vital processes.

The author gave an historical account of the discovery of this method of administration by Paul Bert in 1878, and its subsequent applications. Having used it for many capital operations, Dr. Howland recommends the system unhesitatingly. Some points of its excellence, in addition to those already mentioned, were stated as follows: By augmenting or diminishing the pressure, the degree of anaesthesia may be regulated at will, and with mathematical precision. Therefore there is no danger of any of the accidents incurred through the use of ether or chloroform. When inhalation of nitrous oxide and oxygen is stopped, the patient recovers consciousness in a few seconds, and feels no subsequent discomfort. The action of compressed air on the surgeon and his assistants is not injurious.

After the reading of the paper, the operation of the system was exhibited. The air-chamber in this case was a tight box with glass sides; and the patient was a chicken. Perfect anaesthesia was produced and proved; and then, after the chicken was restored to consciousness, it was again placed in the chamber, and killed by the administration of unmixed nitrous oxide.

Conscious automatism.

BY C. P. HART OF WYOMING, O.

THE author confined his inquiry to the manifestation of conscious automatism in man. The question was whether the centres in the cortex of the brain were essential to the production of automatic functions of this character. Claiming that the destruction of these cortical centres induces complete and permanent motor paralysis, the author drew the conclusion that conscious automatism depends upon the integrity of that portion of the brain in which arise consciousness and volition.

Prof. E. D. Cope, discussing the paper, hinted that the author had raised the question upon mistaken grounds; that conscious automatism, of necessity, originated in the cortical portion of the brain, but by the influences of use and heredity became so far habitual that it is independent of volitional impulses. The question is evidently not one of automatical origination, but of functional independence.

List of other papers.

The following additional papers were read in this section, some of them by title only: A fact bearing upon the evolution of the genus Cypripedium, by *E. S. Bastin;* Leaves of the Gramineae with closed sheaths, by *W. J. Beal;* Observations on Cephalopoda, by *Alpheus Hyatt;* Position of the Compositae in the natural system, by *Joseph F. James.*

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

National museum.

Priestley's apparatus. — Priestley's chemical and physical apparatus, now in the possession of his descendants in Northumberland, Penn., has been presented by the latter to the National museum, and will be placed in the collection illustrating the history of science.

STATE INSTITUTIONS.

Iowa weather service, Iowa city.

Weather bulletin for July. — The weather of July, 1883, was very favorable to the crops, being fair, nearly normal in temperature, with an excess of rainfall, and southerly winds prevailing.

The mean temperature of the air was but a little over one degree below normal: last year July was nearly five degrees below normal. The number of hot days has been high, especially during the first and last decade, while the middle decade was cool.

Insolation has been high, because, even during the stormy period, cloudy days were rare, and during the month clear days were numerous. The sun thermometer exceeded 140° on twenty-one days; its highest reading was 161°, on the 23d.

The total rainfall was below normal in southern-central Iowa, from Union to Jasper counties: in the balance of the state it was considerably above normal, averaging about six inches in the north-west and in the south-east, and nine inches in the north-east. The highest rainfall, of fourteen inches, for the month, was measured at Decorah. The number of rainy days averaged ten for the east and north-west, and about six for the balance of the state.

As usual during July, very heavy rains have occurred, but only in the north. The highest rainfall measured on one day was nearly six inches, at Homedale, south of Sibley, in Osceola county, on the 23d; next to this stands Algona, Kossuth county, with over five inches on the same date. But the most notable rain period of the month occurred in north-eastern Iowa, from the 20th to the 23d inclusive, giving very nearly ten inches of rain in Howard and Winnesheik counties.

No tornadoes have occurred, but several squalls have visited parts of Iowa; yet the most destructive of these storms have but touched Iowa. The squall of the 4th started about 5 P.M. in central Iowa, and reached south-eastern Iowa about 9 P.M.: it was not very severe. The squall of the 12th started about 6 P.M. in Black Hawk county, reached the Mississippi in Scott and Clinton counties about 9 P.M., doing much damage by wind and hail: it continued to spread over central Illinois till about 11 P.M. About noon on the 13th another very severe squall started from south-western Iowa, where considerable damage was done in Fremont and Page counties: the storm increased in fury while spreading over north-western Missouri till about 3 P.M. Another storm of less severity visited north-eastern Missouri and southern Illinois on the evening of the same day. A severe squall with hail reached, on the afternoon of the 18th, into north-western Iowa, coming from Dakota. A southerly squall reached Polk and Jasper counties early on the 16th.

On the whole, the weather during July has been very fine: bright skies, aglow with ripening sunshine, alternated with enriching rains, — summed up in splendid crops of small grain and hay, and excellent pastures, and giving promise of a good crop of corn, for the fall season promises well also.

State university of Kansas, Lawrence.

Weather report for July. — In four of the past fifteen years, the July mean temperature has been lower than in this year; but the July rainfall has been but once exceeded during that period (in 1871).

Mean temperature, 76.18°, which is 2.17° below the July average. The highest temperature was 96.5°, on the 23d; the lowest was 56°, on the 9th: giving a monthly range of 40.5°. The mercury reached or exceeded 90° on seventeen days. Mean temperature at 7 A.M., 71.27°; at 2 P.M., 85.71°; at 9 P.M., 73.90°.

Rainfall, 7.23 inches, which is 2.94 inches above the July average. Rain fell in measurable quantities on nine days. There were five thunder-showers. The rain of the 30th yielded 3.10 inches. The entire rainfall of the seven months of 1883, now completed, has been 29.03 inches, which is 7.99 inches above the average for the corresponding period of the preceding fifteen years, and is 1.43 inches above the total rainfall of the year 1882.

Mean cloudiness, 39.46% of the sky, the month being 1.89% cloudier than the average. Number of clear days (less than one-third cloudy), 18; half-clear (from one to two thirds cloudy), 7; cloudy (more than two-thirds), 6. There were three entirely clear days, and three entirely cloudy. Mean cloudiness at 7 A.M., 38.39%; at 2 P.M., 45.48%; at 9 P.M., 34.52%.

Wind: S.W., 39 times; N.E., 15 times; N W., 12 times; N., 9 times; S., 7 times; W., 5 times; S.E., 5 times; E., once. The entire distance travelled by the wind was 10,901 miles, which is 2,229 miles above the July average. This gives a mean daily velocity of 351.64 miles, and a mean hourly velocity of 14.65 miles. The highest velocity was 40 miles an hour, from 1.30 to 2 A.M. on the 12th.

Mean height of barometer, 29.086 inches; at 7 A.M., 29.111 inches; at 2 P.M., 29.071 inches; at 9 P.M., 29.078 inches; maximum, 29.381 inches, on the 18th; minimum, 28.679 inches, on the 11th; monthly range, 0.702 inch.

Relative humidity: mean for the month, 71.4; at 7 A.M., 80.3; at 2 P.M., 54.7; at 9 P.M., 79.1; greatest, 97, on the 31st; least, 20, on the 2d. There was no fog.

NOTES AND NEWS.

Circumstances were not favorable to the production of remarkable essays at the recent meeting of the American association. The attendance was not large. The officers of the meeting, and especially those who had to make addresses, could scarcely be expected to produce elaborate papers in addition to their other labors. As the number of addresses per meeting has increased, we may observe more readily some of the effects of the system that demands them. The most evident result is, that usually, where we gain one good address, we lose two or three good papers.

The distance of the meeting from their homes affected especially members of sections A, B, C, and D, devoted to the exact sciences. Perhaps it affected the quality as well as the number of their papers. There were not many from the east to present essays, though quite as many as could have reasonably been expected; but there were scarcely any from the locality of the meeting and its neighborhood. Local interest, both as to authors and hearers, was of course deficient. In short, there was nothing remarkable in those sections to spur production, and the product was not remarkable. It was good, but not great.

Some of the papers seem to have lost their way among the sections; a paper that was chiefly botanical having gone before the chemists, and the paleontological papers being divided between biology and geology. In some cases the affinities of authors rather than of subjects may have been consulted, though probably the discrepancy was mostly created in efforts to equalize the amount of work in the different sections.

During the progress of the meeting, it being found that botanists were present in unusual numbers, a botanical club was formed. The immediate object was the organization of botanical excursions. An ultimate object is to arrange for preparing a petition to memorialize congress respecting differences between the rulings of the post-office department as to the sending of plants by mail at home and abroad. The organization of the club was somewhat informal. Prof. W. J. Beal of Lansing, Mich., was appointed president, and John M. Coulter of Crawfordsville, Ind., secretary. The roll was signed by twenty-five botanists who were present at the first session of the club, and their number was increased before the meeting of the association adjourned.

We have before alluded to the singular want of executive ability, or of co-ordination in achieving results, which marred the work of the local committee. That continued throughout the meeting, with many embarrassing results. We again refer to it, not to find fault anew, but to mention that the committeemen themselves acknowledged their blunders most heartily in their farewell speeches, and that their kind intentions were manifest throughout.

— Students of meteorology will be interested in a paper lately read by M. Faye before the French academy of sciences on the whirlwinds of sand observed by Col. Prejevalsky in central Asia. M. Faye believes that such sand-storms, like those of Mexico, India, and the Sahara, have the same origin and mechanical action as the tornadoes of the United States and all water-spouts. They are vertical spiral movements, moving horizontally and nearly in a straight line.

— The operations of France in the region of Annam have naturally excited great interest in the geography and ethnography, statistics and commerce, of Annam. A crowd of publications of all sorts are constantly appearing. References of the briefest sort to some of the more notable may be of interest to those who ignore the political side of the question. J. Gaultier publishes for Mallard-Cressin a chart of the region on the scale of 1: 850,000. This is stated to be on the largest scale of any of the maps of this region, and as perfect as the state of knowledge will admit. Another map by Henri Mager, though smaller, is very carefully executed, and includes a plan of the fortress of Hanoi. The oriental studies of the author have enabled him to unify and correct the nomenclature in a satisfactory manner. Romanet du Caillaud has published a long memoir on the protectorate of France over Annam, and the relations between the latter state and China, in the quarterly bulletin of the Société de géographie.

— The enterprise of Johns Hopkins university is shown by the publication of one of its circulars in midsummer, filled with scientific notes in mathematics, physics, biology, and philology. They are all abstracts of papers read before the different active associations in the university, and in most cases will probably be published in full elsewhere. The circular also reprints, from the Royal society's proceedings, the abstract of Dr. Martin's Croonian lecture; and, from the London *Times*, an account of the eclipse observations of May 6, to which Dr. Hastings appends a brief note, pointing out one mistake made by the writer. A list of mathematical models belonging to the university, and of works in the Assyrian and other oriental languages found in the Peabody institute, are also given.

— The following appointments to fellowships in science in Johns Hopkins university are published: In mathematics, G. Bissing and E. W. Davis of Baltimore, and A. L. Daniels of Kendallville, Ind.; in physics, Gustav A. Liebig, jun., of Baltimore, and Charles A. Perkins of Ware, Mass.; in chemistry, D T. Day of Baltimore, J. R. Duggan of Macon, Ga., and E. H. Keiser of Allentown, Penn.; in biology, W. H. Howell and L. T. Stevens of Baltimore.

— Müller's record of the literature of pollination and dissemination for 1880–81 has recently appeared in Just's *Jahresbericht*, containing abstracts of one hundred and forty-nine papers, with many useful items, both critical and supplementary, by the able reviewer. Though these records are very useful when they reach us, their value would be much increased if it were possible to present them to the public more promptly after their preparation. As it is, they are usually two or three years in appearing.

— *Nature* states that the Dutch government have decided not to grant the sum of thirty thousand guilders, which Baron Nordenskiöld claims as the discoverer of the north-east passage. The decision is founded on the motive which led the States-general, in 1596, to offer this award; viz., to find a passage of *commercial* value to the nation. Baron Nordenskiöld having, however, discovered what may be termed a purely *scientific* one, the award, it is argued, has not been earned. As several reasons have been advanced for this claim made by the gallant Swedish explorer, we do not think we err, says *Nature*, when we assert that it was his intention to have expended the sum in the interest of science; viz., on an expedition to the arctic regions.

— George Mantoux has just edited a volume containing the letters and journals of La Pérouse, on his celebrated and unfortunate voyage around the world; preceded by a memoir of that officer, who was last heard from at Botany Bay, and, with his entire party, was wrecked on one of the South Sea Islands, where the survivors were murdered by the natives. It forms one of the *Bibliothèque d'aventures et de voyages* issued by Dreyfous of Paris.

— A Yokohama paper states that Mr. John Milne, whose researches on earthquakes, as explained by him to the British association at Southampton, have excited great interest in scientific circles, and who has since returned to his duties in Japan, has applied to the Japanese authorities to establish an observatory, in order that he may be able to thoroughly investigate underground phenomena. He has sent the authorities a long treatise upon the earthquakes of Japan.

— The *London daily news* says that the Darwin memorial fund has risen to £3,300. Among the most interesting of the sums that the treasurer has received is a cheque for £91.4, collected in Finland.

— The next number of the *Journal* of the Cincinnati society of natural history will contain an illustrated paper by Professor Mickleborough, upon a specimen found by Mr. D. A. McCord of Oxford, O., which has been creating much interest among the paleontologists of Cincinnati and vicinity. It is a small slab of limestone showing on one side the shell of an Asaphus, and on the other the legs of the animal. Fortunately, the rock was split in such a way as to show both the legs and their cast. The characters of the ambulatory appendages of the trilobite are finely shown, and confirm in a remarkable manner the discoveries of Mr. Walcott, who several years since established beyond a doubt the existence of legs in specimens of Calymene.

— The bodies of Professor Palmer, and his companions Capt. Gill and Lieut. Carrington, assassinated by the Bedouin, have been discovered by Capt. Warren, and transported to England, where it is anticipated they will find a resting-place in St. Paul's cathedral.

— Mr. Charles Depérais read a paper before *l'Institute royal d'encouragement de Naples*, April 5, in which he advocated the embalming of bodies by boiling them in a solution of chloride of calcium, and then in a solution of sulphate of soda.

— The government of Ontario has published for the Entomological society of that province a general index to the thirteen annual reports upon injurious insects which the society has made to the commissioner of agriculture. The index is prepared by William Baynes-Reed, and consists of a serial and a classified list of illustrations, and a general index to the text. It appears to be prepared and printed carefully.

—The death of the famous M'tesa, King of Uganda and baiter of missionaries, is announced.

—The following papers were prepared during the past year by members of the Lawrence scientific school, Harvard university, under the supervision of Dr. E. L. Mark in the embryological laboratory at the Museum of comparative zoölogy:—

On the development of Oecanthus, and its parasite Teleas, by Howard Ayers of Fort Smith, Ark.; on the development of the posterior fissure of the spinal cord, and the reduction of the central canal, in the pig, by William Barnes of Decatur, Ill.; notes on the development of Phryganidae, by William Patten of Watertown, Mass.; the relation of the external meatus, tympanum, and eustachian tube, to the first visceral cleft, by Albert H. Tuttle of Dorchester, Mass.

The papers by Mr. Ayers and Mr. Patten have been awarded respectively the first and one of the second Walker prizes by the Boston society of natural history, as already stated in these columns. All are to be published in the course of a few weeks.

—The eighth annual report of the Buffalo microscopical club shows a membership of forty-six,—a gain of fifteen during the year. The average attendance at the monthly meetings is stated to have been about twenty-five,—certainly a very large percentage.

—Prof. D. P. Penhallow, having resigned his connection with the experiment department of Houghton farm as botanist and chemist, has accepted the lectureship of botany at McGill university.

—Messrs. Allen, Coues, and Brewster sign a call for a convention of American ornithologists, to be held in New-York City, beginning on Sept. 26, 1883, for the purpose of founding an American ornithologists' union, upon a basis similar to that of the 'British ornithologists' union.' The object of the union will be the promotion of social and scientific intercourse between American ornithologists, and their co-operation in whatever may tend to the advancement of ornithology in North America. A special object, which it is expected will at once engage the attention of the union, will be the revision of the current lists of North-American birds, to the end of adopting a uniform system of classification and nomenclature, based on the views of a majority of the union, and carrying the authority of the union.

It is proposed to hold meetings at least annually, at such times and places as may be hereafter determined, for the reading of papers, and the discussion of such matters as may be brought before the union. Those who attend the first meeting will be considered *ipso facto* founders. Active and corresponding members may be elected in due course after organization of the union, under such rules as may be established for increase of membership. Details of organization will be considered at the first meeting.

—'The books of science' is the title of a work announced by Leypoldt as in preparation by William C. Lane of Harvard college library. It is to be an annotated catalogue of the most trustworthy works for the study chiefly of the physical and mathematical sciences. From what we know of the compiler and of the manuscript, a portion of which we have examined, we may confidently predict a very useful work.

—In his address before the American forestry congress last year at Cincinnati, recently printed in the *American journal of forestry*, Prof. F. L. Harvey gives a catalogue of the forest-trees of Arkansas, of which he enumerates a hundred and twenty-nine indigenous species. According to his summary, Arkansas is remarkable for its extensive belts of pine, for the area of hard-wood growth, and for the number of species usually classed as shrubs, which here attain the dimensions of trees. More than half the species belong to the six orders Magnoliaceae, Rosaceae, Urticaceae, Oleaceae, Juglandaceae, and Cupuliferae. Professor Harvey believes that physical conditions, rather than geological horizon, affect the specific character of the vegetation in Arkansas, where the north-western part of the state is upland and paleozoic, and the remainder lowland and of more recent date.

SCIENCE.

FRIDAY, SEPTEMBER 14, 1883.

THE U. S. SIGNAL-SERVICE.

I.

The annual report of the chief signal-officer for 1881, recently issued, is a volume which ought to be of great interest to all concerned in the progress of meteorological science in this country; and it would be, were it not for certain characteristics too apt to be found in government publications. Of these, the most notable at first sight is its ponderous bulk. After one has received the polite notice, 'a package too large for the carrier,' etc., and has achieved its safe delivery in one way or another, he is likely to wonder what end it may be best made to serve. If he be interested in meteorology, he will find it well worth his while to give at least one volume of the series a careful examination, in order that he may know what not to read in the next.

In its thirteen hundred broad pages, together with its maps, charts, etc., he will find much that is valuable; much that, to him, is perfectly useless; and, if his tastes be not too circumscribed, much that is amusing. A government report is not a likely place in which to seek entertainment; but, considered as a scientific publication, the report will furnish its share. In this respect it is, doubtless, clear ahead of all other scientific documents issued by the government.

As a scientific document it must be considered; for, since the organization of the weather bureau of the signal-service, by far the larger part of the operations of that service have had to do with meteorology; in fact, the work in the way of practical meteorology constitutes the only *raison d'être* of the service as at present organized and equipped.

A fair examination of this work can only be made by a comparison of this report with those of the several preceding years: indeed, justice could not be done the present administration without such a comparison, as it indicates changes of considerable moment, which seem likely to greatly increase the efficiency and value of the service.

The first part of the volume consists of the report proper of the chief signal-officer. This seems, in each case, to be made up almost entirely by copying from the report of the previous year. It must have been written, of course, at some time, and by somebody; but when and by whom will soon be lost to the history of meteorological science. A few additions are made, fewer subtractions, and now and then a linguistic blunder has been eradicated, after it has done faithful service for several years. The impression is everywhere conveyed, that the preparation of this, which one might expect to find the freshest and most readable portion of the volume, is annually committed to the skill of a copying-clerk. It is not to be denied, that certain statements in regard to the service will bear, and deserve, repetition; and, indeed, the chief signal-officer himself inserted a sort of an apology for this repetition a few years ago, which has been faithfully reprinted along with the rest ever since. But whole pages are repeated year after year, when it would appear that they had served their purpose in a single publication; and this seems all the more uncalled-for in the case of much which might better have never been published at all.

We are annually informed, that "meagre reports only have been received of the instruction for the field duties of the signal-service elsewhere than at Fort Myer;" and we wonder why whoever is responsible for this neglect is not urged to remedy it, through some other avenue than the annual report. The need of a fire-engine at the post was a standing item for several years; but, as it does not appear in the last report, it may be assumed that the want has been supplied, possibly through the generosity of some distressed reader.

The space occupied by the fire-engine is now filled, however, by the extraordinary and interesting announcement, that "the post-garden is in good condition, and has, for some time, been a source of supply to the company mess." The importance of this statement entirely overshadows that of many others which might be quoted, — such as that the enlisted men have succeeded in managing the coal-oil lamps which have been supplied them, that the buildings of the post will require painting the coming season, etc.

In some instances the annual reprint has not received that attention which might be expected even from clerical supervision. One of the statements which has regularly made its appearance for several years is this: "It is needless, with such facts in view, and after —— years of continuous service, to reiterate the advantages secured to the signal service by its military organization." In spite of this declaration, the reiteration has been religiously kept up; and it was evidently intended that the above blank should be properly filled as the years rolled by. In the report for 1879, it is filled with the word 'nineteen,' and this is exactly copied in that for 1880. In the report for 1881, the word 'twenty' is substituted; so that, unless an effort is made to 'catch up' in the next report, the corps will be deprived of one 'year of continuous service,' and the argument will be proportionately weakened.

Illustrations of useless and careless reprinting might be continued to almost any extent; but it will be of greater interest to pass to Appendix I., which contains the courses of instruction furnished at Fort Myer for the training of officers and men belonging to the service.

If this is to be considered as a school for the education of meteorological observers, its curriculum is certainly marvellous. Although certain portions of the course of study are given in the report in great detail, — even to the paragraph and page at which each lesson begins and ends, other portions are not so well defined; and some assumptions must be made as to the time occupied in certain parts of the work. It is thought that no injustice is done in the following estimate of the distribution of study and practice: —

Officers who are assigned to the school for instruction in the duties of the service remain there about one year. The instruction is theoretical and practical. In the theoretical course, about 37 per cent of the whole time is spent in the study of meteorology and meteorological observations. In the practical course, 8 per cent is a high estimate for the time devoted to that subject. Indeed, out of the year's work, it is prescribed that *eight days* shall be spent in the meteorological observatory; in which time the officer is expected to learn "the use of all instruments used at observation offices of the signal-service, care of and repair of same, and making out of meteorological forms." The remainder of the year is devoted to the study and practice of military signalling, wand-practice, military surveying, electric telegraph, international signals, etc. It is fair to add, however, that for officers who are assigned to the headquarters of the chief signal-officer, and are candidates for service in the 'indication-room,' a very liberal course of advanced study and reading in meteorology is prescribed to be carried on at the office of the weather-bureau accompanied by practice in the preparation of charts and in 'forecasting.'

The enlisted men, however, upon whom falls the burden of collecting the great mass of meteorological material, which is daily digested in the central office, do not fare so well. The period of their stay at Fort Myer is limited to about six months, during the first two of which they cannot be placed under class instruction, but are required to recite in cavalry tactics, to attend wand and telegraph practice, to stand guard, and attend to other military duties. When, at last, they are permitted to begin the study of meteorology, the percentage of their time given to it is not noticeably greater than that of the officers. During their six months at the fort, ten days are spent in the meteorological observatory; and in that time they are expected to learn, and probably do learn, all that the officers acquire in the eight days which is allowed them for practice in meteorology. When it is remembered that the sole occupation of the great majority of these men, during the entire period of their enlistment after leaving Fort Myer, is to make and record meteorological observations, it seems little short of folly to subject them to such a course of training in preparation. That only ten days, out of the one hundred and eighty spent in the school, should be occupied in practical training in observation, and the use of instruments, is certainly an inversion of the true order of things. It is difficult to see the value, to such men, of the long training in 'cavalry tactics,' the 'manual of the carbine,' the 'manual of the kit,'—whatever that may be, —and many other things found in the course. It is true, that, to observers stationed on the seacoast, a knowledge of naval signals is necessary; and, to all, a degree of familiarity with the practical working of the electric telegraph would be desirable: but the business of the great majority of the observers is purely scientific, and, it is to be hoped, peaceful in its character. It is clear that the skill and knowledge necessary to the successful performance of these duties must be largely acquired after active service has begun.

The chief signal-officer very properly remarks, that the criticism to which the service has been subjected is evidence of its success. No well-informed person can fail to feel great pride in the results achieved by the signal-service since the organization of the weather-bureau. The general increase in the accuracy of its forecasts, the efforts made to communicate important meteorological information to localities likely to be seriously affected by probable changes in the weather, and its valuable services in the display of cautionary and danger signals, have given it a hold upon the confidence of the people not easily weakened.

The percentages of verification of predictions since the organization of the weather-service, as given in the various reports, are as follows:

Year.	Per cent of verification.	Year.	Per cent of verification.
1871	69	1877	86
1872	77	1878	84
1873	77	1879	86
1874	84	1880	86
1875	87	1881	85
1876	–		

In the display of cautionary and danger signals, the success has been about equally great. In forecasting, in which the character of the weather only is considered, the percentage of verification is generally as high as ninety.

While these figures do not indicate any marked progress during the past five years, it must be remembered that a point has been reached from which farther advance must necessarily be difficult and slow.

'REX MAGNUS.'

AT the suggestion of the editors of SCIENCE, I have carefully examined the 'viandine' brand of the new preservative 'Rex magnus,' and find it contains boracic acid, sodium, potassium, and water as ingredients; and I believe its composition can be roughly formulated as follows:—

Boracic acid } Borax }	67 per cent.
Potassic chloride	15 "
Water	18 "

The mixture also contains very small amounts of sulphur and magnesium. Both, however, are probably accidental impurities.

To determine the preservative properties of the viandine brand, a number of experiments were undertaken, the general result of which can best be shown by copying some of the notes taken during the course of the experiments, and supplementing them with a formulated table.

July 5, I dissolved one-half pound of viandine in one gallon of water contained in a stone jar, and placed one pound of beef-steak, one pound of veal-steak, and one pound of fresh mackerel in the solution.

July 6, the beef, veal, and fish, which had remained in the solution twenty-six hours, were removed, and, after allowing them to drain for two or three minutes, were placed on plates in the laboratory.

July 7, I boiled the solution which had been used with the meats and fish, and removed the scum that rose to the surface. When cold, I added about two ounces of viandine, and poured the solution into a stone jar containing one pound of mutton-chops and one pound of liver.

Tabular statement of experiments with 'Rex magnus.'

28	75	– –	– –	Eat a piece, palatable.	– –	– –	– –	Cooked, odor so strong I could not remain in the room.

Note.—The temperature is the mean of three daily observations taken at about nine o'clock A.M. and three and ten P.M. The laboratory in which the meats were placed was well ventilated, and protected from flies and insects by wire screens. One pound of the viandine used was obtained from the office of Science, the rest by express from the Boston office of the company.

July 8, I took the mutton and liver out of the solution, allowed them to drain, and placed them on plates in the laboratory.

July 13, the plate in which the liver had been placed was nearly full of a red-colored liquid, and the liver had a hard leathery appearance. The liver and veal had both acquired a slight odor. The other meats and fish smelled sweet.

July 16, the odor of the liver and veal had become stronger than on July 13. The liver was placed on a clean plate, as the first plate was full of the red-colored liquid. The beef, mutton, and fish still looked and smelled fresh.

July 17, I had one-half of the beef-steak which had been treated with the viandine solution on July 5 cooked for breakfast. It was tender and palatable: still, it was not like a fresh steak. There was a slight taste of borax; and there was also a want of flavor, something like what fresh beef-steak might have if it were washed with cold water before cooking. Poured a little viandine solution over the veal and liver.

July 18, a roasting piece of sirloin beef, weighing five pounds, also a leg of mutton weighing four and one-half pounds, — being first punctured in a number of places, especially in the neighborhood of the bones, with an iron skewer, — were placed in two gallons of the viandine solution made up like the solution of July 5. The liquid was in a stone jar, and completely covered the meats.

July 20, the beef and mutton, which had remained in the viandine solution thirty-six hours, were removed, allowed to drain for two minutes, and placed on plates in the laboratory.

July 21, I was obliged to throw away the liver, the odor being very offensive. The veal had a disagreeable odor. A few mould-spots were removed, which had appeared on the steak. No odor, however, was perceptible. The mutton-chops and fish also smelled fresh. Placed steak and mutton in viandine solution for one half-hour.

July 24, it became necessary to throw away the veal. Beef-steak, mutton-chops, mackerel, roasting piece of beef, and leg of mutton appeared fresh.

July 25, the beef-steak and mutton-chops smelled slightly old.

July 26, I had the remaining half of the beef-steak which had been treated on July 5, and the mutton-chops which had been treated on July 7, cooked for dinner. No odor was noticeable; but they had a very high taste, so much so as to be unpalatable, save to a starving man. The roasting piece of beef and the leg of mutton smelled slightly. The mackerel appeared and smelled fresh.

July 27, the mackerel, which had remained in the laboratory since July 5, was cooked for breakfast. It was fresh and fairly good, like mackerel that are served at the average hotel table. There was no taste of borax. The roasting piece of beef was to be served for dinner. On cooking, a very offensive odor was given off. An examination showed a small piece near the bone that had become decayed. The rest of the beef appeared good; but pieces cut from different parts all had a strong odor of putrefaction. The mutton in the laboratory had a perceptible odor.

July 28, the mutton was cooked for dinner; but, when placed on the table, the odor was so strong that I could not remain in the room.

The results obtained from the above experiments seem to show, that pieces of meat having large surfaces in comparison to their thickness, as steaks and chops, and also small fish, can be kept a considerable length of time, although with some deterioration in taste, by the use of the viandine brand of Rex magnus. In the case of larger pieces, such as a roasting piece of beef, or leg of mutton, having tried only two experiments, I do not care at this time to speak positively. I can, however, state, that I should have some hesitation in again allowing to be cooked in the house large pieces of beef and mutton that had been kept in a warm room for ten days after treatment with the solution of viandine.

LEONARD P. KINNICUTT.

Worcester free institute, July 28, 1883.

THE IGLOO OF THE INNUIT.[1] — V.

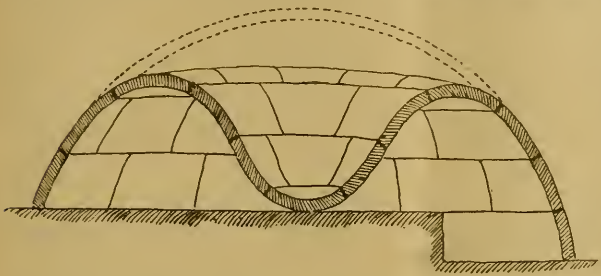
As the spring wears on, and thawing weather comes, the igloo falls into a decline; and when an exposed place can be found to pitch the seal-skin tent, it is abandoned. Before this can be found, however, the igloo assumes a new combination phase, which must be described. When several igloos have fallen in and buried their contents (the women, babies, and puppies managing to wriggle out, and a good share of the things being lost in the *débris* of snow-banks), the Innuit ceases to build any thing more than the walls of snow, using the prospective tent for a roof; this being the same as the autumn igloo, excepting the body, which is of snow, and not of ice. This phase of the igloo is so well shown in the illustration on the next page, taken from the German book of a member of my party, Mr. Klutschak, entitled '*Als Eskimo unter den Eskimos*,' that I transfer it to this article. His sketch of our spring igloos was taken on Cape Herschel, King William's Land, on the 16th of June, 1879, — the day before we abandoned them for the summer, and moved into tents.

The tenacity of some igloos, however, before they tumble in, is truly wonderful. They always give ample warning by slowly sinking on the top and side towards the sun or warm wind; and this the inhabitants counteract by thrusting a pole from the inside through the dome at its most threatening point, and there firmly lashing several small cross-pieces to prevent further sinking, which it will do if not too warm, or some small dog with bone in mouth, and pursued by a larger, does not take refuge on top, as is their wont, — when the snow-dome, dogs and all, come tumbling in on the heads of the hyperboreans. The foot of this pole rests on the floor, hardened by tramping, or a board is put under it to give it support. I have, however, seen a high-domed, abandoned

[1] Concluded from No. 31.

LIEUT. SCHWATKA'S PARTY, ENCAMPED IN SPRING IGLOOS, IN KING WILLIAM'S LAND, JUNE 16, 1879.

igloo, which had been well chinked and lightly banked (the whole mass nearly homogeneous from long use), slowly subside from the top until this touched the floor, and so remain without tumbling in, the igloo being actually inverted in its upper half or two-thirds. Here

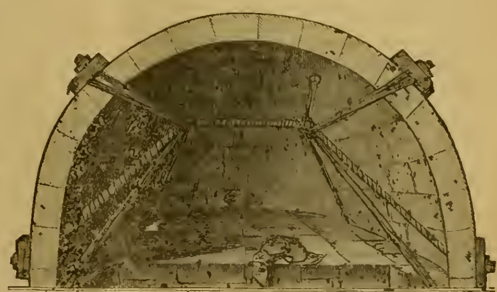


it would remain for a few days before warm weather would cause it to fall to pieces. I have tried to show a cross-section through such an igloo, the broken line showing its original position.

When food is readily procured without much effort, as in seasons of great plenty, the natives do not wholly abandon the necessary exercise to keep them in good muscle and bodily health, as is the general opinion respecting these people, but have been known to keep it up by various gymnastic devices, one of which (tight-ropes made of thongs of walrus-hide neatly and strongly lashed within an empty igloo) is well portrayed by Capt. Hall in the illustration.

I should like to give a few brief descriptions of those appurtenances that might be strictly called igloo accessories, as the native stone lamp and kettle, the well to fresh water through the thick ice, beside the snow-hut and many other minor items all growing out of the igloo itself; but this article has already grown to such dimensions that they must be laid aside.

The utility of the igloo cannot be exaggerated. Habituated as my little party of white men were, during our two winters in these desolate zones, to a constant life in these simple habitations, and the many comforts accruing therefrom, I have often marvelled how white men could stand the hardships and privations of a spring tent-life in the many expeditions wherein they were used, and under circumstances that would have been absolute pleasure to my party. I have read so often of their sufferings while journeying in tents, and the discomforts and even dangers they risked while living in ships and other unsuitable arctic abodes, during short journeys from these places, under such intensely low temperatures as −50°, −60°, or even −70° F., when under almost the same conditions my party was prosecuting a comfortable sledge-journey four hundred to five hundred miles from its base of supplies, with no provisions except such game as was killed from day to day, that the conviction becomes two-edged that the accessories of igloos, and their constant companion of the cold, the reindeer clothing, are absolutely essential to a well-managed arctic sledge-journey. With their help, strange as it may seem, the subject of temperature becomes entirely of secondary importance, if it enters the arctic travelling problem at all; and, were it not for the long dark night which accompanies these thermometrical depressions, I



INNUIT TIGHT-ROPES.

believe that a protracted sledge-journey could be carried successfully forward in the continuous cold of the lowest recorded temperature, all other things being favorable.

Frederick Schwatka,
Lieut. U. S. Army.

A UNIVERSAL LANGUAGE AND ITS VEHICLE,—A UNIVERSAL ALPHABET.

SHALL the world ever see an end of the confusion of tongues? Shall differences of language cease? Or shall, at least, some selected medium of thought be established throughout the world, by which all men may understand each other on occasion, while still preserving their vernaculars for intercourse at home? A consideration of the subject may enable us to answer these questions.

Language in all its varieties is a growth; and every living language is still growing, shedding leaves here, and pushing out new leaflets there, according to its vigor of vitality. The most copious language of to-day was smaller yesterday, and smaller still in every generation through which we can trace its history. We cannot go back to its beginning, for it properly had none: it did not spring from a seed, and so take the definite form of a parent language; but each tongue arose from the crossing and interlocking and blending of shoots from older languages, until they grew together, and became a new stem, from which, in turn, shot other branches, to repeat the process to the end of time.

In the comparative study of languages, and in what we know of human history, we can trace the evidences of this continuous cross-grafting of branch on branch in various directions; and the oldest tongues are those to which some peculiar form of growth can be traced back and back through the greatest number of stages.

If we could follow these oldest languages up to their respective sources, we should find at last a very small vocabulary of simple utterances used to denote an extremely limited number of ideas. But we should find no primitive natural germ of speech from which the first language had sprung into life and shape. The faculty of *expression*, and the instinct of *imitation*, are the only primitive parts of language; but these, at first, were, like primitive creation, 'without form, and void,' until consenting minds agreed on some few associations of sound and sense, and so commenced a form of language.

Any number of different forms may have been thus commenced by isolated families or groups of men. Individual members of different families or groups would occasionally come together, and each would enlarge the other's vocabulary, or modify his methods of expression. Thus one may have previously used only a dual number to indicate plurality; another, only an indefinite plural: but mutual intercourse would incorporate, in the common language that would be developed, both of these methods of expressing and defining the idea of plurality. Primitive languages may thus have acquired from each other the many words and forms of speech which they possessed in common; while their independent characteristics would increase in the absence of association.

On the same principle, a closer intercourse between modern nations must have an amalgamating effect on their languages, and so tend to produce an ultimate unification of human speech. This closer intercourse is being accomplished in our days by railroads and steamships; and strange ears in all quarters of the world are being familiarized with the languages of visitors and immigrants. The interests of commerce, and the influence of example and of social feeling, lead to a more and more general acquisition of the languages thus introduced; so that, without displacing local forms of speech, other media of wider intercommunication are being gradually extended everywhere. A universal language *is thus growing up*. Whether it will ultimately take the lines of English, French, German, or some other tongue, will depend on the relative fitness of the competing languages for universality. At all events, the fittest will survive, and the survivor will gradually occupy the whole field.

The present diffusion of English over the continents of America and Australia, and among sailors of all nations; its growing acceptance throughout the continental countries of Europe; its establishment in many nuclei in Asia and Africa, and over the vast empire of India, as well as the grammatical simplicity of the language, and its power of incorporation of foreign elements, — all point to English as the probable universal tongue of the future.

The only alternative to such adoption of the fittest among existing languages would be the creation of a new form of scientific speech; but this would require a universal consent among nations, and a combined effort, that may fairly be considered impossible as preliminaries to the institution of such a language. The creation of a new form of speech adapted for universal use is certainly within the power of science and invention to accomplish; but the aid of a pre-existing language, all but universal, would be required for its introduction and establishment. In the far future, such a form of scientific speech may find the world prepared for it, and the medium for its diffusion in sufficiently general use: but, in the mean time, the confusion of tongues is being gradually reduced by the struggle for supremacy among established languages; and this process will go on until one tongue shall be intelligible, if not predominant, everywhere.

All languages have their physical material in common: they use the same vocal organs, and essentially the same elementary sounds. The voice is susceptible only of a limited number of modifications, and the lips and the tongue only of a limited number of articulative actions; and, from the combinations of these, all the varieties of human utterance result. This elementary simplicity and uniformity are not, however, reflected in the writing of languages. Alphabets are wholly arbitrary; and, although the same letters are used in many alphabets, a different value is, in nearly every case, associated with the individual letters. A universally intelligible method of representing the sounds of speech is a necessary prerequisite for a universal language. Ordinary alphabetic writing is, indeed, as much a hindrance to combined effort for the unification of language as was the confusion of tongues to the building of the tower of Babel. Some method of classifying and representing all known modifications of voice and articulation, if not of discovering all possible modifications, had long been the great desideratum of philologists. Attempts were made to frame a universal alphabet by collating the elements from local alphabets, ancient and modern; but the number of shades of difference discovered among the elementary sounds, and the difficulty of recognizing sounds under varied associations, rendered any complete classification impracticable. So far as the discovery of the entire category of possible sounds was concerned, the object of endeavor was considered to be hopeless; and the attempt to realize it was finally and formally abandoned at a convention of philologists of different countries, held at London in 1854. The declaration of this convention stands on record, that —

"It would be useless and impossible to attempt to find for each possible variety of sound a different graphic sign."

This 'impossibility' has, however, been since accomplished with completeness and simplicity, in the system entitled 'Visible speech,' the principles of which will now be explained. In this system no sound is arbitrarily represented, but each letter is *built up* of symbols which denote the organic positions and actions that produce the sound. The letters are thus physiological pictures, which interpret themselves to those who have learned the meaning of the elementary symbols of which they are composed.

The first letter of our ordinary alphabet, which we call $\bar{a}$, is known in other countries as *ah;* but we discover, in using the letter, that it represents both *a* and *ah*, and a variety of other sounds in our own language, the letter *a* being employed for the six diverse vowels in the words *ale*, *air*, *an*, *agree*, *ah*, and *all*. In Visible speech each of these sounds has a separate letter, and each letter explains to the eye the organic means by which its sound differs from other sounds. For example:

The letter for the vowel in the word *ale* tells the reader to —

Advance the front of the tongue towards the front of the palate, so as to leave a channel of medium breadth for the passage of the voice.

The letter for the vowel in *air* tells him to —

Place the tongue in the same position as before, but to expand the back cavity of the mouth.

The letter for the vowel in *an* tells him to —

Broaden to the utmost degree the channel between the front of the tongue and the palate, and at the same time expand the back cavity of the mouth.

The letter for the sound of *a* in *agree* tells the reader to —

Place the tongue in a neutral position, — neither advanced nor retracted, raised nor depressed, — *and expand the back cavity of the mouth.*

The letter for the sound *ah* tells him to —

Depress the tongue backward as far as possible, and expand the back cavity as before.

The letter for the vowel in *all* tells him to —

Place the tongue in the same position as for AH, *but compress the back cavity, and round the corners of the lips.*

All these directions are perfectly conveyed at a glance in the different letters; and yet the letters, so far from being complex, consist of forms more simple than the letters of the Roman alphabet. Here, for example, are the symbols, — four in number, — from the combinations of which, not merely the sounds above illustrated, but every vowel in every language, can be expressed to the eye, so as to be at once pronounced with exactitude by the reader.

ELEMENTARY SYMBOLS OF VOWELS.

These symbols have the following invariable meanings: —

1. The straight line means *voice*.
2. The bar across the line means contraction or rounding of the *lips*.
3. The solid point means *compression* of the back cavity of the mouth.
4. The open hook means *expansion* of the back cavity of the mouth.

The position of the point or hook on the straight line denotes the position of the tongue in reference to the palate. Thus: —

a. When on the right side, the meaning is, that the tongue is advanced towards the *front* of the palate.

b. When on the left side, that the tongue is retracted towards the *back* of the mouth.

c. When on both sides, that the tongue occupies a *middle* position between front and back.

d. When at the top of the line, that the tongue is *raised* towards the palate.

e. When at the bottom, that the tongue is *depressed*.

f. When at both ends, that the tongue occupies a *middle* position between high and low.

Nothing could be simpler than these elements, the meanings of which are remembered by every person after a single explanation; yet from these four elements alone the entire series of normal vowels, thirty-six in number, are built up. Two diacritic signs extend the possible number of shades of vowel-sound, which these four elements can be made to represent, to the largely superfluous total of one hundred and eighty.

The English alphabet contains only five vowel-letters, while our speech makes use of at least sixteen vowel-sounds, without including diphthongs. No wonder, therefore, that the relation between letters and sounds is one of irreconcilable confusion. A purely phonetic alphabet, in addition to the common system of letters, is a necessity for the intelligible writing of English alone; much more is it indispensable for the writing of all languages intelligibly to all readers.

The system of Visible speech is the ready vehicle for a universal language, when that shall be evolved; but it is also immediately serviceable for the conveyance of the diverse utterances of every existing language. No matter what foreign words may be written in this universal character, they will be pronounced by readers in any country with absolute uniformity. The means have been explained by which *vowels* are represented for this purpose. The principles are now to be shown on which *consonants* are written with the same effect.

Elementary symbols of consonants.

Five elementary symbols furnish letters for all the consonant actions of the lips and tongue. These symbols are —

C ɛ | ʃ ⁏

As with vowels, so with consonants: all the elements of each class have one symbol in common. The vowel-symbol was shown to be a straight line: the consonant-symbol is a *curve;* and the direction in which the curve is turned denotes the part of the mouth by which the consonant is formed. Thus: —

a. The curve turned to the right denotes the *lips*.

b. The curve turned to the left denotes the *back* of the tongue.

c. The curve turned archwise, with its end down, denotes the *top* of the tongue.

d. The curve turned with its end up denotes the *point* of the tongue.

The five radical symbols have the following meanings in every combination: —

1. The first (C) is the sign of a part of the mouth used to form a *consonant*.
2. The second (ɛ) is the sign of a part of the mouth which *divides* the breath.
3. The third (|) is drawn across the ends of a curve to denote a consonant that *stops* the breath.
4. The fourth (ʃ) is the sign of emission of breath through the *nose*.
5. The fifth (⁏) is added to the ends of a curve to denote simultaneous modification by *two* parts of the mouth.

These elements, combined into *six* forms of letters, suffice for the whole series of consonant actions of the lips and tongue. The six forms turned in the four directions, as above, yield twenty-four letters; and the uniform addition of one sign for *voice* — a straight line in the centre of the curves — converts the twenty-four into forty-eight letters.

Every part of every letter has thus a meaning legible at a glance; and the most complex letter in the alphabet — combining four of the elementary symbols to exhibit the sound of *m* — is as simple in form as the common Roman letter for the same consonant. Thus: —

Ɛ M, m.

The following are the four symbols combined in this letter: —

1. A curve to the right, which denotes the *lips*.
2. A centre straight line, which denotes *voice*.

3. A waving line, which denotes *nasal* emission.

4. A line closing the curve, which denotes *stoppage* of the breath.

The letter thus says to the reader: —

Stop the breath by means of the lips, and sound the voice through the nose.

It must be obvious that such directions, conveyed without words, will be uniformly interpreted by readers of any nationality who have simply learned the meaning of the radical symbols. All the Visible-speech letters are formed in this way, by synthesis of two or more out of a total number of nine elements. Such letters, consequently, make up an alphabet adapted for universality, because independent of explanatory language; also because its symbols are physiological pictures, and because the writing, even of unheard foreign tongues, is self-explanatory to the reader's eye.

Visible speech was first published sixteen years ago (August, 1867); and it has been very generally studied by philologists, and adopted in theoretical works as a necessary exponent of linguistic phonetics. It has also been widely utilized in America for the teaching of articulation to the deaf. But its popular uses for the teaching of vernacular languages to children and illiterates, and of foreign languages in schools and colleges, as well as for the literation of hitherto unwritten Indian and other tongues, have not yet been correspondingly developed. People generally do not take the trouble to investigate the nature of the characters, but suffer themselves to be repelled by fancied difficulty, — as if what is strange must needs be difficult. But the difficulty is only to eyes unacquainted with the principles of the symbolization. When these are known, there is no comparison, in point of simplicity, between Roman letters and Visible-speech letters. To children and illiterates, all letters are equally strange. To one who can already read, the eye is simply prejudiced in favor of established letters. In the present exposition the *letters* of Visible speech have not been made the basis of illustration, but only the rudimentary symbols from which all the letters are derived. This mode of treatment will, it is hoped, leave no room for prejudice to act.

In this stage of the world's history we do not need to concern ourselves about a universal language: that will develop itself in due time. But a universal medium for the communication of languages is a practical necessity, which every day renders of more and higher importance. Without a universal alphabet there never could be a universal language; with a universal alphabet the progress of the fittest language towards universality will be enormously accelerated. At present, English seems the most likely to achieve this distinction; but its natural fitness is antagonized by its defective and irregular system of letters. Give English the advantage of an alphabet simple and phonetically perfect, and, whereas it is now the most difficult of all tongues for foreigners to learn, it will become by far the easiest.

In the system of Visible speech a universal alphabet is for the first time attained: the system is of English birth. Let its native language have the benefit of this instrument of diffusion, and the world-wide predominance of the speech of Britain and America will be assured. A. MELVILLE BELL.

LETTERS TO THE EDITOR.

Variations in butterflies.

BETWEEN the 20th of June and the 10th of July, I obtained three hundred and eighty Vanessa Antiopa from caterpillars fed on swamp willow. Twenty-five of these were varieties, and the balance were of the usual form. Two of the varieties were Lintneri, from which all the blue had disappeared. The third had the primaries Lintneri, while the secondaries had the usual blue spots. The fourth had the secondaries Lintneri, while the primaries bore the blue spots. In the remaining twenty-one, the whole upper surface of the wings had a mottled appearance, showing that the colors had been disturbed. They retained the blue spots, but the spots were much smaller than usual.

The veins in the twenty-five varieties remained soft for several days; not becoming firm and hard, like the veins in the others, although treated in the same manner. I have also found this softness of the veins in the varieties of Turnus, where the red is suffused, and in the rust-colored specimens.

All the Vanessa Antiopa which I have seen this season have the yellow of a much deeper shade than I have ever before noticed.

Colias Philodice is also remarkable this season in this respect. S. LOWELL ELLIOT.

New York City, 3d August, 1883.

Function of the colorless blood-corpuscles.

The interesting abstract of Zawarykin's important investigations into the function of the leucocytes in the absorption of fats from the intestinal canal (SCIENCE, ii. 192) calls to mind an investigation by Franz Hofmeister, into the absorption and assimilation of the peptones, which will be of interest in connection with the abstract referred to.

In a series of papers published in 1881, Hofmeister[1] comes to the interesting conclusion, that "absorption of peptones in the intestinal canal is, accordingly, no simple mechanical process of diffusion or filtration, but is rather a function of particular living cells, the colorless blood-corpuscles; and these play, in the nutrition of the organism, a similar rôle to that of the red corpuscles in respiration."

In his discussion he calls attention to the presence

[1] Zeitschr. phys. chem., v. 151,

of the leucocytes, in great numbers, in the adenoid tissue during digestion; and, also, to certain proofs of the ability of the leucocytes to combine with peptones in a loose form of combination.

The similarity of these two functions of the colorless corpuscles, as determined by Hofmeister for peptones, and by Zawarykin for fats, cannot fail to suggest the probability of a very definite and important function of these corpuscles in general nutrition. Possibly, also, the anomalies observed in the absorption of saccharine food, and in the glycogenic functions of liver and muscles, may in time receive some explanation through the functions of the colorless corpuscles.

It seems as if we were, at last, beginning to obtain an idea of the functions performed by these important cells, whose close connection with the life of the organization has been generally recognized, though but vaguely understood. J. M. S.

HUMAN PROPORTION.

Human proportion in art and anthropometry: a lecture delivered at the National museum, Washington, D.C. By ROBERT FLETCHER, M. R. C. S. E. Cambridge, *King*, 1883. 37 p. illustr. 8°.

FROM the earliest ages, man has found his standards of measurement most conveniently in some bodily measure, like the digit, the palm, the span, the foot, or the cubit. As these measures necessarily vary with the size of the individual, the attempt to ascertain their average led to the first systematic measurements of the human body: hence have sprung the innumerable schemes of human proportion devised by artists and anatomists, all founded on the belief that some one part of the body was a standard of measurement for all its other dimensions. The Egyptians first developed a canon of proportion as early as the thirty-fifth century B.C., which was twice subsequently changed. Their last canon adopted the length of the middle finger as the standard, reckoning it precisely one-nineteenth of the entire stature. But in the 'canon of Polykleitos,' the famous sculptor who flourished about 450 B.C., was embodied the highest rule of Greek art in its most flourishing period. This has fortunately been preserved in a well-known passage of Vitruvius, and is illustrated by a recently discovered drawing by Lionardo da Vinci. The restless spirit of modern life has not remained content with this, as more than a hundred different attempts bear witness by men of all nations, including the celebrated English sculptor Gibson and our own Story. All these methods have been based upon the theory that there is a fixed relation between some one portion of the body and all its other dimensions; and their number proves the fallacy of the idea. Anthropometry, on the other hand, measures with the strictest scientific accuracy the living man, and from an immense mass of measurements obtains the mean of the human form, and thus arrives at the perfect human type. The father of this science is the Belgian Quetelet, and the enormous number of measurements rendered necessary by the draft during our civil war have greatly advanced it. By its tests many a time-honored dogma bearing upon human proportion has been exploded. Thus it has been proved that the length of the outstretched arms is somewhat greater than, and not exactly equal to, the height of the body; that not eight, but seven and a half heads make up the entire stature; and that only in the negro skeleton can be found the length of humerus bestowed upon the Apollo Belvedere.

All these matters the author has illustrated with great learning and in a clear and animated style. We have noticed, however, that his knowledge of archeology is sometimes at fault, — as where he calls the '*crux ansata*' in the hand of the Egyptian standard figure 'a key,' which is really a cross with a loop or handle attached to it, and is the symbol of eternity; or suggests that the 'golden fleece' was in reality 'the secret of Egyptian art;' or states that the Doryphoros of Polykleitos was 'a beautiful youth in the act of throwing a spear,' instead of its being one of the 'spear-bearers,' the body-guard of the Persian king. The most marvellous statement, however, is, that "prior to the time of Phidias, the face, hands, feet, or other exposed parts of the body were carved in marble, and fastened to a wooden block, which was covered with real drapery." This is a complete misunderstanding of the nature of the archaic ξόανα, or wooden statues, which in Greece preceded those made of stone or metal.

WARE'S MODERN PERSPECTIVE.

Modern perspective: a treatise upon the principles and practice of plane and cylindrical perspective. By WILLIAM R. WARE, Professor of architecture in the School of mines, Columbia college. Boston, *James R. Osgood & Co.*, 1883. 321 p. 12°.

PROFESSOR WARE's Modern perspective is in substance a series of papers printed two or three years ago in the *American architect*, but with additions which extend its range, and give it more the scope of a scientific treatise. Scientific it is, both in its idea and its methods; though its treatment is naturally freer than would be given it for scientific uses alone, — freer, perhaps, than the author would have given if it had originally been written as a formal treatise. The purely geometrical method comes out most clearly in the chapters added in the revision, particularly in two (xvii., xviii.), in which, after going over the ground of practical perspective, Professor Ware sums up, first the principles and relations, and then the chief problems, in the most abstract and generalized form. This portion is, therefore, scientifically the essence of the book, and is that which a reader versed in pure mathematics, but unacquainted with perspective, might properly read first. Such a reader would find pleasure in its neatness and comprehensiveness of statement, and in the skilful way in which the whole subject is cast in condensed and logical form; every phenomenon or process being first presented in its most general aspect, — against the usual habit of books on perspective, — and particular cases deduced from it afterwards. These chapters make a sort of inner treatise, whose appeal will be to the geometer and the special student. They are probably too abstract and too concise to be acceptable to the ordinary student, and he may be left to skip them.

The methods of the book are naturally those of descriptive geometry. We could wish Professor Ware had held to the received terminology when he names the perspective of the vanishing-line of a plane its 'trace,' and diverts the word from its received sense as the intersection of the plane with the plane of projection. What in descriptive geometry is called the trace, Mr. Ware calls the 'initial line' of the plane: the point where a line pierces the picture-plane, which might by proper analogy be called the *trace* of the line, he calls its 'initial point.' The use of 'horizon' for the actual vanishing-line of any system of planes is happier. The subscript notation employed is the author's own, and is cleverly contrived to suit the manner of his exposition. It contains in itself a symmetrical record of the principal data and relations, and its neatness and efficiency make one the more regret that the author has not cared to follow an accepted terminology where there is one.

The phenomena of planes in perspective are first discussed, according to the author's uniformly analytical method: first oblique planes, then parallel and normal. So much of the perspective phenomena of lines is accounted for by treating them as intersections of planes, that their separate consideration is much shortened by anticipation; and by the time the point is reached, its discussion is reduced to a minimum. In like manner, instead of confining the discussion of points of distance, as is common, to points in the horizon-line, or the prime vertical, the most general case is first considered, and the circular locus of all the points of distance of a given line is determined. We miss the categorical statement, — implied, to be sure, but worth making distinctly, — that the points of distance are the same for all parallel lines; as in another place it is apparently taken to go without saying, that the vanishing-point of a line, or the vanishing-line of a plane, is enough to determine problems relating to its direction, even when its position is unknown. The chapter of abstract problems presents pretty much all the problems of descriptive geometry, so far as concerns planes and right lines, applied in perspective, and therefore covers, except for a few special cases, all the elements of perspective practice. Here, again, generalization and condensation are carried very far: some, indeed, of the problems in which many alternatives are grouped together are perhaps too succinct and comprehensive to be satisfying to the student.

The same method and quality are found in the other chapters of the book, so far as suits with its practical purpose. Thus parallel perspective, usually taken first, is postponed, and treated as a special case. There is throughout a watchful eye to the needs of the architectural draughtsman and the painter. The work is made interesting by observation of natural and pictorial phenomena, many of which are, so far as we know, new to the books. Some special topics which are taken up in the advanced treatises are here hardly mentioned, — the perspective of curved surfaces and of solids of revolution, for instance; even vaulting being left untouched, and the problems not going beyond plane figures and solids with plane faces. But within its limits, the discussion is very complete; and some subjects are enlarged upon which it is usual to dismiss with slight mention, — the perspective of reflections, and of shadows by both parallel and divergent light, and especially the chapters on the perspective of the circle, and on perspective distortions and corrections. The method of the perspective plan is made much of, as it deserves; and some space is given to M. Adhémar's ingenious devices for avoiding remote vanishing-points, and carrying on all the operations on a small sheet by means of what Mr. Ware calls 'small-scale data,' — points of fractional distance, scales of depth, marginal co-ordinates, and the like, — a method which is much less known than it deserves to be. Mr. Ware adds an ingenious alternative for M. Adhémar's device of enlarging the remote parts of the perspective plan by planes of successively steeper inclination.

The plates which accompany the book are as thoughtfully and ingeniously composed as the text. We commend the whole treatise as the most complete, so far as we know, and the most interesting and instructive for practical use, that has been published in this country.

SEEBOHM'S VILLAGE COMMUNITY.

The English village community, examined in its relations to the manorial and tribal systems, and to the common or open field system of husbandry: an essay in economic history. By Frederic Seebohm. London, *Longmans, Green, & Co.*, 1883. 464 p., 13 maps and plates. 8°.

It is now many years since G. L. von Maurer wrote his Introduction to the history of marks and manors. Since then the subject has attracted many students, and has been much looked into and talked about. Many books have been written upon it; those of Nasse, de Laveleye, and Maine being the best known to American readers. The impression conveyed by these writings is, that the mark or village community, though almost always found upon a manor, under manorial overlordship, was in its origin independent. Manorial overlordship arose, we are told, in later times. The village community was drawn under it, and became subject to it. It has been the work of modern times to restore it to its ancient independence. This is the theory of von Maurer and his followers, which we have gathered from their books. Objections to this theory are from time to time raised. It is urged that the village community is usually found under manorial landlordship; that it is, therefore, an open question whether the village community, or the landlordship over it, is the earlier institution. In Mr. Seebohm's book, which now lies before us, it is maintained that landlordship is more ancient than the village community, that the village community arose under landlordship, as a community of slaves or serfs, that it has been slowly emancipated from slavery and from serfdom in the course of centuries. Our economic history, we are told, begins with the serfdom of the masses under manorial landlordship. Looking through the records, back to the earliest period, we find no free village communities, only manors with village communities in villenage upon them. The argument upon this point is almost conclusive. The existence of a manorial system during the Saxon period of our history is established beyond doubt.

But there were parts of Britain which were not manorial, where village communities (the village community being considered a part of the manor) did not exist. What was there in the parts of Britain where there were no manors? By the side of the manorial system was a tribal system more ancient, perhaps, than the manorial system. Then follows an account of the tribal system of the Welsh and Irish, which is extremely interesting. It is not clear at first, why, in a work upon English economic history, so much space should be given to the institutions of the Welsh and Irish; but we find out directly: it is that we may the more clearly understand the statements of Caesar and Tacitus regarding the Germans. It is well known that the statements of Caesar and Tacitus are very vague; that they become intelligible only in the light of extraneous evidence. We ourselves should not have presumed to draw this evidence from the Welsh laws, nor from the Brehon tracts. It has always seemed to us best to keep the records of different peoples quite distinct. We should, therefore, have turned from Caesar and Tacitus to the German folk-laws, formulae, and documents. The tribal system of the Germans is very well described in the German records. It happens, however, that the tribal system of the Germans resembles very closely that of the Welsh and Irish: so, though we do not follow all the steps of Mr. Seebohm's argument, we come, at last, to very nearly the same conclusion. What we have in the time of Caesar and Tacitus, and afterwards in many places where the manorial system has not been developed, are tribal households (to use Mr. Seebohm's phrase), — isolated farmsteads, occupied by groups of descendants and heirs; the land being held by them as an undivided inheritance for two or three generations, and then divided, several households arising where there was but one before. Mr. Seebohm finds a vestige of this system in the custom of Gavelkind in Kent, where we have divisions among male heirs, with traces of the right of the youngest to the original homestead. Almost everywhere else in England the tribal system has quite passed away.

Already, however, in the time of Tacitus, the manorial system was germinating. The free tribesmen who lived in the tribal households here and there — *ut fons ut campus ut nemus placuit* — had slaves who cultivated the land for them. These slaves were distributed by the tribesmen in village communities, in regard to which they were very much in the position of the later manorial lords. It was only a step, indeed, from this condition of things to the manorial system. This step was taken immediately after the permanent settlement of the Germans within the limits of the Roman empire. The land system of the later empire was very much like a manorial system. So it happened, that, while the Germans were approaching this system on the one hand, the Romans were approaching it on the other. They reached it together.

This is the briefest possible *résumé* of Mr. Seebohm's extremely interesting and valuable book. The argument is well arranged and very convincing. It is, perhaps, a little too much encumbered by details; but we should be sorry not to have these details, and the book is quite readable in spite of them. The account of the manorial system is the most complete that we have. The book is a mine of information upon the subject. It will be found indispensable to students. It is very well printed, and illustrated by plates and maps. It would be worth having for these alone. In conclusion, we must heartily congratulate the writer upon the completion of so excellent and useful a work.

STEARNS AND COUES' NEW-ENGLAND BIRD-LIFE.

New-England bird-life; being a manual of New-England ornithology. Revised and edited from the manuscript of Winfrid A. Stearns, by Dr. Elliott Coues. Boston, *Lee & Shepard*, 1881, 1883. 324+409 p. Illustr. 8°.

UNDER this title Mr. Winfrid A. Stearns and Dr. Elliott Coues have just produced an excellent and much-needed work. Previous to its appearance we have had no complete or satisfactory exposition of the subject, despite several attempts on the part of inexperienced or otherwise incompetent authors to cover the interesting field: hence the present book is doubly welcome.

It has appeared in two volumes, or parts. Part i., issued two years ago, begins with Turdidae, or thrushes, and carries the subject through Oscines, ending with the family Corvidae. In addition to the 270 pages occupied by its main portion, there is an 'Introduction' of fifty pages, which includes useful chapters on the classification and structure of birds; the 'Preparation of specimens for study;' the 'Subject of faunal areas;' and the 'Literature of New-England ornithology.' Including those devoted to its special index as well as to the introduction, part i. contains 324 pages.

Part ii. was published early in the present year. It has in all 409 pages, of which ten are occupied by an 'editor's preface,' and eight by the index; the remaining 397 pages treating the general subject from Tyrannidae through the successive families to Alcidae, last and lowest in the scale of New-England bird-life. Both volumes are rather copiously illustrated with fairly good woodcuts; some of which are full-length figures, others representations of the heads, feet, wings, etc., of birds, designed to show technical or distinguishing characters. Most of these cuts have done similar duty before, but on this account they are none the less useful in the present connection.

The plan of the book is so clearly and tersely outlined in the preface to part i., that we cannot do better than give it in the editor's own words: —

"It is the object of the present volume to go carefully over the whole ground, and to present, in concise and convenient form, an epitome of the bird-life of New England. The claims of each species to be considered a member of the New-England fauna are critically examined, and not one is admitted upon insufficient evidence of its occurrence within this area; the design being to give a thoroughly reliable list of the birds, with an account of the leading facts in the life-history of each species. The plan of the work includes brief descriptions of the birds themselves, enabling one to identify any specimen he may have in hand; the local distribution, migration, and relative abundance of every species; together with as much general information respecting their habits as can conveniently be brought within the compass of a hand-book of New-England ornithology."

This plan is consistently and faithfully carried out. The descriptions of the birds, to be sure, are a little meagre and unsatisfactory at times; but it must be remembered that they are intended primarily for a class of amateurs who are not fitted, either by experience or inclination, to wade through more exact, technical diagnoses.

The biographical matter is written in the editor's well-known and eminently characteristic style, — a style not wholly free from faults perhaps, but, in the main, so finished and picturesque that it is sure to attract and interest every lover of birds. In the present instance, the only fault we have to find with these biographies is that they are often too brief and general, — in short, that there is too much condensation. Especially is this the case among water-birds, where the account of habits, distribution, etc., is frequently crowded into a few lines. Doubtless this was necessary to keep the work within its assigned limits, but it is none the less a disappointment.

One of the most valuable features of the book — to the scientific ornithologist, at least — is the bringing together of previous records pertaining to the rarer birds. In almost all cases these have been exhaustively collated, a work chiefly, if not wholly, performed by Mr. Purdie, whose well-known fitness for the task is a practical guaranty of its thorough accomplishment.

The weakest spot in the structure is that of the editor's rulings on questions affecting the comparative abundance and seasonal distribution of the less-known birds. In many — far too many — cases, his conclusions are more or less unwarranted or premature; in not a few, they are positively and demonstrably erroneous. This was to be expected, however, in view of the fact that neither editor nor author is known to have had an extensive experience in New-England fields or woodlands; and, considering such limitations, it is chiefly remarkable that they have done so well.

But, despite its shortcomings, 'New-England bird-life,' as a whole, may be honestly characterized as a work of real merit and unquestioned utility. Its faults are seldom vital, its excellences many and obvious. Although a manual, rather than a comprehensive general treatise, it cannot fail to take a high and permanent place among the literature of North-American ornithology. To the student of New-England birds, it is sure to prove a valuable hand-book, adequate for the determination of most problems which the limited field is likely to furnish. There is still room, of course, for the more extensive structures which some future builders will doubtless rear on this substantial corner-stone.

Before concluding, we find it necessary to revert to a rather delicate subject, — that of the ostensible authorship of the book. In the preface to part i., the editor touches on this, as follows: —

"Mr. Stearns undertook this work several years ago, at the writer's suggestion, that such a treatise was much to be desired, and could not fail to subserve a useful purpose. Having been diligently revised from time to time, in the light of our steadily increasing knowledge, Mr. Stearns's manuscripts have been submitted to the editor's final corrections. In revising, and to some extent rewriting, them for publication, the editor has been influenced by the author's request that he would alter and amend at his own discretion."

Perhaps we are bound to accept this explanation literally; but the reader familiar with Dr. Coues's characteristic style and methods will find few traces of Mr. Stearns's alleged participation. Clearly the 'revising' was very thoroughly done. We might go even farther, and venture the surmise that Dr. Coues not only edited, but *wrote*, the entire book. But is this a matter with which we have any business to meddle? Probably not so far as Dr. Coues's interests are at stake. If he chooses to do all the work, and take less than half the credit, it is his own affair. Nevertheless, it certainly *is* our right to challenge a reputation unfairly won, and until further proofs are forthcoming we shall refuse to believe that Mr. Stearns's agency in 'New-England bird-life' has been much more than nominal. Perhaps the inside history of the book will never be made public, but intelligent ornithologists are likely to see through a millstone with a hole in the middle.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

PROCEEDINGS OF SECTION H. — ANTHROPOLOGY.

ADDRESS OF OTIS T. MASON OF WASHINGTON, D.C., VICE-PRESIDENT OF THE SECTION, AUG. 15, 1883.

THE SCOPE AND VALUE OF ANTHROPOLOGICAL STUDIES.

EVERY thing that comes before the human mind has to pass through a process of weighing and measuring, and receives a valuation according to the thinker's standards of merit. In this critical spirit let us pass in review those studies called anthropological, in order to form some estimate of their value according to the measures commonly applied to various departments of learning.

Anthropology is the application of the instrumentalities and methods of natural history to the inductive study of man. The anthropologist, in this sense, is not a dilettante philosopher, who inquires into old things because they are old, or into curious things while they are curious, omitting all the great movements and needs of society, and overloading the baggage-train of progress with trumpery picked up along the march. The practical spirit of our age demands that we ask what truth, or good, or beauty comes from such investigations, and how we can make them subservient to human weal.

As to the scope of anthropology, we may be instructed by the work of others. The natural history of any species, say of the domestic horse, includes many inquiries, such as the time and place of its origin; its ancestry; its pristine size, appearance, and mode of living. We should afterwards inquire concerning the archeology or the paleontology of the Equidae, their embryology, anatomy, physiology, diseases, abnormalities, and external characteristics. Mr. Romanes would have a chapter on the intelligence of the animal, as to its nature and amount, supplementing the discussion with notes on the various ways in which the horse manifests its mind, its wills, emotions, and opinions. Horses do not construct elaborate houses like the ants and the beavers; but the members of all species occupy their daily lives in some habitual industries by means of which they wear out the excess of muscle. Sir John Lubbock would lead us farther, and show us that horses go in droves, follow a leader, plan migrations, attacks, and defence, amuse themselves, enjoy one another's company, improve in appearance, intelligence, and usefulness by cultivation, — in a thousand ways show themselves to be social creatures. At last Mr. Mivart would insist that the horse has its habitude (ἕξις), its manner of action, its economy (oecology), and its members are affected in a characteristic manner by heat, light, moisture, winds, the kind and quality and abundance of food and drink, by beneficial or injurious animal neighbors, and by the vital, procreative, inheritable energy with which they are endowed. These and many other kindred inquiries concerning this homogeneous group would constitute the science of hippology.

The conscientious devotee to this science would frequently ask himself what practical good would result from all this expenditure of time, thought, and resources necessary to collect specimens and facts, and to formulate his science. Could they be employed on some subject more ennobling and profitable to himself, better calculated to inform, enrich, and beatify mankind?

Now, instead of horses, let us substitute the *genus homo*, laying aside all predilections; and, if possible, let us imagine the student of anthropology to belong to quite another genus than the subject of his research. He would have, in the fourteen hundred millions of human beings now living on the earth, and the remains of their congeners slumbering in its bosom, perhaps the best defined group of animals. Calling them a genus or a species, as you like, they are so well hedged off from all other animal groups that not the least embarrassment has ever disturbed the naturalist in distinguishing the anthropos even from the anthropoid. No one was ever puzzled to tell, concerning any living thing, whether or not it was a human being. The earth has never yielded a bone concerning which the practical anatomist stood in doubt whether it had been once part of a human body.

Now, I take it for granted that any inquiry whatever which would be useful or entertaining respecting another species would be intensified in importance having man for its object. Indeed, there are few questions which naturalists are wont to propose to their groups which ought not to be carefully considered when we are studying man. Before entering upon the weighing process, therefore, it may make our task more easy if we consider the present scope of anthropology, and briefly pass in review some of the questions which are being propounded by anthropologists every day.

When did man first appear on earth, — at what time and in what geological horizon?

Have all the individuals of our race descended from a common human ancestry? in other words, are we monogenists, or polygenists?

Where was the birthplace of humanity?

What manner of creature was that first man in specific characteristics, in size, aspect, intelligence, and social condition? and how did he get here?

To all such queries, Haeckel aptly gives the name of anthropogeny: therefore, in order to be anthropologists we must be anthropogenists.

Another set of questions relates to that stretch of time which lies between the pristine man, or the pristine condition, and the beginnings of recorded history.

Have we complete, irrefragable evidence that our race has progressed from a brute-like condition, in which it was devoid of all experience and appliances?

What application must we make of Professor Tylor's belief that civilization has progressed upward like a column of vapor, some parts advancing while other parts are being rolled downward, but, on the whole, ascending and expanding?

Granting that there has been improvement, what paths have been pursued?

Speaking of our own peculiar province, what is the real import of such discoveries as those of Dr. Abbott and Professor Whitney in establishing the great antiquity and early rudeness of the American savage?

Who were the builders of the mounds, earthworks, cliff-dwellings, and the stone structures of Middle America?

What were the functions of these various edifices?

What credence is to be given to the early historians of American culture?

Already we have our schools of interpretation, such as the Bancroft school and the Morgan school. Where, among these opposing schemes, does the truth lie?

In the administration of this science, there is occupation for the greatest diversity of talent. The biologists of our time are entering into the minutest inspection of the life-history of each animal form. With enthusiasm the embryologists trace the modifications of structure as they succeed one another in the germ. Before their eyes the very play of creation is dimly shadowed, and organic structure built up. They pass their work on to the anatomists and physiologists. Now, the anthropologist must endeavor to comprehend the whole in its synthesis. As Newton and Laplace grasped the unity and organization of the stellar world, as Humboldt gazed upon all created things as elements of the universal cosmos, as Darwin first conceived the consanguinity of all living beings and their mutual help or harm, so the anthropologist seeks to unite all that can be known respecting man into a comprehensive science, and to study the innumerable correlations which bind the most incongruous actions and thoughts together in harmony.

May we gain help, in solving questions of human origin, by carefully observing the evolution of the embryo?

Does a knowledge of the life history of the individual furnish a clew to the life history of the species?

What does a comparison of the anatomy of man with that of the quadrumana say respecting the genealogy of the species?

What are the proper methods and instruments of anthropometry, — observing the growth of children, the dimensions, angles, and curves of the cranium, the diversity and size of the brain according to age and sex and race, the weight of the body, the color of the skin, hair, and eyes, the muscular movements, the development of faculties, longevity, fecundity, plasticity under change of environment, and vigor? and what are the legitimate inferences to be drawn from such investigations?

Finally, by what devices can the multitudinous correlations of structure and function in the human body find expression in graphic methods?

Another set of observers must now be brought into this great laboratory. We have to deal with a group of animals in which intelligence has manifested itself to such a degree as to dominate all other functions. Teleological inquiries can be no longer excluded. Hitherto the application of scientific methods to the mind has required that we should be satisfied with sensuous results of thought, and forbidden us to inquire into the nature of the mind itself. Now, we are met at the outset with this puzzling question: Shall consciousness or introspection be admitted as an instrument of observation?

How are we to record its dicta? and how (to borrow a term from the astronomers) shall we eliminate the personal equation?

Or, if we are not in a position to admit introspection among our tools of observation, can we not invent some delicate apparatus by means of which the strength of feeling and the inmost thoughts may be known and measured?

Does the brain generate thought as the liver generates bile?

What can science tell us concerning the existence of a human soul, non-material, and not susceptible of measurement by the standards of well-known forces?

How does it come about that children inherit the traits, tendencies, and faculties of their progenitors?

By what routes does the mind pass on its way from infancy to maturity?

What use should be made of the multitudes of inquiries prosecuted with reference to the minds of animals, in the study of human reason?

The student of anthropology frequently finds himself in sympathy with Wordsworth, singing, —

> "Our birth is but a sleep and a forgetting;
> The soul that rises with us, our life's star,
> Hath had elsewhere its setting,
> And cometh from afar."

If, as Mr. Spencer says, that which we inherit represents the accumulated experiences of a thousand generations, is it also possible to retain the consciousness of those experiences? Will the sensitiveness of consciousness keep pace with the growth of knowledge, and obviate the necessity of laborious records? In which case we should have mental and spiritual atavism explained, and that universal sympathy felt by cultivated people for those standing on the lower steps of civilization.

Now, whatever thoughts any other creature than ourselves may have, and leaving out the possibility of mechanical mind-reading in the future, up to this time the only knowledge men have gained about one another's thoughts has been acquired from expression. The expression of thought is language. Dr. Hoffman finds language in rock paintings and carvings; Col. Mallery, in gestures; Mr. Thomas, in the Maya hieroglyphics; and the glossologists, in human utterance. Happily for us, they are a clever set, and well up in their craft. Let us hear some of the questions they are discussing: —

What are all the devices employed by living creatures to express their thoughts, emotions, and volitions?

Which took precedence in the origin of language, signs, or vocal utterances?

What is the explanation of the origin of language?

What light does language throw upon the origin of species?

Is the evolution of language a safe guide to the knowledge of the unfolding of the human mind?

By what lines have the forms of speech progressed?

How far is similarity of language an evidence of consanguinity among peoples?

Is there a genetic relationship between monosyllabism, polysynthetism, and inflection?

What credit must be given to the ear, and the invention of writing, in the conservation, and lines of progress, of language?

How should languages be classified?

Here we may leave the students of language, and take a new guide. Looking over the earth, we behold men divided into races or consanguineous groups, filled with race prejudices, and restricted by race capabilities.

What are those external and anatomical characteristics which have become transmissible by inheritance? When and how were they fixed? Are we to imagine, with Dr. Kollmann, that certain race forms were fixed far back in the past, just as the chemical elements were made irresolvable by a former state of matter?

Of these heritable marks, which is the best criterion of race, — the skull, the color of the skin, the texture of the hair, language, art, social organization, or mythology? or is it certain fixed correlations of these and other characteristics? If so, what are the laws of correlation and conservation in the races? Should the same set of structures be depended on in each race? How many races of men are there? and are these species, or varieties?

In what manner should the question of race enter into the administration of politics, economy, education, and colonization?

It is impossible to say when this subject of race first became attractive to human minds. In the oldest histories and on very ancient monuments, are to be seen attempts to classify the families of mankind. In all the encyclopaedias, under the word 'ethnology' will be found the schemes of modern writers. But, since the commencement of our century, the subject has been taken out of the hands of individuals, and has engrossed the attention of societies. Manuals of instruction have guided the voyager and the traveller in recording the characteristics of races. In Stanford's Compendiums, based on von Hellwald, Mr. A. H. Keane has commenced a codification and synonymy of all the tribes of men. This he proposes to follow up with a biographical dictionary of tribes. The Bureau of ethnology has collated the names, priscan homes, migrations, and bibliography of all the North-American Indian tribes. So that we are in a fair way to know something about the races of men, by proceeding from particulars to a general view.

Passing from man to his works, we are face to face with aesthetic and practical art as a unique study. All art relates to human desires for food, clothing, shelter, for activity in peace and war, for beauty, for social and spiritual happiness. Mr. Tylor has taught us to look upon art products as species that have had an evolution, a life history; and this was very much the plan of Gustav Klemm. This sort of study has captivated many anthropologists, and they are asking such questions as these: —

Admitting that the arts have been progressive, what have been the lines of their elaboration?

May we, by a process of elimination, trace backward the life history of each art, as a patent attorney or a chancery lawyer?

At what degree of workmanship may we be sure that flakes of flint, gashed bones, and wrought wood, give evidence of human handicraft?

When does similarity of art-forms indicate social or commercial contact? when, consanguinity? and when, merely the same gradus of culture?

Is degenerate art a facsimile of early, progressive art?

Is it allowable to fill up the gaps in the arts of any tribe by seemingly intermediate forms from other tribes?

Whence is the sense of beauty?

The answers which we unconsciously give to these queries are the major premises of our arguments respecting the history of civilization.

By marriage in some of its forms, human beings are united into consanguineous groups, whose other needs demand and produce other bonds of union, and widen the separation from other groups. With reference to each set of duties in the tribe, unwritten or written codes embody a system of ethics, regulating conduct in every particular. Farther on in their history, groups have relations of war and peace, and the absorption of homogeneous and heterogeneous peoples into a defined area gives rise to nationalities.

Were men ever herded together in promiscuity?

What were the earliest forms of social life?

What were the most primitive forms of marriage in groups?

Have all the tribes of men passed through the same systems of consanguinity and affinity?

Can the highest systems of altruistic ethics be explained by natural processes?

What are the most beneficial relations of labor to natural resources? and how have the present relations been brought about?

What is the history of the control of the body politic over the individual, and of the jurisdiction of corporations? and to what extent may individual freedom be controlled without discouraging private ambition?

What has been the life history of communism, crime, fashion, and politics?

Is it possible to regard and define facts in sociology by the terms of physical science?

Again, these human beings spend a great portion of their time acting and speaking as if other eyes and ears than those of mortals were cognizant of them. In the darkest nights, at the rising sun, throughout the day, at certain seasons of the year, this unseen world is involved. In groves, in caverns, in estufas, or in costly temples, it is all the same: praises, petitions, and offerings confront the inscrutable power that can work men weal or woe.

How did man come to believe in the animation of things, fetiches, the wanderings of ghost-souls, spirits benevolent and malignant, the gods of classic mythology, and the Great Father of all?

What are the first conceptions of children respecting such things? and will these guide us aright to the childhood of faith?

Has the history of mythology run parallel with the history of material and intellectual progress?

How may we divest ourselves of the personal equation, and learn the true psychology of savage worship?

Is Dr. Brinton right in applying the rules of interpretation adopted for Aryan mythology to American Indian myths, and in assuming that their crude stories are disguised deifications of the phenomena and powers of nature?

Finally, as men wander about the earth, and certain families are to be found chiefly in certain localities, so is it with races. Longevity, fecundity, and vigor are influenced by such causes as height above the sea-level, purity of the atmosphere, amount and distribution of heat, moisture, winds, fertility of the soil, and proximities, whether they be vegetal, animal, or human, whether they be beneficial or injurious.

By what subtle chemistries of the things around us, by what exposures in this terrestrial camera, come to pass the various hues of the skin and hair and eyes, the long skull and the short skull, the long face and the broad face, and the fixed compounds called natural characteristics?

By what processes of selection and adaptation has this cosmopolitan species come to occupy the whole earth, its genial climes, its frozen areas, and its fever-cursed tropics?

Is it possible to control these phenomena, or to adjust the human machine so as to anticipate and assist nature, to expedite natural selection and the survival of the fittest? or even to subdue nature, and decide for her what shall be the fittest to survive?

From this hasty survey of the scope of anthropology, we return to inquire what benefit the world derives from the cultivation of this science.

I answer, firstly, that every study is improved by study. All things become clearer to him who steadily fixes his gaze upon them. The sciences all began with vain speculations, — astronomy with astrology, chemistry with alchemy, geology with cosmogonies, biology with nature-worship, and theology with mythology. Long before the word 'anthropology' was employed in its present acceptation, Alexander Pope wrote, "The proper study of mankind is man." But, millenniums before his day, mankind studied mankind by the light of their time. The study of man is no new thing, therefore. Now, since human thought has run, and will continue to run, in that direction, it becomes our privilege to rejoice that the stream has in these last days run wider and deeper and clearer. The proper study of mankind is the scientific study of man, the multiplication of rigorously exact observations, the collection of thousands of well-authenticated specimens, the classification of both observations and specimens on rational bases, and the limitation of our conclusions to the extension of our premises. Some of my hearers have worked systematically and patiently for years at American archeology, or the anthropology of the modern Indians; and you rejoice with me to-day that our science has at last attained dignity and respect. With profound veneration I mention the names of Hildreth, Atwater, Stephens, Gibbs, Schoolcraft, Morton, Gallatin, Wyman, Squier, and Davis: with what buoyant hope they looked forward to this day, and with what exquisite pleasure must such living witnesses of the beginning as Horatio Hale, Col. Whittlesey, Dr. Jones, and Mr. Hempstead now contemplate the progress of solid work! The Smithsonian institution will have to republish Squier and Davis, with many additions and corrections by Dr. Rau; the Bureau of ethnology will antiquate Schoolcraft and Gallatin and Gibbs; Morton's and Wyman's work will be entirely susperseded by that of the Peabody museum and the Army medical museum. The Archaeological institute of America will throw new light upon the researches of Stephens; and Mr. H. H. Bancroft will make it entirely unnecessary to wade through thousands of pages of ancient Spanish literature. Therefore the first and most beneficial result of modern anthropology has been the direction of an immense amount of rambling and disorganized labor into systematic and rational employment. This clearing of rubbish, correction of misconceptions, cultivation of a modest spirit, willingness to abide the result, multiplication of materials, refinement of instruments, improvement of processes, in a study which thousands are determined to pursue, must strike every thinking person as a wonderful reformation.

Secondly, the value of a study must be estimated by its effects upon human weal. Farmers, miners, fishermen, lumbermen, mechanics, are slow to recognize their debts to the man of science. But who can estimate the millions of dollars saved by such studies as those of Packard, Riley, and Thomas, on the grasshopper, potato-beetle, and army and cotton worms, and the confidence engendered by the belief that a knowledge of the habits of these animals would lead to their conquest? It would take but a few moments to show that this argument applies with manifold force to the study of man himself.

It is not enough for the good physician to know the nature of remedies, or the use of knives and diagnostic apparatus. Sad will be his use of these if he has not familiarized himself with the structure of the human body in health and in disease, and, above all, if he has not made a correct diagnosis of his patient's case. Are not all the questions asked in the first part of this discourse, and many others agitated by anthropologists, connected with human welfare? Do they not relate to the body, mind, and speech of man, to the races of mankind, their arts, amusements, social needs, political organizations, religion, and dispersion over the earth? For instance, the French in Africa, the British in India, and our own citizens in malarious and fever-laden regions, — have they not learned from loss of treasure, ruined health, and the shadow of death, that there is a law of nature which cannot be transgressed with impunity?

It is the same with sociology and religion. The pages of history glow with the narratives of crusades against alleged wrongs, which were in reality campaigns against the sacred laws of nature. Social systems, which had required centuries to crystallize, have been shattered in the effort to bend them to some new order of things. Arts and industries planted in uncongenial soil, at great expense, have brought ruin upon their patrons, who had not studied the intricate laws of environment.

What a modification of temper, for instance, has been wrought among Indo-Germanic peoples by those studies in comparative philology which have led them by the hand back to their priscan home, and demonstrated, that though they may have aggregated into antagonistic nationalities, and fostered inimical industries, the same blood courses through their veins!

The better knowledge of race and race peculiarities has revolutionized and humanized the theories of aborigines. The doctrine of extermination, formerly thought to be the only legitimate result of colonization, has become as odious as it is illogical.

The inductive study of mind has hardly begun; but how much more successfully and rapidly will education and the development of the species progress when the teacher and the legislator can proceed at once from diagnosis to safe prescription, when natural selection and human legislation shall co-operate in the more speedy survival of the fittest! The time seems to me to have arrived when our great anthropological societies and institutions should institute a systematic, co-operative study of psychology.

In a land where the archeologist may tally off most of his finds by savage implements in use at his very door, it seems like presumption to speak to you of the advantages of the most careful archeological methods. But there is a difference between the old and the new archeology. There are times in the settlement of a new country, when every man is his own carpenter, smith, and physician. But how soon your energies have worked out of that! Now I speak only of professional archeology and its advantages. How many mistakes of his predecessors has Mr. Putnam alone corrected? We have all read with pleasure his recent correction of Dr. Hildreth's mistakes about iron in the mounds. It is so with your archeological collections: only those gathered in a scientific spirit will have any lasting value. But in the accumulation and preservation of such, you are the storers of force of the greatest value. You are recovering the scattered fragments of an ancient mosaic which will one day be reset, and its legend will be the lost history of prehistoric man.

The third benefit to which I will call your attention is the opportunity which the science affords for the exercise of every talent, even the highest. The difficulty of any problem depends upon the number or the degree of its unknown quantities. When facts were few, and the data of the science were beclouded with many sources of error, no wonder that men of logical minds left these investigations to those of a more imaginative disposition. Their crude, preliminary efforts have given place to organized work, directed by men of the greatest executive ability, assisted by skilful specialists, and endowed both by private munificence and by public appropriation. Not to go beyond the limits of our own country, we all point with pride to the Peabody museum, the Archaeological institute of America, the American antiquarian society, the museums of New York city and of Philadelphia, the Smithsonian institution, National museum, Bureau of ethnology, Army medical museum, and the Anthropological society at Washington, the academies of Cincinnati, St. Louis, and Davenport, and the historical societies of many of our states, including the Minnesota collections.

Now, the special merit of such great centralization of resources is that everybody can study something. It is possible for every craft and profession thus to prosecute its researches and to make its contributions. During the past winter, papers were read before the Anthropological society at Washington by comparative anatomists, biologists, archeologists, geologists, physicians, paleographers, sign-linguists, philologists, patent-examiners, artists, statisticians, sociologists, clergymen, metaphysicians, and ethnographers. And this does not exhaust the scheme. Mothers, school-teachers, those in charge of the insane, the criminal, and the defective classes, lawyers, mechanics, musicians, philanthropists, legislators, may all contribute to this science some handiwork which will help to make the pile complete. To be still more personal, permit me to say to each one before me, that there is anthropological work which your peculiar occupation fits you to do better than any one else on earth. For example, a distinguished ornithologist, Mr. Henshaw, has recently identified all the birds in the well-known mound-pipes. An artist, Mr. Holmes, has succeeded in bringing order out of confusion in the shell ornaments of the mounds. A patent-examiner, Mr. Seely, traces backward aboriginal art. A general in the British army, Pitt-Rivers, worked out the history of the elaboration of the implements of war. An educator, Mr. Peckham, has recently given us the result of a laborious investigation on the growth of children. The geologists must interpret for us the significance of our discoveries in the drift. Where can I stop? I will boldly avow that the day of tyros is gone. There is a great multitude of collectors throughout our states who will have to go to school to Professor Putnam, or Dr. Rau, or Dr. Thomas, before they will have the faintest conception of the significance of their treasures.

The inevitable result of special research is generalization. Kepler, Newton, Count Rumford, Kirchhoff, Bunsen, and Darwin, are names that stand for these processes in material science. To Herbert Spencer we are indebted for the first effort in this direction respecting human phenomena, and his work will be revised and corrected by those who will approach the task with better instruments and more reliable material.

In this heaving mass of humanity, returning into itself ever with vast gulf-streams and eddies, each actuated by its special forces, there is, after all, orderly motion. We discover that our little circle is part of a greater circle, and for a moment the mind is satisfied in the contemplation of this wider truth. Recovering, and renewing our investigation, the fact is reached, that this and its congeneric circles are part of a greater movement more complicated and perplexing. By the pursuit of this wider knowledge the intellect is strengthened, and thereby is brought about the natural selection of the mind. While many tire, or are unable to comprehend the situation, others press on, and grow strong by the effort.

The last advantage of which my time will allow me to speak is the assistance which such studies render to philanthropy and legislation.

Standing on the deck of a steamer, and looking at the land left behind, we seem to be but a mile or two away. We are surprised with the information, that what seems so near is many miles distant. It is so with human history. In our childhood we believed that the first man walked the earth only a few centuries ago. All the events known to us then could easily have occurred in that brief period. The increase of knowledge expands the boundaries of time, and the origin of man is now lost in the mists of the past. Could any thing fill our minds with greater love for our race than the magnificent struggle they have made in these millenniums? At the other end of the journey we were no better than brutes, and now we look out upon the cosmos as something reasonably comprehended.

If 'pity for a horse o'er-driven' fills the heart of the poet, with what tenderness should we look upon the savage races, and remember that the whole family of man has stopped, some time or other, at that wayside inn! Each aberrant form, abnormality, criminal, dwarf, and giant shows the by-paths of human growth into which our life-stuff may have wandered. The arrow is the parent of the cannon-ball; the stone or bone spear-point, of the bayonet; the flint chip, of all edged tools; the cave-man, of the French *savant;* the hut, of the palace; the tattoo, of regalia; the gorget, of the crown jewels; the quipo and pictograph, of the printed book; promiscuous concubinage, of holy wedlock; the hunting-party, of society; the clan, of the state; the fetich, of the pantheon; and universal animism, of universal causation. Instead of our ancestral belief in a tree with roots in the earth and branches in heaven, our tree has its roots in the past, and is ever putting forth leaves and flowers in a brighter present.

All sciences are retrospective. The astronomer, the physicist, the biologist, find the bases of their prophecies in the past history of the universe. The statesman, if he be wise, will imitate their example, and feel secure of his legislation for the future only so far as it is founded upon an intimate knowledge of the past.

The value of this study to philanthropy is easily shown. With what admiration do we read of the devotion of those missionaries who have suffered the loss of all things in their propagandist zeal! Science has her missionaries as well as religion, and the scientific study of peoples has notably modified the methods of the Christian missionary. The conviction that savage races are in possession of our family records, that they are our elder kindred, wrinkled and weatherbeaten mayhap, but yet worthy of our highest respect, has revolutionized men's thoughts and feelings respecting them. The Bureau of ethnology has its missionaries among many of the tribes in our domain, no longer bent on their destruction, but treating them with the greatest consideration, in order to win their confidence, to get down to their level, to think their thoughts, to charm from them the sibylline secrets. It sounds something like the old Jesuit relations, to hear of Mr. Cushing at Zuñi, eating vile food, wearing savage costume, worshipping nature-gods, subjecting himself to long fastings and vigils, committing to memory dreary rituals, standing between disarmed Indians and their white enemies on every hand, in order to save their contributions to the early history of mankind. You will recall the fact, that an honorable senator more than a year ago offered, as an argument against sudden disruption of tribal affinities, an elaborate scheme of the Wyandotte confederacy. Max Müller says, "He who knows little of those who preceded him is likely to care little for those that come after. Life would be to him a chain of sand, while it ought to be a kind of electric chain that makes our hearts vibrate with the most ancient thoughts of the past as well as the most distant hope of the future."

In the study of this anthropo-cosmos, as in other studies, we are brought face to face with the inscrutable. In these voyages of discovery we have no right to expect that we shall ever find a passage to the ultimate truth. As with the child, so with the man; as with the individual, so with the race; as in the past, so in the present and the future, — the solution of one problem only prepares the way for many far more complicated. With all our sciences comes the consciousness of new ignorances. There is more known to be unknown now than when wise men knew that they did not understand many things well known to us. So will it ever be. Just about one hundred years ago, Peter Camper's measurements of the facial angle, with a few observations on height and weight, were thought to be all that anthropometry could furnish to the natural history of man. In 1881 Paul Broca laid down for the skull and the encephalon more than one hundred and fifty measurements; and the Germans go beyond that. Think you, the weighing and measuring will stop at these? We are just on the threshold of applying experienced training and instruments of precision to the study of man. Examine, if you please, the circulars for information issued by the old Paris ethnological society, Albert Gallatin, Lepsius, Max Müller, and the Smithsonian institution, with those published for the Novara expedition, by the British association, Kaltbrünner, Roberts, the new Paris society, or Major Powell, and you will have ocular evidence of the advance of anthropology.

But there is no Ultima Thule in science. No question propounded to nature will ever be answered. I can imagine the night of despair that would settle around any one of my hearers when he had reached the consciousness of having gathered the whole harvest of truth. On the other hand, I am sorry to hear any of our great thinkers uttering the words *ignoramus et ignorabimus* as a wail of despair. They should be to all the sweet voice of hope. They do not mean that we know nothing, or that we shall ever remain totally ignorant. Fresh, vigorous, buoyant, science feels itself to be on a pleasant journey, whose destination may remain unknown, but every mile of whose progress unfolds new vistas of beauty and variety in nature, each transcending the other.

I congratulate you, dear friends, that the American association has delegated to you such an important trust. The illustrious names to be found among our members and fellows are a sufficient guaranty that you have lighted your torches, and that our science will not be a laggard in this grand march. Professor Henry said, in 1859, "The statement cannot be too often repeated, that each branch of knowledge is connected with every other, and that no light can be gained in regard to one which is not reflected upon all" (Smith. rep., 1859, p. 15). We may go farther, and say, that, whenever any marked generalization is made in any science, all other sciences proceed at once to put themselves in line with the new order. It is the duty of the anthropologists, therefore, not only to rejoice in the growing light of chemistry and biology, but, quickened by their warmth, to put forth new life and vigor, and to apply to their investigations the most refined instrumentalities and the most subtle thought; believing with Lord Lytton that man is a subject of far nobler contemplation, of far more glowing hope, of a far purer and loftier vein of sentiment, than all the 'floods and fells' in the universe.

PAPERS READ BEFORE SECTION H.

(MOUNDS AND MOUND-BUILDERS.)

The great mounds of Cahokia.

BY WILLIAM McADAMS OF ALTON, ILL.

The mounds referred to are in the locality known as the 'American bottom.' The region so called is a strip of alluvial land in the state of Illinois, lying between the bluff and the Mississippi river, and extending from the city of Alton to a point below the city of East St. Louis. A map of the locality, showing the places and dimensions of the mounds, was exhibited before the section. The mounds are over two hundred in number, and are the largest in the United States. A group of seventy-two mounds on the Cahokia creek was specially considered. The central mound of the group is the largest: it is a hundred feet high, and covers fourteen acres of ground. It is a truncated pyramid with two terraces: its flat top has an area of one and a half acres. The surrounding mounds are thirty to forty feet high: they are square, in this respect differing from the conical mounds of Ohio. The mounds on the bluff seem to be of a different order, being only four or five feet high, and round or oval. Unquestionably the mounds of the Cahokia valley are artificial, being made of black alluvial earth, entirely different from the ground on which they rest.

The author accounted for the fact that there were few mounds on the banks of the Mississippi river, by supposing that the mound-builders were afraid of their enemies beyond the stream.

Numbers of relics have been found in the Cahokia mounds, mostly of flint, some of them eighteen inches long. The finest is a white flint axe, which is of a smoothness and polish like ivory. In reply to an inquiry, the author stated that there had been considerable alluvial deposit formed since the mounds were built. The subsoil is a yellow clay loam: under the mounds is a floor of white sand.

In discussing the paper, Gov. Bross stated that he had discovered, on the top of the only round mound of the group, a large flat stone, which he thought might have been used for sacrificial purposes. A skeleton had been found, of a man more than six feet high: the whole series of mounds gave evidence of the energy and industry the men of that time had possessed. Dr. Hoy said that there was in Africa a mere bird that threw up a mound fifteen feet high, so that these men might not have been even large. Mr. Putnam expressed the opinion that the mounds were simply a site for a town, and not a worshipping-place. Mr. McAdams said he had been led to believe they were places of worship, by the use of just such mounds for places of worship in Mexico, their sun-worship being their government. There are few, if any, evidences of habitation.

Metrical standard of the mound-builders, by the method of even divisors.

BY CHARLES WHITTLESEY OF CLEVELAND, O.

In the absence of the author, an abstract of the paper was read by the secretary of the section. An endeavor was made, by the method named, to ascertain the standard of linear measurement which was used by the mound-builders. It is supposed that they, in common with other early races, used the length of some part of the human body as a linear unit. Several theories of the kind were tested mathematically, but, thus far, with only negative results.

The mound-builders identified.

BY JOHN CAMPBELL OF MONTREAL, CAN.

This paper was read by the secretary of the section, in the absence of the author.

It was a pains-taking attempt to trace the origin of the mound-builders in the eastern hemisphere, chiefly by means of a comparison of ancient languages along the line of a supposed route. The line of similarity was believed to indicate that the original people were Khitan or Khitos, Kathaei, Katei, Khilon, or Citem; and that they had made their way across Europe and northern Asia to Alaska, and thence to the United States, down the Mississippi valley, to Mexico.

Professor Mason, the president of the section, expressed the opinion that Professor Campbell was on the wrong track, while complimenting him upon his exceeding zeal and patience in his research. Professor Mason consoled himself, however, with the thought that the author had so thoroughly exhausted the subject that no one would ever attempt a similar experiment. Mr. D. A. Robertson of St. Paul differed from the president, and expressed the opinion that Professor Campbell was on the right track, and that the migration of the mound-builders would be traced from Siberia, or by the European isles, and, if not in one migration, in several.

Typical shapes among the emblematic mounds.

BY S. D. PEET OF CLINTON, WIS.

By means of diagrams, the author exhibited the ground-outlines of different mounds which he had surveyed in Wisconsin, which showed that they had been made in the form of animals, in different postures. There were flying geese, eagles, jack-rabbits, panthers in the act of jumping upon their prey. Many of the supposed effigies were of great size, the tail of one squirrel having a length of three hundred feet. One of the mounds was in the shape of an elephant, with a very pronounced trunk. This mound, however, is now destroyed; and the only authority for its existence is that of a man now dead. There were mounds, also, in the shape of water-animals, such as turtles, crawfish, etc. His theory of these mounds was, that the animals were supposed to be scattered about to guard the central sacrifice or altar mound. He was led to this belief by observing that the altar mounds are nearly always situated on high ground, overlooking a river, while the emblematic mounds are so disposed around the altar mounds, as to suggest the notion of guarding the latter.

Personal observations of the Missouri mounds from Omaha to St. Louis.

BY E. P. WEST.

IN the absence of the author, the paper was read by Dr. Case of Kansas City.

Observations were given with some detail, by which it appears that the Missouri mounds are built on the lower bluffs or terraces. The author shows also that these mounds must have been coeval with the loess deposits. He says we have reason to believe that the occupancy of the mound-builders was prior to the subsidence of the Missouri river and Kansas lakes, and that it was not continued long thereafter. It must have begun previous to the subsidence, since the remains and implements of this people are found in the undisturbed primitive deposits. Their ingress was probably from the south, and extended northward after the close of the glacial period. Turning northward after the close of the ice reign, they found the warm waters of the Champlain lakes filled with fish, inviting an occupancy along their hospitable shores. Here they erected their abodes, and drew their principal food-supply from the lakes. In time, owing to geological changes, the lakes were drained. The conditions for existence being altered, the lake-dwellers either suffered extinction, or were forced to change their mode of life. Their distinctive characteristics, at any rate, ceased long before the European touched foot on this continent. We have no means of knowing whether they were exterminated by neighboring nomadic tribes, or became themselves nomadic in their habits.

Game-drives among the emblematic mounds.

BY S. D. PEET OF CLINTON, WIS.

INDIAN mounds are divided by the author into five classes, as follows: 1. Emblematic, and built by hunters who worshipped animals. 2. Burial-mounds: this class mostly prevails in Michigan, Illinois, and Minnesota. 3. Mounds which are probably the remains of the stockades of an agricultural people. 4. Village mounds, — the remains of villages, and their high places for worship. 5. The peculiar mounds of the Pueblos and Aztecs.

The first of these classes was the special subject of the paper. The author's theory is, that the emblematic mounds, having the form of the animals hunted, served a useful, as well as a religious. purpose. He regards them as having been employed by the hunters as screens from behind which to shoot the animals which would pass along the game-drives between the mounds. Diagrams and charts were used to illustrate the theory.

(OTHER ANTHROPOLOGICAL PAPERS.)

In-door games of the Japanese.

BY E. S. MORSE OF SALEM, MASS.

IN introducing this subject, Mr. Morse said that there are curious affiliations between the Japanese and the American Indians, which may some time show a connection by family ties. Among the simple in-door games of the Japanese are some that are played with balls, jackstones, and cat's-cradle; but all these are more elaborate than with us, and the cat's-cradle goes through a far greater variety of changes. The author believes that the greater intricacy of Japanese simple games is due to the fact that older people take more interest in them. Among these games, there is one similar to 'Simon says thumbs up;' there are tricks with the hands, much like our own; and there are numerous games of striking hands, which appear easy, but require much practice to acquire adroitness. There are many games that test strength or endurance; among them are some in which ears and noses are pulled, and others where the competitors each hop on one foot, and try to push their rivals over.

They have a more elaborate game of checkers than ours. The pieces are placed on intersections instead of on squares. It frequently takes a month to play one game, and the players often deliberate over a move for an hour or two. Experts in the game acquire a wide reputation. Japanese chess is probably the most intricate game in the world. The board has 81 squares, and 20 pieces are used, which have moves somewhat like our own, though none are exactly similar. The pieces change in grade when they arrive at a certain position on the board. The strangest feature of the game is, that either player can take any piece which has been captured from him, replace it on the board, and use it against his adversary. This makes the game utterly bewildering to a foreigner.

The Japanese have no games with spotted and court cards like ours; but they have a card game of 'authors,' which compels players to cap verses of classic poetry. Mr. Morse was delighted to find this intellectual amusement a favorite with the Japanese; and he hopes they will never substitute for it our inferior struggles in seven-up, whist, and euchre.

Life among the Mohawks in the Catholic missions of Quebec province.

BY ERMINNIE A. SMITH OF JERSEY CITY, N.J.

THE paper was an interesting account of the Indians brought under Roman-Catholic influence by missionary labors continued through many generations. These Indians regard their priests as temporal directors as well as spiritual fathers. The manners and customs of the Indians were described, and some account was given of the studies of the author in the

Indian dialects of the province; noting, especially, the more curious peculiarities of the language, the dialectic differences of the tribes, and the modes in which such changes have been effected.

The principal occupation of the men is that of boatmen on the St. Lawrence, though the bead-work goods of the tribe are sold everywhere. The speaker detailed her exciting experience in shooting the rapids of the St. Lawrence, on a raft, under the skilful charge of these Indian boatmen. Many of the laws of the old aboriginal Mohawks are forgotten by the tribe described. The significance of some of the wampum-belts was outlined; and the speaker recited the legend of the old bell in the chapel, closing with a tribute to the zeal and the results of the labors of the old Catholic priests who have worked so long among these Indians.

An exhibition was made, in connection with the reading of the paper, of wampum-belts, drawings of ornaments, and the work of the earlier priests, including some literature.

Observations on the laws and privileges of the gens in Indian society.

BY ALICE C. FLETCHER OF NEW YORK.

This paper was read by the secretary of the section, in the absence of the author.

An elucidation of the customs and circumstances under which the gens system in Indian tribes supersedes parental ties, was the chief feature of this paper. The author had an excellent opportunity for observations of this character, during the work of placing the Omaha tribe of Indians upon their lands in severalty, and while adjusting the line of descent and inheritance according to our laws.

"A child who has lost its father or mother is considered an orphan. Its particular place is gone, and it passes into the gens." Beyond the foregoing statement, the paper does not make it quite clear, whether, in case of the death of the mother only, the child remains somewhat under direction of the father, or is wholly assigned to a family of the father's relatives.

But as to the results when the father dies, leaving offspring, the paper is quite explicit. In that case, the mother loses all maternal rights. Each child, unless of very tender age, will be separated from the mother, and will go into the family of some one of the father's relatives. It may thereafter be claimed as his own child by the male head of the family to which it has been allotted. This separation of her children from a widow is permanent. She usually marries again, and in that event is not burdened with her offspring by previous husband or husbands; but if she should remain unmarried, she would be expected to work for the family that has adopted her children, rather than for the children themselves. If she dies when her children are young, it is probable, that, at maturity, they will have forgotten even her name.

The women are not wanting in affection for the children of whom they are bereft; but the separation is looked upon as a matter of course, none of the interested parties regarding it as a grievance, or even a hardship. It surprises an Indian to have the propriety of this arrangement questioned. No point of our law of inheritance is so difficult for him to understand, as that which binds together the child and the surviving parent.

Young men whose mothers are of the same gens are accounted brothers to each other, and the brothers of the mothers are uncles. Between these uncles and the nephews and neices, there is an easy familiarity, not unlike that of parents and children.

The author has observed a decided lack of family likeness among Indians. This observation applies, however, to entire families, which include cousins, aunts, and uncles; a striking resemblance between parents and children being not unusual.

The Indian may be 'the stoic of the woods;' but he is neither averse to pleasantry, nor deficient in sensitiveness of a certain kind. He delights in chaffing his fellow Indian; and dreads, more than aught else, being made a laughing-stock.

Symbolic earth formationa.

BY ALICE C. FLETCHER OF NEW YORK.

This paper was read by the secretary of the section, in the absence of the author.

By the foregoing title, the author refers to certain heaps of earth which are piled up with care and formality during religious ceremonies of Indian tribes. Miss Fletcher has in previous papers described the preparation of these little mounds among the Sioux, where it formed part of every religious ceremony she witnessed. The present paper described this practice among the Winnebagoes in the 'buffalo-dance,' which is given by them four times in May and early June. The Winnebagoes, the author says, are admitted to be one of the older branches of the great family to which their tribe belongs. Their antiquity is shown by the construction of their language, by finding many religious ceremonies of different tribes referred to the Winnebagoes, and by Winnebago words used by other tribes in connection with religious ritual.

The buffalo-dance was described in detail. As the dancers enter, each woman brings in a handful of fine earth, and deposits it, so that two small mounds are raised midway between the eastern entrance and a fire which is about fifteen feet from the entrance. The mounds thus formed are truncated cones; and an old Indian said to Miss Fletcher, "That is the way all mounds were built: that is why we build so for the buffalo." The mounds were about four inches high, and not far from eighteen inches in diameter. When the mounds were completed, the head-gear of the four male dancers was placed upon them, consisting of claws, tails, and other trophies of the chase. The men imitate the buffalo in his wild tramping and roaring. The women follow in single file, each with her feet nearly straight and her heels together, propelling herself by a jerk of the body, or a kind of hop. The appearance of the entire line of female dancers is suggestive of the undulating movement of a herd of buffaloes. The track left by the women's feet is a regular pattern like a close-leaved vine, each woman hopping exactly into her predecessor's footsteps.

The fire before referred to is built east of the centre of the tent, and contains four logs placed with their inner ends joining, and their outer ends toward the points of the compass. During the initiation of a candidate, at a certain point in the ceremony when he has fallen dead to the old life, and is raised to the new, the four logs are taken away, and the ashes are heaped in a sharply conical mound.

The essayist also described one of the sacred resting-places for spirits on the bluffs of the Missouri river. Such places are at intervals about fifty miles apart. They are cleared and cleaned by sacred hands every year. The place contained a depression in the ground, of circular form except as to an extension of the outline in an elongation or entrance exactly pointing to the east. The depression is just one foot in circumference, and about six inches deep. An adjoining tree, now partly blown down, has the reputation among Indians of being haunted by spirits. The author hoped that other observers would be able to trace the probable connection between these observances and the building of the larger mounds.

Osage war customs.

BY J. O. DORSEY OF WASHINGTON, D.C.

THE paper was read by the president of the section, in the absence of the author.

By means of an illustration the preparations were shown which the tribe makes for a war-march, the order followed being that of rank in the tribe. The paper described the tactics by which the Osages camp in a circle, the war-men on one side, and the noncombatants on the other. The road travelled by the Indians forms the line down through the centre of the camp, and the division-line. The great war-tent is placed with the rear to the west, the place of honor being at the east. The author detailed at considerable length, with the aid of illustrated charts, the method of selecting the forces, and the ceremonials preparatory to war, the decoration of the Kean Woctake, or Cheezhoe peacemaker, the form of the dance around the village, the nature of the moving dance, the order of march from home by twos four abreast. Marriage ceremonials and funeral rites were also described and explained in detail. A marked feature of this paper was its use of drawings illustrating the grouping of participants in ceremonies.

The Charnay collection at Washington.

BY O. T. MASON OF WASHINGTON, D.C.

THE collection referred to contains the material obtained by the Charnay expedition to Mexico and Central America. The expenses of the expedition were defrayed by Mr. Pierre Lorillard. The author of the paper called attention to the fact that Mr. Lorillard was not himself proficient in any branch of science. The success of the expedition showed how a gentleman of fortune might render valuable service to the cause of science, although not specially conversant with scientific lore.

In this expedition, a point was made by obtaining, as far as possible, casts (in plaster strengthened with tow) of the objects of antiquity. By means of these casts, the drawings of this and other exploring expeditions can be verified and corrected. Great success was attained, as to casts from little-known and almost inaccessible ruins; and many new objects of beauty and curiosity were brought to light, among them a large number of interesting reliefs and statues. The casts will be preserved in the museum at Washington, and in duplicate at the Trocadéro museum in Paris. Numerous photographs and drawings were obtained; and measures have been taken, under the auspices of the Smithsonian institution, to reproduce several of the more important ruins by correctly arranging the casts in position with suitable accessories. Good success has already been attained, both in making restorations of ancient temples and other ruins, and in correcting recorded measurements and drawings.

The correspondence between the prehistoric map of North America and the system of social development.

BY S. D. PEET OF CLINTON, WIS.

IN introductory remarks, the author claimed that the American continent was peculiarly favorable for the study of primitive life. The isolation of the continent, and the freedom from historical impressions, had contributed to a unique development. There is no trace of a Homeric age. The symbolism and mythology are homogeneous. In the eastern hemisphere, we have mountain ranges running east and west, which divided races: here we find little trace of such divisions, and the people were to be regarded as a unit.

The theory of the author was, that the development of the North-American aborigines depended upon their surroundings. Dividing the development into three successive grades of savagery, barbarism, and civilization, he found these in successive parallels from colder to warmer climates. The isothermal lines of this continent do not follow parallels of latitude; and due allowance must be made for their deflections to the north and south, in considering the effect of climate upon development. The author differed from Mr. Morgan on certain points. The production of pottery is not so certain an evidence of emergence from barbarism as is the pursuit of agriculture. While Mr. Morgan regarded the development of village-life as a distinguishing feature, Dr. Peet had found traces of village-life everywhere among the aborigines.

In respect to the origin of the American races, the author believed that some aboriginal tribes came from the east, and others from the west. It is possible that this diversity of descent can be detected by careful observation of the tribes on the Pacific coast.

The kitchens of the east.

BY E. S. MORSE OF SALEM, MASS.

The author, during his travels in eastern Asia, had made some observations on the cooking-apparatus there in common use. The Japanese largely employ a mere fireplace, over which the vessels containing food are suspended by hooks: they have, however, two or three kinds of regular stoves of different designs. In China, stoves of a definite character are in use: one was found in Canton which was very elaborate; it was long, and had numerous openings. In Singapore, there appears to be only one kind of stove; and it is of decidedly primitive construction. In fact, it is little more than a rough trough filled with earth and sand, on which are laid rough stones selected with reference to pots of various sizes; and the fire is built among the stones. The kitchens in which these constructions are found are invariably very dark and dirty. In northern Java the author found a stove made of arched clay, as half an earthen pipe would be if cut through the axis of the cylinder. This half-cylinder is set with the open part down, and fire is built under its arch. Holes are cut through the crown of the arch, to hold some of the pots, while others are merely set upon the surface.

Methods of arrow release.

BY E. S. MORSE OF SALEM, MASS.

The author recited the rules at present applied in the American system of archery; the bow being drawn with the right arm, the arrow being placed on the left side of the bow, and three fingers being used to hold the arrow. Among the Japanese, a different system prevails: the arrow is placed on the right side of the bow as it is held perpendicularly, and the drawing of the bow is performed with only the thumb and one finger on the shaft. China, Japan, and the Corea are alike in this manner of drawing the bow. Among Indian tribes, the methods of arrow-release differ very widely. In general it may be stated that our system of arrow-release (which the author designated as the Saxon method) is substantially the same as that of the majority of European races, the modifications of the system among them not being important.

The Japanese use a glove with a heavy thumb, and sometimes a heavy ring on the thumb. Mr. Morse exhibited the Japanese archery-glove. It has a filling of wood and pitch in the thumb, which aids in grasping the arrow. He considered this glove the best of its kind.

Our system of three-finger release is certainly as good as any other, and probably is the best. With this system our archers — for instance, some in Ohio — are able to outshoot any Indian, tried by all the usual tests. As to the methods of stringing the bow, the author had not been able to find much uniformity. A number of different modes were exhibited.

Vestiges of glacial man in central Minnesota.

BY FRANC E. BABBITT OF LITTLE FALLS, MINN.

In the absence of the author, this paper was read by Mr. Upton.

The field of the discoveries detailed in this paper lies on the bank of the Mississippi river, in central Minnesota, about one hundred miles north-west of St. Paul, and within the township and village of Little Falls, Morrison county. In his report for 1877, Prof. N. H. Winchell, state geologist of Minnesota, described certain rudely worked pieces of quartz discovered by him in this locality. The author of this paper describes a discovery of worked bits of quartz in a much older stratum than the one explored by Professor Winchell.

Fragments of sharp, opaque quartz were found by the author in 1879, in a gap or notch, cut by drainage, in an ancient river-terrace, which has an elevation of twenty-five feet above the present river. The gap had been deepened by use as a wagon-track, which has latterly become a highway. Ultimately the source of these fragments was traced, and found in the form of a thin layer, situated from ten inches to two feet above the point in the notch where Miss Babbitt began her discoveries.

The ancient terrace consists of stratified gravel and sand. The layer of quartz-chips extended in a nearly horizontal plane into the terrace, and was partially broken up on the edge where the gap, with its wagon-road, had disturbed a portion. Both the inferior and superior planes of the quartz-bearing stratum were sharply defined: its thickness averaged a few inches, varying a little with the size of included pieces. The quartz-bed rested upon a few inches of sandy soil, which passed downward into a coarse water-worn gravel immediately overlying till. Above the quartz-bed, stratified gravel and sand extend up to the surface of the terrace, which is twelve to fifteen feet higher than the plane of the quartz. The pebbles of the gravel lying directly on the quartz were small well-rounded, and less angular than those of the gravel below. These observations show that the quartz-chips were spread originally upon an ancient surface that was afterward covered deeply by the modified drift that forms the terrace. The quartz-chips and implements discovered by Dr. Winchell were in the upper stratum of the terrace-plain. The two sets of objects cannot be synchronous in deposit: between the periods when they were left there, an interval of time must have passed sufficient for the deposit of twelve or fifteen feet of modified drift.

The specimens are mostly small, and very numerous. Among them are some of a type unknown to the author, of which the most finished have delicate, fragile edges, formed by a single thin leaf of the quartz prolonged beyond the mass of the object in a series of minute, irregular notches. The specimens of different types were found in groups, each of its own type, in this deposit. Some are thus described: 'Axe-like quartzes,' 'rasping-stones,' 'long prong-shaped objects,' 'hammer-stones of different shapes, sharp pieces adaptable as cutting-blades, and a great many sharp and long splinters.' They are made of many different varieties of the quartz mineral; but the greater part appears to have been taken from quartz-bearing slate in the vicinity. Numbers have evidently been formed from water-worn pebbles. Objects shaped from some special variety or tint of quartz were found generally together in loose groups of two or three to a dozen pieces. Where a piece is of large size, the chips surrounding it are usually much smaller.

Professor Henry W. Haynes of Boston, to whom a collection of the specimens was submitted, has written, that he believes some of them to be implements; many, chips and refuse struck off in the work; many are natural forms, and a few are rolled pebbles. Those which he thinks are implements, he supposes were held in the hand of the workman; masses of quartz were fitted for use by having most of their projections battered off by another stone. He believes, also, that he has found traces of moss or leaves being used to soften the roughness of these implements when held in the hand.

Mr. Warren Upham, assistant of the state geological survey, contributed the following statement on the subject, showing how man could live while the modified drift was deposited, and how relics of his work might be enclosed within that formation. He says, —

"As soon as the ice had so far retreated as to uncover the present valley of the Mississippi river in Morrison county, the deposition of the modified drift, constituting the terrace-plain in which are found the quartz chippings, ensued, during the continued retreat of the ice. It seems very probable, that vegetation and animals followed close upon the retiring ice-border; and that even man, who lived near the Atlantic coast in this closing stage of the glacial period, as abundantly proved by recent discoveries in the drift-gravel near Trenton, N.J., may also have lived here at that time, and occupied the Mississippi valley directly after the ice-sheet retired. While the deposition of the valley-drift at Little Falls was still going forward, men may have lived there, and left, as the remnants of their manufacture of stone implements, the multitude of quartz fragments here described. By the continued deposition of the modified drift, lifting the river upon the surface of its glacial flood-plain, these quartz-chips were deeply buried in that formation. The date of this valley-drift must be that of the retreat of the ice of the last glacial epoch, from whose melting were supplied both this sediment and the floods by which it was brought. The glacial flood-plain, beneath whose surface the quartz-fragments occur, was deposited in the same manner as additions are now made to the surface of the bottom-land; but the flooded condition of the river, by which this is done, was doubtless maintained through all the warm portion of the year, while the ice-sheet was being melted away upon the region of its head waters. In spring, autumn, and winter, or, in exceptional years, through much of the summer, it seems probable that the river was confined to a channel, being of insufficient volume to cover its flood-plain. At such a time this plain seems to have been the site of human habitations and industry, as shown in this paper. After the complete disappearance of the ice from the basin of the upper Mississippi, the supply of both water and sediment was so diminished that the river, from that time till now, has been occupied more in erosion than in deposition, and has cut its channel far below the level at which it then flowed, excavating and carrying to the Gulf of Mexico a great part of its glacial flood-plain, the remnants of which are seen as high terraces or plains upon each side of the river."

An animated discussion followed the reading of Miss Babbitt's paper. Mr. Putnam referred briefly to the discoveries made by Dr. Abbott in New Jersey, some of which are unquestionably artificial productions, and prove that man resided in that region prior to the last glacial deposit, or, as some claim, between two glacial deposits. The discoveries made here seem to be of the same character as those in New Jersey. Their age belongs to geologists to ascertain. He considered the discovery very important, and the paper one of great value. Rev. Mr. Peet took issue with Mr. Putnam as to the value of the discoveries, and thought, that, if paleotiths had to depend upon such a shallow foundation as was furnished by these alleged discoveries, the matter would better be dropped. He thought there was absolutely no evidence that the specimens discovered by Miss Babbitt were the work of man, and was of the opinion that the whole theory was without any foundation whatever.

A classification of the sciences.

BY J. W. POWELL OF WASHINGTON, D.C.

THIS is an endeavor to classify sciences in the order of the evolution of phenomena, and with reference to complexity. The first group of science, relating to physics, the author divided into molecular, stellar, and mechanical science. In the second group, the biological sciences, he placed botany and zoölogy. In the third group, anthropology, we have pyschology, sociology, philology, technology, and philosophy. Geology is a compound of the first group; paleontology, of the second.

The following subdivisions of the third group were suggested: As branches of philology: 1. sign language: 2. spoken language; 3. written language. Under technology: 1. activital; 2. regulative; 3. ethics. Under philosophy: 1. mythology; 2. metaphysic; 3. scientific. Technology is also either industrial or aesthetic. The author explained in further detail the reasons for this order of classification, and the relations of the members of different groups to each other.

List of other papers.

THE following additional papers were read in this section, some of them by title only: An ancient village of the emblematic mound-builders; caches guarded by effigies; effigies guarding the village and sacrificial places not far away; high places connected with ancient villages; The religious structures common to villages in prehistoric time, by *S. D. Peet*. An abnormal human skull from a stone grave in Tennessee; A new stand for mounting skulls, devised by E. E. Chick, by *F. W. Putnam*. Accidents, or mode-signs of verbs in the Iroquois dialects; Studies in the Iroquois concerning the verb 'to be,' and its substitutes, by *Erminnie A. Smith*.

PROCEEDINGS OF SECTION I.—ECONOMIC SCIENCE AND STATISTICS.

ADDRESS OF FRANKLIN B. HOUGH OF LOWVILLE, N. Y., VICE-PRESIDENT OF THE SECTION, AUG. 15, 1883.

THE METHODS OF STATISTICS.

I INVITE your attention to a few thoughts upon the *methods of statistics*—using the term 'statistics' in its broadest sense, as a 'statement of facts.'

The subject naturally divides itself into two distinct operations,—the collection of the data from which information is to be obtained, and their classification in a manner that shall without error, and with the least labor, present the results in a form most convenient for use.

Commencing with the first of these,—the collection of facts,—it would be needless to remark, that every thing depends upon the simplicity, accuracy, and completeness with which they are obtained, and that by no subsequent operation can their errors be eliminated, or their deficiencies satisfactorily supplied.

It may be remarked, in general, that no intelligent person, business firm, or corporation, can safely begin any enterprise,—nor can any government, from the lowest municipal to the highest national form, undertake any measure with prudence,—without first knowing all that can be ascertained beforehand concerning it.

In private business, inquiries are naturally made as to the cost and the profits. If it requires the use of a raw material, the parties will endeavor to make themselves sure as to its abundance,—the probability that the supply will be maintained,—or, if it be of limited amount, the quantity, and the time that it will hold out. They will need to know the changes that may happen in amount, quality, and cost; and similar inquiries will be made as to the expenses that may be incurred while in their hands,—the chances of loss, or of change in value,—and, finally, the extent of the demand for whatever may be the product of their skill, industry, and investment, its probable permanence, and its tendencies to change.

These questions, being well considered in the beginning, will enable the careful operator to avoid losses from imprudent investment, from over-supply of the markets, or from the depression of receipts below the limits of cost.

By a train of reasoning analogous to this, those intrusted with the government of towns, cities, or states, may determine as to how far the cost and maintenance of public enterprises will be justified by the results; but with this difference, that the benefits or profits, instead of being measured by a money value, are often to be found in an advancement of the public welfare, and in the security, convenience, and prosperity that may ensue.

But, whether in private enterprise or public undertaking, we may attribute success alike, in both, to an attentive notice of the facts and the circumstances upon which they depend; and, if loss or failure follow, the reasons may very generally be traced to ignorance or inattention as to the facts and probabilities that should have been known beforehand.

These thoughts lead us directly to the point we are first to consider; viz., How shall the knowledge of the required information be obtained? In the primitive way (and for a small business this may be the best one), the person will, from his own observation, 'look over the ground,' and consider the various points to be taken into the account. He will make inquiries of others, as to the supply, demand, prospects of competition, and the like; and thus accumulate a certain amount of information, upon the extent and accuracy of which, his success or failure will in a great degree depend.

Advancing a step farther, we find, in most great industries and interests of the country, that those in the same business or pursuit, whether in the arts or sciences, or in financial operations, however they may be influenced by local rivalries or petty jealousies, are constantly tending to the formation of associations or societies, for the advancement of their common interests. They meet for the discussion of methods by which expenses may be saved, or profits increased. They inquire of one another as to their experience or observation upon doubtful points. They seek to gather light and aid from science, to stimulate and reward invention, and to excite rivalries in the comparison of improved products. They discuss financial and national questions that may affect their welfare; and not unfrequently they appoint committees or agents, from their own number, to gather statistical facts and details for their own use and guidance.

We consider the information thus obtained, as deserving high rank in point of accuracy. It is chiefly taken from records, without a motive for concealment or evasion, and with a full knowledge that self-deception and loss would result from error, whether above or below the truth.

From this combined experience, each member who participates obtains a standard for comparing his own results with the general average. He cannot afford to fall below it, and he has the strongest motives for reaching the highest limits that have been reached by others.

Still these statistics, however accurate they may be, are necessarily special, and often technical in their nature. They cannot be compared with those of another business, and may be incomplete within themselves, as naturally relating to methods, rather than to financial details. They might show *how*, rather than *how much*. They will seldom contain a balance-sheet of profit or loss, or any thing that would advance the fortunes of a rival in business, or reveal the secrets of an unprofitable enterprise. We must receive them as we find them, — good only as far as they go.

Besides these associated business inquiries, prompted and guaranteed by self-interest, we find various others, voluntarily undertaken with reference to particular subjects, often for the promotion of a moral, religious, benevolent, educational, or political object, and ranging in value all the way between the accuracy of statements taken from records, or gathered by faithful inquiry, by chosen special and zealous agents on the one hand, and the random conjectures carelessly returned by those who know but little, and care still less, about the subject of inquiry, on the other. It would be wholly impossible to assign a scale of value to statistics thus obtained, where every thing depends upon the circumstances of the case, and the accuracy of information on the part of those who make returns, — the fulness with which they are reported, and the care with which they are combined.

We have another class of non-official statistics collected and published by private enterprise, for the information of particular trades or professions, or for use by the general public; their reputation and success depending wholly upon their accuracy, and being brought to the test of local and personal knowledge every day and everywhere, we may naturally expect them to be as accurate as they can be made. In this class, we may include directories, trade and market reports, financial transactions, and the current commercial statistics generally.

There may be instances where they are tainted with a suspicion of private or speculative motive: but such is the vigilance of rival enterprise, that detection will quickly follow; and an exposure would at once degrade a reputation for independence and impartial statement, to the rank of a private job for a speculative end.

Exhibits openly made, for the avowed purpose of presenting the favorable side of a business enterprise, may be taken for what they are worth, and are often trustworthy; but, when concealed under a false pretence, they deserve suspicion, and, when exposed, they generally injure the interest that they represent.

The best of these statistics are taken from records, and are entirely correct; others are collected by special agents, and should be approximately near the truth; and there is still another class, made up from the estimates of those supposed to know the facts, and which must wander more or less from the actual conditions that they attempt to represent.

It may be said of all of them, that their greatest value is for present use. They quickly pass by, to give place to the next issue, and remain only as historical records; but, as such, they still afford a most valuable means of comparison between the present and the past, and become landmarks of progress, ever instructive to those who may be seeking to trace the origin and growth of our industries and our resources; and now and then they are recalled as precedents, where new questions arise, under circumstances deemed similar to the past.

We will next consider some points relating to inquiries undertaken by authority of government, either for the intelligent discharge of its own functions, or for general information, the good of its citizens, and the advancement of knowledge among mankind.

We may, in general, remark, that nothing can be properly done, in the machinery of government, without leaving its record. If money or property is received, there is an entry; if a payment is made, or if property is issued, there is also an entry, and a receipt to prove it. In short, the whole theory of our government involves the necessity of a record of every official transaction; and it is only in cases of intentional fraud, or gross neglect, or unavoidable accident, that the history of every public act cannot be traced from these records.

A record, to be trustworthy, should be made at the time of the transaction, and while all the facts as to time, subject, and amount, or other points of statement, are fresh in mind. Nothing should be trusted to the memory, and for record at a more convenient season. It should be concise, and easily understood, and may often be very greatly assisted by tabular arrangement.

The summaries of these records, as published by the government, are, we believe, with few exceptions, entitled to great confidence, as far as they present transactions done by authority, or passing under the notice of government agents.

We may classify the official statistics of the government under the following heads: —

First, Summaries of current business, published annually or at shorter intervals.

Second, Periodical inquiries made at wider intervals, as in the census, and requiring special agencies for their execution.

Third, The inquiries made by experts, or by special commissions or agencies created for a particular purpose. This class is sometimes associated with one or the other of the preceding.

Taking from among these classes the census, as one of the most important, let us notice some of the methods by which it has been taken.

The earliest returns that I have found, in colonial times, were made by sheriffs and constables. At a later period, the national census was for a long period taken by the marshals of the district courts, or their deputies, — officers whose duties are quite analogous to the former; and this practice of assigning the task to sheriffs still prevails in several of the states.

In many other cases, assessors discharge the duty. In New York, before 1855, special agents were appointed by local authorities; and, commencing with that year, they have since been appointed by the secretary of state. The appointing power has been vested in state boards, in boards of county commissioners, and in the judges of inferior county courts. Assuming what I think all will admit, that census inquiries should be made entirely free from any suspicion that some tax or some personal liability is to be incurred, it is evident that an assessor cannot question an ignorant man about his property and his crops, without exciting his fears that some tax is to be laid. The sheriff or the constable seldom makes a professional call, except to serve some papers or make an arrest. There is, therefore, a strong reason for appointing persons who are to make the census inquiries their only business, and for making it widely known that there is no taxation, enrolment, or other liability incurred by giving full and true returns, and that there is no sectarian or political end to be served by the inquiry.

This excellent end is now well enough secured under the national law, and in several of the states. They have a still better method in Great Britain, where a system of registration of births, marriages, and deaths, has its districts and its agents under constant organization, and to which, once in ten years, the census can be assigned, without creating new offices. In Sweden, where a system of registration, including also a record of change of residence, is in charge of the parish-clerks, they take a census whenever they choose to post the books, without any special inquiries being made, more than what these records contain.

In the national census before 1850, — in New York before 1855, — and in some of the states still, each family had one line upon the blanks; and the number of persons of different ages, sexes, and colors, was entered in columns provided. The limit of classification was of course restricted to these columns; and, although the totals of each class were easily obtained by adding, the results were meagre and unsatisfactory.

The change that allowed a line for each name, one column for the exact age, and other columns for native country, profession or occupation, etc., while it simplified the labor of taking, allowed ample field for classification; and it made it necessary to employ a large force of clerks, in a central office, for the reduction of the returns for publication.

By a method now generally used in Europe, the census is taken upon 'householders' schedules,' which are distributed one to each family, some days beforehand, filled out by the head of the family, and collected upon *one day*. The only instance in which this has been done in the United States, within my knowledge, was in the District of Columbia, upon the 11th of November, 1867. This census was taken by the metropolitan police, under my own direction, and with entire success. It was attempted in the city of Baltimore some months afterwards, and failed, apparently from want of proper management on the part of those in charge.

For all kinds of official inquiries, relating to business, as well as to personal statistics, I think the true and proper method is, by means of *special blanks*, carefully prepared, simple, and fully explained. These should be distributed some little time beforehand, and should be taken up, if not in one day, within a short period of time, but with reference to a given day. The chief difficulty to be encountered is the illiteracy of those who should fill the blanks; but in the District of Columbia, which in 1867 contained a large number of colored families, but recently freed from slavery, the blanks had been, in almost every case, filled out by some one to whom they had been carried.

In following our subject, — the 'methods of statistics,' — we may notice some points in the condensation and arrangement of facts that may be of interest.

With a vast amount of information before us, as, for example, in the returns of a census, let us consider what is to be done, and how it can be done with the least labor and greatest certainty. After inspection to make sure that the work is all together, in proper order and condition, it will be found that several distinct operations are necessary, in preparing the results for the press. Columns of figures must of course be added, and carefully revised. As the totals of several sheets will often be consolidated into one sum, it is best to use spare sheets of the same schedule for entering the totals of pages, so that these partial totals can be easily combined. It is always a good practice, where long columns, of many figures in each, are to be entered for adding, to provide paper with narrow vertical ruling, that shall allow of but one figure in a space. In cases where the first two or three right-hand characters are generally ciphers, they may be left out altogether, the significant figures only being entered in their proper places. It saves a little time and labor, and does not lead to error.

Where a great amount of statistical material is reported, — as, for example, the names in a census, — the blanks should always be plainly divided by horizontal and vertical lines, *printed in preference to ruled*. The horizontal lines should be numbered from the top downward, upon both margins. This numbering is the more important where an entry is carried across to another page. Each line should contain but one entry, and there should be, if possible, no blank lines except at the end. Then, with a little multiplication-table at hand, showing the number of lines in a full sheet, and for each number up to the highest that are likely to be found in a return, the totals can be rapidly and accurately ascertained, as follows: The number of sheets is first counted on the back edge, and the number of entries they should contain, if full, is set down. Then, by glancing over each page separately, it is easy to notice whether there are any lines with two entries, any blanks, or any lines in excess. The deficiencies are set down in one column, the excess in another, and their difference is added or subtracted, as the case may require, when the true sum is at once found. This operation, which is the first thing done, should be repeated by another person; and, when found to agree, it should be kept as a test-number for verifying the accuracy of much of the work that is to follow. In measuring parts of pages, a scale made of a strip from the margin of a blank schedule, and pasted upon a card, will save all labor of counting.

In statistical labors, where the same returns afford material for a considerable number of deductions, — as, for example, the population sheet of the census, — it is generally best to take *but one thing at a time.* Thus, the ages, professions, nativities, civil condition, etc., should be taken by separate operations, and not two or more at once. There is not, however, the least need of confusion in keeping the subdivisions of these subjects, in two or four classes, — as, for example, ages by sex and color, — by a simple arrangement of heavy and light horizontal lines upon the tally-sheet, and a little practice in its use.

There is much to be gained, both in time and accuracy, by a proper arrangement of a tally-sheet. The grouping together of tally-marks, by making four down and one across, so as to divide the work into groups of fives, is so natural and obvious a method, that few who have had occasion for this kind of work could have failed to adopt it. By an arrangement which I have used to a large extent in census work, I have had my tally-sheets printed off into squares, so that each compartment should receive one group of five, and no more. Then, by a series of numbers with a common difference of five, printed across the top of the sheet, at the head of each vertical column, the number of tally-marks in a horizontal row can be known at once, by glancing along the vertical column containing the last full group of fives, to the number printed at the top, and then adding the marks in excess, but less than five, in the next compartment. This saves all counting, and a considerable amount of time. There is also an advantage, on account of the eye-sight, in having the tally-sheets of some other color than white: a neutral tint might be best, but I have found common manilla paper answer every purpose.

Plans have been proposed for using cards of different sizes and colors, properly inscribed or numbered, as counters, for classifying a variety of facts, forming together a definite whole. By using colors, the eye becomes, without mental effort, a guide to the hand, in their distribution into piles or cells in a case; and, when the work is done, their number may be accurately known by weighing, or by measuring the height of each pile. Those of different sizes could be separated by mechanical devices, without handling, and, by a little practice, without liability to error.

It may be said generally, that the chief, indeed the only real, difficulty, in the preparation of statistical data, consists in getting the facts correctly. There is nothing in the operation of a central office that needs to involve error; or, if an error is committed, there should be no difficulty in tracing it to the clerk who is responsible for it. An efficient way to secure accuracy in work would be, to make a money-charge against the clerk who commits an error, to be paid to the one who finds it. I believe that something of the kind is done in some of the statistical offices in Europe, a class of revisers being employed, who are paid by the fines thus imposed upon the careless.

With respect to statistics obtained by circulars addressed to persons supposed to have the information desired, we have every grade of value, from good to good for nothing. The result depends upon many circumstances: as, for example, whether the person making the return is paid, or is under some obligation to, or expects some favor from, the person or office making the inquiry; whether the inquiry can be answered by reference to a record, or by some research more or less conveniently made, or is to be supplied from personal opinion, and a general knowledge of the subject; or, finally, whether the question can be answered by any thing better than a guess, by one who knows perhaps very little about it.

I would hold it to be the general rule, that where the inquiries are few and simple, exact as to their object, and, if they refer to a record, exact as to time and subject, and especially if they can be returned upon the same blank, and without expense for postage or otherwise,a very large percentage will be answered without a second application. A repeated call would probably bring a third or a half of the remainder; but there will be, now and then, one who will fail to reply, unless under official or personal obligation to do so.

We have thus far considered the dealing with statistics that have been gathered from the whole of a given field of inquiry: there are other methods that deserve notice, and the first of these is that 'by samples.' A portion of some whole is carefully studied, and the results obtained are deemed applicable to the entire field.

The French statistician Moreau de Jonnès has given some instances of this method, as applied in times past, by persons who had acquired eminence, and whose work gained confidence; and very properly asks, 'What is such work worth?'

Vauban, distinguished as a military engineer, at the beginning of the eighteenth century, wishing to know the agricultural production of France, and the revenue it would yield, resorted to a method which would appear strange enough now, but still may be called ingenious. He attempted to reach his object by taking an exact account of the production of a square league, reckoning the arable land, vineyards, pastures, and woodlands, with their products in quantity and value; and then, by the simple "rule of three," he said, "as 1 is to 25,000, so is the result to the whole of France."

The English agriculturist, Arthur Young, sought to ascertain the proportions of meadow-land, mountains, and the like, in France, by cutting up a map by lines following these features of the surface, and weighing the parts.

In 1790 Lavoisier, distinguished in science, and for this reason consulted by the national assembly upon a question of imposts, found no existing data that applied to the internal resources of the country, until he himself supplied them, by a method that is now altogether neglected in statistical researches. He proposed to ascertain the number of ploughs in the country, and from this to calculate the quantities, production, and consumption of agricultural crops.

In 1784 M. Necker, the distinguished statesman, deduced the population of France from an assumed percentage of the birth-rate; and this was taken for a census!

But coming down to a much later period, we find a remarkable application of the law of induction in a work upon the industries of France, by the minister Chaptal. He presents agricultural tables, which have been received with great confidence, since they bear the appearance of official statistics, and were executed under the Empire. His tables are found to have been computed, without acknowledgment, from a statement addressed by M. Hennet, director of the cadastral survey, in 1817, at a time when not more than a seventh part of this work had been finished. The other six-sevenths were obtained by a simple multiplication of the finished part.

Many years ago, a 'distinguished statistician' published, with great apparent precision, the yield of potatoes in France. There had been no official inventory taken; but when one came to be made, some time afterwards, it was found that this deduction had been obtained by mutiplying the yield of a single commune by 37,000, the number of communes in France.

These examples might be multiplied indefinitely; and we need not cross the Atlantic, nor go far back in time, to find them. There is scarcely a day, but that we see passing through the newspapers, estimates, deductions, and statements, that have no more solid foundation than those that we have cited. Nevertheless, we must not wholly disregard the inductive method in statistics: there are many cases in which we can get nothing else.

The chemist must analyze the soils and the ores from samples. In every operation of testing the quality and the value of any commodity whatever, we must select from the material before us what appears to be the average quality. And so of statistics generally: if there is no actual and general inventory made, we must collect from what is deemed a fair average, and, from these data, obtain such conclusions as they afford. The result in this, as in every thing, will depend upon the intelligence and honesty of the person who makes the estimate, the extent of his opportunities, his experience, and his skill.

Returning to the field of exact statistics, we may remark, that we can never have an accurate census of the population until we have a thorough and uniform registration of births, marriages, and deaths; a measure which this association undertook to promote, more than a quarter of a century ago, but which has not made successful progress.

We cannot have a faithful statement of the industries, without a record kept of the production, the consumption, and the cost of operation. This is already done by most of the important ones, as an incident of business; but we lose the advantages by the hurried manner in which the official inquiries are made. Yet upon these returns we rely for all that is collectively known about them.

It follows, that, until we can realize these desirable features, the best we can expect is, to afford more time for previous preparation, by submitting beforehand the questions that are to be answered; which can only be done by the aid of 'householders' schedules' for population, on 'special blanks' for each of the industries, or other subjects, that come within the range of inquiry.

It was my intention to dwell at some length upon the illustration of statistical facts by graphic methods; but time will not permit, and opportunity for full preparation has not been found. For more than thirty years I have been accustomed to note down the principles involved in these methods, whenever, in the course of a wide and varied range of opportunity, a new one was found; and it has been with me a cherished intention to present the whole subject in a systematic form.

We may concisely state, that graphic illustrations, using lines, areas, or angular spaces, often supplemented by colors, may be employed for representing either —

1. *Quantities*, with or without reference to time.
2. *Time*, in recurring, interrupted, or progressive periods.
3. *Direction*, or *relative position*; and
4. *Intensity* or *force*.

In general, but two elements can be clearly presented at once; but by a skilful use of different colors, or kinds of lines, subjects of the same nature may be admirably compared, and the relations of cause and effect not only illustrated, but even discovered and proved. It is often admissible to introduce subjects having dissimilar notation, — as, for example, degrees of temperature, and height of barometer, — in the same drawing; but in these cases each must have its own scale, and, in a general way, every diagram must have a scale for every element of the subject that is represented, either expressed or implied.

Quantities may be shown either as they exist at certain periods of time, or as they form parts of a general total; and they may be presented so as to exhibit successive subdivisions, down to any desirable degree. If the divisions of a general total do not require subdivision, they may best be shown by angular spaces, as sectors, which together make up the whole of a circular area. If the divisions have some qualities in common, the shades of color may be of different intensity, significant of the degrees of quality that may exist. But where there are successive subdivisions, or *parts of parts* of a whole, there is no way so exact as by means of rectangular areas, which may also be shaded in different tints, as well to separate them one from another as to show differences of intensity or degree.

In both of these methods, as well of angular spaces as of rectangular areas, we can only show quantities as they exist at a given point of time. We catch, as it were, the conditions, as does the light, the image in a camera. They admit of no such thing as motion or change; but these changes may often be strikingly represented by a series of diagrams, presenting the conditions at different periods of time.

Where time and quantity are combined, we have an easy and striking means of illustration; and in this the time may be in recurring periods, such as the hours of a day, or the months of a year, or it may be progressive, as in a series of years.

For the recurring periods, I think there is nothing so convenient and instructive as the *circle*, in which the quantities are measured along the radii, from the centre as their base. The entire radius may sometimes represent the whole of that of which these partial measurements are a part.

For a progressive series, the ordinates representing quantities should be measured from a level base-line, and the scale of graduation shown upon the side margin, while the time is measured from left to right by a scale along the upper margin.

For simple comparison, a series of bars or lines, measured from a common base, and either horizontal or vertical, is a convenient and striking mode of illustration, and has now come into very common use.

A rectangular area, with parallel divisions, amounts to the same thing as a line; but with this difference, that a secondary subdivision may sometimes be represented with great effect.

Having thus stated some points in reference to graphic illustrations upon a true principle, I should not leave the subject without a word of censure for some that are false. I will specify, particularly, such as attempt to represent comparative quantities by *concentric figures*, such as circles or squares. The eye has, in these cases, no means of just comparison; and they are very apt to mislead, where they are intended to instruct.

The same objection may be made against similar geometrical solids; for, although they may be literally true, their contents being to each other as the cubes of similar lines, the eye does not readily see the difference. It would be better, in such cases, to use cylinders or prisms of the same base, but proportioned in length to the quantities that they represent.

PAPERS READ BEFORE SECTION I.

Life-insurance and self-insurance.

BY ELIZUR WRIGHT OF BOSTON, MASS.

THIS subject has been a favorite theme with Mr. Wright for several years. His ability as an actuary is acknowledged; and his theory on this subject has at least the merit of disinterestedness, so far as insurance-companies are concerned. Without going into the technicalities and mathematical considerations that must be met in a thorough review of Mr. Wright's theory, its object may, perhaps, be stated correctly in a few words. A reserve is accumulated by the practical workings of life-insurance in a well-regulated company, which is more than sufficient to meet the claims upon it as fast as they mature. The usual system divides that reserve, less the amount which the company withholds as a surplus for extraordinary emergencies, among the policy-holders. Mr. Wright takes the view that each policy earns, during its continuance, an ascertainable part of that reserve. He supplies the means for determining what this part is. for each policy: of course, it is a matter of calculation for each. He denominates this part of the reserve, or surplus, the 'self-insurance.' By his system it is possible to ascertain at any time how much this self-insurance on a given policy amounts to, or how much it will amount to at any future time, if kept in force. Mr. Wright believes that the self-insurance is the property of the policy-holder; and that, if not payable to him on demand, it should at least be applicable for a renewal of the policy to prevent forfeiture.

The increase of the colored population of the United States.

BY C. S. MIXTER OF WASHINGTON, D.C.

IT is frequently asserted that the colored population of the United States is increasing more rapidly now than it did prior to 1861. The large apparent increase shown by a comparison of the census-returns of 1880 with those of 1870 seems to justify this opinion; but the results of investigations made by the superintendent of census in South Carolina and Mississippi show that the census in 1870 was seriously defective in this respect, while that of 1880 was very full and complete. The accompanying statistical table presents the returns of these people according to each U. S. census from 1840 to 1880, and gives the numbers reported from the South in detail. These results seem to indicate that they are not increasing as rapidly as formerly. The burden of supporting their minor children, and their disregard of the rules of health, seem to furnish additional reasons for thinking that their future rate of increase will be less than it has been heretofore.

Oyster-farming in Connecticut waters.

BY H. C. HOVEY OF NEW HAVEN, CONN.

AN explanation of the difference between seed oysters and those fit for market gave the author occasion to mention that 'saddle rock' oysters in their best edible condition were six or seven years old. A history of Connecticut experience and legislation in relation to oysters was given in detail. There are now 325,000 acres of disposable space for oyster-beds, and 100,000 are occupied. The area of the natural beds is only 6,000 acres, and this furnishes the seed for new beginners. The present expansion of oyster-farming is due to the use of steam-power in gathering the harvest.

The first thing done on an oyster-farm is to stake it out into sections, and then the bottom is examined. The next step is to scatter oyster shells over the farm, and the oyster spawn is scattered. After this, in some muddy localities, small trees, mainly birch, are thrust into the water, in a standing position; and the young oysters set on these trees. The spawn is cast out from June until November, and for a few days the young oysters swim everywhere they please, leading a happy life for a brief period. Shelling begins about June 15, and ends about Aug. 15. When the oysters fill the trees, the latter are pulled up and cleaned off. From one acre of bushes, 1,000 bushels of oysters have been gathered in one year. The oysters set on anything which is clean. They had been found on old boots, old wrecks, and a pair were found on an old padlock. Oyster-farming was not profitable every year; one firm having lost $20,000 by the ravages of the star-fish in one bed, and another firm $100,000 in two years from the same cause. Oysters were formerly imported, but are now exported in immense quantities.

The German carp, and its introduction into the United States.

BY C. W. SMILEY OF WASHINGTON, D. C.

The United States fish-commission, he said, had some years ago imported from Germany thirty or forty pairs of this fish. They were placed in breeding-ponds in Washington, and have increased many-fold, the number spawned this year being 400,000. The carp is naturally a warm-water fish, and in the waters of the southern states grows with astonishing rapidity, and to great size. They will also do well in the cold water of the north, even in Minnesota. Nearly every state and county in the United States has a fish-commission, and they are all propagating carp. It has also been taken up as a private speculation, and carp are sold for breeding-purposes as high as $5 per pair.

The carp roots about in the mud for aliment, and much resembles poultry in its manner of getting food. Carp aged three years are often found to weigh twelve to fifteen pounds, and a gain in weight of four pounds has been observed in a carp in one year. The carp is sluggish; while trout, bass, and other lively fish frisk about, and do not fatten so fast as the carp. Experiments have shown that female carp spawn at the age of one year in southern waters, at two years in colder waters, and in the extreme northern waters of the United States at three years. Other fish, turtles, muskrats, snakes, and even birds, eat young carp. A bird shot in Washington recently had in its stomach the heads of seventy-nine young carp. The U.S. fish-commissioner recently sent out requests for information about carp experimented with in this country; most of the replies placing the carp on an equality with trout, bass, and shad as a food fish, while a few classed them with pike, and a very few said they had a muddy taste. The carp is the best pond fish yet known, and in a very small pond will thrive well, so that families may easily have their own fish-garden if they have enough water to make a permanent pond. The carp is a very hardy fish for shipment, requiring little water to keep alive in. The U.S. fish-commissioner is giving away carp, sending them by express to any point, the receiver paying express charges. The fish will thrive on table-refuse and almost any thing edible. Carp can be kept in winter in a tub in the cellar, the water requiring to be kept fresh. Care should be taken to keep poisonous substances out of carp-ponds, and too much food should not be thrown in. In cooking carp, thorough cleansing is needed; and frying should be done in hot pans and hot grease.

As to the economics of this subject, Mr. Smiley said that fish-culture was more and more becoming a part of the farmer's occupation, and thought that, not very long in the future, most of the farmers of the country would have little fish-ponds in their dooryards, both as a method of obtaining food and as an ornament to the homestead.

Cable-cars for city passenger traffic.

BY E. T. COX OF NEW HARMONY, IND.

Professor Cox, though devoted to geology, has always taken a kindly interest in schemes for industrial advancement. In the present paper he describes the success of the cable system as a substitute for horse-cars; and urges its general adoption, on the ground of its convenience and comfort to humanity, as well as the diminution of suffering to the horse. Some of the collateral statistics presented in the paper are interesting; e.g., the figures given by Mr. Moody Merrill, chairman of the horse-car railroad convention held at Boston last March: "There are in the United States and Canada 415 street-railways, giving employment to about 85,000 men, 18,000 cars, and 100,000 horses in daily use. These horses consume 150,000 tons of hay, and 111,000,000 bushels of grain. 3,000 miles of track represent an invested capital of $150,-000,000. The number of passengers annually carried is 1,212,460,000. In the city of New York there are 110 miles of horse-railway, and 11,866 horses are used to operate them. The horses, together with their harness, expensive lands and stables, feed and grains, make the operating expenses, by including interest, $5,104,596.79 per annum. The average life of the street-car horse in New York is less than three years."

The paper quotes an opinion of Gen. W. Sewell of New Jersey, a practical railroad engineer, who prophesies that, within ten years, the cable system will supersede horse-cars on every considerable street line. The great advantage of the system is its applicability to very steep grades. The paper states, in respect to the most vital question to capitalists, that the cost of the plant in the cable system is shown to be about $70,000 per mile of roadway. We have heard it recently stated, in other quarters, at $120,000; but perhaps one estimate applies to single and the other to double tracks. This makes it, at best, somewhat expensive as an experiment; and that is the light in which it is regarded by many horse-railroad managers at present.

Improved method of spraying trees for protection against insects.

BY C. V. RILEY OF WASHINGTON, D.C.

THE paper gave a summary of results obtained from experiments made during the past two years at the U. S. department of agriculture. An ordinary barrel is used as a reservoir, in which is inserted a force-pump with automatic stirrer. A long rubber hose extends from the pump, and is attached to the spraying apparatus. The nozzle has been called the cyclone or eddy nozzle; its action carries out new principles of spraying. It is a shallow, circular, metal chamber, with two flat sides, in the centre of one of which is a small circular outlet. The fluid is forced into this chamber tangentially, producing rapid rotation, and a spray which is easily regulated from a mist scarcely visible to a strong shower. This nozzle is adjusted to the end of a bamboo rod (of varying length, according to requirement), through which the rubber hose has been passed; or several nozzles may be attached, in different positions, to the sides of a stiff metal tube, sufficiently slender to be handled by the operator, and thrust among the branches of the tree. By these means, trees from twenty to thirty feet high can be rapidly sprayed without the use of a ladder. The substances used are either London purple, one-half pound, and flour, one pound, in from forty to fifty gallons of water; or Paris green, one pound, to the same amount of flour and water; or petroleum emulsions made as Professor Riley indicated at the last meeting of the association.

Enhancement of values in agriculture by reason of non-agricultural population.

BY J. R. DODGE OF WASHINGTON, D.C.

THE paper begins by showing that national industry is prosperous in proportion to its diversity. The productions of agriculture would be unsalable if all the people were agricultural producers. A civilized nation, with the smallest proportion of non-agricultural workers in it, will be low in the scale of prosperity: with the largest proportion of non-agriculturists consistent with proper food-supply, the nation will be most prosperous. To a great extent, this is true also of the subdivisions of this country. It may be illustrated by the statistics of geographical sections that embrace groups of states, or by comparison of individual states. The author is even prepared to show, that, in a partly agricultural community, the increased employment of labor in industries that are non-agricultural stimulates improvement, compels higher culture, and makes the products of land, and the land itself, more valuable. Such is the theory. In support of it, the author adduces striking facts, obtained by compilation from U.S. census returns of 1880.

The states and territories are grouped for this comparison in four classes, which are thus designated: first class, having less than 30 per cent of agricultural workers; second, having over 30 and less than 50 per cent; third, having 50 and less than 70 per cent; fourth, having over 70 per cent, *i.e.*, being almost exclusively agricultural states.

Classes.	No. of states and territories.	Acres.	Value.	Value per acre.	Per cent of workers in agriculture.
First class . .	15	77,250,742	$2,985,641,197	$40.91	16.59
Second class .	13	112,321,257	3,430,915,767	22 21	40.12
Third class .	13	237,873,040	3,218,108,970	13.03	58 85
Fourth class .	6	108,636,796	562,430,842	5.28	77.46

In the first class are Massachusetts, Connecticut, New York, New Jersey, and Pennsylvania in the east, and some of the mining states and territories of the west, diverse in many points, yet alike in the fact of a large non-agricultural population. This class has only one-sixth of the population in agriculture. The fourth class consists of North and South Carolina, Georgia, Alabama, and Mississippi. It has nearly four-fifths engaged in agriculture, on lands worth only an average of $5.28 per acre. The states having only two-fifths in agriculture have farm-lands valued at $22.21 per acre, while those having nearly three-fifths in agriculture have lands valued at $13.03. These figures speak for themselves, and scarcely need comment from the author.

When individual states are compared, the results are equally marked. The author compares pairs of states, — Virginia and Pennsylvania, Kentucky and Ohio, Iowa and Illinois, — as follows (for convenience we place these comparisons in tabular form): —

Items of comparison.	Virginia.	Pennsylvania.	Kentucky.	Ohio.	Iowa.	Illinois.
Per cent of agricultural workers	51.41	20.68	61.67	39.97	57.46	43.65
Value of farm lands per acre	$10.89	$49.30	$13.92	$45.97	$22.92	$31.87
Wages of agricultural laborers per annum .	180.00	431.00	199.00	394.00	[1]	467.00

Similar computations give figures for the State of New York not widely different from those for Pennsylvania. The average value of farm-lands per acre in New Jersey is greater than in any other state, viz., $65.16: this is owing to a position between two great city markets, with proximity and easy access to both. Her percentage of agricultural workers is only 14.92; their average annual wages are $501. It will be seen that the wages of agricultural labor are subject to the same law. If computed for the first table in this paper, the wages per month of the agricultural

[1] The annual wages of agricultural labor in Minnesota are $376.

laborer would be found, for the first class of states, fully $25; for the second, nearly $25; for the third, less than $20; for the fourth, about $13.50.

An application of the same test to the value of annual production for each man engaged in agriculture brings equally interesting results in the following table: —

Classes.	No. engaged in agriculture.	Value of products of agriculture.	Value per capita.	Per cent of workers in agriculture.
First class . .	1,060,681	$484,780,797	$457	16.51
Second class .	1,566,875	616,850,959	394	40.12
Third class . .	3,017,971	786,681,420	261	58.85
Fourth class .	2,024,966	325,099,388	161	77.46

The states with less than 30 per cent in farm-labor realize nearly three times as much per man as those which have over 70 per cent in farm-work. In other words, one man in the first class realizes as much as the three men who are competing with each other, having little outlet for surplus production. Three brothers in Alabama, laboring through the year, get as much for their aggregate produce as one farmer receives in Pennsylvania, simply because that farmer has a brother engaged in manufacture and another in mining. It is because in one case there is a market for one product only, thousands of miles away: in the other, there are markets at every door.

It appears evident that the proportion between agricultural and non-agricultural population is a measure of the values of the land, of the production, and of the labor of the farm. These values are rapidly enhanced by the increase of non-agriculturists. This is the lesson of the most authentic statistics of our own and of other countries.

A new system for the treatment of sewer-gas.

BY T. E. JEFFERSON, HUDSON, WIS.

In this paper, which was well illustrated by diagrams, special reference was made to a series of important inventions which of late have attracted much attention both in this country and Europe. This system chiefly consists in making sewers approximately air-tight by sealing the sewer inlets so as to admit sewage, but exclude the air; making pipe connections between sewers and buildings, and different heating-apparatus arranged to admit the in-flow of atmosphere and the products of combustion into the sewer, and, at the same time, prevent the back-flow of gas; when by the connection of a powerful suction apparatus with the sewer, near its outlet, the removal of sewer-gas and smoke from furnaces and fires, and the thorough ventilation of buildings, is positively effected and regulated as desired.

By employing mechanical force for creating draught for fires, the large percentage of heat heretofore required for this purpose is retained, effecting a corresponding saving in the consumption of fuel.

The main portion of these important discoveries, including the removal of sewer-gas, and the positive means of ventilating buildings and carrying the vitiated atmosphere and poisonous vapors away from contact with the inhabitants, was recently made by Hon. John Comstock of Hudson, Wis., and first introduced in one of the districts of the city of Paris, France, during the present year, where its great utility and practical success are fully demonstrated.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Hyperelliptic functions. — M. E. Wiltheiss starts out from a memoir of Prof. Kronecker's which appeared in the *Monatsberichte* of the Berlin academy for the year 1866, in which a method was developed for obtaining the parameters τ_{ik} of those theta-functions, which, for a certain definite transformation, remain unaltered. Prof. Kronecker started out from a purely algebraical stand-point, and solved the equations which connect the original and the transformed parameters τ_{ik} and τ'_{ik}. Corresponding to the transformation of the theta-functions, there is a transformation referring to the integrals belonging to these functions. Noting this fact, the author of the present paper has arrived at these singular values of the τ_{ik} in another manner, and his results bring into evidence a certain property which is analogous to the complex multiplication of elliptic functions. The author confines his attention solely to the theta-functions of two variables. — (*Math. ann.*, xxi.) T. C. [214

Curvature of surfaces. — M. Rud. Sturm has given here a very interesting theorem analogous to Gauss' well-known theorem concerning the measure of curvature at a point on a surface. Gauss' theorem, stated briefly, is, that if a curve p enclosing an area F is drawn around a point P of a surface, and if a corresponding curve p' enclosing an area F' is traced out on a sphere of radius unity by the extremities of radii drawn parallel to the normals to the given surface at each point of p, then the limit value of the ratios of F' and F will be equal to the inverse product of the radii of curvature R_1, R_2, of the given surface in the point P. M. Sturm's theorem is, that if the curve p is cut out of the given surface by a sphere whose centre is at P, then the mean curvature, viz., $\frac{1}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right)$, is equal to the limit value of the ratios of the two perimeters p and p'. — (*Math. ann.*, xxi.) T. C. [215

ENGINEERING.

Pressure on valves. — Professor S. W. Robinson presented to the American society of mechanical engineers, at its meeting in New York, November, 1882, a paper on the theoretical and the experimental determinations of the mean pressure on steam-valves exposed to pressure both above and below. He finds that a line can be determined, circumscribing an area which he calls the equilibrium area of the valve. This area being multiplied by the maximum pressure gives the total mean pressure acting to hold the valve to its seat. The extent of this area is determined by experiment; and a theory of the case is constructed, which is given at length, with the practical formulas derived by means of it for use in designing. — (*Van Nostrand's mag.*, July.) R. H. T. [216

The performance of the Worthington pumping-engine. — Messrs. Shedd and Ward present to the water-commissioners of the city of Buffalo a report upon the performance of a Worthington pumping-engine, recently built for the city. The delivery was 28.8% greater than was demanded under the contract with the makers, amounting to above 19,000,000 gallons per day; and the 'duty' was something above 70,000,000 pounds of water raised one foot high per thousand pounds of steam used. This was above the duty demanded by the city. — (*Ibid.*) R. H. T. [217

CHEMISTRY.

(*Organic.*)

Reconversion of nitro-glycerine into glycerine. — Great difficulty having been experienced in destroying the dynamite recently captured in England, Prof. C. L. Bloxam has tried several methods for decomposing its nitro-glycerine constituent. 1. Nitro-glycerine was shaken with methylated alcohol, and the solution was mixed with an alcoholic solution of KHS. Considerable rise in temperature resulted, the liquid became red, a large quantity of sulphur separated, and the nitro-glycerine was entirely decomposed. 2. Nitro-glycerine was shaken with a strong aqueous solution of commercial K_2S. The same changes were observed as in 1; but the rise in temperature was not so great, and the liquid became opaque very suddenly when the decomposition was completed. 3. The ordinary yellow solution of ammonium sulphide was mixed with the nitro-glycerine, and the mixture evaporated to dryness on the steam-bath, when bubbles of gas were evolved, due to the decomposition of the ammonium nitrite. The pasty mass was treated with alcohol to extract the glycerine. 4. Calcium sulphide, made by boiling flowers of sulphur with slaked lime, was used. Reduction took place as above, but more slowly, and more agitation was required. This last is the cheapest process. — (*Chem. news*, April 13.)

The reducing action of alkaline sulphides on nitro-glycerine was pointed out some time since, and A. H. Elliott, F.C.S., showed in the *School of mines quarterly*, Sept. 15, 1882, that the method admitted of quantitative application. — C. E. M. [218

METALLURGY.

Water-gas as a fuel. — Mr. W. A. Goodyear believes that the fuel of the future in cities, for all domestic as well as for most manufacturing and metallurgical purposes, will be gas of some kind. The ease and cheapness of its distribution, the cleanliness and economy of its use, will, in his opinion, cause at no distant day a revolution in the present use of fuel. As a contribution to that end, he describes an apparatus of his own devising for the manufacture of water-gas, by means of which, he claims, this gas can be made in any desired quantity; and, while leaving a handsome profit to the manufacturers, it can be supplied at a cost that will render its general use more economical than that of any kind of solid fuel. — (*Trans. Amer. inst. min. eng., Boston meeting.*) M. E. W. [219
